# --- knobs ---------------------------------------------------------------
price, cost = 5.0, 2.0            # sell at 5, buy at 2, unsold stock is worth 0
N, trials, seed = 20, 2000, 0     # data points per trial, repeated trials
def demand(n):                    # try rng.lognormal(4.55, 0.4, n) for a skewed world
    return np.maximum(rng.normal(100, 20, n), 0)
# -------------------------------------------------------------------------
rng = np.random.default_rng(seed)
frac = (price - cost) / price                 # critical fractile c_u / (c_u + c_o)
big = demand(1_000_000)                       # stands in for "the true distribution"
profit = lambda q: (price * np.minimum(q, big) - cost * q).mean()
q_true = np.quantile(big, frac)

q_saa = np.array([np.quantile(demand(N), frac) for _ in range(trials)])
q_mean = np.array([demand(N).mean() for _ in range(trials)])   # "plan for the average"

print(f"critical fractile {frac:.2f}, true optimal order {q_true:.1f}, profit {profit(q_true):.2f}")
for name, q in [("SAA", q_saa), ("mean", q_mean)]:
    lost = profit(q_true) - np.array([profit(x) for x in q[:300]])
    print(f"{name:5s}: order {q.mean():6.1f} +- {q.std():4.1f}, expected profit lost {lost.mean():.2f}")

plt.hist(q_saa, 60, alpha=0.6, label="SAA order (empirical quantile)")
plt.hist(q_mean, 60, alpha=0.6, label="order = sample mean")
plt.axvline(q_true, color="k", ls="--", label="true optimum")
plt.xlabel("order quantity"); plt.legend(); plt.show()
```

With the default knobs the true optimum is to order 105.1 for an expected profit of 261.4. SAA with only 20 data points orders 104.8 ± 5.5 and loses 1.48 of profit on average; ordering the sample mean loses 1.99. Things to change:

- `N = 200` and `N = 2000`: SAA's loss falls to 0.14 and then 0.02, roughly by a factor of ten for each factor of ten in data, because the profit curve is flat at its peak and the loss goes like the *square* of an error that shrinks like $1/\sqrt{N}$. The mean-based order stays wrong, losing about 1.3 however much data it has: more data cannot fix the wrong question.
- `cost = 4.5`: a thin margin, fractile 0.1. The optimal order drops to 74.3 with profit 32.4. SAA with 20 points loses about 1.2; ordering the mean loses about 24, three quarters of the attainable profit.
- Switch `demand` to the lognormal line. Which estimator suffers more from the skew?
- Make the shop paranoid: order the *worst-case* optimal quantity over all demands between the smallest and largest of the N observations. What does maxmin choose, and what does it cost on average?

54.6 The challenge

1. **Intuition.** In the hook, the nominal optimum failed 75% of the time because two constraints were active. A three-variable LP typically has three active constraints at its optimum. What failure probability do you predict, and why must it be at least $\frac{1}{2}$ for *any* LP whose optimum lies on at least one uncertain constraint with symmetric noise? What property of the optimal solution would make it immune?
2. **Derivation.** Derive the robust counterpart of $\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b$ for the box $|a_j - \bar{a}_j| \le \delta_j$, and rewrite it as a set of linear inequalities using auxiliary variables $t_j \ge |x_j|$. Then generalize: for $\mathcal{U} = \{\bar{\mathbf{a}} + \mathbf{u} : \|\mathbf{u}\| \le \rho\}$ in an arbitrary norm, show that the margin is $\rho\|\mathbf{x}\|_*$, where $\|\cdot\|_*$ is the dual norm.
3. **Implementation.** Implement the scenario approach for the factory with `scipy.optimize.linprog`: draw $N = 326$ perturbed copies of each constraint, solve, then estimate the true violation probability of the solution with 10^5 fresh samples. Repeat 1,000 times and plot the histogram of violation probabilities against $\varepsilon = 0.05$. How conservative is the Campi–Garatti bound in this example?
4. **Open investigation.** For a *joint* chance constraint on both factory machines, $P(\text{both safe}) \ge 0.95$, compare three strategies: Bonferroni (2.5% per machine), an optimized split of the risk budget between the machines, and the scenario approach with the same reliability. Now correlate the noise between coefficients. How does the best split depend on the correlation? Is there a rule for allocating risk among m constraints that is near-optimal in general?

54.7 Loose threads

The chapter treated decisions made once, here and now, before the uncertainty is revealed. Real plans unfold.

> **? Decisions that wait for information**
>
> A grid operator commits generators today, but adjusts their output tomorrow after seeing the wind. The second decision is not a number but a *function* of what will be observed, and optimizing over functions makes robust problems intractable in general. A popular escape restricts the recourse to be an affine function of the uncertainty, which turns the problem back into a cone program, at an unknown cost in optimality. When is that loss small, and what is the exact answer? The exact answer is a dynamic program over information states, Bellman's recursion of Ch. 52, with all the curse of dimensionality that implies. How much the affine shortcut gives up in general is still an open question.

The other threads lead outward. The Wasserstein ball of 54.3 is defined, and its duality proved, in Ch. 55. The reinforcement-learning agent of Ch. 53 that must explore without breaking anything faces a robust MDP, in which the transition probabilities themselves lie in an uncertainty set. Robust control, where the uncertainty is a disturbance signal of bounded energy, turns the worst case into an H_∞ norm. And the stochastic processes of Ch. 36 supply the scenario generators that SAA needs.

55.1 The hook

Play a game of hot-and-cold. I hide a coin somewhere on a line, at position 0. You stand at position θ and want to find it, and after each step I tell you how far off you are. The game is easy because my answers change as you move: "warmer" tells you which way to go.

Now play it with a very strict referee. Instead of measuring distance, he compares *where you are* with *where the coin is* and reports how much the two pictures overlap. You are a single point at θ; the coin is a single point at 0. Unless $\theta = 0$ exactly, the overlap is zero. Move from $\theta = 5$ to $\theta = 0.01$ and his answer does not change at all. You are told you are wrong, but never *how* wrong, so you have no idea which way to step.

That strict referee is not a straw man. He is the Kullback–Leibler divergence of Ch. 33, and its symmetrized cousin, the Jensen–Shannon divergence, and the total-variation distance. All of them compare two probability distributions *point by point*, density against density. Put the coin's distribution δ_0 against yours, δ_θ, and for every $\theta \neq 0$ the KL divergence is $+\infty$, the Jensen–Shannon divergence is exactly $\ln 2$, and the total variation is exactly 1. These numbers have no slope. A learning algorithm that adjusts θ by gradient descent on any of them stands still.

This happened in practice. Around 2014–2017, generative adversarial networks were trained to make realistic images by, in effect, minimizing a Jensen–Shannon divergence between generated and real images. Real images occupy a thin, low-dimensional sliver of the space of all pixel arrays, and so, early in training, do the generator's. Two thin slivers in a huge space almost never overlap. Training stalled, or oscillated, or collapsed onto a few outputs. In 2017 Arjovsky, Chintala and Bottou proposed replacing the strict referee with one who *measures distance*. Their fix was a quantity first studied by a French engineer in 1781 who wanted to move dirt.

How do you measure the distance between two probability distributions so that it knows how far apart they are, not merely whether they overlap? And why should the answer be an optimization problem?

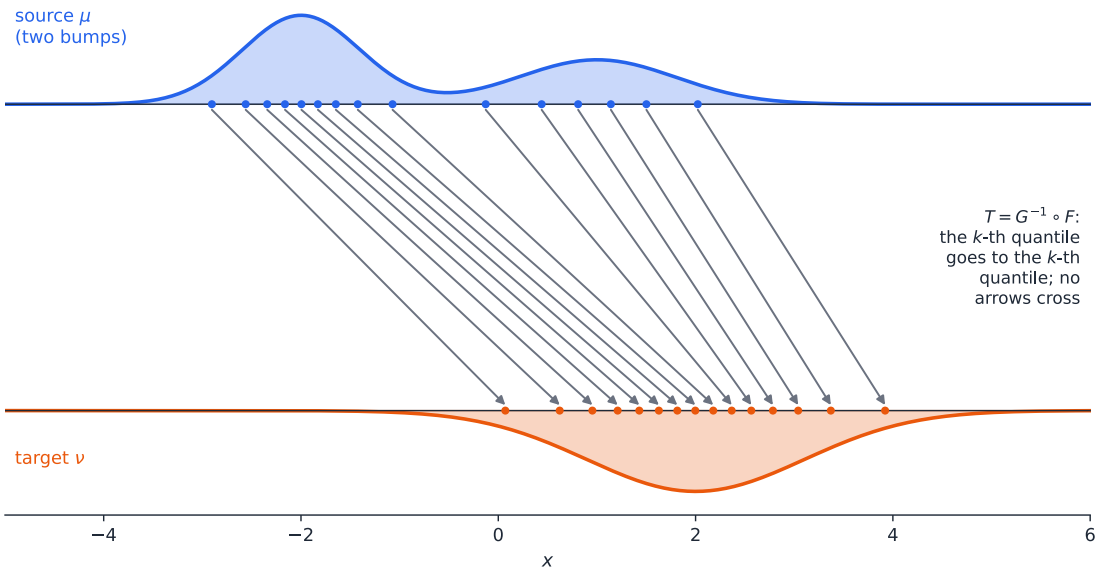
55.2 The big idea

Think of each distribution as a pile of sand of total mass 1. The first pile is where the probability is now; the second is where you want it. Moving a grain from x to y costs $c(x, y)$, say the distance $|x - y|$ or its square. The **optimal transport cost** is the least total effort needed to reshape the first pile into the second.

Gaspard Monge posed this in 1781 for building fortifications: the *déblais* (earth dug out of a trench) had to be carried to the *remblais* (embankments) as cheaply as possible. In 1942 Leonid Kantorovich, working on Soviet production planning, recast it as a linear program, the kind of problem he had invented a few years earlier, complete with its dual prices. (He shared the 1975 economics Nobel prize for that work.)

The cost of transport is a distance that "knows geometry". Move a pile a distance d without changing its shape and the transport cost is exactly d (with $c = |x - y|$): every grain travels d. Back to the coin: transporting δ_θ to δ_0 costs $|\theta|$, which shrinks smoothly as you approach and has slope ± 1 pointing the right way. Hot-and-cold works again.

In one dimension the optimal plan is something you would guess: **never let paths cross.** Sort both piles from left to right. Send the leftmost grain of the first pile to the leftmost position of the second, the median to the median, the 90th percentile to the 90th percentile.



The optimal transport map in one dimension sends each quantile of the source (blue, two bumps) to the same quantile of the target (orange, one bump). Grains from the left bump travel far; grains from the right bump travel little. No two arrows cross: crossing would always waste effort.

Notice what this picture is *not*. The point-by-point comparison would say these two densities differ a lot on the left and a little on the right. Transport says something more useful: *how* to turn one into the other, and how much work that takes. Distances between distributions become distances between *places*.

Two further consequences make optimal transport more than a better ruler. First, it gives a way to *interpolate* between distributions: let each grain travel only halfway along its arrow. The halfway pile between two narrow bumps is a narrow bump in the middle. Averaging the densities would instead give two half-height bumps, a picture of no physical situation at all. Second, the set of all distributions with this distance has a geometry of its own, with straight lines (those half-way piles), angles and curvature. Physics turns out to live there.

55.3 The mathematics

Two formulations

Let μ and ν be probability distributions on $\mathbb{R}^d$ and $c(x,y)\ge 0$ a cost.

Monge and Kantorovich problems

Monge: find a map T that pushes μ to ν (if $X\sim\mu$ then $T(X)\sim\nu$) and minimizes $E_{X\sim\mu}\,[c(X,T(X))]$.

Kantorovich: find a joint distribution π of a pair (X,Y), called a **coupling** or **transport plan**, whose marginals are $X\sim\mu$ and $Y\sim\nu$, and which minimizes $E_{(X,Y)\sim\pi}\,[c(X,Y)]$. The set of couplings is written $\Pi(\mu,\nu)$.

A map must send each grain to one place. A plan can split a grain. That matters: a point mass at 0 cannot be mapped onto two half-masses at ± 1 by any map, but a plan can split it. Kantorovich's relaxation always has a solution under mild conditions, and when an optimal map exists it is also an optimal plan.

For discrete distributions $\mu=\sum_i a_i\delta_{x_i}$ and $\nu=\sum_j b_j\delta_{y_j}$, a plan is a nonnegative matrix $\mathbf{P}$ with row sums $\mathbf{a}$ and column sums $\mathbf{b}$, and the problem is the linear program

$$\min_{\mathbf{P}\ge 0}\ \sum_{i,j} C_{ij}P_{ij}\quad\text{s.t.}\quad \sum_j P_{ij}=a_i,\quad \sum_i P_{ij}=b_j,\qquad C_{ij}=c(x_i,y_j).$$

This is the transportation problem of operations research (§23.3), with nm variables and $n+m$ constraints.

Wasserstein distance

For $p\ge 1$ and $c(x,y)=\|x-y\|^p$,

$$W_p(\mu,\nu)=\left(\min_{\pi\in\Pi(\mu,\nu)} E_\pi\left[\|X-Y\|^p\right]\right)^{1/p}.$$

W_p is a genuine metric on distributions with finite p-th moments: symmetric, zero only when $\mu=\nu$, and obeying the triangle inequality (glue an optimal plan from μ to ν to one from ν to ρ along their common marginal). Unlike KL, it is finite even when the supports are disjoint.

The one-dimensional solution

Theorem 55.1 — Monotone matching is optimal on the line

Let $x_1\le\cdots\le x_n$ and $y_1\le\cdots\le y_n$ be points on $\mathbb{R}$, each carrying mass $1/n$, and let $c(x,y)=h(x-y)$ with h convex. Among all one-to-one assignments σ, the total cost $\sum_i h(x_i-y_{\sigma(i)})$ is minimized by the identity, $\sigma(i)=i$.

Proof. First the key inequality, for two points and two targets. Take $x_1\le x_2$ and $y_1\le y_2$, and compare the uncrossed pairing with the crossed one. Set

$$\alpha=x_1-y_2,\qquad \beta=x_1-y_1,\qquad \gamma=x_2-y_2,\qquad \delta=x_2-y_1.$$

Then $\alpha\le\beta\le\delta$, $\alpha\le\gamma\le\delta$ and $\beta+\gamma=\alpha+\delta$. So $\beta=(1-t)\alpha+t\delta$ for some $t\in[0,1]$, and then $\gamma=\alpha+\delta-\beta=t\alpha+(1-t)\delta$. By convexity,

$$h(\beta)+h(\gamma)\le\big[(1-t)h(\alpha)+th(\delta)\big]+\big[th(\alpha)+(1-t)h(\delta)\big]=h(\alpha)+h(\delta).$$

The left side is the cost of the uncrossed pairing $(x_1\to y_1,\ x_2\to y_2)$, the right side that of the crossed one. Uncrossing never costs more.

Now take any assignment σ other than the identity. It has an *inversion*: indices $i<k$ with $\sigma(i)>\sigma(k)$, a pair of crossing arrows. Swap their targets. By the inequality the total cost does not increase, and the number of inversions strictly decreases. After finitely many swaps we reach the identity, at a cost no greater than that of σ. $\square$

Two remarks extend this. The LP above, with uniform weights and $n=m$, always has an optimal solution that is a permutation matrix: its feasible set is the Birkhoff polytope, whose vertices are exactly the permutation matrices, and an LP attains its optimum at a vertex. So restricting to assignments lost nothing. And for general distributions on $\mathbb{R}$ with CDFs F and G, the same sorting becomes "match quantiles": the optimal map is $T=G^{-1}\circ F$ and

$$W_p^p(\mu,\nu)=\int_0^1 \left|F^{-1}(u)-G^{-1}(u)\right|^p\,du.$$

In one dimension, optimal transport costs a sort: $O(n\log n)$.

Theorem 55.2 — Wasserstein distance between Gaussians on the line

$$W_2^2\left(\mathcal{N}(m_1,\sigma_1^2),\,\mathcal{N}(m_2,\sigma_2^2)\right)=(m_1-m_2)^2+(\sigma_1-\sigma_2)^2.$$

Proof. The quantile function of $\mathcal{N}(m,\sigma^2)$ is $m+\sigma\,\Phi^{-1}(u)$. If U is uniform on $(0,1)$ then $Z=\Phi^{-1}(U)$ is standard normal, so by the quantile formula

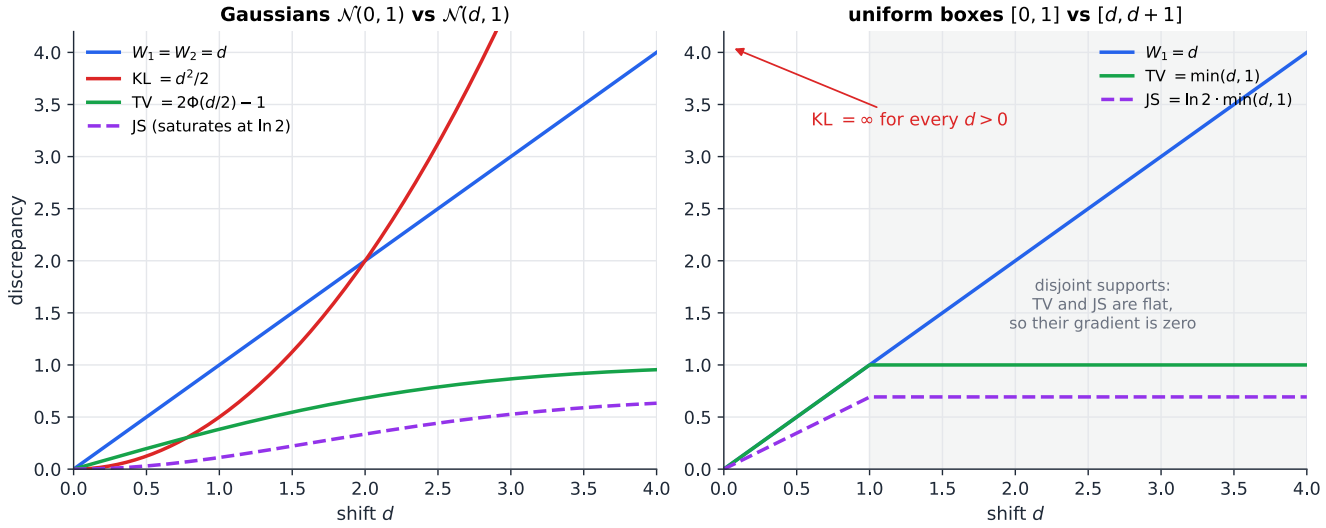
$$W_2^2 = E\left[\big((m_1-m_2)+(\sigma_1-\sigma_2)Z\big)^2\right] = (m_1-m_2)^2 + 2(m_1-m_2)(\sigma_1-\sigma_2)E[Z] + (\sigma_1-\sigma_2)^2E[Z^2],$$

and $E[Z]=0$, $E[Z^2]=1$. $\square$

Compare the Kullback–Leibler divergence between the same two Gaussians,

$$D\left(\mathcal{N}(m_1,\sigma_1^2)\,\|\,\mathcal{N}(m_2,\sigma_2^2)\right) = \ln\frac{\sigma_2}{\sigma_1} + \frac{\sigma_1^2+(m_1-m_2)^2}{2\sigma_2^2} - \frac{1}{2}.$$

Three differences jump out. W_2 is symmetric and KL is not. W_2 measures a shift in the units of x; KL measures it in units of the *width*, $(m_1-m_2)^2/(2\sigma^2)$ for equal widths, so as both bumps become narrow KL explodes while W_2 stays put. And as $\sigma\to 0$, W_2 becomes the plain distance between the means: the coin game. For $\mathcal{N}(0,1)$ against $\mathcal{N}(1,4)$, $W_2=\sqrt{2}=1.414$ while the KL divergence is 0.443 nats.



Four ways to compare a distribution with its shifted copy. With Gaussians (left) every measure increases with the shift, but TV and Jensen–Shannon flatten out quickly. With boxes (right) the supports stop overlapping at $d=1$; from then on TV and JS are constant, KL is infinite throughout, and only the Wasserstein distance still says how far there is to go.

Duality: the price of moving dirt

Ch. 48 promised a dual for this LP. Attach a price φ_i to each source constraint and ψ_j to each target constraint. Think of a haulage company that offers to take over the whole job. It charges $\varphi(x)$ per unit for picking sand up at x and $\psi(y)$ per unit for dropping it off at y, so your bill is $\sum_i a_i\varphi_i + \sum_j b_j\psi_j$, and it wants that bill as large as possible. You accept only prices that are never dearer than doing the job yourself, on every possible route:

$$\varphi(x)+\psi(y)\le c(x,y) \qquad \text{for all } x,y.$$

Theorem 55.3 — Kantorovich duality

$$\min_{\pi\in\Pi(\mu,\nu)} E_\pi[c(X,Y)] = \max_{\varphi(x)+\psi(y)\le c(x,y)} \Big(E_\mu[\varphi(X)] + E_\nu[\psi(Y)]\Big).$$

Proof of $\ge$ (weak duality). For any coupling π and any admissible prices, $(X,Y)\sim\pi$ has $X\sim\mu$ and $Y\sim\nu$, so

$$E_\mu[\varphi(X)] + E_\nu[\psi(Y)] = E_\pi\left[\varphi(X)+\psi(Y)\right] \le E_\pi\left[c(X,Y)\right].$$

Take the max over prices on the left and the min over plans on the right. $\square$

For discrete distributions equality is LP strong duality (Ch. 48); for general ones it needs a compactness argument we do not give. The optimal prices are not arbitrary. Given φ, the best admissible ψ is the largest one allowed,

$$\psi(y) = \varphi^c(y) = \inf_x \big(c(x,y)-\varphi(x)\big),$$

the c**-transform** of φ: the cheapest way to deliver to y, net of what you were paid at the pickup. For $c(x,y)=-x^{\mathsf T}y$ it is, up to signs, the convex conjugate of convex analysis. This is the "strange conjugate operation" Ch. 48 mentioned.

For the cost $c(x,y)=|x-y|$ the conjugation simplifies dramatically. Admissible prices can be taken to satisfy $\psi=-\varphi$ with φ **1-Lipschitz**, $|\varphi(x)-\varphi(y)|\le|x-y|$, giving the **Kantorovich–Rubinstein formula**

$$W_1(\mu,\nu) = \sup_{\mathrm{Lip}(f)\le 1} \Big(E_\mu[f(X)] - E_\nu[f(Y)]\Big).$$

The easy half is again one line: for any coupling and any 1-Lipschitz f, $E_\mu f - E_\nu f = E_\pi[f(X)-f(Y)] \le E_\pi|X-Y|$. This is the formula behind the Wasserstein GAN of 55.1. A second network, the "critic", searches over (approximately) 1-Lipschitz functions f for the one that best tells real data from generated data. The value it achieves estimates W_1, and its gradient tells the generator which way to move.

The same easy half settles a promise of Ch. 54. Let $\hat{P}$ be the empirical distribution of your data and ℓ an L-Lipschitz loss. If $W_1(Q, \hat{P}) \le r$, apply the formula to $f = \ell / L$:

$$E_Q[\ell] \le E_{\hat{P}}[\ell] + L\, W_1(Q, \hat{P}) \le E_{\hat{P}}[\ell] + Lr.$$

Robustness against every distribution in a Wasserstein ball costs at most a Lipschitz penalty, which is why "Wasserstein distributionally robust" learning so often reduces to ordinary learning with a regularizer. For many losses the bound is attained.

> **? Why is the optimal map a gradient?**
>
> In $\mathbb{R}^d$ with cost $\|x - y\|^2$ there is no sorting, yet Brenier's theorem (1991) says that, if μ has a density, the optimal plan is a map, and that map is the *gradient of a convex function*, $T = \nabla u$. In one dimension a gradient of a convex function is just an increasing function, so this is the "no crossing" rule in disguise. Pushing a density f forward to g by ∇u then forces $g(\nabla u(x))\, \det \nabla^2 u(x) = f(x)$, the **Monge–Ampère equation**, one of the most important fully nonlinear PDEs. Why it is so hard, and what regularity its solutions have, is a story for Ch. 89.

55.4 The algorithm

In one dimension, sort and match. In higher dimensions the transport LP has nm variables; with $n = m = 10^4$ points that is 10^8 unknowns, and exact network-flow solvers cost roughly $O(n^3)$. For years this made optimal transport a beautiful theory with few applications. What changed it, around 2013, was a small perturbation.

Entropic regularization. Add a penalty that rewards spreading the plan out:

$$\min_{\mathbf{P} \ge 0} \sum_{i,j} C_{ij} P_{ij} + \varepsilon \sum_{i,j} P_{ij} \left(\ln P_{ij} - 1\right) \quad \text{s.t.} \quad \mathbf{P}\mathbf{1} = \mathbf{a}, \quad \mathbf{P}^{\mathsf{T}}\mathbf{1} = \mathbf{b}.$$

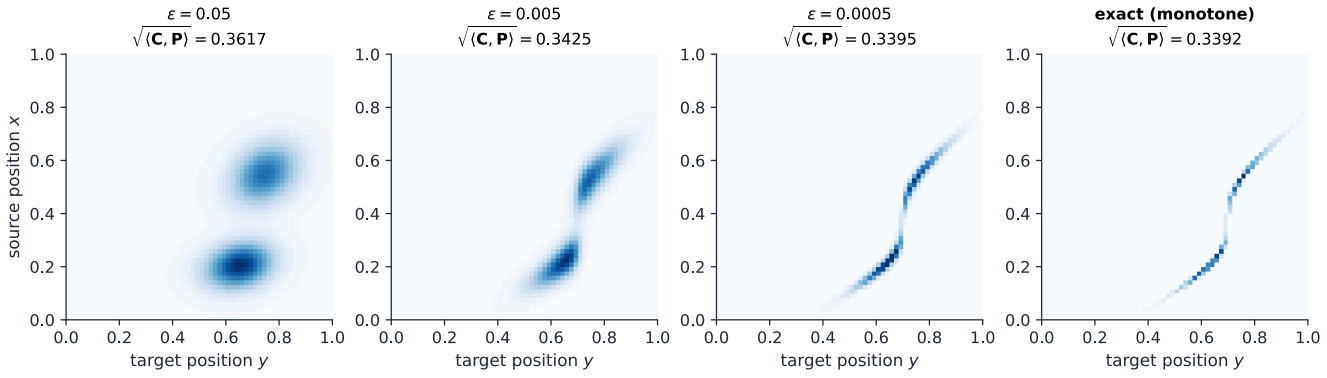
The penalty is strictly convex, so the solution is unique. Attach multipliers f_i and g_j to the two sets of constraints and set the derivative of the Lagrangian with respect to P_{ij} to zero:

$$C_{ij} + \varepsilon \ln P_{ij} - f_i - g_j = 0 \quad \Longrightarrow \quad P_{ij} = \underbrace{e^{f_i/\varepsilon}}_{u_i}\, \underbrace{e^{-C_{ij}/\varepsilon}}_{K_{ij}}\, \underbrace{e^{g_j/\varepsilon}}_{v_j}.$$

So the optimal plan has the form $\mathbf{P} = \operatorname{diag}(\mathbf{u})\, \mathbf{K}\, \operatorname{diag}(\mathbf{v})$ for a fixed **Gibbs kernel** $\mathbf{K} = e^{-\mathbf{C}/\varepsilon}$ (elementwise), and only the $n + m$ scaling factors are unknown. The row-sum condition reads $\mathbf{u} \odot (\mathbf{K}\mathbf{v}) = \mathbf{a}$, the column-sum condition $\mathbf{v} \odot (\mathbf{K}^{\mathsf{T}}\mathbf{u}) = \mathbf{b}$. Solving each one for its own unknown, alternately, gives **Sinkhorn's algorithm**:

```
K ← exp(−C / ε);   v ← 1
repeat until the marginals match:
    u ← a ./ (K v)          fix the row sums
    v ← b ./ (Kᵀ u)         fix the column sums
P ← diag(u) K diag(v)
```

Each sweep is two matrix–vector products, $O(nm)$ operations, perfectly suited to GPUs. The number of sweeps grows as ε shrinks, roughly like $1/\varepsilon$.



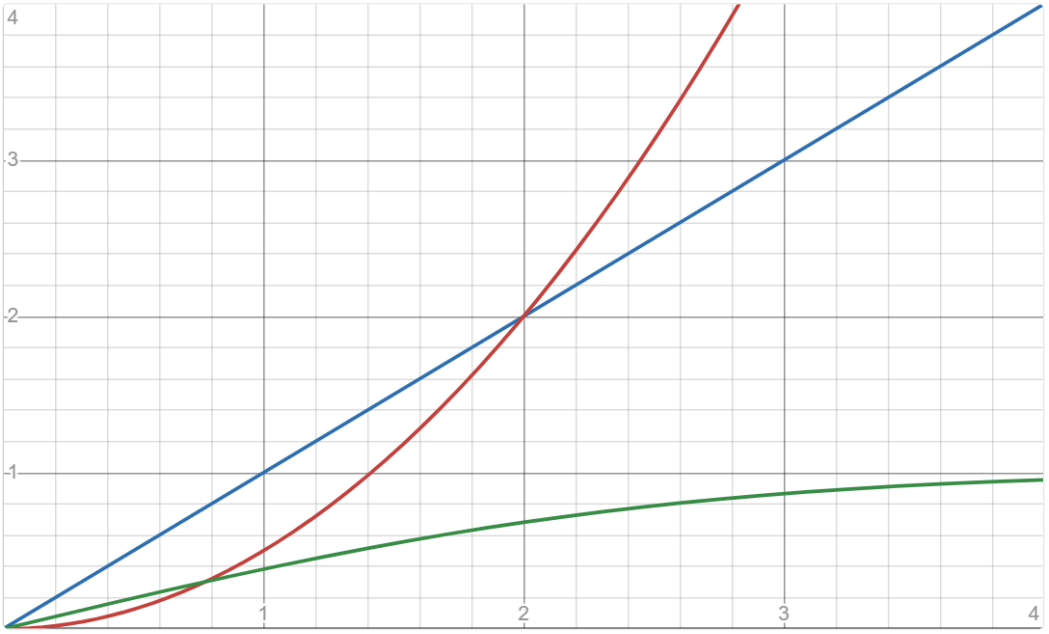
Entropic plans for the source and target of the first figure (now on $[0, 1]$). With $\varepsilon = 0.05$ the plan is a blur and its cost $\sqrt{\langle \mathbf{C}, \mathbf{P} \rangle} = 0.3617$ overestimates $W_2 = 0.3392$ by 7%. At $\varepsilon = 0.0005$ it is within 0.1% and has sharpened onto the monotone map: an increasing curve, steep where the source's gap between its two bumps is squeezed into a narrow stretch of the target.

Failure modes.

- *Bias.* For $\varepsilon > 0$ the plan is blurred and its cost overestimates the true one. A corrected quantity, the **Sinkhorn divergence** $S_\varepsilon(\mu, \nu) = \mathrm{OT}_\varepsilon(\mu, \nu) - \frac{1}{2}\mathrm{OT}_\varepsilon(\mu, \mu) - \frac{1}{2}\mathrm{OT}_\varepsilon(\nu, \nu)$, removes the self-blur and vanishes when $\mu = \nu$.
- *Underflow.* $e^{-C/\varepsilon}$ is below the smallest double ($\approx 10^{-308}$) once $C/\varepsilon > 708$. Then $\mathbf{K}\mathbf{v}$ has zeros, the division produces infinities, and the iteration returns `nan`. The cure is to iterate on $f = \varepsilon \ln u$ and $g = \varepsilon \ln v$ with a log-sum-exp, which costs a little speed and never overflows.
- *Slow convergence for small ε*, exactly when the answer is most accurate. Practical codes start with a large ε and decrease it, warm-starting each stage.
- *High dimension.* Estimating W_p from n samples in $\mathbb{R}^d$ converges like $n^{-1/d}$, so in dimension 100 more data barely helps. Regularization partly escapes this; see the challenge.

55.5 The experiment

First the shape of the comparison. The graph shows, against the shift d between two Gaussians of equal width $\sigma = 1$, the Wasserstein distance (blue), the KL divergence $d^2/(2\sigma^2)$ (red) and the total variation $\operatorname{erf}\left(d/(2\sqrt{2}\,\sigma)\right)$ (green).



Discrepancy between $\mathcal{N}(0,\sigma^2)$ and $\mathcal{N}(d,\sigma^2)$ as a function of d, with $\sigma = 1$. Change both `1`*s (the width) to* `0.3`*. The Wasserstein line does not move at all, the KL parabola shoots up eleven times faster, and the total variation jumps to 1 almost immediately: narrow distributions are "completely different" to point-by-point measures, but only d apart to transport.*

Now Sinkhorn against the exact answer. The script builds a two-bump source histogram and a shifted, widened target on a grid, runs Sinkhorn, and compares the result with the exact quantile formula of 55.3.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
n, eps, iters = 200, 0.01, 2000       # grid size, entropic blur, Sinkhorn sweeps
shift, width = 0.3, 0.05              # target = source moved right and widened
# -------------------------------------------------------------------------
x = np.linspace(0, 1, n)
bump = lambda m, s: np.exp(-0.5 * ((x - m) / s) ** 2)
a = bump(0.25, 0.05) + 0.6 * bump(0.45, 0.04); a /= a.sum()   # source histogram
b = bump(0.25 + shift, 0.05 + width);           b /= b.sum()   # target histogram
C = (x[:, None] - x[None, :]) ** 2                             # squared-distance cost

K = np.exp(-C / eps)                  # Gibbs kernel; underflows when eps is tiny
v = np.ones(n)
for k in range(iters):
    u = a / (K @ v)                   # fix the row sums
    v = b / (K.T @ u)                 # fix the column sums
P = u[:, None] * K * v[None, :]       # the entropic transport plan

# exact 1-D answer: match quantiles, W2^2 = integral of (F^-1 - G^-1)^2
q = np.linspace(0.0005, 0.9995, 4000)
Finv = np.interp(q, np.cumsum(a), x)
Ginv = np.interp(q, np.cumsum(b), x)
print("Sinkhorn  sqrt(<C,P>) =", np.sqrt((C * P).sum()))
print("exact W2 (quantiles)  =", np.sqrt(np.mean((Finv - Ginv) ** 2)))

ax[1].set_xlabel("to y"); ax[1].set_ylabel("from x")
plt.show()
```

With the default knobs Sinkhorn reports 0.2452 against the exact $W_2 = 0.2367$, with the row sums matched to 10^{-17}. Things to change:

- `eps = 0.001`: the estimate tightens to 0.2378, and the plan in the right panel sharpens into a curve.
- `eps = 0.0001`: everything becomes `nan`. Look at `K`: most of its entries are exactly zero. This is the underflow of 55.4.
- `shift = 0.5`, then `0.7`: the exact W_2 grows from 0.237 to 0.434 to 0.588, tracking the shift, while the L^2 distance between the histograms barely moves (0.150, 0.176, 0.198) once the bumps have separated.
- `width = 0.0`: a pure shift of the second bump only. How does the plan change?

- Replace `C` by `np.abs(x[:, None] - x[None, :])` to compute W_1 instead. Does the plan still look like a monotone curve? (In one dimension many plans can be optimal for W_1; Sinkhorn picks the most spread-out one.)

55.6 The challenge

1. **Intuition.** Two narrow bumps, one at 0 and one at 1. Describe the mixture $\frac{1}{2}\mu + \frac{1}{2}\nu$ and the Wasserstein midpoint (each grain travels half-way). If μ and ν are images of a moving object at two instants, which one looks like the object at the middle instant? Give one engineering situation where the mixture is the right answer instead.
2. **Derivation.** Show from the quantile formula that, in one dimension, $W_1(\mu,\nu) = \int_{-\infty}^{\infty} |F(x) - G(x)|\,dx$, the area between the two CDFs. (Hint: draw both CDFs and compute the same area by horizontal and by vertical strips.) Use it to find W_1 between the uniform distributions on $[0,1]$ and on $[0,2]$, then between δ_0 and $\mathcal{N}(0,1)$.
3. **Implementation.** Rewrite the experiment's Sinkhorn loop in the log domain: iterate on $f = \varepsilon \ln u$ and $g = \varepsilon \ln v$ using a numerically stable log-sum-exp. Confirm that it works at $\varepsilon = 10^{-4}$, where the plain version fails. Then plot the number of sweeps needed to reach a row-sum error of 10^{-9} against ε on log–log axes. What power law do you see?
4. **Open investigation.** Draw two independent samples of size n from the *same* standard Gaussian in $\mathbb{R}^d$ and compute the exact W_2 between them as an assignment problem (`scipy.optimize.linear_sum_assignment`). Measure how W_2 shrinks with n for $d = 1, 2, 3, 5, 10$ and estimate the exponent. Now repeat with the Sinkhorn divergence at fixed ε. Does it escape the curse of dimensionality, and at what price in what it actually measures?

55.7 Loose threads

The chapter used optimal transport as a ruler. Its deeper life is as a geometry.

? Heat flow is the steepest descent of entropy

Equip the space of probability densities with the W_2 distance. Now ask: which way should a density move to *increase its entropy* as fast as possible, per unit of Wasserstein distance travelled? The answer, found by Jordan, Kinderlehrer and Otto in 1998, is the heat equation $\partial_t \rho = \nabla^2 \rho$. Diffusion is gradient descent on entropy, in this geometry and in no other. Many other PDEs turn out to be gradient flows of the same kind. Making sense of "gradient" on a space of distributions requires a Riemannian structure on it, the subject of Ch. 59.

? Why does Sinkhorn converge so reliably?

Alternately rescaling rows and columns of a positive matrix looks naive, yet it converges linearly from any start, at a rate that depends only on $\mathbf{K}$. The reason is that each rescaling is a contraction in Hilbert's projective metric, a way of measuring distance between positive vectors that ignores their overall scale, by the Birkhoff–Hopf theorem on positive linear maps. The geometry of cones and positive operators that makes this work is part of Ch. 61.

The first mystery of 55.3, Brenier's map and the Monge–Ampère equation, waits in Ch. 89. A rigorous account of couplings, of weak convergence and of why the duality holds beyond the discrete case needs measure theory (Ch. 97). Other doors open from here: colour transfer and image registration in Ch. 76, matching markets in economics, and the Wasserstein balls of Ch. 54, which this chapter has now made precise.

Track E — The Abstract Mathematics Behind Everything

> **Level 2 — Specializations.** The common structures hiding beneath seemingly unrelated problems.

Suggested reading order for Track E. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 1 — Mathematical Language and Algebra
- Ch. 2 — Complex Numbers and Engineering Representation
- Ch. 4 — Differential Calculus
- Ch. 8 — Matrices and Linear Systems
- Ch. 9 — Vector Spaces and Linear Transformations
- Ch. 10 — Eigenvalues and Eigenvectors

Chapters

Ch.	Chapter	What it explores
56	Abstract Algebra: Symmetry as a Language	Groups, rings, fields, homomorphisms, quotient structures, group actions, and symmetry. Applications: cryptography, coding theory, geometry, physics.
57	Number Theory: The Hidden Arithmetic of the Digital World	Primes, modular arithmetic, congruences, Diophantine equations, finite fields, elliptic curves, computational number theory. Applications: cryptography, pseudorandom generators, error-correcting codes.
58	Topology: What Survives When Shapes Bend?	Continuity, compactness, connectedness, homeomorphisms, fundamental groups, homology, topological data analysis. Applications: geometry, robotics, data analysis, dynamical systems.
59	Differential Geometry: Mathematics on Curved Worlds	Manifolds, tangent spaces, differential forms, curvature, geodesics, tensors, Riemannian geometry. Applications: robotics, computer graphics, mechanics, relativity.
60	Real Analysis: Making Calculus Rigorous	Limits, continuity, sequences, series, metric spaces, completeness, measure, integration, convergence theorems. Applications: probability theory, optimization, mathematical proof.
61	Functional Analysis: Infinite-Dimensional Thinking	Normed and Banach spaces, Hilbert spaces, operators, dual spaces, spectral theory, weak convergence. Applications: quantum mechanics, PDEs, signal processing, inverse problems.
62	Category Theory: Mathematics About Mathematics	Categories, functors, natural transformations, universal properties, limits, adjunctions. Applications: type theory, programming language design, abstract algebra, compositional systems.

Ch.	Chapter	What it explores
99	Abstract Linear Algebra: Vectors Without Coordinates	Vector spaces over arbitrary fields, linear maps as the primary objects, dual spaces, quotients, direct sums, invariant subspaces, Jordan and rational canonical forms, multilinear forms. An independent advanced module bridging the core linear algebra chapters to functional analysis, representation theory and tensors.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 56 — Abstract Algebra: Symmetry as a Language

> **Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on:** Ch. 1, Ch. 2, Ch. 8, Ch. 9 · **Leads to:** Ch. 57, Ch. 62, Ch. 95, Ch. 99 · **Related:** Ch. 29, Ch. 70, Ch. 77, Ch. 79 **Reading time:** ~25 min

56.1 The hook

In the 1880s a small wooden toy swept across America and Europe. Fifteen numbered tiles sat in a 4-by-4 frame with one empty slot, and you slid tiles into the gap to put them in order. Puzzle columnist Sam Loyd stirred up the craze by publicising a cruel variant: start with the tiles in order except that **14 and 15 are swapped**, and restore the natural order. Loyd claimed to offer $1,000 for a solution. People missed work over it. Ship captains were said to have run aground.

Nobody ever collected, and nobody ever will. The 14–15 puzzle cannot be solved.

Think about what kind of claim that is. The frame can hold the 16 objects (15 tiles and a blank) in $16! = 20{,}922{,}789{,}888{,}000$ arrangements. You cannot try them all by hand, and "I tried for a month and failed" proves nothing. Yet there is a short, airtight argument that no sequence of slides, however long or clever, swaps two tiles and leaves everything else in place. Moreover, the same argument tells you that *exactly half* of all arrangements are reachable, 10,461,394,944,000 of them, and the other half are forever cut off.

The Rubik's cube has the same flavour. Its reachable positions number

$$43{,}252{,}003{,}274{,}489{,}856{,}000 = 2^{27}\,3^{14}\,5^{3}\,7^{2}\,11,$$

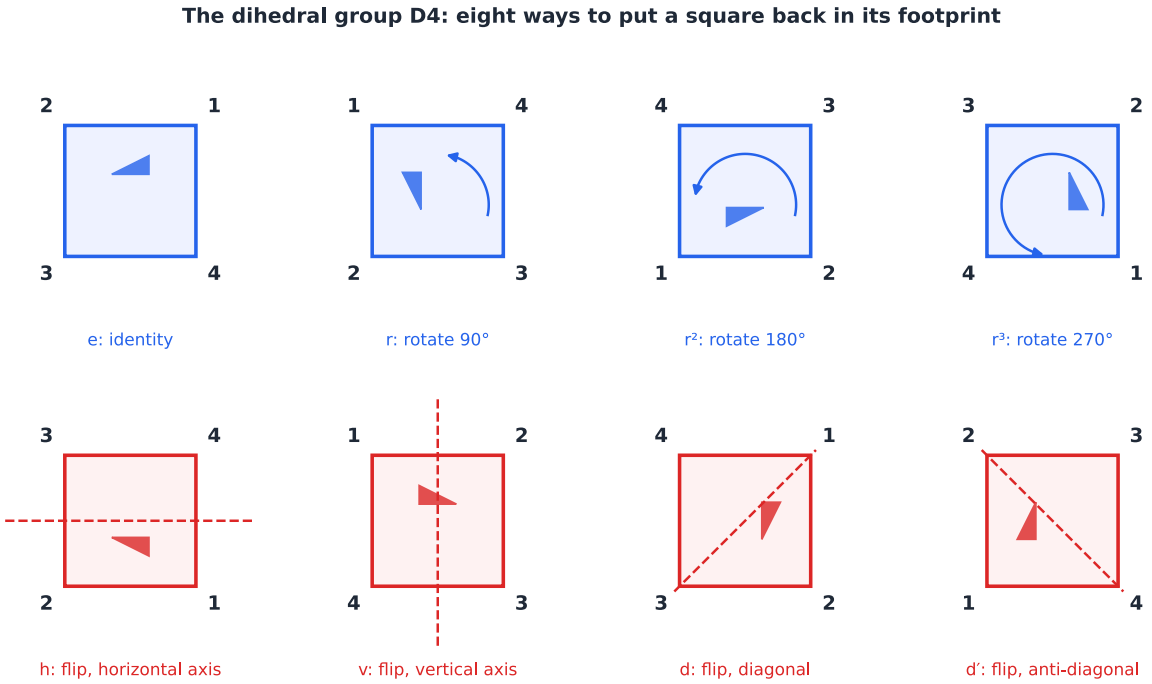
and you can know that exact number, and know that twisting a single corner in place is impossible, without ever building a list.

> **How can you prove that a move is impossible, or count an astronomically large set of states exactly, without searching?**

The answer is that the moves of a puzzle are not just a list. They *compose*, they can be *undone*, and those two facts force a rigid structure on everything the puzzle can do. That structure is called a **group**, and once you can see it you will find it inside crystals, codes, ciphers, quantum particles and the rotations of a spacecraft.

56.2 The big idea

Pick up a square tile and ask: in how many ways can I put it back into its square hole? You can leave it alone. You can turn it by 90°, 180° or 270°. You can flip it over along a horizontal, vertical or diagonal axis. That is eight ways, and there are no others.



The dihedral group D_4. Each panel shows where the corner labels 1–4 end up; the small flag shows orientation. Blue panels are rotations, red panels are reflections (dashed line = mirror).

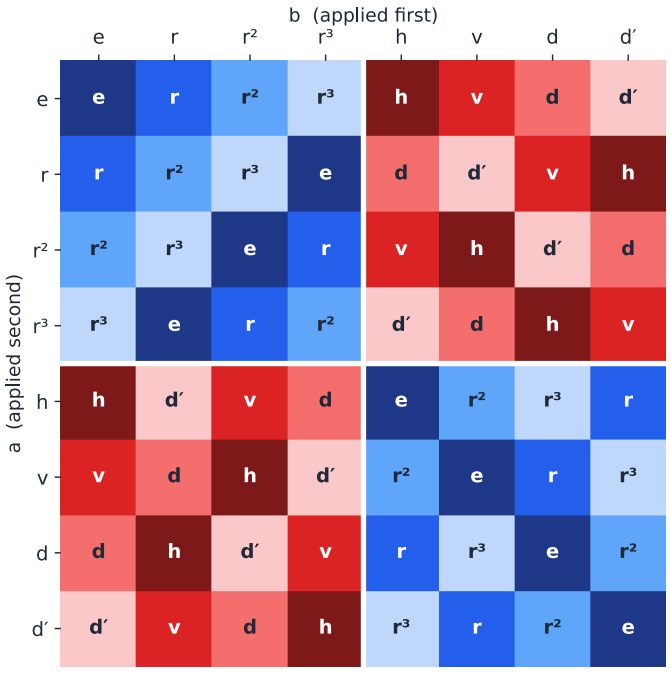
The eight motions are interesting not individually but as a system:

- **Doing one after another gives another one.** Rotate 90°, then flip horizontally: the result is one of the eight (a diagonal flip, as it turns out).
- **Doing nothing is one of them.**
- **Every one can be undone by one of them.** A 90° turn is undone by a 270° turn; every flip undoes itself.

Those three facts, plus the harmless observation that "first a, then b, then c" doesn't care how you bracket it, are the whole definition of a group. Notice what is *missing*: there is no mention of squares, angles or tiles. The same three facts hold for the twelve hours on a clock, for the invertible 3×3 matrices, for the rotations of a quantum spin, for the shuffles of a deck of cards. Abstract algebra is the decision to study the pattern and forget the costume.

Here is the payoff, stated as an analogy. A detective who knows that a suspect is 1.80 m tall can rule out everyone shorter without interviewing them. An algebraist who knows that some quantity is *preserved by every allowed move* (an **invariant**) can rule out every state where that quantity differs without exploring them. For the 15 puzzle the invariant is a single bit, the *parity* of a permutation, and it is enough to kill Loyd's challenge.

The whole Cayley table of D_4 fits in one picture:



Cayley table of D4: entry = a∘b. Blue = rotation, red = reflection

Row a, column b holds $a \circ b$ (do b first, then a). The four blocks tell a story: rotation∘rotation and reflection∘reflection are rotations; mixed products are reflections. That block pattern is a homomorphism onto $\{+1, -1\}$ in disguise. Also, the table is not symmetric: $r \circ h = d$ but $h \circ r = d'$.

Look at the table for a moment. Every row and every column contains each element exactly once (a **Latin square**), which is the "undo" axiom in visual form. The four colour blocks say that "is it a reflection?" behaves like a sign: two reflections make a rotation, just as two minus signs make a plus. Remembering only that sign throws away information yet respects composition. That is the first example of the most important idea in the chapter: a structure-preserving map, or **homomorphism**.

56.3 The mathematics

Groups

Group

A **group** $(G, *)$ is a set G with an operation $* : G \times G \to G$ such that

1. (associativity) $(a * b) * c = a * (b * c)$ for all a, b, c;
2. (identity) there is $e \in G$ with $e * a = a * e = a$ for all a;
3. (inverses) for every a there is a^{-1} with $a * a^{-1} = a^{-1} * a = e$.

The group is **abelian** if also $a * b = b * a$ for all a, b. The number of elements $|G|$ is its **order**.

Closure is built into "$* : G \times G \to G$". Usually we write ab for $a * b$. Some examples you already know:

Group	Elements	Operation	Order	Abelian?
$\mathbb{Z}$	integers	$+$	infinite	yes
$\mathbb{Z}_n$	$\{0, 1, \dots, n-1\}$	addition mod n	n	yes
μ_n	n-th roots of unity $e^{i2\pi k/n}$	complex multiplication	n	yes
D_n	symmetries of a regular n-gon	composition	$2n$	no, for $n \geq 3$
S_n	permutations of $\{1, \dots, n\}$	composition	$n!$	no, for $n \geq 3$
$GL_n(\mathbb{R})$	invertible $n \times n$ matrices	matrix product	infinite	no, for $n \geq 2$
$SO(3)$	rotations of 3-D space	composition	infinite	no

The roots of unity are covered in Ch. 2 §2.6; non-commuting matrix products are in Ch. 8 §8.2. Non-commutativity is the rule, not the exception: put on socks then shoes, versus shoes then socks.

Two small consequences of the axioms are used constantly. The identity is unique (if e and e' both work, $e = ee' = e'$), and so is each inverse. And $(ab)^{-1} = b^{-1}a^{-1}$, the socks-and-shoes rule: to undo "socks then shoes" you remove shoes first.

A **subgroup** $H \le G$ is a subset that is itself a group under the same operation. The rotations $\{e, r, r^2, r^3\}$ form a subgroup of D_4; so do $\{e, h\}$ and $\{e, r^2\}$. The **order of an element** g is the smallest $k \ge 1$ with $g^k = e$, and the powers $\langle g \rangle = \{e, g, g^2, \dots, g^{k-1}\}$ form the **cyclic subgroup** generated by g.

Lagrange's theorem: sizes are not free

Here is the first sign that the axioms are stronger than they look.

> **Lagrange's theorem**
>
> If G is finite and $H \le G$, then $|H|$ divides $|G|$. In particular the order of every element divides $|G|$.

Proof. For $g \in G$ define the **left coset** $gH = \{gh : h \in H\}$.

1. *Every coset has $|H|$ elements.* The map $h \mapsto gh$ is one-to-one, because $gh_1 = gh_2$ implies $h_1 = h_2$ after multiplying on the left by g^{-1}.
2. *Two cosets are equal or disjoint.* Suppose $x \in g_1H \cap g_2H$, so $x = g_1h_1 = g_2h_2$. Then $g_1 = g_2h_2h_1^{-1}$, and for any $h \in H$, $g_1h = g_2(h_2h_1^{-1}h) \in g_2H$ because H is closed. So $g_1H \subseteq g_2H$, and by symmetry they are equal.
3. *The cosets cover G,* since $g = ge \in gH$.

So G is cut into disjoint pieces of equal size $|H|$, and $|G| = [G : H]\,|H|$ where the **index** $[G : H]$ counts the pieces. For an element g, apply this to $H = \langle g \rangle$, whose size is the order of g. ∎

Immediately, a group of prime order p has no subgroups except $\{e\}$ and itself, so it is generated by any non-identity element and is cyclic. And $g^{|G|} = e$ for every g. Applied to the multiplicative group of non-zero residues mod p (order $p - 1$), this last fact is **Fermat's little theorem**, the engine of RSA. Ch. 57 takes it from there.

Homomorphisms, and the death of the 14–15 puzzle

> **Homomorphism, kernel, isomorphism**
>
> A map $\varphi : G \to H$ between groups is a **homomorphism** if $\varphi(ab) = \varphi(a)\varphi(b)$ for all a, b. Its **kernel** is $\ker \varphi = \{g : \varphi(g) = e_H\}$. A bijective homomorphism is an **isomorphism**, written $G \cong H$: the two groups are the same up to renaming.

Examples: $\det : GL_n(\mathbb{R}) \to \mathbb{R}^\times$, because $\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}$. The exponential $x \mapsto e^x$ turns $(\mathbb{R}, +)$ into $(\mathbb{R}_{>0}, \times)$, which is why logarithm tables worked. The map $k \mapsto e^{j2\pi k/n}$ is an isomorphism $\mathbb{Z}_n \cong \mu_n$: adding hours on a clock *is* multiplying roots of unity.

The homomorphism that solves the hook is the **sign of a permutation**. A **transposition** swaps two items and fixes the rest; every permutation is a product of transpositions (sort a list by swaps). Count the **inversions** of a permutation σ, the pairs $i < j$ with $\sigma(i) > \sigma(j)$. One can check that composing with a single transposition changes the number of inversions by an odd amount, so the parity of "number of transpositions used" does not depend on how you write σ. That makes

$$\operatorname{sgn} : S_n \to \{+1, -1\}, \qquad \operatorname{sgn}(\sigma) = (-1)^{\#\text{transpositions}}$$

well defined, and it is a homomorphism: write σ with a swaps and τ with b swaps, and $\sigma\tau$ uses $a + b$. Its kernel, the **even** permutations, is the **alternating group** A_n, of order $n!/2$.

> **The 14–15 puzzle is unsolvable**
>
> No sequence of slides returns the blank to its corner with tiles 14 and 15 exchanged and all other tiles fixed.

Proof. Treat the blank as a 16th tile and colour the board like a chessboard. Each slide swaps the blank with a neighbouring tile, so it is a transposition of the 16 objects, and it moves the blank to a square of the opposite colour. If the blank ends where it started, it has made an even number of moves, so the overall permutation is a product of an even number of transpositions and has sign $+1$. The target configuration differs from the start by one transposition, $(14\ 15)$, of sign -1. Since sgn is well defined, no sequence of moves produces it. ∎

The full story is that the reachable configurations are exactly those whose sign matches the colour parity of the blank, which is why exactly half of the 16! arrangements are reachable. Proving the "every even one is reachable" half takes a constructive argument; the impossibility half took four lines.

Normal subgroups and quotients

The kernel of a homomorphism is not just any subgroup. If $k \in \ker \varphi$ then $\varphi(gkg^{-1}) = \varphi(g)\varphi(g)^{-1} = e$, so gkg^{-1} is in the kernel too. Subgroups with this property, $gNg^{-1} = N$ for every g, are called **normal**, written $N \trianglelefteq G$. For a normal subgroup the cosets themselves form a group, the **quotient** G/N, with $(aN)(bN) = (ab)N$.

The quotient is how algebra "forgets on purpose". $\mathbb{Z}/n\mathbb{Z}$ is the integers with multiples of n forgotten, which is clock arithmetic. $D_4/\{\text{rotations}\}$ has two elements, "rotation" and "reflection", and is exactly the block pattern of the Cayley table. The general principle is:

> **First isomorphism theorem**
>
> If $\varphi : G \to H$ is a homomorphism, then $G/\ker \varphi \cong \varphi(G)$.

So $S_n/A_n \cong \{\pm 1\}$, $GL_n(\mathbb{R})/SL_n(\mathbb{R}) \cong \mathbb{R}^\times$ (where SL_n is the determinant-one matrices), and $\mathbb{Z}/n\mathbb{Z} \cong \mu_n$. Every homomorphic image of a group is one of its quotients. We state this without proof; the proof checks that $g \ker \varphi \mapsto \varphi(g)$ is well defined and bijective.

> **? The atoms of symmetry**
>
> Integers factor into primes. Groups "factor" too: if N is normal in G, you can study N and G/N separately. Groups with no normal subgroups except $\{e\}$ and themselves are called **simple**, and they are the atoms. After about 10,000 journal pages written over half a century, mathematicians finished classifying every finite simple group: a few infinite families plus 26 "sporadic" exceptions, the largest being the Monster, with about 8×10^{53} elements. Why the Monster's numbers turn up in the coefficients of a function from 19th-century complex analysis ("monstrous moonshine") is a story about representations of groups as matrices: see Ch. 95.

Group actions and the orbit–stabilizer theorem

Groups are most useful when they *do* something. An **action** of G on a set X assigns to each g a map $x \mapsto g \cdot x$ with $e \cdot x = x$ and $g \cdot (h \cdot x) = (gh) \cdot x$. D_4 acts on the corners of the square, on colourings of the square, on the cells of a chessboard. The **orbit** of x is everything you can reach from it, $Gx = \{g \cdot x\}$. The **stabilizer** is what leaves it alone, $G_x = \{g : g \cdot x = x\}$, and it is a subgroup.

> **Orbit–stabilizer**
>
> For a finite group acting on a set, $|Gx| \cdot |G_x| = |G|$.

Proof. Send each coset gG_x to the point $g \cdot x$. This is well defined and one-to-one, because $g \cdot x = g' \cdot x \iff g^{-1}g' \cdot x = x \iff g^{-1}g' \in G_x \iff gG_x = g'G_x$. It is onto the orbit by definition. So the orbit has as many points as there are cosets of G_x, namely $|G|/|G_x|$ by Lagrange. ■

This is a counting machine. The rotation group of a cube acts on its 6 faces; one face can be sent to any face (orbit size 6), and the rotations fixing it are the 4 turns about its axis. So the cube has $6 \times 4 = 24$ rotational symmetries, found without listing them. The same trick gives 12 rotations for a tetrahedron and 60 for an icosahedron.

Counting *orbits* rather than group elements needs one more step. Count the pairs (g, x) with $g \cdot x = x$ in two ways: by x it is $\sum_x |G_x|$, and by g it is $\sum_g |\mathrm{Fix}(g)|$. Each orbit O contributes $\sum_{x \in O} |G|/|O| = |G|$ to the first sum. Hence

$$\#\text{orbits} = \frac{1}{|G|} \sum_{g \in G} |\mathrm{Fix}(g)|,$$

Burnside's lemma. How many genuinely different ways are there to colour the corners of a square with 3 colours, counting two as the same if a symmetry carries one to the other? The identity fixes all $3^4 = 81$ colourings. The quarter turns r, r^3 fix only the 3 one-colour ones; r^2 fixes $3^2 = 9$. The diagonal flips d, d' fix two corners and swap a pair, $3^3 = 27$ each; the edge flips h, v swap two pairs, $3^2 = 9$ each. The average is $(81 + 3 + 9 + 3 + 27 + 27 + 9 + 9)/8 = 168/8 = 21$.

Rings and fields: two operations at once

Groups have one operation. Numbers have two, and they interact through the distributive law.

> **Ring, field**
>
> A **ring** $(R, +, \cdot)$ is an abelian group under $+$, with an associative multiplication that distributes over addition: $a(b + c) = ab + ac$ and $(a + b)c = ac + bc$. A **field** is a commutative ring with $1 \neq 0$ in which every non-zero element has a multiplicative inverse.

$\mathbb{Z}$ is a ring but not a field (no $1/2$). $\mathbb{Q}, \mathbb{R}, \mathbb{C}$ are fields. Polynomials with real coefficients form a ring, as do $n \times n$ matrices (a non-commutative one). The clock $\mathbb{Z}_n$ is a ring, and here algebra gets its first surprise: in $\mathbb{Z}_6$, $2 \cdot 3 = 0$. Non-zero things multiplying to zero are **zero divisors**, and a ring with them cannot be a field. $\mathbb{Z}_n$ is a field exactly when n is prime, a fact Ch. 57 proves with the extended Euclidean algorithm.

The ring analogue of a normal subgroup is an **ideal**, a subset closed under addition and under multiplication by *anything* in the ring, and the analogue of a quotient group is a **quotient ring**. Take real polynomials, forget multiples of $x^2 + 1$, and what is left is $\mathbb{R}[x]/(x^2 + 1)$. In that ring $x^2 = -1$. You have just built $\mathbb{C}$, with x playing the role of j, and without ever saying "imagine a square root of -1". Do the same with polynomials over $\mathbb{Z}_2$ modulo $x^8 + x^4 + x^3 + x + 1$ and you build the 256-element field in which the AES cipher does its arithmetic.

Where the structures live

Structure	Where engineers meet it	Chapter
cyclic group $\mathbb{Z}_p^\times$	Diffie–Hellman key exchange, discrete logs	Ch. 57, Ch. 77
elliptic-curve group	ECDSA signatures, TLS	Ch. 78
finite field $\mathbb{F}_{2^m}$, ideals in $\mathbb{F}_2[x]$	CRC checks, Reed–Solomon and cyclic codes	Ch. 79
$SO(3)$, unit quaternions	attitude control, 3-D graphics	Ch. 70
μ_n acting on sequences	the DFT is the "character table" of $\mathbb{Z}_n$	Ch. 16
space groups (230 of them)	crystallography, band structure	Ch. 92

> **? Symmetry that you can't see but can conserve**
>
> Every physical law you use is unchanged if you shift the clock by Δt, slide the lab by $\Delta \mathbf{x}$, or rotate it. Those are *continuous* groups, not finite tables. In 1918 Emmy Noether proved that each such continuous symmetry of a system's action forces a conserved quantity: time shifts give energy, space shifts give momentum, rotations give angular momentum. Why should a symmetry *produce* a number that never changes? The answer needs the calculus of variations and the infinitesimal version of a group: see Ch. 92.

56.4 The algorithm

A computer cannot hold "the set of all symmetries" as an idea, but it can hold a few **generators** and close them up. Represent each symmetry as a permutation, a tuple `p` where `p[i]` is where point `i` goes, and repeatedly multiply by the generators until nothing new appears.

```
def compose(p, q):            # (p o q)(i) = p[q[i]]: do q first, then p
    return tuple(p[i] for i in q)

def generate(gens):
    """All elements of the group generated by permutations gens (breadth-first closure)."""
    n = len(gens[0])
    e = tuple(range(n))
    group, frontier = {e}, [e]
    while frontier:
        new = []
        for g in frontier:
            for s in gens:
                h = compose(s, g)
                if h not in group:
                    group.add(h)
                    new.append(h)
        frontier = new
    return group

def count_orbits(group, k):
    """Burnside: number of k-colourings of the points, up to the group."""
    def cycles(p):
        seen, c = set(), 0
        for i in range(len(p)):
            if i not in seen:
                c += 1
                while i not in seen:
                    seen.add(i); i = p[i]
        return c
    return sum(k ** cycles(g) for g in group) // len(group)

r = (1, 2, 3, 0)              # quarter turn of the square's corners
s = (0, 3, 2, 1)              # flip across the diagonal through corner 0
D4 = generate([r, s])
print(len(D4), count_orbits(D4, 3))          # 8 21
S5 = generate([(1, 2, 3, 4, 0), (1, 0, 2, 3, 4)])
print(len(S5))                               # 120
```

Two details deserve comment.

Why closing under the generators is enough. In a finite group the inverse of s is a power of s (Lagrange says $s^{|G|} = e$, so $s^{-1} = s^{|G|-1}$), so products of generators already reach every inverse. The breadth-first search is just a graph search on the **Cayley graph**, whose vertices are group elements and whose edges are "multiply by a generator". Its cost is $O(|G| \cdot m \cdot n)$ for m generators acting on n points, plus memory for every element.

Why Burnside counts cycles. A colouring is fixed by g exactly when it is constant on each cycle of g, so $|\mathrm{Fix}(g)| = k^{c(g)}$ where $c(g)$ is the number of cycles. Running the code on the rotation group of a cube acting on its 6 faces gives 24 elements, 10 two-colourings and 57 three-colourings, numbers you can check against the orbit–stabilizer count above.

> **Common Pitfall: listing the group is the wrong plan for big groups**
>
> Breadth-first closure stores every element. The Rubik's cube group has about 4.3×10^{19} elements, far beyond any memory. Real computer-algebra systems use the **Schreier–Sims algorithm**, which stores a chain of stabilizers $G \geq G_{x_1} \geq G_{x_1 x_2} \geq \cdots$ and uses orbit–stabilizer at each level, so that $|G|$ comes out as a product of orbit lengths. It handles the cube in milliseconds. The cube's exact order in §56.1 drops out of such a computation.

The 15 puzzle also shows a second failure mode: if you search *configurations* rather than the group, you need an invariant to know when to stop. A solver that does not check the sign first will search all 10^{13} reachable states before admitting that the 14–15 position is not among them.

56.5 The experiment

The script below builds the dihedral group D_n of a regular n-gon from scratch, checks that its Cayley table is a Latin square, tests Lagrange on every element, and counts necklaces with Burnside's lemma.

```
import numpy as np
import matplotlib.pyplot as plt

n = 6          # knob: symmetries of a regular n-gon (try 3, 4, 5, 12)
k = 2          # knob: number of bead colours for the necklace count

# D_n as permutations of the n corners: rotations r^a, reflections s r^a
rot = [tuple((i + a) % n for i in range(n)) for a in range(n)]
ref = [tuple((a - i) % n for i in range(n)) for a in range(n)]
G = rot + ref
index = {g: t for t, g in enumerate(G)}
comp = lambda p, q: tuple(p[i] for i in q)           # do q first, then p

T = np.array([[index[comp(a, b)] for b in G] for a in G])
assert all(sorted(row) == list(range(2 * n)) for row in T)   # Latin square

def order(g):
    e, h, m = tuple(range(n)), g, 1
    while h != e:
        h, m = comp(g, h), m + 1
    return m

orders = [order(g) for g in G]
print("element orders:", orders)
print("all divide |G| =", 2 * n, ":", all((2 * n) % o == 0 for o in orders))
print("abelian:", (T == T.T).all())

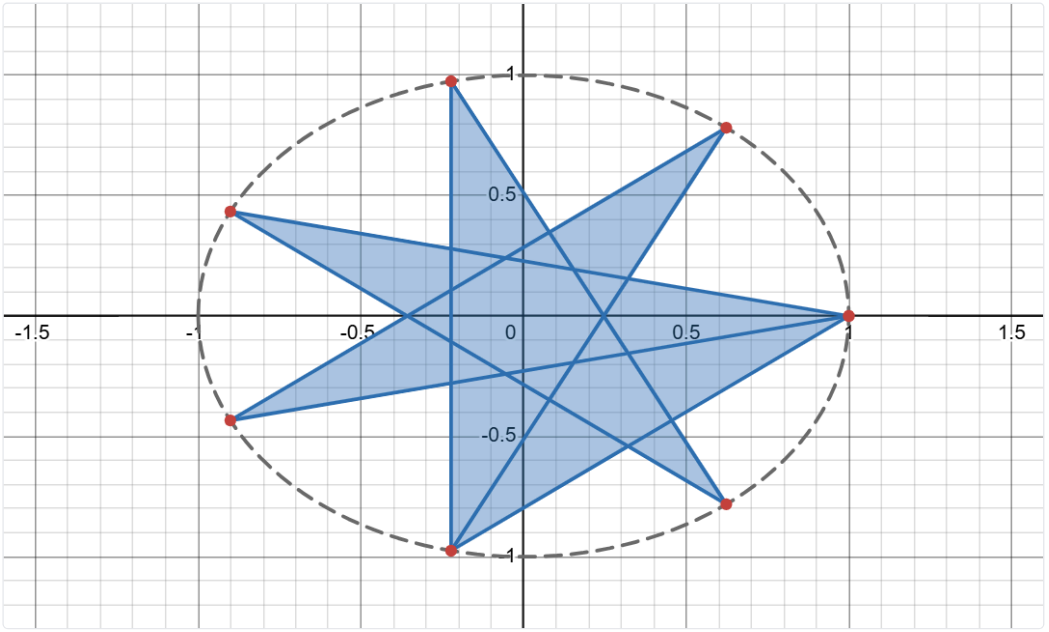
def cycles(p):
    seen, c = set(), 0
    for i in range(n):
        if i not in seen:
            c += 1
            while i not in seen:
                seen.add(i); i = p[i]
    return c

print("necklaces (rotations only):", sum(k ** cycles(g) for g in rot) // n)
print("bracelets (with flips):   ", sum(k ** cycles(g) for g in G) // (2 * n))
plt.imshow(T, cmap="tab20"); plt.title(f"Cayley table of D{n}"); plt.show()
```

With $n = 6, k = 2$ it reports element orders 1, 6, 3, 2, 3, 6 for the rotations and 2 for all six reflections, all dividing 12; the group is not abelian; and there are 14 two-colour necklaces of six beads but only 13 bracelets, because one pair of necklaces are mirror images. Things to try:

- Change `n` to 7, then 8. For a prime n every non-trivial rotation has order n; for $n = 8$ you see orders 2, 4 and 8. Why are there never orders like 3 when $n = 8$?
- Set `k = 3` and increase `n`. How fast does the bracelet count grow compared with $k^n/(2n)$, the naive "divide by the group size" guess? When is the naive guess exactly right?
- Change `ref` so that reflections are omitted from `G` and rerun the Latin-square check on `rot` alone. Is the rotation subgroup normal? (Test ghg^{-1}.)

For a geometric view of the cyclic group μ_7, the graph below joins the powers of ω^3 where $\omega = e^{j2\pi/7}$. Because 3 and 7 share no factor, the star visits every seventh root of unity before closing.



Powers of ω^3 in μ_7. In the blue line, change both 7s to 8 and both 3s to 2: the path now closes after 4 steps, tracing the subgroup of order $8/\gcd(8,2) = 4$. Try 8 and 3 next, then 12 and 4. The red dots are the seventh roots for reference.

56.6 The challenge

No answers are given.

1. **Intuition.** On a Rubik's cube, twisting a single corner cubie by 120° in place, leaving everything else solved, is impossible. Guess the invariant: assign each corner a twist of 0, 1 or 2, and ask what every face turn does to the *sum* of the eight twists. Why does a homomorphism to $\mathbb{Z}_3$ settle the question, and what is its kernel?
2. **Derivation.** Prove that every group of order 4 is isomorphic either to $\mathbb{Z}_4$ or to the Klein four-group $\mathbb{Z}_2 \times \mathbb{Z}_2$. (Use Lagrange to list the possible element orders.) Then show D_4 has exactly 10 subgroups and decide which of them are normal.
3. **Implementation.** Extend `generate` to the 15 puzzle restricted to a 2×3 board (5 tiles and a blank). Generate all reachable configurations by breadth-first search, confirm that exactly half of the $6! = 720$ arrangements are reached, and record the largest number of moves needed (the board's "God's number").
4. **Open investigation.** Burnside's lemma counts colourings up to symmetry. Choose a structure you care about (6-bit binary words up to cyclic shift, which is relevant to cyclic codes; chemical isomers of a ring molecule; seating plans at a round table) and compute counts for several sizes. Then look for a closed formula, and investigate what happens when you weight colours unequally (Pólya's enumeration theorem is the place to end up).

56.7 Loose threads

The hook asked how to prove impossibility without searching. The answer is an **invariant that is a homomorphism**: a map from the group of moves to a small group that respects composition. The sign $\operatorname{sgn} : S_{16} \to \{\pm 1\}$, combined with the colour of the blank's square, kills the 14–15 puzzle in four lines and simultaneously shows that half of all arrangements are unreachable. Exact counting comes from the same structure: Lagrange's theorem forces sizes to divide, orbit–stabilizer turns "how many symmetries?" into a product, and Burnside's lemma turns "how many different-looking things?" into an average.

What we did not tell you:

- **Why the symmetries of a polynomial's roots decide whether it can be solved.** There is a formula for the roots of quadratics, cubics and quartics, but provably none, using only arithmetic and radicals, for the general quintic. The reason is that S_5, the group permuting five roots, contains the simple group A_5 (order 60, which you generated in §56.4), and it is not abelian. That is Galois theory, which deserves a book of its own; Stewart's in the reading list is the friendliest route.
- **How groups become matrices.** Every finite group can be realised as a group of matrices, and the traces of those matrices (its **characters**) carry almost everything about it. The DFT is the character table of the cyclic group $\mathbb{Z}_n$, which is why convolution diagonalises. The first mystery points to Ch. 95.
- **What the common shape of all these definitions is.** Groups, rings and vector spaces each have substructures, structure-preserving maps, quotients and an isomorphism theorem. That family resemblance is not a coincidence; it is the subject of Ch. 62.

> **? A group drawn on a curve**
>
> Draw the curve $y^2 = x^3 - x + 1$. Through two points on it, draw the straight line; it meets the curve in exactly one more point. Reflect that point in the x-axis and call it the "sum". Astonishingly, this rule is associative and makes the curve's points into an abelian group, and the hardness of undoing repeated addition in that group protects most of the world's secure web connections. Why is a rule made of lines associative? See Ch. 57 for the arithmetic, and Ch. 78 for the proof and the cryptography.

Chapter 57 — Number Theory: The Hidden Arithmetic of the Digital World

> **Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on:** Ch. 56, Ch. 1, Ch. 29 · **Leads to:** Ch. 77, Ch. 78, Ch. 79, Ch. 81 · **Related:** Ch. 26, Ch. 38, Ch. 18, Ch. 94 **Reading time:** ~25 min

57.1 The hook

The English mathematician G. H. Hardy wrote in 1940 that number theory was gloriously useless: nobody had found a warlike purpose for it, and he did not expect anyone to. Thirty-seven years later, three researchers at MIT turned the arithmetic of primes into the lock on the world's secrets.

Here is the puzzle they solved. You want to buy something from a website you have never visited. Every bit you send crosses networks owned by strangers, and an eavesdropper can copy all of it. You and the website have never met and share no secret password. Yet within a fraction of a second your browser and the server agree on a secret key that the eavesdropper, who saw *every message*, cannot work out.

That sounds impossible. If I tell you everything I tell my partner, how can my partner know something you don't?

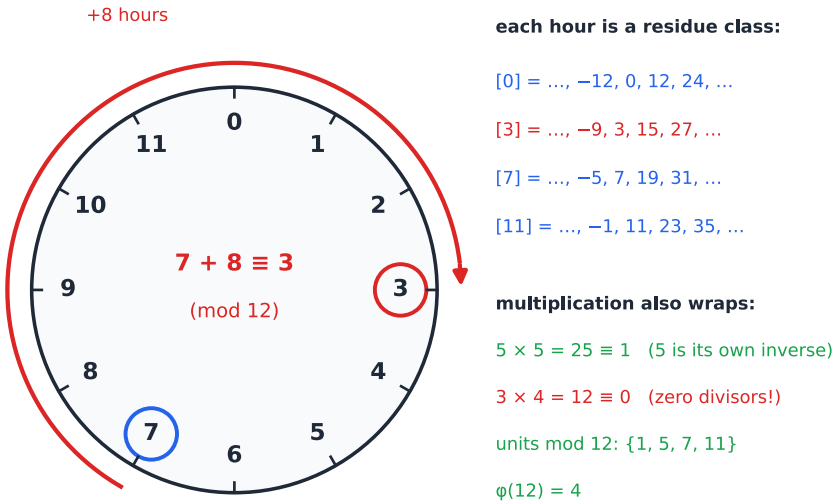
The trick is an asymmetry of effort that lives entirely in whole numbers. Multiply two 300-digit primes and a laptop finishes in microseconds. Hand someone only the 600-digit product and ask for the two primes back, and every computer on Earth working together would not finish before the Sun burns out, as far as anyone knows. Similarly, raising 5 to the 6th power and keeping the remainder after dividing by 23 is easy ($5^6 = 15625 \equiv 8$). Recovering the exponent 6 from the remainder 8 is, for large numbers, believed to be hopeless.

> **How can arithmetic on remainders make some calculations effortless one way and practically impossible the other way, and how do two strangers use that to share a secret in public?**

The answer needs four ideas that are each more than 200 years old: Euclid's algorithm, the clock arithmetic of Gauss, Fermat's little theorem and Euler's generalisation of it. You will see the full machine working by the end of §57.3, on numbers small enough to check by hand.

57.2 The big idea

Number theory studies the integers, but its modern power comes from looking at them through a keyhole: **remainders**. Fix a modulus n and identify any two integers that differ by a multiple of n. On a 12-hour clock, 7 o'clock plus 8 hours is 3 o'clock, and 15, 27 and -9 all "are" 3.

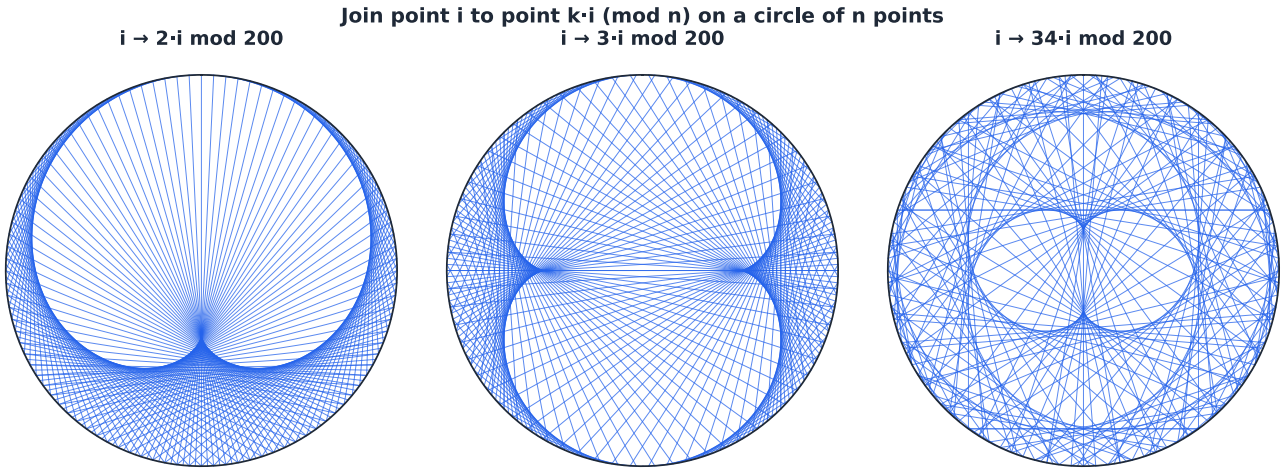


Arithmetic mod 12. Each hour stands for an entire class of integers. Addition wraps around; so does multiplication, which brings surprises: some numbers have inverses ($5 \times 5 \equiv 1$) and some multiply to zero ($3 \times 4 \equiv 0$).

Wrapping around destroys size. In ordinary arithmetic, 5^k grows steadily and you can recover k with a logarithm. Mod 23, the powers of 5 go

$$5,\ 2,\ 10,\ 4,\ 20,\ 8,\ 17,\ 16,\ 11,\ 9,\ 22,\ 18,\ 21,\ 13,\ 19,\ 3,\ 15,\ 6,\ 7,\ 12,\ 14,\ 1,\ \ldots$$

visiting all 22 non-zero residues in an order that looks scrambled. Computing forward is easy; going backward (the **discrete logarithm**) has no landmarks. The second picture shows how strange modular multiplication looks when drawn. Put n points on a circle and join point i to point $ki \bmod n$:



Multiplication mod 200 by 2, 3 and 34. Small multipliers trace smooth envelopes (a cardioid, a nephroid); larger ones give tangled, nearly structureless webs. The same operation can look orderly or chaotic depending on the numbers.

Here is the one-paragraph version of the public-key idea, using a paint analogy. Alice and Bob agree in public on a common colour. Each mixes in a secret colour of their own and sends the mixture across. Each then adds their own secret to what they received. Both end up with "common + Alice's + Bob's", while the eavesdropper holds only the two half-mixtures and cannot un-mix paint. In number theory, "mixing" is exponentiation mod a prime, and un-mixing is the discrete logarithm.

Underneath all of this sit the **primes**, the numbers with no divisors but 1 and themselves. They are the atoms of multiplication, they make clock arithmetic into a field, and their distribution is the deepest unsolved mystery in mathematics.

57.3 The mathematics

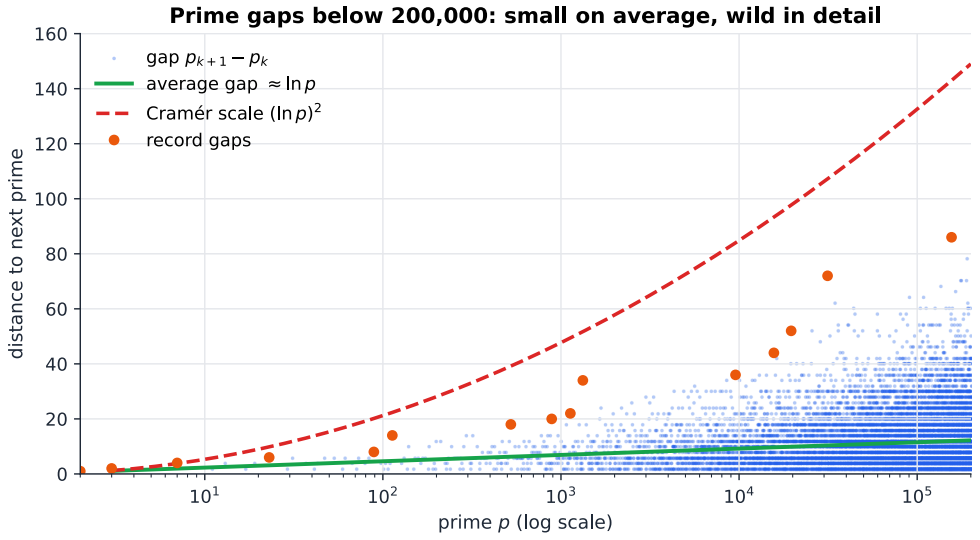
Primes and the fundamental theorem

Every integer $n \geq 2$ factors into primes, and the factorisation is unique up to order: $3120 = 2^4 \cdot 3 \cdot 5 \cdot 13$. (Existence is a short induction; uniqueness needs Euclid's lemma below.) The first great theorem about primes is also the oldest.

> **Euclid (c. 300 BC)**
>
> There are infinitely many primes.

Proof. Suppose $p_1, \dots, p_k$ were all of them. Let $N = p_1 p_2 \cdots p_k + 1$. Dividing N by any p_i leaves remainder 1, so no p_i divides N. But $N \geq 2$ has some prime factor, which is then a prime missing from the list. ■

How many are there? The **prime number theorem** (Hadamard and de la Vallée Poussin, 1896) says the number $\pi(x)$ of primes up to x satisfies $\pi(x) \sim x / \ln x$. There are 78,498 primes below 10^6, against $10^6 / \ln 10^6 \approx 72{,}382$. So near a large number p the average gap between primes is about $\ln p$, and a random 300-digit number is prime with probability roughly $1/\ln(10^{300}) \approx 1/691$. That is why finding big primes for keys is cheap: test a few hundred random odd candidates.



Gaps between consecutive primes below 200,000. The average gap tracks $\ln p$ (green), but individual gaps scatter wildly; record gaps (orange) stay below the $(\ln p)^2$ curve that a random model of the primes predicts. The longest here is 86, after 155,921.

Congruences and Euclid's algorithm

Congruence

$a \equiv b \pmod{n}$ means n divides $a - b$. The residue classes mod n form the ring $\mathbb{Z}_n = \{0, 1, \dots, n-1\}$ of Ch. 56, with addition and multiplication done mod n.

Congruences can be added and multiplied like equations, but **not divided** freely: $2 \cdot 3 \equiv 2 \cdot 9 \pmod{12}$, yet $3 \not\equiv 9$. Division by a is legal exactly when a has a multiplicative inverse mod n, and the tool for finding inverses is the oldest non-trivial algorithm still in daily use. Euclid's algorithm computes $\gcd(a, b)$ by repeatedly replacing (a, b) with $(b,\ a \bmod b)$; Ch. 29 §29.4 proves it correct with a loop invariant. Running it *backwards* gives more.

Bézout's identity

For integers a, b not both zero there are integers x, y with $ax + by = \gcd(a, b)$.

Proof. Let $S = \{ax + by > 0 : x, y \in \mathbb{Z}\}$ and let $d = ax_0 + by_0$ be its smallest element. Divide a by d: $a = qd + r$ with $0 \le r < d$. Then $r = a - qd = a(1 - qx_0) + b(-qy_0)$ is again a combination of a and b, and it is smaller than d, so it cannot be in S; hence $r = 0$ and d divides a. Likewise d divides b. Any common divisor of a and b divides $ax_0 + by_0 = d$. So d is the greatest common divisor. ■

The **extended Euclidean algorithm** finds x, y explicitly (§57.4). Two consequences matter everywhere:

1. *a is invertible mod n if and only if* $\gcd(a, n) = 1$. If $ax + ny = 1$ then $ax \equiv 1 \pmod{n}$, so x is the inverse. Conversely, if $ax \equiv 1$ then $ax - 1 = ny$ for some y, and any common divisor of a, n divides 1.
2. *$\mathbb{Z}_p$ is a field when p is prime*, since every $a \not\equiv 0$ is coprime to p. For composite n it is not: a factor d of n is a zero divisor. This also gives **Euclid's lemma** (if a prime divides ab it divides a or b), which proves uniqueness of factorisation.

The same identity solves the simplest **Diophantine equations**, equations where only integer solutions count. $ax + by = c$ has integer solutions exactly when $\gcd(a, b)$ divides c: with 6-litre and 10-litre jugs you can measure 4 litres, but never 5. Other Diophantine equations are wildly harder. $x^2 + y^2 = z^2$ has infinitely many solutions (3, 4, 5; 5, 12, 13; …), while $x^n + y^n = z^n$ has none in positive integers for $n \ge 3$, as Fermat claimed in 1637 and Andrew Wiles proved in 1994 using elliptic curves. Hilbert asked in 1900 for an algorithm that decides whether any given Diophantine equation has a solution; in 1970 Matiyasevich showed none exists, which is the halting problem of Ch. 30 wearing integer clothes.

The units, the invertible residues, form a group $\mathbb{Z}_n^\times$ under multiplication. Its size is **Euler's totient** $\varphi(n)$, the count of $1 \le a \le n$ with $\gcd(a, n) = 1$. For a prime, $\varphi(p) = p - 1$; for distinct primes, $\varphi(pq) = (p-1)(q-1)$.

Chinese remainder theorem

If $\gcd(m, n) = 1$, the map $x \mapsto (x \bmod m,\ x \bmod n)$ is a ring isomorphism $\mathbb{Z}_{mn} \cong \mathbb{Z}_m \times \mathbb{Z}_n$.

So a congruence mod 12 is the same information as one mod 3 plus one mod 4: "$x \equiv 2 \pmod 3$, $x \equiv 3 \pmod 4$" has the unique solution $x \equiv 11 \pmod{12}$. Engineers use this to split a big modular computation into small parallel ones (residue number systems, fast RSA decryption).

Fermat, Euler and the trapdoor

Euler's theorem

If $\gcd(a, n) = 1$, then $a^{\varphi(n)} \equiv 1 \pmod{n}$. For a prime p not dividing a, this is **Fermat's little theorem**, $a^{p-1} \equiv 1 \pmod{p}$.

Proof. Let $u_1, \dots, u_k$ be the $k = \varphi(n)$ units mod n. Multiplying each by the unit a gives $au_1, \dots, au_k$. These are again units, and they are distinct, because $au_i \equiv au_j$ implies $u_i \equiv u_j$ after multiplying by a^{-1}. So they are the same k units in a different order, and their products agree:

$$\prod_{i=1}^{k} (au_i) \equiv \prod_{i=1}^{k} u_i \pmod{n} \quad \Longrightarrow \quad a^k \prod u_i \equiv \prod u_i .$$

The product of units is a unit, so cancel it: $a^k \equiv 1$. ■

(Equivalently: $\mathbb{Z}_n^\times$ is a group of order $\varphi(n)$, and by Lagrange's theorem in Ch. 56 every element's order divides it.)

Now the machine. **RSA** (Rivest, Shamir, Adleman, 1977):

1. Choose primes p, q; publish $n = pq$. Compute $\varphi(n) = (p-1)(q-1)$ privately.
2. Choose a public exponent e with $\gcd(e, \varphi(n)) = 1$; compute the private $d = e^{-1} \bmod \varphi(n)$ by extended Euclid.
3. Encrypt a message $m < n$ as $c = m^e \bmod n$. Decrypt as $c^d \bmod n$.

Why it works. $ed = 1 + t\varphi(n)$ for some integer t, so when $\gcd(m, n) = 1$,

$$c^d \equiv m^{ed} = m \cdot \left(m^{\varphi(n)}\right)^t \equiv m \cdot 1^t = m \pmod{n}.$$

(The rare case $\gcd(m, n) > 1$ also works, by checking mod p and mod q separately and gluing with the CRT.)

RSA with toy numbers

Take $p = 61$, $q = 53$: $n = 3233$, $\varphi(n) = 3120$. With $e = 17$, extended Euclid gives $17 \cdot 2753 = 46801 = 15 \cdot 3120 + 1$, so $d = 2753$. The message $m = 65$ encrypts to $65^{17} \bmod 3233 = 2790$, and $2790^{2753} \bmod 3233 = 65$. Anyone can encrypt with $(n, e) = (3233, 17)$. To find d you need $\varphi(n)$, which means factoring 3233, trivial here and believed infeasible when n has 600 digits.

The secret-sharing trick of the hook is **Diffie–Hellman** (1976). Publish a prime p and a base g. Alice picks secret a and sends $A = g^a \bmod p$; Bob picks b and sends $B = g^b \bmod p$. Alice computes B^a, Bob computes A^b, and both get $g^{ab} \bmod p$. With $p = 23$, $g = 5$, $a = 6$, $b = 15$: $A = 8$, $B = 19$, and $19^6 \equiv 8^{15} \equiv 2 \pmod{23}$. The eavesdropper sees 23, 5, 8 and 19, and must solve a discrete logarithm to get the shared 2.

That answers the hook. Modular exponentiation is fast (§57.4), but its inverses, factoring and discrete logarithms, have no known efficient classical algorithm. The best general factoring method, the number field sieve, runs in roughly $\exp\big(1.92\,(\ln n)^{1/3}(\ln \ln n)^{2/3}\big)$ steps: sub-exponential, but still astronomically slow for 2048-bit n.

? A machine that factors

Every public key built on factoring or discrete logs shares one weakness: both problems reduce to *finding the period* of a function like $k \mapsto a^k \bmod n$. In 1994 Peter Shor showed that a quantum computer can find such periods efficiently, using a quantum version of the Fourier transform you met in Ch. 16. Why does period-finding crack factoring, and what are cryptographers replacing RSA with before such machines exist? See Ch. 77.

Finite fields

$\mathbb{Z}_p$ is a field with p elements. Are there others? Yes, exactly one (up to isomorphism) of each prime-power size p^k, and none of any other size. The field $\mathbb{F}_{p^k}$ is built like $\mathbb{C}$ in Ch. 56: take polynomials with coefficients mod p and reduce modulo an irreducible polynomial of degree k. Engineers live in $\mathbb{F}_{2^8}$, whose 256 elements are bytes: addition is XOR, and multiplication is polynomial multiplication reduced mod $x^8 + x^4 + x^3 + x + 1$. AES encryption, Reed–Solomon codes on QR codes and in deep-space links, and RAID-6 disk arrays all compute there. The multiplicative group of every finite field is **cyclic**, which is why a generator g like the 5 mod 23 above always exists.

Elliptic curves, in one paragraph

An **elliptic curve** over a field is the set of solutions of $y^2 = x^3 + ax + b$ (with $4a^3 + 27b^2 \neq 0$), plus one extra "point at infinity". Its points form an abelian group under a chord-and-tangent rule (the mystery at the end of Ch. 56). Over $\mathbb{F}_p$ the curve is a finite cloud of points: $y^2 = x^3 + 2x + 3$ over $\mathbb{F}_{97}$ has exactly 100 points. **Hasse's theorem** says the count N always satisfies $|N - (p+1)| \le 2\sqrt{p}$; here $|100 - 98| = 2 \le 19.7$. The discrete logarithm in these groups appears to be much harder than in $\mathbb{Z}_p^\times$, which is why a 256-bit elliptic-curve key offers security comparable to a 3072-bit RSA key.

? The shortcut that elliptic curves seem to lack

For $\mathbb{Z}_p^\times$ and for factoring there are sub-exponential "index calculus" attacks that exploit the fact that ordinary integers factor into small primes. For a well-chosen elliptic curve, the best known attack is generic and takes about $\sqrt{N}$ steps. Is there a hidden notion of "small" points on a curve that would let index calculus in? Nobody knows; if there were, much of the internet would need new locks. The current state of play is in Ch. 78.

Pseudorandomness and codes

Number theory also manufactures *fake* randomness. A **linear congruential generator** iterates $x_{k+1} = (a x_k + c) \bmod m$. Its outputs look random but sit on a few lattice planes when plotted in pairs or triples, and the Hull–Dobell theorem says the period reaches its maximum m exactly when $\gcd(c, m) = 1$, $a - 1$ is divisible by every prime factor of m, and $a - 1$ is divisible by 4 if m is. The Mersenne Twister, the default generator in NumPy's legacy interface and many languages, has period $2^{19937} - 1$, a Mersenne prime. None of these generators is safe for cryptography: Ch. 81 explains what "unpredictable" must mean. The same finite fields carry **error-correcting codes**: a Reed–Solomon code treats a block of data as the coefficients of a polynomial over $\mathbb{F}_{2^8}$ and transmits its values at extra points, so that a few corrupted bytes can be located and repaired (Ch. 79).

57.4 The algorithm

Three short routines carry nearly all of computational number theory: fast exponentiation, the extended Euclidean algorithm, and a randomised primality test.

```
import random

def power_mod(a, k, n):
    """a^k mod n by square-and-multiply: O(log k) multiplications."""
    result, a = 1, a % n
    while k > 0:

print(is_probable_prime(561), is_probable_prime(2**127 - 1))  # False True
```

Cost. Square-and-multiply reads the exponent bit by bit, so $a^k \bmod n$ costs at most $2\log_2 k$ modular multiplications. For a 2048-bit RSA exponent that is about 4,000 multiplications instead of 2^{2048}. Euclid's algorithm takes $O(\log \min(a, b))$ division steps; its worst case is consecutive Fibonacci numbers (Lamé, 1844). These two facts are the "easy direction" of the hook.

Why Miller–Rabin and not plain Fermat. Fermat's theorem suggests testing whether $a^{n-1} \equiv 1 \pmod n$. Composites can pass: $341 = 11 \cdot 31$ fools base 2, and **Carmichael numbers** such as $561 = 3 \cdot 11 \cdot 17$ fool *every* base coprime to them. Miller–Rabin adds a second check. Since n prime makes $\mathbb{Z}_n$ a field, the only square roots of 1 are ± 1; the inner loop watches the chain $a^d, a^{2d}, a^{4d}, \ldots$ for a square root of 1 that is not ± 1. For an odd composite, at least three quarters of the bases expose it, so 20 rounds leave an error chance below $4^{-20} \approx 10^{-12}$. (A deterministic polynomial-time test exists, AKS from 2002, but it is far slower in practice.)

> **Common Pitfall: textbook RSA is not secure RSA**
>
> The toy RSA above is deterministic: the same message always encrypts to the same ciphertext, so an attacker can test guesses. Encrypting m^e with a tiny m and $e = 3$ may never wrap mod n, and an ordinary cube root recovers it. Real systems pad messages with structured randomness (OAEP), use $e = 65537$, and use constant-time arithmetic so that the *timing* of square-and-multiply doesn't leak the bits of d. The number theory is the easy part; Ch. 77 covers the rest.

57.5 The experiment

The script counts primes, hunts for composites that fool the Fermat test, and measures the period of a linear congruential generator, plotting successive outputs so you can see the lattice structure hidden inside "random" numbers.

```
import numpy as np
import matplotlib.pyplot as plt

N = 100_000        # knob: search range for primes and pseudoprimes
BASES = [2]        # knob: Fermat-test bases, try [2, 3] or [2, 3, 5, 7]
a, c, m = 21, 7, 64  # knob: linear congruential generator x -> (a x + c) mod m

sieve = np.ones(N + 1, bool); sieve[:2] = False
for p in range(2, int(N ** 0.5) + 1):
    if sieve[p]:
        sieve[p * p::p] = False

def fermat(n):           # "probably prime" if b^(n-1) = 1 (mod n) for every base
    return all(pow(b, n - 1, n) == 1 for b in BASES if b % n)

liars = [n for n in range(3, N + 1, 2) if fermat(n) and not sieve[n]]
print("primes below N:", sieve.sum(), "   N/ln N =", round(N / np.log(N)))
print("composites that fool the test:", len(liars), liars[:8])

# period of the LCG from seed 0
x, seen = 0, {}
for step in range(m + 1):
    if x in seen:
        print("LCG period:", step - seen[x], "out of a possible", m)
        break
    seen[x] = step
    x = (a * x + c) % m

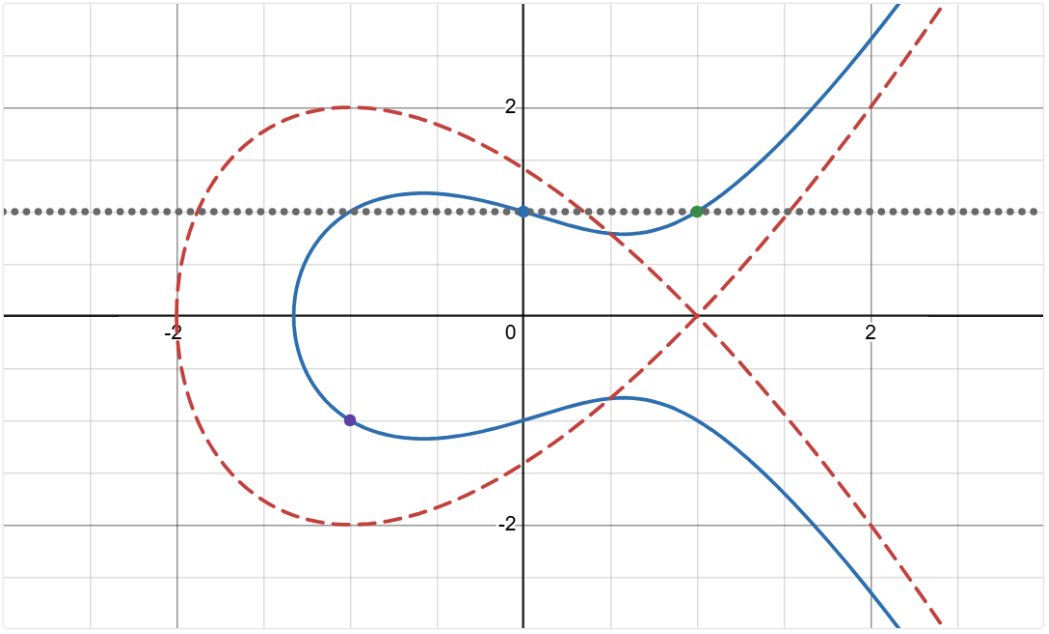
xs = [0]
for _ in range(2000):
    xs.append((a * xs[-1] + c) % m)
xs = np.array(xs) / m
plt.plot(xs[:-1], xs[1:], ".", ms=4)
plt.title(f"successive LCG outputs, a={a}, c={c}, m={m}")
plt.xlabel("$x_n/m$"); plt.ylabel("$x_{n+1}/m$"); plt.show()
```

With the settings shown it finds 9,592 primes below 10^5 (against $N/\ln N \approx 8{,}686$) and 78 odd composites that fool base 2, starting 341, 561, 645, 1105. With `BASES = [2, 3, 5, 7]` only three survive: 29341, 46657 and 75361, all Carmichael numbers. The LCG reaches its full period 64, and its 64 points fall on a handful of parallel lines.

Things to change:

- Set `a = 20`. The Hull–Dobell condition fails ($a - 1 = 19$ shares no factor with 64), and the generator collapses into a fixed point. Try `c = 8` with `a = 21`: now $\gcd(c, m) \neq 1$ and the period drops to 8.
- Set `a, c, m = 17, 1, 256`. Hull–Dobell holds, so the period is the full 256, yet the plotted pairs fall on just a few steep lines. A long period is not the same thing as randomness.
- Increase `N` to 10^6 and compare `liars` for base 2 with the Carmichael numbers you find with many bases. Do the Carmichael numbers get rarer or more common relative to the primes?

The elliptic curves of §57.3 also have a real picture. The graph shows a smooth curve and a singular one:



$y^2 = x^3 - x + 1$ (blue) with $P = (0, 1)$ and $Q = (1, 1)$. The line through them meets the curve again at $(-1, 1)$; reflecting gives $P + Q = (-1, -1)$. The red curve has $4a^3 + 27b^2 = 0$ and crosses itself at $(1, 0)$, where the group law breaks. Change $-3x + 2$ to $-3x + 3$ and the crossing opens into a smooth curve; change the blue curve's $+1$ to $+0.3$ and it splits into two pieces.

57.6 The challenge

No answers are given.

1. **Intuition.** Explain without symbols why the times-table picture for $i \mapsto 2i \bmod n$ approaches a cardioid as n grows, while $i \mapsto (n/2+1)\,i \bmod n$ (for even n) looks completely different. Which pictures are permutations of the points, and how can you tell from $\gcd(k, n)$?
2. **Derivation.** Prove that if $2^k + 1$ is prime then k is a power of 2, and that if $2^k - 1$ is prime then k is prime. Then show that every Carmichael number is odd and has at least three prime factors.
3. **Implementation.** Write a function that counts points on $y^2 = x^3 + ax + b$ over $\mathbb{F}_p$ for all a, b with $p = 101$, and plot the histogram of $N - (p+1)$. Check Hasse's bound, then implement the chord-and-tangent addition and find a point whose multiples visit the whole group.
4. **Open investigation.** Twin primes are pairs $p, p+2$ both prime. Count them below x for x up to 10^7 and compare with the Hardy–Littlewood prediction $2C_2\,x/(\ln x)^2$ with $C_2 \approx 0.6602$. Then look at the *last digits* of consecutive primes: is a prime ending in 1 more likely to be followed by one ending in 1, 3, 7 or 9? (This bias was only noticed in 2016.)

57.7 Loose threads

The hook asked how arithmetic can be easy one way and hard the other. Modular reduction throws away size, so the landmarks that make logarithms and factoring easy over the real numbers vanish. Euclid's algorithm and square-and-multiply keep the forward direction fast, Euler's theorem guarantees that the RSA exponents e and d undo each other, and Diffie–Hellman lets two strangers build g^{ab} in public. The hard direction, factoring or taking discrete logarithms, has resisted every classical attack for almost fifty years. That is a belief, not a theorem; no one has proved that these problems are hard.

What we did not tell you:

- **Why the primes are where they are.** The prime number theorem gives the average density, but the error term, how far $\pi(x)$ strays from its smooth approximation, is controlled by the zeros of a single complex function.
- **What a quantum computer changes.** The first mystery points to Ch. 77.
- **Whether elliptic curves really are harder.** The second mystery points to Ch. 78, and the geometry of such curves, which links them to Fermat's last theorem, is the territory of Ch. 94.

> **? A million dollars for the zeros**
>
> Euler noticed that $\sum_{n\ge 1} n^{-s} = \prod_{p\ \text{prime}} (1 - p^{-s})^{-1}$, which ties all integers to all primes. Riemann extended this **zeta function** to complex s using the analytic continuation of Ch. 18 and conjectured in 1859 that all its non-trivial zeros lie on the line $\operatorname{Re}\{s\} = \tfrac{1}{2}$. If true, the primes are as evenly spread as a random model allows: $\pi(x)$ differs from its smooth approximation by roughly $\sqrt{x}\ln x$. More than ten trillion zeros have been checked. Nobody has a proof; it is one of the Clay Millennium Problems, and how mathematicians attack such problems is the subject of Ch. 98.

58.1 The hook

A factory robot has a single rotating joint: a shoulder that can spin all the way round. Its controller needs a **motion planner**, a rule that takes the current angle a and a target angle b and returns a path from one to the other. The engineers add one sensible requirement. The planner should be **continuous**: if you nudge the target slightly, the planned path should change only slightly. Nobody wants a robot that swings left for a target at 179.9° and right for one at 180.1°.

The obvious rule is "take the shorter way round". It is perfect, until the target is directly opposite the start. Then the two ways are equally short and the planner must pick one; just past that point it must suddenly switch to the other. Fine, say the engineers, always turn counter-clockwise. Now a target just *clockwise* of the start is reached by turning almost a full circle, while a target exactly at the start needs no motion at all. Again a jump.

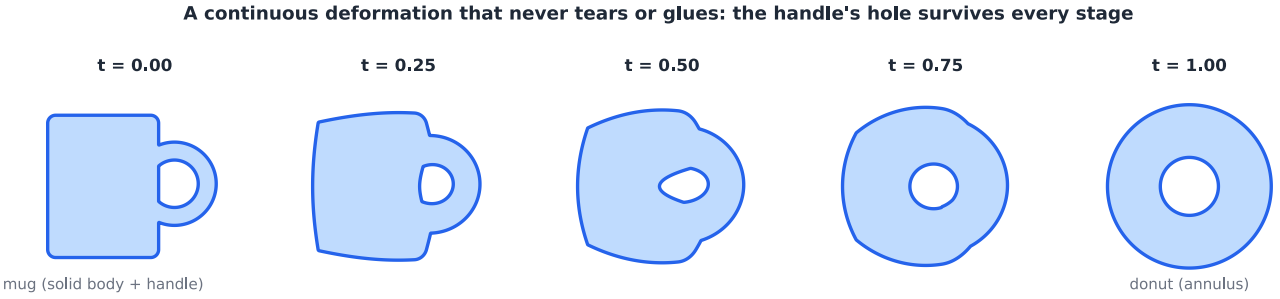
Every rule the team tries breaks somewhere. Two joints, a shoulder and an elbow, make things worse, and a drone's orientation in 3-D space is worse still.

> **Is there any continuous motion planner for a rotating joint, or is a discontinuity unavoidable? And if it is unavoidable, what property of the space of poses forces it?**

The answer has nothing to do with angles, lengths, motors or the particular formula you write. It depends only on the *shape* of the space of poses, in a sense of "shape" so loose that a coffee mug and a doughnut count as the same. That sense of shape is topology.

58.2 The big idea

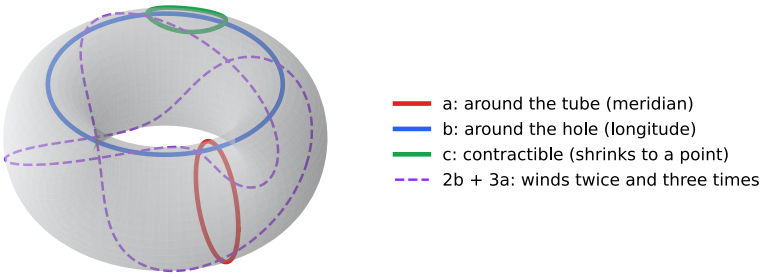
Geometry measures: lengths, angles, curvature. Topology asks what is left when you are allowed to **stretch, bend and squash, but never tear or glue**. A circle and a square are the same; so is a wobbly closed loop. A doughnut and a coffee mug are the same, because the mug's handle *is* the doughnut's hole and the cup part can be squashed into the handle's base.



A continuous deformation from a mug's silhouette to a donut's. Each stage is a blend of the two shapes' distance functions; the hole through the handle is never created or destroyed, only moved and widened.

So what *can't* be bent away? Holes. Pieces. Whether a loop can be shrunk to a point. Those are the **topological invariants**, and they are the whole point of the subject: if two spaces differ in an invariant, no amount of clever stretching turns one into the other.

Now think of the robot again. The set of all its poses is a space. One rotating joint gives a circle S^1: angles 0° and 360° are the same pose. Two joints give a pair of angles, each on a circle, which is a **torus**, the surface of a doughnut.



Configuration space of a two-joint arm. Loop a spins the elbow once, loop b spins the shoulder once, loop c wiggles a little and comes back. Only c can be shrunk to a point while staying on the surface. Any loop is, up to deformation, "m times b plus n times a".

Here is the intuition for the hook. On a circle, a loop that goes once round can't be shrunk to a point without leaving the circle. A continuous motion planner would let you *build* such a shrinking, as §58.3 shows, so it can't exist. The obstacle is a hole in the configuration space, and topology turns "there is a hole" into a theorem.

The same thinking applies to data. A cloud of sensor readings has no edges or surfaces, only points. But if you thicken every point into a small ball and watch which holes appear and disappear as the balls grow, you can measure the shape of the data. That is **topological data analysis**, and it closes the chapter.

58.3 The mathematics

Open sets and continuity

In Ch. 4 §4.1, f is continuous at x_0 if for every $\varepsilon > 0$ there is a $\delta > 0$ with $|x - x_0| < \delta \Rightarrow |f(x) - f(x_0)| < \varepsilon$. Topology rewrites that definition without distances. A set $U \subseteq \mathbb{R}^n$ is **open** if around each of its points there is a small ball still inside U. Then, as you can check by unpacking the definitions, f is continuous everywhere exactly when **the preimage of every open set is open**.

That reformulation mentions only open sets, so it can be used on any set where we have *declared* which subsets are open.

> **Topological space, continuity, homeomorphism**
>
> A **topology** on a set X is a collection of subsets called open sets, containing $\varnothing$ and X, and closed under arbitrary unions and finite intersections. A map $f : X \to Y$ between topological spaces is **continuous** if $f^{-1}(V)$ is open for every open $V \subseteq Y$. A **homeomorphism** is a continuous bijection whose inverse is also continuous; X and Y are then **homeomorphic**, written $X \cong Y$.

The inverse must be continuous too. Wrapping the interval $[0, 2\pi)$ onto the circle by $t \mapsto (\cos t, \sin t)$ is a continuous bijection, but it is not a homeomorphism: points near $(1, 0)$ on the circle come from both ends of the interval, so the inverse tears the circle open. Indeed the two spaces are not homeomorphic, as we are about to prove.

Connectedness and the intermediate value theorem

> **Connected**
>
> A space X is **connected** if it cannot be written as the union of two disjoint non-empty open sets.

The real interval $[a, b]$ is connected. (Sketch: if $[a, b] = U \cup V$ with $a \in U$, let c be the supremum of the points t for which all of $[a, t]$ lies in U; openness of U and V makes c lie in neither, a contradiction. This is where completeness of $\mathbb{R}$ enters, the subject of Ch. 60.)

> **Continuous images of connected spaces are connected**
>
> If $f : X \to Y$ is continuous and X is connected, then $f(X)$ is connected.

Proof. Suppose $f(X) = U \cup V$ with U, V disjoint, non-empty and open in $f(X)$. Then $f^{-1}(U)$ and $f^{-1}(V)$ are open (by continuity), disjoint, non-empty, and cover X. That separates X, which is impossible. ■

Apply this to a continuous $f : [a, b] \to \mathbb{R}$. The image is a connected subset of $\mathbb{R}$, and the connected subsets of $\mathbb{R}$ are exactly the intervals. So if $f(a) < 0 < f(b)$, the value 0 lies in the image: **the intermediate value theorem** is a statement about connectedness. It is the guarantee behind bisection root-finding in Ch. 22 §22.4.

Connectedness is also a cheap invariant. Remove one point from an open interval and it falls into two pieces; remove any one point from a circle and it stays in one piece. A homeomorphism would carry "interval minus a point" to "circle minus a point", so **an interval and a circle are not homeomorphic**. Similarly, the letter X is not homeomorphic to the letter O (removing the centre of X leaves four pieces).

Compactness

Compact

A space is **compact** if every covering of it by open sets has a finite sub-covering. In $\mathbb{R}^n$ (Heine–Borel), the compact sets are exactly the closed and bounded ones.

Compactness is "finiteness in disguise". Its key property has the same one-line proof shape as connectedness: the continuous image of a compact space is compact (pull back an open cover, pick a finite sub-cover, push it forward). Since compact subsets of $\mathbb{R}$ are closed and bounded, a continuous real function on a compact space is bounded and **attains** its maximum and minimum. That is the extreme value theorem, the existence guarantee behind every "minimise the cost over a closed, bounded design region" problem in Ch. 23. Over the open interval $(0,1)$, $f(x) = 1/x$ has no maximum: the open interval is not compact. So $[0,1] \not\cong (0,1)$, even though both are connected.

Homotopy and the fundamental group

Connectedness counts pieces. To detect holes we need loops. Two continuous maps $f, g : X \to Y$ are **homotopic** if one can be deformed continuously into the other: there is a continuous $H : X \times [0,1] \to Y$ with $H(x,0) = f(x)$ and $H(x,1) = g(x)$. You have seen this idea before. Deforming a contour of integration without crossing a singularity, in Ch. 18 §18.5, is a homotopy, and Cauchy's theorem says the integral cannot tell the two contours apart.

Fundamental group

Fix a base point $x_0 \in X$. The **fundamental group** $\pi_1(X, x_0)$ is the set of loops starting and ending at x_0, with two loops identified if they are homotopic through loops based at x_0. The product of two loops is "do one, then the other". The identity is the constant loop, and the inverse runs a loop backwards.

The group axioms of Ch. 56 hold *up to homotopy*: for example, running a loop and then its reverse is not literally the constant loop, but it shrinks to it. A space is **simply connected** if π_1 is trivial, meaning every loop shrinks to a point. Some answers, stated without proof:

Space	π_1	What a loop "remembers"
$\mathbb{R}^n$, a disk, a ball	trivial	nothing
circle S^1	$\mathbb{Z}$	how many times it winds round
torus $S^1 \times S^1$	$\mathbb{Z} \times \mathbb{Z}$	windings (m, n) round each circle
sphere S^2	trivial	nothing: a rubber band slides off a ball
figure-eight	free group on two letters	the word in a, b, a^{-1}, b^{-1} it spells; $ab \neq ba$
plane minus a point	$\mathbb{Z}$	the winding number about the point

The entry for the circle is the deep one. The integer attached to a loop is its **winding number**. In the complex plane, the winding number of a closed curve γ about the origin is $\frac{1}{2\pi j}\oint_\gamma \frac{dz}{z}$, the integral behind the argument principle and the Nyquist stability criterion of Ch. 18 §18.9. Proving that it is a *complete* invariant, that loops with equal winding numbers are homotopic and loops with different ones are not, uses the lifting of loops on the circle to paths on the real line; we take it as given.

No continuous motion planner on a circle

There is no continuous rule s that assigns to each pair of angles $(a, b) \in S^1 \times S^1$ a path $s(a,b) : [0,1] \to S^1$ from a to b, depending continuously on (a, b).

Proof. Suppose s existed. Fix a starting pose a_0 and define $H(b,t) = s(a_0, b)(t)$ for $b \in S^1$, $t \in [0,1]$. By assumption H is continuous. At $t = 0$, $H(b,0) = a_0$ for every b: the constant map. At $t = 1$, $H(b,1) = b$: the identity map of the circle. So H is a homotopy from the constant map to the identity. Now trace the identity map once round the circle: it is the loop of winding number 1. The homotopy H deforms it continuously, through closed loops $b \mapsto H(b,t)$, into a constant loop, which has winding number 0. On the circle the winding number cannot change under such a deformation, even one that moves the base point, because it is an integer that varies continuously. So $1 = 0$, a contradiction. ■

That answers the hook. A discontinuity is unavoidable for any planner on a single rotating joint, and the reason is the hole in the circle, $\pi_1(S^1) \cong \mathbb{Z} \neq 0$. The best you can do is split the configuration pairs into pieces and use a different continuous rule on each. For the circle two pieces suffice: on pairs that are not exactly opposite, take the shorter way round; on opposite pairs, always turn counter-clockwise. Each rule is continuous on its own piece. The minimum number of pieces is a topological invariant of the space, Farber's **topological complexity**, and it grows with the number of independent holes. A two-joint arm on a torus needs three pieces.

? The loop test for spheres

In two dimensions the sphere is the only closed surface on which every loop shrinks to a point. In 1904 Henri Poincaré asked whether the same is true one dimension up: is every closed, simply connected 3-dimensional space homeomorphic to the 3-sphere? It took a century. Grigori Perelman proved it in 2003 by letting the *geometry* of the space flow like heat, smoothing curvature until the shape revealed itself, and then declined both the Fields Medal and a million-dollar prize. How can a curvature flow prove a purely topological fact? Curvature is the subject of Ch. 59.

Homology: counting holes with linear algebra

The fundamental group is powerful but hard to compute, and non-abelian groups are awkward to compare. **Homology** trades some information for computability: it counts holes of each dimension with ranks of matrices.

Build a space out of simple pieces: vertices, edges, filled triangles (a **simplicial complex**). Write C_k for the vector space, over $\mathbb{F}_2 = \{0, 1\}$ to keep signs out of it, spanned by the k-dimensional pieces. The **boundary map** $\partial_k : C_k \to C_{k-1}$ sends an edge to the sum of its two end vertices and a triangle to the sum of its three edges. The key identity is

$$\partial_{k-1} \circ \partial_k = 0,$$

because the boundary of a boundary is empty: each vertex of a triangle appears in exactly two of its edges, and $1 + 1 = 0$ in $\mathbb{F}_2$. So every boundary is a **cycle** (an element of $\ker \partial$), and the k-th homology counts cycles that are *not* boundaries:

$$H_k = \ker \partial_k / \operatorname{im} \partial_{k+1}, \qquad \beta_k = \dim H_k = \dim \ker \partial_k - \operatorname{rank} \partial_{k+1}.$$

This is the quotient construction of Ch. 56 applied to vector spaces, and the dimensions come from rank–nullity (Ch. 8 §8.5). The **Betti number** β_0 counts connected pieces, β_1 counts independent loops that bound nothing, and β_2 counts enclosed voids.

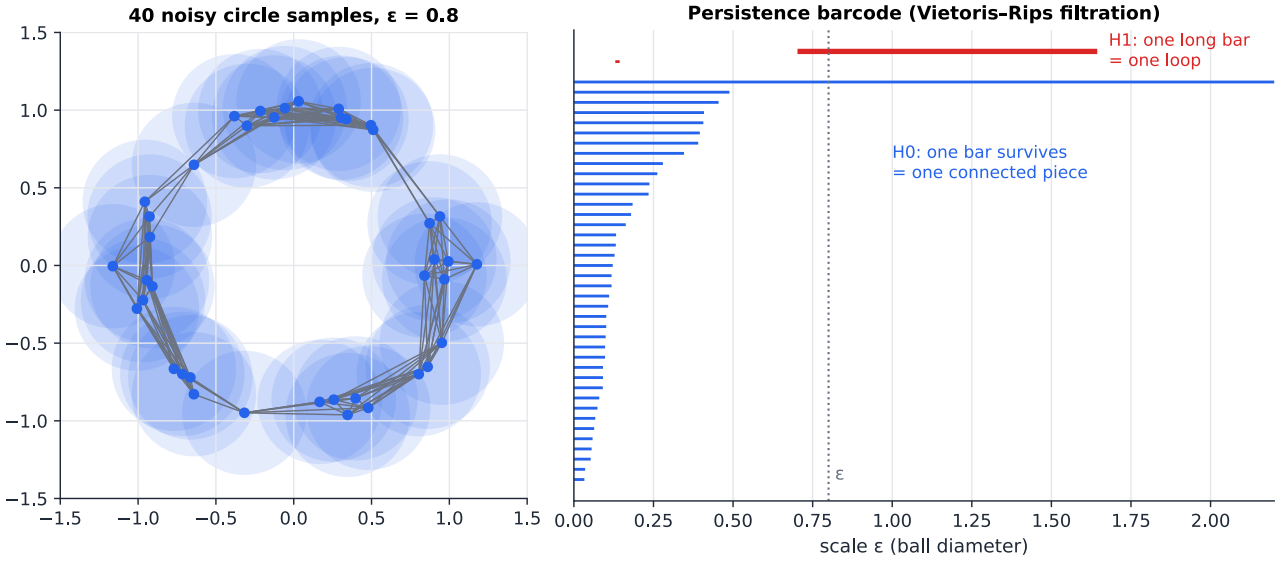
> **A hollow triangle versus a filled one**
>
> Take vertices u, v, w and edges uv, vw, wu. The boundary map ∂_1 is a 3×3 matrix over $\mathbb{F}_2$ in which every column has two 1s; its columns sum to zero, so its rank is 2. Then $\beta_0 = 3 - 2 = 1$ (one piece), and $\dim \ker \partial_1 = 3 - 2 = 1$. With no triangle filled in, $\operatorname{rank} \partial_2 = 0$, so $\beta_1 = 1$: one loop, the hole. Fill in the triangle uvw: now ∂_2 sends it to $uv + vw + wu$, which is exactly the cycle, so $\operatorname{rank} \partial_2 = 1$ and $\beta_1 = 0$. The hole is gone.

For the surfaces we have met, the answers are: circle $(\beta_0, \beta_1) = (1, 1)$; sphere $(\beta_0, \beta_1, \beta_2) = (1, 0, 1)$; torus $(1, 2, 1)$, one piece, two independent loops a and b, and one enclosed void. The alternating sum $\chi = \beta_0 - \beta_1 + \beta_2$ is the **Euler characteristic**, and a short rank–nullity computation shows it also equals $V - E + F$, counted on *any* triangulation. A cube has $8 - 12 + 6 = 2$, like the sphere; a torus has 0. That is why Euler's polyhedron formula $V - E + F = 2$ holds for every convex polyhedron: they are all homeomorphic to a sphere.

> **? Why you can't comb a hairy ball**
>
> Because $\chi(S^2) = 2 \neq 0$, every continuous field of tangent arrows on a sphere must vanish somewhere: at any moment there is a point on Earth where the horizontal wind speed is zero, and a smooth "hairy ball" always has a cowlick. The torus, with $\chi = 0$, can be combed flat. A cousin of this result, Brouwer's theorem that every continuous map of a disk to itself has a fixed point, is exactly what John Nash needed to prove that every finite game has an equilibrium. How does a statement about shapes guarantee a stable strategy? See Ch. 39.

From shapes to data: persistent homology

A point cloud has $\beta_0 =$ number of points and $\beta_1 = 0$: on its own it has no interesting homology. The fix is to look at it **at every scale**. For each $\varepsilon \geq 0$, the **Vietoris–Rips complex** R_ε has a vertex per data point, an edge between any two points closer than ε, and a filled triangle on any three points that are pairwise closer than ε. As ε grows, simplices are only ever added, so the complexes are nested: $R_\varepsilon \subseteq R_{\varepsilon'}$ for $\varepsilon < \varepsilon'$. A hole is **born** at the scale where its loop closes and **dies** when it gets filled in. Plotting every hole as a bar from birth to death gives a **persistence barcode**.



Left: 40 noisy samples of the unit circle, with edges drawn at scale $\varepsilon = 0.8$. Right: the barcode. Many short H_0 bars die quickly as nearby points merge; one infinite bar survives. In H_1 a single long bar, born near $\varepsilon \approx 0.70$ when the ring closes and dying near 1.64 when triangles fill the disk, says "this data has one loop". A tiny H_1 bar near 0.13 is noise.

The principle is that **long bars are features and short bars are noise**. It is used on protein structures, on the activity of neurons that encode an animal's head direction (the data really does lie on a circle), on sensor networks checking for coverage holes, and on time series embedded with delays to detect periodic behaviour in a dynamical system (Ch. 83).

58.4 The algorithm

Computing a barcode is linear algebra over $\mathbb{F}_2$, done in a clever order.

1. **Build the filtration.** List every simplex with the scale at which it appears: points at 0, an edge at its length, a triangle at its longest edge. Sort by scale, breaking ties so that every face comes before the simplices it bounds.
2. **Form the boundary matrix D**, with one column per simplex in that order. Column k holds the faces of simplex k (two vertices for an edge, three edges for a triangle).
3. **Reduce the columns left to right.** Let $\mathrm{low}(k)$ be the row of the lowest 1 in column k. While some earlier column has the same low, add it to column k (mod 2). Adding *earlier* columns only is what keeps the answer faithful to the order of the filtration.
4. **Read off the bars.** If reduced column k is non-zero with $\mathrm{low}(k) = i$, simplex i created a hole that simplex k killed: a bar from the scale of i to the scale of k, in dimension $\dim(i)$. A simplex that creates a hole and is never paired gives an infinite bar.

```
for k in 0 .. N−1:                      # columns in filtration order
    while column k is non-zero and low(k) == low(j) for some j < k:
        column k += column j  (mod 2)
    if column k is non-zero:
        record bar  [ scale(low(k)),  scale(k) )
```

Why does this work? Step 3 is Gaussian elimination restricted to adding columns from the left, so at every stage ε the reduced matrix still has the same rank structure as the boundary maps of R_ε. A zero column means the new simplex closed a cycle, so it gives birth to a homology class. A non-zero column means it filled one in, and the lowest-1 rule pairs it with the *youngest* class it kills, the "elder rule" that makes barcodes well defined.

Cost and failure cases. The reduction is cubic in the number of simplices in the worst case, and the number of simplices explodes: n points give up to $\binom{n}{3}$ triangles, about 1.7×10^8 for $n = 1000$. Practical software (Ripser, GUDHI) caps the maximum scale, computes cohomology instead (which reduces far fewer columns), and never stores the full matrix. Rips complexes are also sensitive to **outliers**: a single stray point can split a long bar in two, which is why robust variants weight points by local density. And barcodes depend on the metric you choose; Euclidean distance on raw features with different units can create holes that are artefacts of scaling.

58.5 The experiment

The script samples a noisy circle, builds the full Rips filtration up to triangles, runs the column reduction above, and plots the bars longer than 0.02.

```
import numpy as np
import matplotlib.pyplot as plt
from itertools import combinations

n, noise, seed = 40, 0.08, 7   # knobs: number of points, noise level, random seed
two_loops = False               # knob: True samples a figure-eight instead of a circle
rng = np.random.default_rng(seed)
t = rng.uniform(0, 2 * np.pi, n)
P = np.c_[np.cos(t), np.sin(t)]
if two_loops:
    P[n // 2:, 0] += 2.2                 # second circle, touching the first
P += rng.normal(0, noise, P.shape)
D = np.linalg.norm(P[:, None] − P[None], axis=2)

# Vietoris–Rips filtration up to triangles: each simplex enters at its longest edge
S = [(0.0, (i,)) for i in range(n)]
S += [(D[i, j], (i, j)) for i, j in combinations(range(n), 2)]
S += [(max(D[i, j], D[i, k], D[j, k]), (i, j, k)) for i, j, k in combinations(range(n), 3)]
S.sort(key=lambda s: (s[0], len(s[1])))
index = {s: k for k, (_, s) in enumerate(S)}

cols, pivot, bars = [], {}, []
for k, (val, s) in enumerate(S):           # column reduction over GF(2)
    col = {index[f] for f in combinations(s, len(s) − 1)} if len(s) > 1 else set()
    while col and max(col) in pivot:
        col ^= cols[pivot[max(col)]]
    cols.append(col)
    if col:
        pivot[max(col)] = k
        birth = S[max(col)][0]
        bars.append((len(s) − 2, birth, val))   # dimension, birth, death

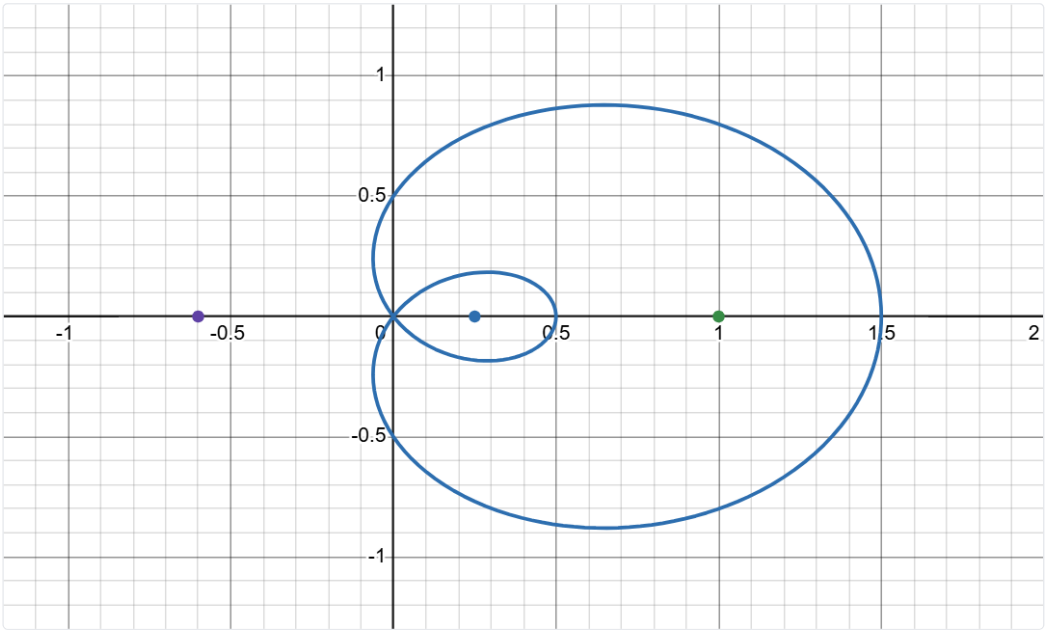
for dim in (0, 1):
    life = sorted((d − b for k, b, d in bars if k == dim), reverse=True)
    print(f"H{dim}: longest finite bars", np.round(life[:4], 3))
for k, b, d in bars:
    if d − b > 0.02:
        plt.plot([b, d], [k + rng.uniform(−0.3, 0.3)] * 2, color="C%d" % k, lw=2)
plt.yticks([0, 1], ["H0", "H1"]); plt.xlabel("scale"); plt.show()
```

With the settings shown, the longest finite H_1 bar has length 0.942 and the next one 0.014: one loop, unmistakably. (The infinite H_0 bar is not listed, since it never dies.) Things to try:

- Set `two_loops = True`. Two H_1 bars appear, but the second is short (0.32) because each circle has only 20 points. Raise `n` to 80 and both bars are long (about 1.09 and 0.92). Sampling density, not just shape, controls what you can see.

- Raise `noise` to 0.3. The H_1 bar shrinks to about 0.67 and a second bar of 0.23 appears. Where would you draw the line between feature and noise? Try several seeds before you decide.
- Replace the circle with points on a line segment (`P = np.c_[t, 0 * t]`). Every H_1 bar should vanish. Then sample a filled disk; why does it look like the segment, not like the circle?

The winding number of §58.3 is easy to explore by eye. The limaçon below winds twice round points inside its small loop, once round points in the big loop only, and not at all round points outside.



$r = 0.5 + \cos\theta$. Change 0.5 to 1.2 and the inner loop disappears (every inside point now has winding number 1); change it to 0 and the curve becomes a circle traced twice. Count the winding numbers in each case by tracing the curve with a finger.

58.6 The challenge

No answers are given.

1. **Intuition.** Classify the capital letters A to Z (in a plain sans-serif font, drawn as curves of zero thickness) up to homeomorphism. Which invariant separates the classes you cannot tell apart by counting holes? (Hint: remove a point.)
2. **Derivation.** Prove that every continuous map $f : [0,1] \to [0,1]$ has a fixed point, using only the intermediate value theorem. Then explain why the same argument says nothing about continuous maps of a circle to itself, and give a fixed-point-free example.
3. **Implementation.** Triangulate a torus as an $m \times m$ grid of squares, each cut into two triangles, with opposite edges identified. Build ∂_1 and ∂_2 over $\mathbb{F}_2$, compute their ranks, and verify $(\beta_0, \beta_1, \beta_2) = (1, 2, 1)$ and $V - E + F = 0$. Repeat with the identification that makes a Klein bottle; what changes, and what changes if you work over $\mathbb{R}$ instead of $\mathbb{F}_2$?
4. **Open investigation.** Record a periodic signal $x(t)$ (a sine wave, a heartbeat trace, a vowel sound) and embed it as points $(x(t), x(t+\tau))$ or in 3-D with a second delay. Compute barcodes as you vary τ and add noise. How well does the length of the longest H_1 bar work as a "periodicity score", and how does it compare with an autocorrelation peak (Ch. 21)?

58.7 Loose threads

The hook asked whether a robot joint can have a continuous motion planner. It cannot. Any such planner would continuously deform the loop that goes once round the circle into a point, and the winding number, the generator of $\pi_1(S^1) \cong \mathbb{Z}$, forbids that. The discontinuity is not a defect of any formula; it is forced by the hole in the configuration space. The same tools that prove this (connectedness, compactness, loops and homology) also gave the intermediate and extreme value theorems their real meaning, and, turned towards data, let us read the shape of a point cloud from its barcode.

What we did not tell you:

- **Why topology needs geometry to finish its biggest proofs.** The first mystery points to Ch. 59.
- **Why fixed points guarantee equilibria.** The second mystery points to Ch. 39.
- **What all these invariants have in common.** Every invariant in this chapter is a rule that turns spaces into algebraic objects (numbers, groups, vector spaces) and continuous maps into homomorphisms, compatibly with composition. That pattern is called a **functor**, and it is the founding example of Ch. 62.

? How far apart are two barcodes?

If you jiggle the data a little, does the barcode only jiggle a little? It does: the **stability theorem** of Cohen-Steiner, Edelsbrunner and Harer (2007) bounds the distance between barcodes by the size of the perturbation. But "distance between barcodes" needs a definition: it is a matching problem, pairing bars of one barcode with bars of the other at least cost, with unmatched bars sent to zero length. That is optimal transport in disguise, and the Wasserstein distance it produces is the subject of Ch. 55.

Chapter 59 — Differential Geometry: Mathematics on Curved Worlds

> **Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on:** Ch. 6, Ch. 7, Ch. 10 · **Leads to:** Ch. 93, Ch. 92, Ch. 70 · **Related:** Ch. 58, Ch. 55, Ch. 69 **Reading time:** ~30 min

59.1 The hook

New York and Madrid sit at almost the same latitude: 40.7° N and 40.4° N. Draw them on a classroom wall map and the obvious route is a straight line due east across the Atlantic, about 5,940 km along the 40th parallel.

No airline flies it. A flight leaving JFK for Madrid sets off on a heading of about 66°, well north of east. It climbs to about 46° N, passes south of Newfoundland, and then curves back down into Spain. That route is 5,770 km, roughly 170 km shorter than "straight east". On the wall map it looks like a detour. On a globe it is the straightest path there is.

So which line is straight? Your eyes, trained on flat paper, say the parallel. The globe says the arc that bulges toward the pole. The disagreement is not a quirk of map projections. It is a fact about the surface itself, and it can be detected without ever leaving it.

In the 1820s Carl Friedrich Gauss ran a land survey of the Kingdom of Hanover. As part of it he measured the angles of a huge triangle whose corners were three mountain tops, the Hohenhagen, the Brocken and the Inselsberg, with sides of roughly 69, 85 and 107 km. In a flat world the angles of every triangle add up to 180°. Gauss's added up to 180° plus about 15 seconds of arc. That is exactly what a triangle of that size on a sphere the size of the Earth should give. (Gauss probably also wondered whether *space itself* might be curved. His triangle was too small to tell, and the question waited a century for Einstein.)

Now push the idea to its extreme. Start at the North Pole. Walk due south to the equator. Turn left 90° and walk a quarter of the way around the equator. Turn left 90° again and walk north. You arrive back at the pole, having walked a triangle with **three right angles**: an angle sum of 270°.

Here is the question this chapter is built around:

> **How can a creature that lives *inside* a surface, and can only measure lengths and angles on it, discover that its world is curved, and by how much?**

The answer leads to manifolds, tangent spaces, geodesics and curvature: the language in which robots plan motions on curved configuration spaces, graphics engines measure distance across a mesh, and GPS satellites correct their clocks for the curvature of spacetime.

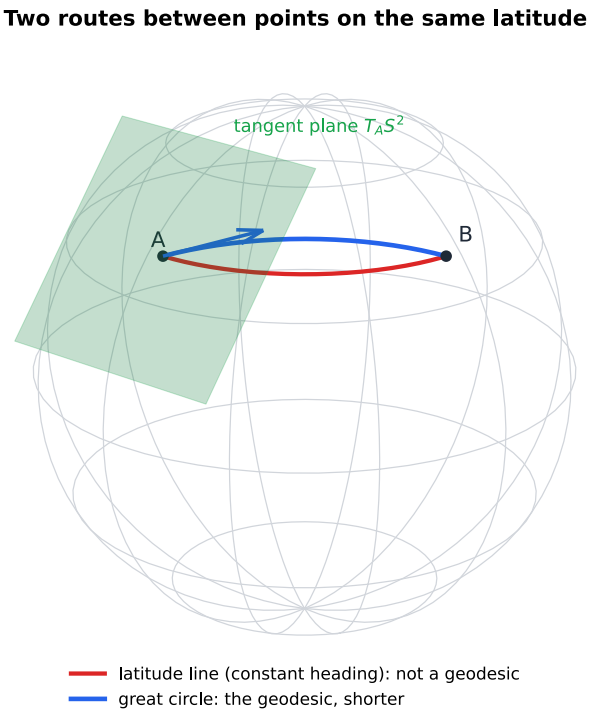
59.2 The big idea

Two ideas carry the whole subject.

Idea 1: curved worlds are flat up close. The Earth looks flat from your garden. Any smooth surface, looked at under a strong enough magnifier, looks like a piece of plane. A **manifold** is anything with this property: a space that, near each point, looks like ordinary $\mathbb{R}^n$. The flat approximation at a point p is the **tangent space** T_pM. Calculus happens there: velocities, gradients and linear approximations all live in tangent spaces, exactly as in §4.8.

The catch is that the flat pictures don't glue together into one flat picture. An atlas of the Earth needs many pages, and where two pages overlap they disagree about distances. That disagreement *is* the curvature.

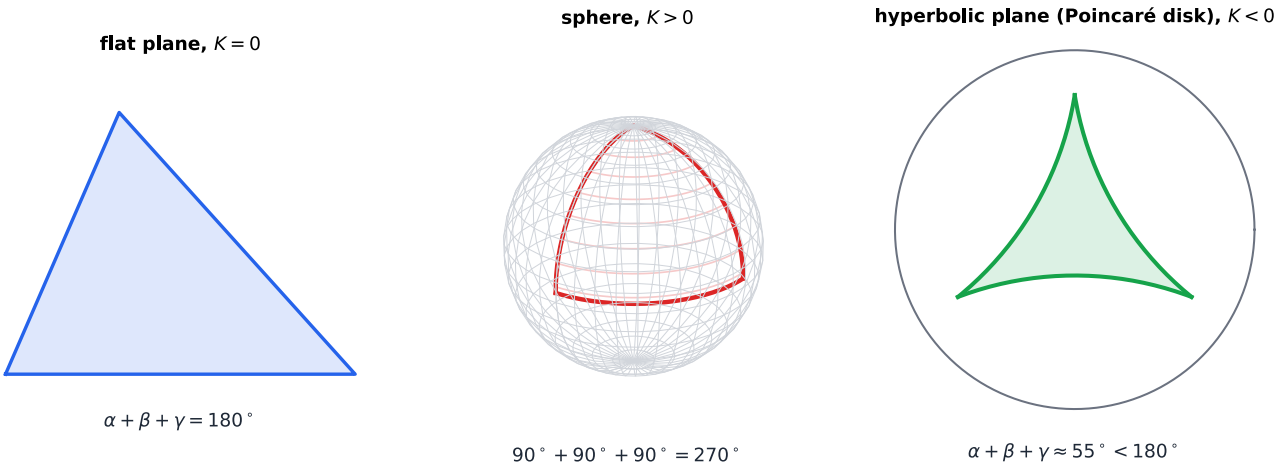
Idea 2: "straight" means "not turning, as seen from inside". An ant walking on a globe can't see that its path bends in three-dimensional space. All it can tell is whether it is steering left or right. A path along which the ant never steers is a **geodesic**. On a sphere the geodesics are the great circles: the equator and every circle cut by a plane through the centre. A latitude line other than the equator is *not* a geodesic. An ant walking along the 40th parallel has to keep steering slightly toward the pole, as you would when driving around a large roundabout.



Two routes from A to B on the same latitude. The great circle (blue) is the geodesic and is shorter. The latitude line (red) keeps a constant compass heading but is always turning, as seen from inside the surface. The green plane is the tangent space at A, where the geodesic's initial velocity lives.

How does an insider measure curvature? Through **triangles and circles**. Draw a triangle whose sides are geodesics and add up its angles:

- on a flat plane the sum is exactly 180°;
- on a sphere it is *more* than 180°, and the excess grows with the triangle's area;
- on a saddle-shaped surface it is *less* than 180°.



Angle sums reveal curvature. Flat: exactly 180°. Sphere: the octant triangle has three right angles. Hyperbolic plane, drawn in the Poincaré disk where geodesics are circular arcs meeting the boundary at right angles: this triangle's angles add up to only about 55°.

An analogy: a pizza slice. A flat slice of pizza can bend in one direction without stretching, which is why folding it lengthwise stiffens it: once it curves one way, it cannot also droop the other way without tearing. That rule, that the *product* of the two bendings is fixed by the dough's intrinsic geometry, is Gauss's great theorem in disguise. A flat sheet has curvature zero, so if it bends one way it must stay straight the other way. Curvature in this sense is something the dough itself knows, not something about how it is held in space.

59.3 The mathematics

Manifolds, charts and tangent spaces

Smooth manifold (informal)

An n-dimensional **manifold** M is a space covered by **charts**: one-to-one maps $\varphi : U \to \mathbb{R}^n$ from open pieces $U \subset M$ onto open sets of $\mathbb{R}^n$. Wherever two charts overlap, the **transition map** $\psi \circ \varphi^{-1}$ must be smooth (infinitely differentiable). The collection of charts is an **atlas**.

Examples you already know:

- The sphere S^2, charted by latitude and longitude (which fail at the poles, so you need at least two charts).
- The torus T^2: the configuration space of a robot arm with two revolute joints, one angle per joint, each angle wrapping around.
- The rotation group $SO(3)$: every possible orientation of a drone or a camera. It is a 3-dimensional manifold, but not a sphere, and no single chart covers it without singularities. Gimbal lock is a chart failing. That story belongs to Ch. 70.

The **tangent space** T_pM is the set of velocities $\dot\gamma(0)$ of smooth curves γ through $\gamma(0) = p$. For a surface sitting in $\mathbb{R}^3$ it is the familiar tangent plane. For the unit sphere it is $T_pS^2 = \{\mathbf{v} : \mathbf{v}\cdot\mathbf{p} = 0\}$, the vectors perpendicular to the radius. It is a vector space of dimension n in the sense of Ch. 9. The derivative of a map between manifolds is a linear map between tangent spaces. In coordinates it is the Jacobian of §6.6.

The metric: measuring from inside

To measure lengths we need an inner product on every tangent space, varying smoothly from point to point. In a chart with coordinates $x^1, \dots, x^n$ it is a symmetric positive-definite matrix $g_{ij}(x)$, the **metric tensor**:

$$ds^2 = \sum_{i,j} g_{ij}(x)\, dx^i\, dx^j, \qquad L[\gamma] = \int_a^b \sqrt{\sum_{i,j} g_{ij}\big(x(t)\big)\, \dot x^i \dot x^j}\; dt.$$

A manifold with a metric is a **Riemannian manifold**. On a sphere of radius R in colatitude θ (measured from the north pole) and longitude ϕ, which is the spherical system of §6.9 with the radius frozen:

$$ds^2 = R^2\left(d\theta^2 + \sin^2\theta\, d\phi^2\right), \qquad g = \begin{pmatrix} R^2 & 0 \\ 0 & R^2\sin^2\theta \end{pmatrix}.$$

The factor $\sin^2\theta$ says that a degree of longitude is long at the equator and shrinks to nothing at the poles. That is all the sphere's geometry, written in one matrix.

Why "tensor"? If you change coordinates $x \to y$ with Jacobian $J^i{}_a = \partial x^i/\partial y^a$, the metric must transform as $\tilde g_{ab} = \sum_{i,j} J^i{}_a J^j{}_b\, g_{ij}$, so that lengths come out the same in every chart. A **tensor** is any array of numbers that transforms by such a rule, one Jacobian factor per index. The rule guarantees that the geometric object, not its coordinate shadow, is what you are computing with. Ch. 93 builds the full algebra.

Geodesics

A geodesic is a curve that is locally the shortest path. Minimizing length directly is awkward because of the square root, and because length doesn't care how fast you traverse the curve. The standard trick is to minimize the **energy** $E[\gamma] = \frac12\int g_{ij}\dot x^i\dot x^j\, dt$ instead. Its minimizers are the shortest curves, traversed at constant speed.

Geodesic equation

A curve $x(t)$ is a critical point of the energy if and only if

$$\ddot x^k + \sum_{i,j} \Gamma^k_{ij}\, \dot x^i \dot x^j = 0, \qquad \Gamma^k_{ij} = \tfrac12 \sum_l g^{kl}\left(\partial_i g_{jl} + \partial_j g_{il} - \partial_l g_{ij}\right),$$

where g^{kl} is the inverse matrix of g_{kl}. The Γ^k_{ij} are the **Christoffel symbols**.

The equation says "acceleration, as seen from inside, is zero". The Γ terms are the corrections needed because the coordinate grid itself bends and stretches. The general derivation is the Euler–Lagrange equation applied to $\frac12 g_{ij}\dot x^i\dot x^j$. Here it is done explicitly for the sphere, where it answers the hook.

Derivation on the sphere. The Lagrangian is $\mathcal{L} = \frac12 R^2(\dot\theta^2 + \sin^2\theta\,\dot\phi^2)$. The Euler–Lagrange equation $\frac{d}{dt}\frac{\partial\mathcal{L}}{\partial\dot q} = \frac{\partial\mathcal{L}}{\partial q}$ for each coordinate gives:

$$\begin{aligned} \theta: &\quad R^2\ddot\theta = R^2\sin\theta\cos\theta\,\dot\phi^2 &&\Longrightarrow \quad \ddot\theta - \sin\theta\cos\theta\,\dot\phi^2 = 0,\\ \phi: &\quad \frac{d}{dt}\left(R^2\sin^2\theta\,\dot\phi\right) = 0 &&\Longrightarrow \quad \sin^2\theta\,\dot\phi = \text{const}. \end{aligned}$$

Reading off the Christoffel symbols: $\Gamma^\theta_{\phi\phi} = -\sin\theta\cos\theta$ and $\Gamma^\phi_{\theta\phi} = \Gamma^\phi_{\phi\theta} = \cot\theta$, all others zero.

Which circles of latitude are geodesics

The circle of colatitude θ_0, traversed at constant speed, is a geodesic of the sphere if and only if $\theta_0 = \pi/2$, the equator.

Proof. Put $\theta(t) = \theta_0$ and $\phi(t) = \omega t$ with $\omega \neq 0$. The ϕ equation holds, since $\sin^2\theta_0\,\omega$ is constant. In the θ equation $\ddot\theta = 0$, so it reduces to $\sin\theta_0\cos\theta_0\,\omega^2 = 0$. With $0 < \theta_0 < \pi$ we have $\sin\theta_0 \neq 0$, so the equation forces $\cos\theta_0 = 0$, which means $\theta_0 = \pi/2$. ∎

The leftover term $\sin\theta_0\cos\theta_0\,\omega^2$ is exactly the steering an ant on the 40th parallel must apply. Rotations of the sphere carry geodesics to geodesics, and every great circle is a rotated equator. So every great circle is a geodesic, and since a geodesic is fixed by its starting point and direction, there are no others.

The conserved quantity $\sin^2\theta\,\dot\phi$ is **Clairaut's relation**. For a unit-speed path it says $\sin\theta\,\sin a = \text{const}$, where a is the compass heading measured from north. Leaving New York (colatitude 49.29°) on heading 65.66°, the path is heading due east ($a = 90^\circ$) at the colatitude where $\sin\theta = \sin 49.29^\circ\,\sin 65.66^\circ = 0.6905$, which is $\theta = 43.68^\circ$, or latitude 46.3° N. That is the northernmost point of the flight in the hook.

Curvature from circles

Here is the cleanest way for an insider to measure curvature. Stand at a point, walk out a distance r along geodesics in every direction, and measure the circumference $C(r)$ of the circle you trace out.

On a sphere of radius R, centre the circle at the north pole. Walking a geodesic distance r takes you to colatitude $\theta = r/R$. That circle of latitude has Euclidean radius $R\sin(r/R)$, so

$$C(r) = 2\pi R \sin\frac{r}{R} = 2\pi r\left(1 - \frac{r^2}{6R^2} + O(r^4)\right).$$

The circle is *short*: less than $2\pi r$. The relative shortfall, at leading order, is $r^2/(6R^2)$. Turn this into a definition:

Gaussian curvature (Bertrand–Diguet–Puiseux)

$$K(p) = \lim_{r\to 0} \frac{3}{\pi}\,\frac{2\pi r - C(r)}{r^3}.$$

For the sphere, $2\pi r - C(r) \approx \pi r^3/(3R^2)$, so $K = 1/R^2$. A flat plane has $K = 0$. On the hyperbolic plane circles are *long*: $C(r) = 2\pi\sinh r$ for $K = -1$. For the Earth, a circle of geodesic radius 1,000 km has circumference about 25.8 km less than $2\pi \times 1000$ km, and a careful enough surveyor could measure that.

Everything in this definition is measured from inside the surface. That gives the punchline of Gauss's career:

Theorema Egregium (Gauss, 1827)

For a surface in $\mathbb{R}^3$, the Gaussian curvature equals the product of the two principal curvatures, $K = \kappa_1\kappa_2$, which describe how the surface bends in space. Yet K depends only on the metric g_{ij} and its derivatives. It is unchanged by any bending of the surface that preserves lengths.

This is why no flat map of the Earth can preserve all distances: the sphere has $K = 1/R^2$, paper has $K = 0$, and a distance-preserving map would have to preserve K. It is also the pizza rule: a flat slice has $K = \kappa_1\kappa_2 = 0$, so if you force $\kappa_1 \neq 0$ by folding it, then $\kappa_2 = 0$ and the tip can't droop.

? How can the ant compute $\kappa_1\kappa_2$ without seeing the third dimension?

Each principal curvature on its own depends on how the surface sits in space: a flat sheet and a rolled-up cylinder have different κ_1 but the same metric. Yet their product can be computed from g_{ij} alone. Gauss called this "remarkable", and the proof he gave is a page of brute calculation that hides the reason. The reason is the **Riemann curvature tensor**, built from derivatives of the Christoffel symbols. It measures how a vector fails to come back to itself when carried around a tiny loop. That tensor, and why it only exists because of the transformation law above, is the subject of Ch. 93.

Triangles: Girard's theorem

Now for the angle sums. On the sphere the result can be proved with nothing more than areas.

Girard's theorem

A geodesic triangle on a sphere of radius R with angles α, β, γ and area T satisfies

$$\alpha + \beta + \gamma = \pi + \frac{T}{R^2} = \pi + K\,T.$$

Proof. Two great circles meeting at angle α cut the sphere into four **lunes** (orange-segment shapes). The lune with angle α takes the fraction $\alpha/(2\pi)$ of the sphere's area, so its area is $\frac{\alpha}{2\pi}\cdot 4\pi R^2 = 2\alpha R^2$.

Extend the three sides of the triangle to full great circles. At vertex A they bound a lune containing the triangle, and its antipodal twin, which contains the antipodal triangle. Together the two have area $4\alpha R^2$. Do the same at B and C. These six lunes cover the whole sphere. Every point is covered exactly once, except points of the triangle and of its antipodal copy, which are each covered three times. So the six lunes overcount the sphere by $2T + 2T$:

$$4\alpha R^2 + 4\beta R^2 + 4\gamma R^2 = 4\pi R^2 + 4T.$$

Divide by $4R^2$. ∎

Check: the octant triangle of the hook has area $\frac{1}{8}\cdot 4\pi R^2 = \frac{\pi}{2}R^2$, so its angle sum is $\pi + \pi/2 = 3\pi/2 = 270^\circ$. Gauss's mountain triangle has area about 2,930 km². Dividing by $R^2 = 6371^2$ km² gives an excess of 7.2×10^{-5} rad, which is 14.9″.

For a general surface where K varies, the same statement holds with KT replaced by $\iint_T K\,dA$. This is the local **Gauss–Bonnet theorem**. Triangles on saddles, where $K < 0$, have angle deficits.

? Curvature that counts holes

Apply Gauss–Bonnet to a whole closed surface, triangulated into geodesic triangles, and something strange falls out. The total curvature $\iint_M K\,dA$ of *any* surface shaped like a sphere (a potato, a pear, a dented ball) is exactly 4π, and for any doughnut it is exactly 0. A number built from local bending comes out as a topological invariant, 2π times the Euler characteristic from Ch. 58. Why should integrating geometry produce topology? The bookkeeping uses $V - E + F$, but the reason runs much deeper. Its higher-dimensional heir, the Chern–Gauss–Bonnet theorem, and its cousins the Chern numbers of gauge fields, are waiting in Ch. 92.

Differential forms in one paragraph

Vector calculus has four "fundamental theorems": the ordinary one, Green's, Stokes' and the divergence theorem (§7.9–§7.11). On a manifold they become one. A **k-form** is a machine that eats k tangent vectors and returns a number, linearly and antisymmetrically. A 1-form such as df eats a velocity and returns a rate of change. A 2-form such as $dx \wedge dy$ eats two vectors and returns the signed area of the parallelogram they span. The **exterior derivative** d turns k-forms into

$(k+1)$-forms, and $d(d\omega) = 0$ packages both "curl of a gradient is zero" and "divergence of a curl is zero". Then, for any oriented k-manifold M with boundary ∂M and any $(k-1)$-form ω:

$$\int_M d\omega = \int_{\partial M} \omega.$$

This single line is the generalized Stokes theorem. Forms need no metric at all, which is why physicists write Maxwell's equations as $dF = 0$ and $d{\star}F = J$: the same equations in every coordinate system, flat or curved.

59.4 The algorithm

Shooting a geodesic. To fly a geodesic from a starting point in a given direction, integrate the geodesic equation as a first-order system in $(\theta, \phi, \dot\theta, \dot\phi)$. Fourth-order Runge–Kutta (§22.9) is ideal.

```
import numpy as np
R = 6371.0                                  # Earth radius, km

def rhs(s):
    th, ph, dth, dph = s                    # colatitude, longitude, and their rates
    return np.array([dth, dph,
                     np.sin(th) * np.cos(th) * dph**2,           # -Gamma^th_phph dph^2
                     -2 * np.cos(th) / np.sin(th) * dth * dph])  # -2 Gamma^ph_thph

def rk4(s, h, n):
    for _ in range(n):
        k1 = rhs(s); k2 = rhs(s + h/2*k1); k3 = rhs(s + h/2*k2); k4 = rhs(s + h*k3)
        s = s + h/6*(k1 + 2*k2 + 2*k3 + k4)
    return s

lat0, lon0, heading = 40.71, -74.01, 65.66   # New York, compass heading (deg)
th0, ph0, a = np.radians(90 - lat0), np.radians(lon0), np.radians(heading)
s0 = np.array([th0, ph0, -np.cos(a), np.sin(a) / np.sin(th0)])   # unit speed
L = 5768.6 / R                              # arc length to fly, radians
s = rk4(s0, L / 2000, 2000)
print("arrive at lat %.2f, lon %.2f" % (90 - np.degrees(s[0]), np.degrees(s[1])))
print("speed^2 drift:", s[2]**2 + np.sin(s[0])**2 * s[3]**2 - 1)
```

It lands at 40.42° N, 3.70° W, which is Madrid. The squared speed $\dot\theta^2 + \sin^2\theta\,\dot\phi^2$ stays equal to 1 to about 10^{-15}. This is a free accuracy check: geodesics have constant speed, so any drift is integration error.

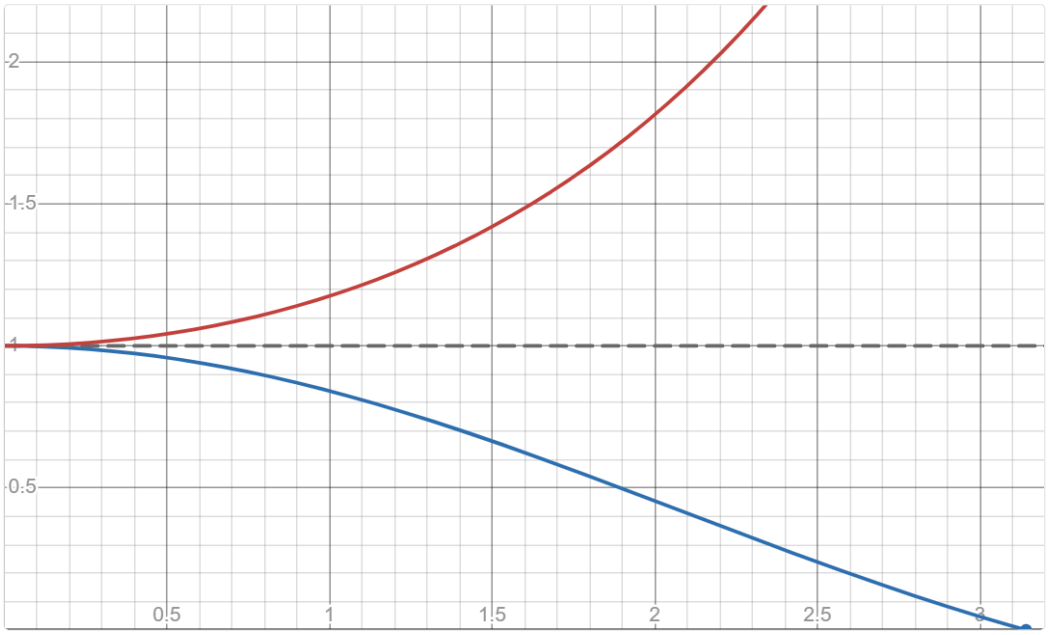
Cost and accuracy. Each step costs $O(n^2)$ Christoffel evaluations on an n-manifold ($O(n^3)$ terms in general, fewer when most vanish). RK4 has global error $O(h^4)$.

Failure cases worth knowing.

- *Chart singularities.* The term $\cot\theta$ blows up at the poles. That is a defect of the latitude–longitude chart, not of the sphere. A route over the pole needs a second chart, or an integration in the embedding $\mathbb{R}^3$ that projects back onto the sphere. Every serious geometric code switches charts or avoids them.
- *Boundary-value problems.* "Find the geodesic from A to B" is harder than "fly from A in direction v". The usual fix is shooting: adjust the initial heading with Newton's method or bisection until the endpoint hits B.
- *Non-uniqueness.* Between antipodal points there are infinitely many shortest geodesics. A geodesic that runs past such a **conjugate point** stops being the shortest path, even though it still satisfies the equation. Satisfying the geodesic equation means "critical", not "minimal".
- *Meshes.* On a triangle mesh in graphics, running Dijkstra's algorithm along edges overestimates geodesic distance by an error that does not shrink as the mesh is refined: up to about 8% on a square grid with diagonal links. Fast-marching and heat-method algorithms work on the faces instead.

59.5 The experiment

Circles tell curvature. The ratio $C(r)/(2\pi r)$ is plotted below for a unit sphere ($K = 1$, blue), the plane (grey) and the hyperbolic plane ($K = -1$, red). Change the sphere's radius by replacing $\sin(x)/x$ with $2\sin(x/2)/x$ (radius 2), and watch the curve flatten. Larger spheres look flatter for longer.



Circumference of a geodesic circle divided by $2\pi r$: below 1 on the sphere, exactly 1 on the plane, above 1 on the hyperbolic plane. The initial curvature of each graph is $-K/6$.

Angle sums grow with area. Run this script, which builds right-angled isosceles triangles at the north pole with legs of geodesic length d on the unit sphere, and compares the angle excess with the area:

```
import numpy as np

def angle(P, Q, S):
    """Angle at P of the spherical triangle PQS (unit vectors)."""
    t1 = Q - (P @ Q) * P; t2 = S - (P @ S) * P      # tangent directions at P
    return np.arccos(t1 @ t2 / np.linalg.norm(t1) / np.linalg.norm(t2))

def area(A, B, C):                                   # Van Oosterom–Strackee formula
    num = abs(A @ np.cross(B, C))
    den = 1 + A @ B + B @ C + C @ A
    return 2 * np.arctan2(num, den)

for d in [0.01, 0.1, 0.3, 0.6, 1.0, 1.4]:            # leg length, radians
    A = np.array([0, 0, 1.0])
    B = np.array([np.sin(d), 0, np.cos(d)])
    C = np.array([0, np.sin(d), np.cos(d)])
    s = angle(A, B, C) + angle(B, C, A) + angle(C, A, B)
    print(f"d={d:4.2f}  angle sum={np.degrees(s):8.3f} deg   "
          f"excess={s-np.pi:.5f}   area={area(A,B,C):.5f}")
```

The excess column and the area column agree to every printed digit: 180.003° at $d = 0.01$, 190.9° at $d = 0.6$, 250.7° at $d = 1.4$. Things to change:

- Set $d = \pi/2$ to recover the 270° triangle.
- Rotate `B` and `C` so the vertex angle at `A` is 60° rather than 90°.
- Replace the area formula with $d^2/2$, the flat answer, and see when the flat world's prediction becomes visibly wrong.

59.6 The challenge

1. **Intuition.** Carry a spear around the 270° octant triangle, always keeping it pointed in the same direction as seen from inside the surface: never rotating it relative to the path's turns. Show by a sketch that it comes back rotated by 90°. Then guess the rotation after a trip around a small triangle of area T on a sphere of radius R.
2. **Derivation.** For the surface of revolution $ds^2 = dr^2 + f(r)^2\,d\phi^2$, find the Christoffel symbols and the geodesic equations, and show that $K = -f''/f$. Check that $f = \sin r$ gives $K = 1$, $f = r$ gives $K = 0$, and $f = \sinh r$ gives $K = -1$. Then verify the circle formula $C(r) = 2\pi f(r)$ against the Bertrand–Diguet–Puiseux definition.
3. **Implementation.** Turn the RK4 geodesic code into a *boundary-value* solver. Given two airports, use Newton's method on the initial heading and arc length to hit the destination. Compare its answer with the closed-form great-circle distance $R\arccos(\sin\varphi_1\sin\varphi_2 + \cos\varphi_1\cos\varphi_2\cos\Delta\lambda)$, where φ is latitude and λ longitude, and make it survive routes that pass over a pole.
4. **Open investigation.** The Earth is not a sphere but an oblate ellipsoid, with polar radius 21 km less than the equatorial radius. Write the metric of an ellipsoid of revolution and integrate its geodesics. Do they close up after one circuit, the way great circles do? Explore numerically how much a geodesic "precesses" per orbit as a function of its maximum latitude, and look for a pattern.

59.7 Loose threads

This chapter measured curvature on surfaces, where one number K says everything. In three or more dimensions curvature depends on *which* 2-dimensional slice you look at, and a single number is no longer enough. That is why the Riemann tensor of the first mystery has $n^2(n^2-1)/12$ independent components: 1 on a surface, 6 in three dimensions, 20 in four.

> **? Matter tells spacetime how to curve**
>
> A GPS satellite's clock runs fast by about 45 microseconds per day because it sits higher in Earth's gravity. It runs slow by about 7 microseconds per day because of its orbital speed. Uncorrected, the net 38 µs per day would put your position off by about 11 km after a single day. Einstein's explanation is that gravity is not a force at all. Spacetime is a 4-dimensional manifold whose metric is curved by mass, and falling objects simply follow its geodesics. Which curvature does matter control, and why that one? The Einstein field equations, and the Riemannian geometry they need, are waiting in Ch. 92.

The spear of challenge problem 1 is the start of **holonomy**: the rotation a vector picks up when it is carried around a loop. It explains the Foucault pendulum and the way a falling cat turns over with zero angular momentum. It is also why interpolating rotations for a robot or a game camera is a geodesic problem on the curved manifold $SO(3)$ (Ch. 70). Spaces of probability distributions carry geometries too, and moving mass optimally across a space has its own Riemannian structure (Ch. 55).

Chapter 60 — Real Analysis: Making Calculus Rigorous

> **Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on:** Ch. 4, Ch. 5, Ch. 15 · **Leads to:** Ch. 61, Ch. 97, Ch. 64 · **Related:** Ch. 63, Ch. 31, Ch. 22 **Reading time:** ~30 min

60.1 The hook

Here is a proof that $1 = \frac{1}{2}$.

Start from a series every calculus student meets, the alternating harmonic series:

$$S = 1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \frac{1}{5} - \frac{1}{6} + \frac{1}{7} - \frac{1}{8} + \cdots = \ln 2 \approx 0.6931.$$

Now write the same terms in a different order: one positive term, then two negative ones.

$$S = \left(1 - \frac{1}{2}\right) - \frac{1}{4} + \left(\frac{1}{3} - \frac{1}{6}\right) - \frac{1}{8} + \left(\frac{1}{5} - \frac{1}{10}\right) - \frac{1}{12} + \cdots$$

Every term of the original series appears exactly once. Nothing has been added or removed. Now do the subtractions in brackets:

$$S = \frac{1}{2} - \frac{1}{4} + \frac{1}{6} - \frac{1}{8} + \frac{1}{10} - \frac{1}{12} + \cdots = \frac{1}{2}\left(1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \cdots\right) = \frac{1}{2}S.$$

So $S = \frac{1}{2}S$, and since $S = \ln 2 \neq 0$, dividing by S gives $1 = \frac{1}{2}$.

Addition is commutative. Every schoolchild knows that $a + b = b + a$. So where did it go wrong?

This isn't an isolated trick. In the nineteenth century calculus was the most successful tool in science, and it kept producing nonsense whenever it was pushed:

- In 1821 Augustin-Louis Cauchy published a "theorem" that a convergent sum of continuous functions is continuous. Fourier's series had already shown sums of smooth sine waves converging to a square wave with jumps in it (§15.6). Abel spotted the contradiction in 1826.
- Everyone "knew" that a continuous curve must be smooth at most of its points, apart from a few corners. In 1872 Karl Weierstrass presented a function that is continuous everywhere and differentiable *nowhere*. Charles Hermite wrote that he turned away "with fright and horror from this lamentable plague".
- Engineers and physicists swapped limits, sums, integrals and derivatives freely: $\frac{d}{dt}\int = \int \frac{d}{dt}$, $\lim \int = \int \lim$, $\sum \int = \int \sum$. Usually it worked. Sometimes it gave nonsense, and nobody could say in advance which.

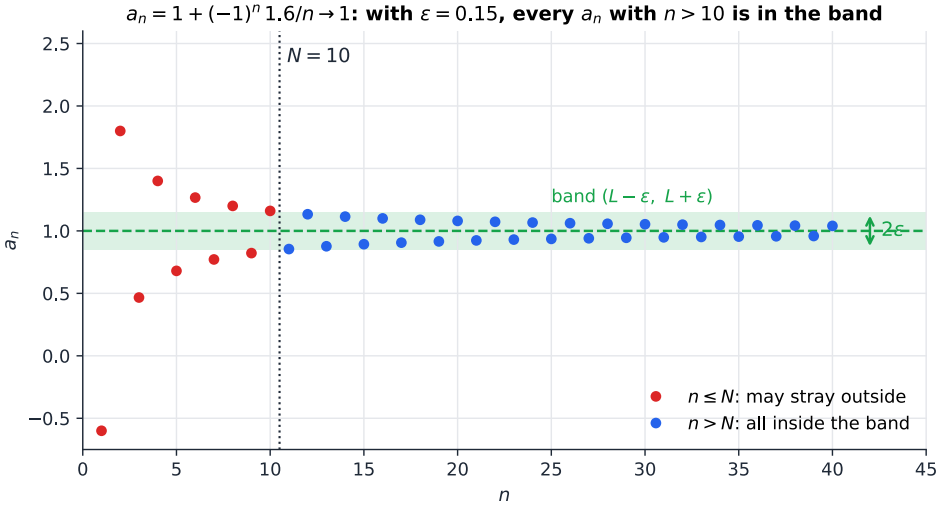
The central question of this chapter:

> **When can you trust the moves of calculus, such as reordering a sum, swapping a limit with an integral, or calling a limit "the answer", and how do you prove it?**

Real analysis is the answer the nineteenth century built. It is the reason the core chapters of this book can say "converges", "continuous" and "integrable" and mean something exact.

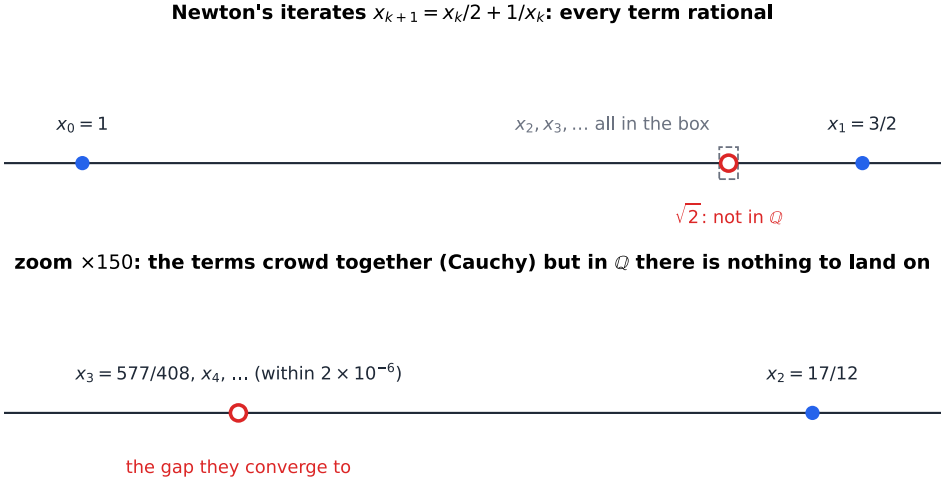
60.2 The big idea

Idea 1: a limit is a game against an adversary. "The sequence a_n approaches L" sounds like motion, but there is nothing moving. Analysis turns it into a challenge-and-response game. Your opponent names a tolerance $\varepsilon > 0$, as small as they like. You must reply with an index N such that *every* term after N lies within ε of L. If you can always reply, whatever ε they pick, then $a_n \to L$. The phrase "gets closer and closer" is gone, and so is the paradox.



The ε–N game. For the tolerance $\varepsilon = 0.15$ the reply $N = 10$ works: every term after it lies in the band. A smaller ε needs a later N, but there is always one.

Idea 2: the real numbers have no holes, and that is an axiom. The rationals $\mathbb{Q}$ are fine for arithmetic but useless for limits. You can write down a sequence of fractions whose terms crowd ever closer together, yet the point they crowd toward isn't a fraction. Calculus needs a number line where every such crowd has a landing spot. The reals $\mathbb{R}$ are, by definition, that number line. This property, **completeness**, is behind every existence theorem you have used: the intermediate value theorem, the maximum of a continuous function on $[a, b]$, the convergence of bisection (§22.4), and the existence of $\int_a^b f$.



A Cauchy sequence in $\mathbb{Q}$. Newton's iterates for $\sqrt{2}$ are all fractions. They bunch together ever more tightly, but the point they bunch toward is missing from $\mathbb{Q}$. In $\mathbb{R}$ it is there.

Idea 3: "infinitely many" comes in different strengths. The rearrangement paradox happens because the alternating harmonic series converges only through cancellation. Its positive terms alone add up to $+\infty$ and its negative terms alone to $-\infty$. Reordering lets you spend the two infinite budgets at different rates, and you can steer the total anywhere you like. Series whose absolute values add up to something finite are immune to this. Much of analysis is the art of telling the safe kind of infinity from the dangerous kind.

60.3 The mathematics

Sequences and the completeness axiom

Limit of a sequence

$a_n \to L$ means: for every $\varepsilon > 0$ there is an N such that $|a_n - L| < \varepsilon$ for all $n > N$.

(a_n) is a **Cauchy sequence** if for every $\varepsilon > 0$ there is an N such that $|a_m - a_n| < \varepsilon$ for all $m, n > N$.

A Cauchy sequence is one whose terms eventually crowd together. The definition doesn't mention any limit, which is the point: you can check it without knowing where the sequence is going. Every convergent sequence is Cauchy, by the triangle inequality with $\varepsilon/2$. The converse is what can fail.

A Cauchy sequence in $\mathbb{Q}$ with no limit in $\mathbb{Q}$

Let $x_0 = 1$ and $x_{k+1} = \dfrac{x_k}{2} + \dfrac{1}{x_k}$. Every x_k is rational, the sequence is Cauchy, and it has no rational limit.

Proof. By induction each x_k is a positive rational, since the recursion uses only field operations. A direct computation gives

$$x_{k+1}^2 - 2 = \left(\frac{x_k}{2} + \frac{1}{x_k}\right)^2 - 2 = \left(\frac{x_k}{2} - \frac{1}{x_k}\right)^2 = \left(\frac{x_k^2 - 2}{2x_k}\right)^2 \geq 0.$$

So $x_k^2 \geq 2$ for $k \geq 1$, and then $x_{k+1} - x_k = \dfrac{2 - x_k^2}{2x_k} \leq 0$. From $k = 1$ on, the sequence is decreasing and bounded below by 1. The terms are $\frac{3}{2}$, $\frac{17}{12}$, $\frac{577}{408}$, $\frac{665857}{470832}$, $\ldots$.

Next we show it is Cauchy, using only rational arithmetic. Write $e_k = x_k^2 - 2 \geq 0$. For $k \geq 1$ we have $x_k \geq 1$, so the identity gives $e_{k+1} = e_k^2/(4x_k^2) \leq e_k^2/4$. Starting from $e_1 = \frac{1}{4}$ this gives $e_k \leq 4^{1-2^k}$, which tends to zero extremely fast. Since $x_k - x_{k+1} = e_k/(2x_k) \leq e_k/2$, the tails satisfy $|x_m - x_n| \leq \sum_{k \geq n} e_k/2$ for $m > n$. That sum is as small as we like for large n, so the sequence is Cauchy.

Finally, suppose $x_k \to L \in \mathbb{Q}$. Then $L \geq 1$, and passing to the limit in the recursion gives $L = L/2 + 1/L$, so $L^2 = 2$. But no rational number squares to 2: if p/q in lowest terms did, then $p^2 = 2q^2$ would make p even, then q even, a contradiction. ∎

The errors are 8.6×10^{-2}, 2.5×10^{-3}, 2.1×10^{-6} and 1.6×10^{-12}. The number of correct digits roughly doubles at each step. This is Newton's quadratic convergence, running in a number system where the answer doesn't exist.

Completeness axiom

Every non-empty set of real numbers that is bounded above has a **least upper bound** (supremum) in $\mathbb{R}$.

This is the one axiom that separates $\mathbb{R}$ from $\mathbb{Q}$. The set $\{q \in \mathbb{Q} : q^2 < 2\}$ is bounded above in $\mathbb{Q}$ but has no least rational upper bound. In $\mathbb{R}$ its supremum is $\sqrt{2}$. Everything else follows from it, beginning with this.

Monotone convergence theorem

A sequence of reals that is increasing and bounded above converges, to its supremum.

Proof. Let $s = \sup_n a_n$, which exists by completeness. Given $\varepsilon > 0$, the number $s - \varepsilon$ is not an upper bound, so some $a_N > s - \varepsilon$. Because the sequence is increasing, $s - \varepsilon < a_N \le a_n \le s$ for every $n > N$, and so $|a_n - s| < \varepsilon$. ∎

Two more consequences, stated without proof:

- **Bolzano–Weierstrass:** every bounded sequence of reals has a convergent subsequence.
- **Cauchy criterion:** in $\mathbb{R}$, a sequence converges if and only if it is Cauchy.

From these, the familiar theorems of calculus follow: the intermediate value theorem, the extreme value theorem, and the integrability of continuous functions. Each is an "existence" statement, and each one fails over $\mathbb{Q}$. For example, $f(x) = x^2 - 2$ changes sign on $[1, 2]$ but has no rational root.

Series: why the hook went wrong

A series $\sum a_n$ converges if its partial sums do. It converges **absolutely** if $\sum |a_n| < \infty$, and **conditionally** if it converges but not absolutely.

Rearrangements (Dirichlet; Riemann)

If $\sum a_n$ converges absolutely, every rearrangement converges to the same sum. If it converges only conditionally, then for any target $T \in \mathbb{R}$ (or $\pm\infty$) some rearrangement converges to T.

Why Riemann's half is true. In a conditionally convergent series the positive terms and the negative terms each add up to an infinite total, while the terms themselves shrink to zero. The greedy recipe goes like this. Add positive terms until the partial sum passes T. Then add negative terms until it drops below T. Repeat. You can never get stuck, because each budget is infinite. The overshoot is never more than the last term used, and the terms tend to zero, so the partial sums close in on T.

The hook used one positive term for every two negative ones. In general, taking p positive terms for every q negative terms of the alternating harmonic series gives the sum $\ln 2 + \tfrac{1}{2}\ln(p/q)$. With $p = 1$, $q = 2$ that is $\ln 2 - \tfrac{1}{2}\ln 2 = \tfrac{1}{2}\ln 2$, the hook's result: about 0.3466 rather than 0.6931. So the error in the hook was never about arithmetic. It was the assumption that an infinite sum behaves like a finite one.

Continuity and the two kinds of convergence

The ε–δ definition of continuity is in §4.1. For sequences of *functions* there are two different notions of convergence, and Cauchy's 1821 mistake was to treat them as the same.

Pointwise and uniform convergence

$f_n \to f$ **pointwise** on D if $f_n(x) \to f(x)$ for each $x \in D$ separately: the N may depend on x.

$f_n \to f$ **uniformly** on D if $\sup_{x \in D} |f_n(x) - f(x)| \to 0$: one N works for every x at once.

The standard example is $f_n(x) = x^n$ on $[0, 1]$. It converges pointwise to 0 for $x < 1$ and to 1 at $x = 1$. Every f_n is continuous, but the limit has a jump. The convergence isn't uniform: for any n, the point $x = 2^{-1/n}$ has $f_n(x) = \tfrac{1}{2}$.

Uniform limits of continuous functions are continuous

If each f_n is continuous at x_0 and $f_n \to f$ uniformly, then f is continuous at x_0.

Proof (the ε/3 argument). Let $\varepsilon > 0$. Choose n with $\sup_x |f_n(x) - f(x)| < \varepsilon/3$. Since f_n is continuous at x_0, choose $\delta > 0$ with $|f_n(x) - f_n(x_0)| < \varepsilon/3$ whenever $|x - x_0| < \delta$. Then for such x:

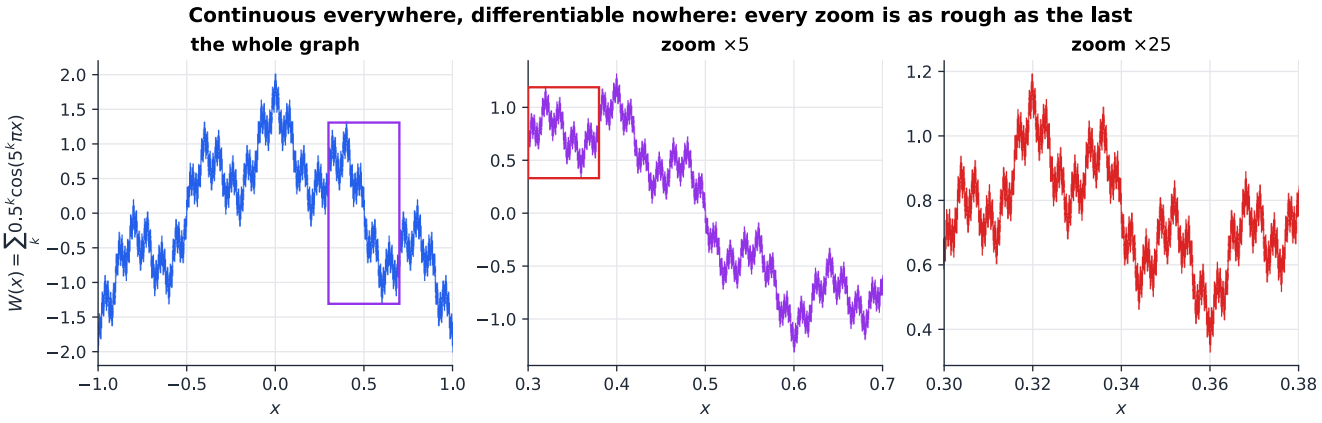
$$|f(x) - f(x_0)| \le \underbrace{|f(x) - f_n(x)|}_{<\varepsilon/3} + \underbrace{|f_n(x) - f_n(x_0)|}_{<\varepsilon/3} + \underbrace{|f_n(x_0) - f(x_0)|}_{<\varepsilon/3} < \varepsilon. \quad \blacksquare$$

The proof needs one n that works at x and at x_0 at the same time, and that is exactly what uniformity provides. A practical test is the **Weierstrass M-test**: if $|g_k(x)| \le M_k$ for all x and $\sum M_k < \infty$, then $\sum g_k$ converges uniformly.

Apply it to Weierstrass's monster:

$$W(x) = \sum_{k=0}^{\infty} a^k \cos\!\left(b^k \pi x\right), \qquad 0 < a < 1.$$

The terms are bounded by $M_k = a^k$, a convergent geometric series, so W is a uniform limit of continuous functions and is continuous. Yet when $ab \ge 1$ (Hardy, 1916; Weierstrass needed a stronger condition), W has no derivative at any point. Each new term adds wiggles that are b times faster but only a times smaller. Their slopes grow like $(ab)^k$, and no tangent line can survive.



Weierstrass's function with $a = 0.5$, $b = 5$. A smooth curve flattens into a straight line under magnification. This one never does: every zoom shows new corners.

? Monsters are the majority

Weierstrass's function looks like a pathological exception, built by hand to embarrass calculus. The truth is stranger. In a precise sense, *most* continuous functions are differentiable nowhere, and the smooth functions of engineering are a thin and exceptional set. Making "most" precise needs a way of measuring the size of sets inside an infinite-dimensional space of functions. That is the Baire category theorem, and it is one of the tools of Ch. 61.

Metric spaces: distance, abstracted

Every argument above used only one thing about numbers: the distance $|x - y|$ and its triangle inequality. Abstracting that one thing gives analysis a much bigger stage.

Metric space

A set X with a function $d : X \times X \to [0, \infty)$ such that $d(x, y) = 0 \iff x = y$, $d(x, y) = d(y, x)$, and $d(x, z) \le d(x, y) + d(y, z)$. It is **complete** if every Cauchy sequence converges to a point of X.

Examples:

- $\mathbb{R}^n$ with the Euclidean distance, or with the taxicab distance $\sum |x_i - y_i|$.
- Bit strings with the Hamming distance (Ch. 79).
- Continuous functions on $[0, 1]$ with the uniform distance $d_\infty(f, g) = \max_x |f(x) - g(x)|$. The theorem above says exactly that this space, $C[0, 1]$, is complete.
- The same functions with $d_1(f, g) = \int_0^1 |f - g| \, dx$. This space is *not* complete: continuous ramps steepening toward a step function form a Cauchy sequence whose limit is not continuous.

The payoff of the abstraction is that one theorem serves everywhere:

Banach fixed-point theorem (contraction mapping)

Let (X, d) be complete, and let $T : X \to X$ satisfy $d(Tx, Ty) \le q \, d(x, y)$ for some $q < 1$. Then T has exactly one fixed point x^*. The iteration $x_{n+1} = T x_n$ converges to it from any start, with

$$d(x_n, x^*) \le \frac{q^n}{1 - q} \, d(x_1, x_0), \qquad d(x_n, x^*) \le \frac{q}{1 - q} \, d(x_n, x_{n-1}).$$

The iterates form a Cauchy sequence, since their steps shrink geometrically. Completeness supplies the limit, and the contraction makes it unique. With X a space of functions, this one theorem proves that solutions of $\dot{y} = f(t, y)$ exist and are unique (Picard's theorem, behind Ch. 11). It also proves that value iteration in reinforcement learning converges (Ch. 52).

Measure and integration: Lebesgue's idea

The Riemann integral of Ch. 5 slices the *domain* into thin strips. It breaks down on functions that are too wild. The Dirichlet function, equal to 1 on rationals and 0 on irrationals, has every upper Riemann sum equal to 1 and every lower sum equal to 0 on $[0, 1]$, so it has no Riemann integral. Worse, limits of Riemann-integrable functions can fail to be Riemann integrable, so the Riemann integral is "incomplete" in the same sense as $\mathbb{Q}$.

Lebesgue (1902) sliced the *range* instead. To integrate f, ask for each height y how much of the domain has $f(x) > y$, and add up. This needs a way to measure the "length" of complicated sets.

Null set

$A \subset \mathbb{R}$ has **measure zero** if for every $\varepsilon > 0$ it can be covered by countably many intervals of total length less than ε.

The rationals have measure zero

$\mathbb{Q}$ is a null set, even though it is dense in $\mathbb{R}$.

Proof. List the rationals as $q_1, q_2, q_3, \ldots$, which is possible because they are countable (Ch. 64). Cover q_k by an interval of length $\varepsilon/2^k$. The total length is $\sum_k \varepsilon/2^k = \varepsilon$. ∎

So the Dirichlet function equals 0 except on a set of measure zero. Its Lebesgue integral is 0, which is surely the right answer. Lebesgue measure extends "length" to an enormous family of sets, the measurable ones, and the Lebesgue integral comes with the swap theorems the nineteenth century lacked:

Convergence theorems (stated)

Monotone convergence: if $0 \le f_1 \le f_2 \le \cdots$ and $f_n \to f$ pointwise, then $\int f_n \to \int f$.

Dominated convergence: if $f_n \to f$ pointwise and $|f_n| \le g$ for a single g with $\int g < \infty$, then $\int f_n \to \int f$.

The domination hypothesis is not decoration. Let $f_n = n$ on $(0, 1/n)$ and 0 elsewhere. Then $\int f_n = 1$ for every n, while $f_n(x) \to 0$ at every point. So $\lim \int f_n = 1 \neq 0 = \int \lim f_n$. The mass escapes into an ever-taller, ever-thinner spike, and no single integrable g can lie above all of them.

These theorems are why probability theory works. An expectation is a Lebesgue integral (§19.9). Swapping a derivative with an expectation, $\frac{d}{d\theta} E[f(X,\theta)] = E[\partial_\theta f]$, is the step behind every stochastic-gradient method (Ch. 54), and it is valid exactly when a domination condition holds.

? A set too wild to measure

Lebesgue measure assigns a length to a vast family of sets. Can it be extended to *every* subset of $\mathbb{R}$, keeping the two properties that make it "length": translating a set doesn't change its measure, and countable unions of disjoint pieces add up? In 1905 Giuseppe Vitali showed the answer is no, by building a set no consistent length can be assigned to. His construction uses the axiom of choice, and in some models of set theory *without* choice, every set of reals is measurable. Whether non-measurable sets "exist" turns out to depend on which axioms you accept. See Ch. 64 for choice and Ch. 97 for the measure theory.

60.4 The algorithm

Analysis is usually thought of as the opposite of computation, but its central proofs are algorithms with error certificates. The Banach theorem's bound turns fixed-point iteration into a method that tells you when to stop, and *guarantees* that its answer is correct to the stated tolerance.

```
import math

def fixed_point(T, x0, q, tol=1e-6, max_iter=10_000):
    """Iterate x <- T(x) for a contraction with constant q < 1.
    Stops when the a-posteriori bound q/(1-q)*|x_n - x_{n-1}| <= tol."""
    x = x0
    for n in range(1, max_iter + 1):
        x_new = T(x)
        bound = q / (1 - q) * abs(x_new - x)   # guaranteed |x_new - x*| <= bound
        x = x_new
        if bound <= tol:
            return x, n, bound
    raise RuntimeError("no convergence: is T really a contraction?")

q = math.sin(1.0)                   # |T'(x)| = |sin x| <= sin 1 on [0, 1]
x, n, b = fixed_point(math.cos, 0.0, q)
print(f"x* ~ {x:.10f} after {n} steps, certified error <= {b:.1e}")
print("a-priori estimate of steps:", math.ceil(math.log(1e-6 * (1 - q)) / math.log(q)))
```

For $T(x) = \cos x$ on $[0,1]$, the mean value theorem gives $|\cos x - \cos y| \le \sin(1)\,|x - y|$ with $q = \sin 1 \approx 0.841$. The cosine maps $[0,1]$ into itself, and $[0,1]$ is complete. The run stops after 40 steps at 0.7390850787, with a certified error of at most 7.2×10^{-7}. The true fixed point is 0.7390851332, so the actual error is 5×10^{-8}. The a-priori bound predicted 91 steps. It is pessimistic because near the fixed point the true contraction factor is $\sin(0.739) \approx 0.67$, not 0.84.

Cost and failure modes.

- Each step costs one evaluation of T. The error falls like q^n, which is linear convergence: about $\log_{10}(1/q)$ digits per step, so 0.075 digits per step here. Compare Newton's digit-doubling in §60.3.
- If q is close to 1, convergence is painfully slow. If $q \ge 1$, the theorem is silent: the iteration may still converge, cycle, or diverge.
- Estimating q wrongly, too small, voids the certificate. The bound is only as honest as the Lipschitz estimate behind it.
- Floating-point rounding means the computed iterates aren't exactly those of T. The certificate then holds only up to about $\epsilon_{\text{mach}}/(1-q)$ (§22.1).

The same skeleton, a monotone or contracting sequence plus completeness, gives bisection's certified bracket $[a_n, b_n]$ of width $(b-a)/2^n$ and Picard iteration for ODEs.

60.5 The experiment

Steer a series anywhere. This script runs Riemann's greedy rearrangement of $1 - \frac{1}{2} + \frac{1}{3} - \cdots$ toward any target you choose:

```
import numpy as np

target = np.pi          # any real number you like: try -1, 0, 100
N = 200_000             # how many terms to use

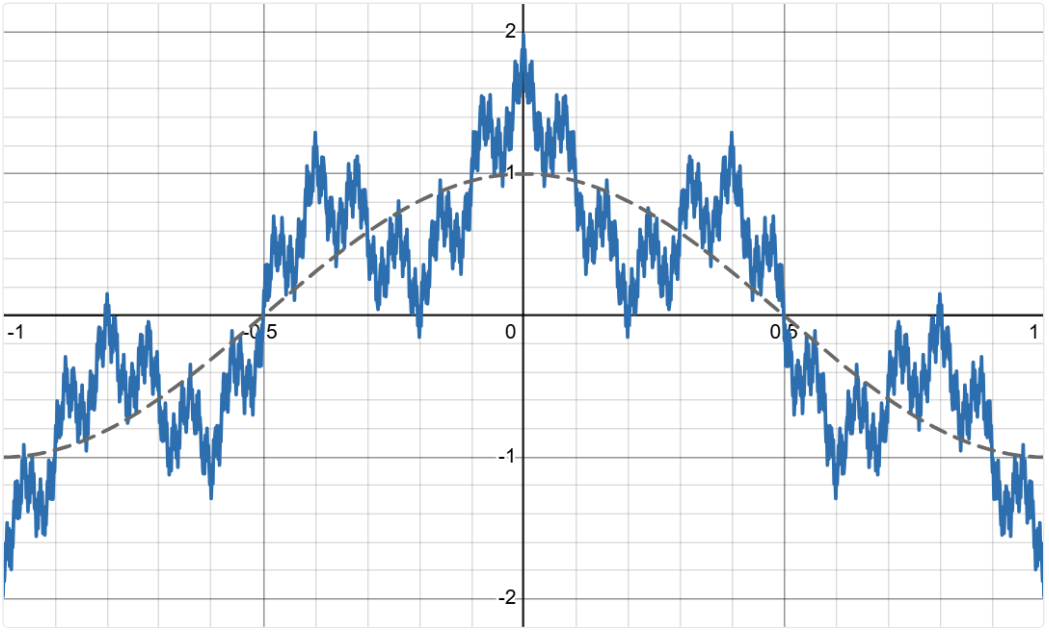
pos = iter(1 / k for k in range(1, 10**9, 2))     # +1, +1/3, +1/5, ...
neg = iter(-1 / k for k in range(2, 10**9, 2))    # -1/2, -1/4, ...
s, partial, used_pos = 0.0, [], 0
for _ in range(N):
    if s <= target:
        s += next(pos); used_pos += 1
    else:
        s += next(neg)
    partial.append(s)

print(f"sum after {N} terms = {s:.6f}  (target {target:.6f})")
print(f"positive terms used: {used_pos}, negative: {N - used_pos}")
print(f"ratio pos/neg ~ {used_pos / (N - used_pos):.1f};  e^(2*target)/4 = {np.exp(2*target)/4:.1f}")
```

With target π the sum after 200,000 terms is 3.14138. The greedy rule spends about 134 positive terms for every negative one, matching $e^{2T}/4 = e^{2\pi}/4 \approx 133.9$, which is what the formula $\ln 2 + \frac{1}{2}\ln(p/q) = T$ predicts. Things to try:

- Set `target = 100`. How many terms would you need? (Hint: e^{200}.)
- Plot `partial` with matplotlib and watch it oscillate around the target.
- Replace the series with $\sum(-1)^{k+1}/k^2$, which converges absolutely, and show that no amount of greed can move its sum.

Zoom into a monster. Below are the first seven terms of Weierstrass's function with $a = 0.5$ and $b = 5$. Change the upper limit from 6 to 2, then back to 6, and watch the corners appear. Then change b from 5 to 2, which makes $ab = 1$, the borderline case. Then zoom in with Desmos's own controls.



Partial sums of Weierstrass's function. The dashed curve is the first term. Every extra term adds wiggles five times faster and only half as tall.

60.6 The challenge

1. **Intuition.** Explain, without formulas, why reordering the terms of $\sum(-1)^{k+1}/k^2$ can never change its sum, while reordering $\sum(-1)^{k+1}/k$ can produce anything. What is the one property of the terms that decides it?
2. **Derivation.** Prove that $f_n(x) = nx\,e^{-nx^2}$ converges pointwise to 0 on $[0, 1]$. Compute $\int_0^1 f_n\,dx$ exactly and its limit. Is $\lim \int = \int \lim$? Find $\sup_x f_n(x)$, and explain which hypothesis of the dominated convergence theorem fails.
3. **Implementation.** Write a function that takes a contraction T on $\mathbb{R}^2$, given as code, plus a Lipschitz constant q, and returns a certified fixed point. Use it on $T(x, y) = \left(\frac{1}{2}\cos y,\ \frac{1}{2}\sin x + 0.1\right)$. Then estimate q numerically by sampling $\|T(\mathbf{u}) - T(\mathbf{v})\|/\|\mathbf{u} - \mathbf{v}\|$, and explain why a sampled estimate can never be trusted for the certificate.
4. **Open investigation.** For the Weierstrass function with $a = 0.5$, estimate numerically how the oscillation $\max_{|t|\le h}|W(x + t) - W(x)|$ scales with h as $h \to 0$, for several values of b. You should find a power law h^{α}. Guess a formula for α in terms of a and b, then compare it with the box-counting dimension of the graph estimated from your plots. Does the relationship hold for every x, or only for most?

60.7 Loose threads

The ε–N game, completeness, and Lebesgue's integral are the foundations. This chapter showed you the ground floor and closed several doors without opening them.

? When does a Fourier series actually converge?

Ch. 15 promised that well-behaved periodic signals equal their Fourier series. In 1873 Paul du Bois-Reymond built a *continuous* function whose Fourier series diverges at a point. Later it was shown that for continuous functions divergence can even happen on a dense set. Then in 1966 Lennart Carleson proved that the Fourier series of every square-integrable function converges at *almost every* point, meaning everywhere except on a set of measure zero. The statement uses only this chapter's words, but the proof is among the hardest in twentieth-century analysis. The framework it lives in is Ch. 97.

Two more threads to follow. The space $C[0,1]$ with the distance d_1 was not complete. Completing it, the way $\mathbb{R}$ completes $\mathbb{Q}$, produces the Lebesgue space L^1, and that construction opens Ch. 61. The careful logic of ε–N proofs, with its nested "for every… there exists", is a subject in its own right in Ch. 63. And probability, rebuilt on measure by Kolmogorov in 1933, is the destination of Ch. 31 and Ch. 97.

61.1 The hook

In the summer of 1925, a 23-year-old Werner Heisenberg, recovering from hay fever on the island of Heligoland, invented a new mechanics. In it, the position and momentum of an electron were no longer numbers but arrays. Max Born recognised the arrays as matrices, and with Pascual Jordan he found the rule at the centre of the theory: position X and momentum P don't commute. Instead,

$$XP - PX = j\hbar\mathbf{I}.$$

Everything quantum follows from this one line: the uncertainty principle, discrete energy levels, the stability of atoms.

Here is the strange part. The equation has **no solution in matrices**. Not 2×2, not 1000×1000, not any finite size. The proof takes one line, and you will see it in §61.3. Yet the theory worked, its predictions were confirmed to many decimal places, and transistors, lasers and MRI scanners are all built on it.

So what are X and P, if they can't be matrices?

The same puzzle shows up wherever engineers work with signals rather than lists of numbers:

- A signal $x(t)$ is a vector with one coordinate for every instant. Fourier series write it in a basis of sines (Ch. 15), but there are infinitely many basis vectors. Is "orthogonal projection" still the best approximation? Does every Cauchy sequence of signals have a limit?
- Differentiation is a linear map on signals. So is integration. Integration smooths, so a small change in the input gives a small change in the output. Differentiation does the opposite: a tiny high-frequency wiggle in the data becomes a huge error in the derivative. Why are two inverse operations so different?
- Deblurring a photo, or reconstructing a CT image, means inverting a linear map. With exact data the inverse exists. With real data, however good the instrument, the naive inverse returns garbage. Why?

The question of this chapter:

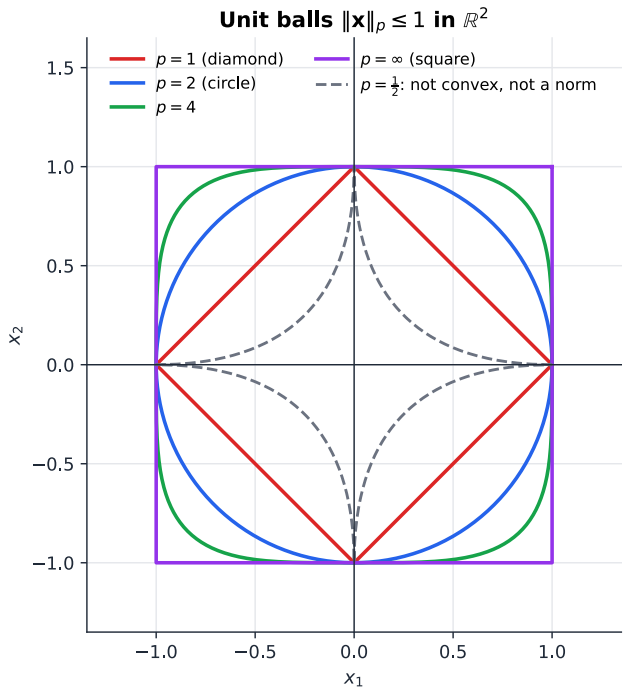
> **What survives of linear algebra when the dimension becomes infinite, and what new phenomena appear that no matrix could ever show?**

The subject that answers it is functional analysis. It was built in the 1900s–1930s by Hilbert, Riesz, Banach and von Neumann, and von Neumann used it to put Heisenberg's matrices on solid ground.

61.2 The big idea

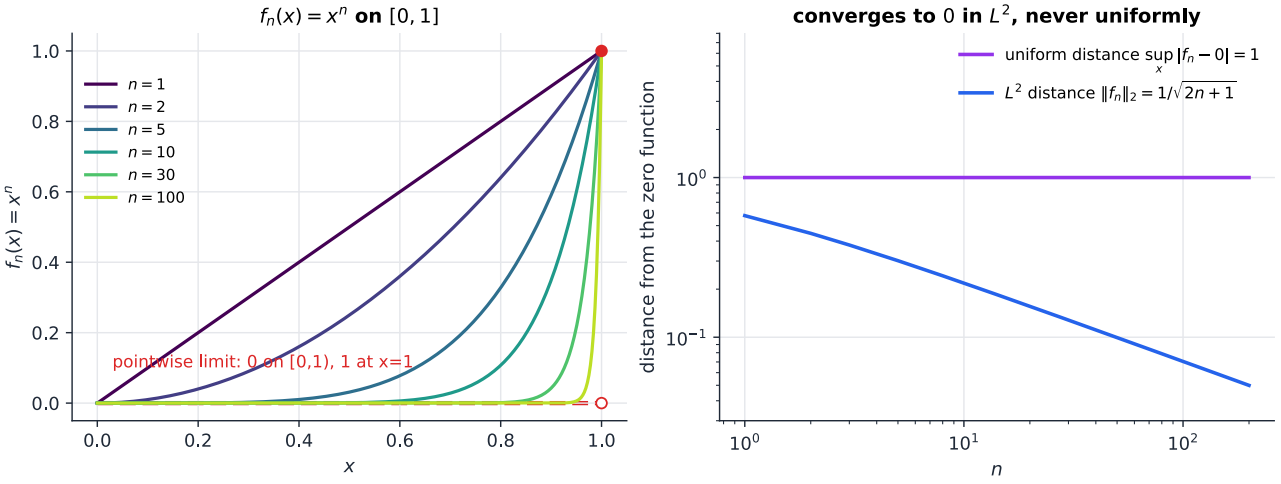
Functions are vectors. You can add two signals and scale a signal, so signals form a vector space (§9.1). Everything you know about linear maps, projections and eigenvectors has a candidate meaning for them. The catch is that no finite basis spans the space.

In infinite dimensions, "how you measure" changes "what converges". In $\mathbb{R}^n$ it doesn't matter whether you measure the size of a vector by the largest component, the sum of components, or the Euclidean length: a sequence that converges in one measure converges in all of them. The unit balls of these norms differ in shape (a square, a diamond, a disc), but each fits inside a scaled copy of the others.



The unit balls of $\|\mathbf{x}\|_p = (|x_1|^p + |x_2|^p)^{1/p}$. As p grows they swell from the diamond to the square. For $p < 1$ the "ball" is not convex and the triangle inequality fails, so it isn't a norm.

For functions that comfort disappears. Take $f_n(x) = x^n$ on $[0, 1]$. Measured by *energy*, the L^2 norm $\left(\int_0^1 |f|^2\right)^{1/2}$, the sequence shrinks to zero: $\|x^n\|_2 = 1/\sqrt{2n+1}$. Measured by *peak value*, the sup norm, it never shrinks at all, because $\max x^n = 1$ for every n. One norm says "converges to zero" and the other says "stays at distance 1 forever". Both are right. You have to choose, and the choice is physics: energy-type questions call for L^2, and questions about peak voltage call for the sup norm.



Same sequence, two verdicts. In L^2 the functions x^n converge to the zero function. In the sup norm they never get closer than 1. Gibbs' overshoot in Fourier series (§15.6) is the same phenomenon.

An analogy: an infinite orchestra. A finite-dimensional vector is a chord played by a fixed set of instruments. A signal is a chord played by infinitely many instruments, each a little higher in pitch. In finite dimensions you can't hide energy anywhere. In an infinite orchestra the energy can drift up to ever-higher instruments and *leak away* while the total stays constant. The sequence $\sin(nt)$ has fixed energy but moves to ever-higher pitch. Its overlap with any fixed signal fades to zero, yet it never converges to anything. Most of what is new in functional analysis is this escape to infinity: how to see it, how to forbid it, and how to use it.

61.3 The mathematics

Normed and Banach spaces

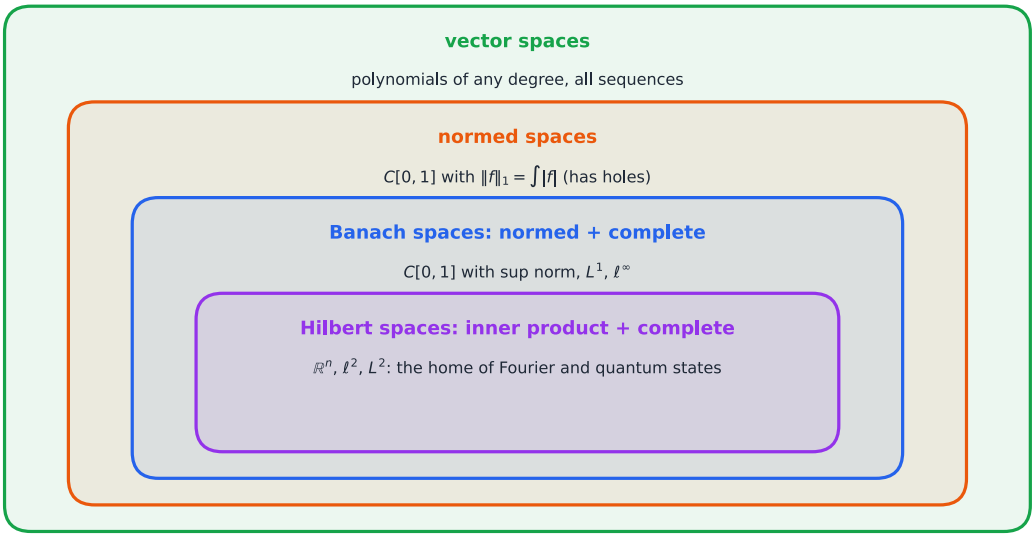
Normed space, Banach space

A **norm** on a vector space V is a function $\|\cdot\| : V \to [0, \infty)$ with $\|v\| = 0 \iff v = 0$, $\|\alpha v\| = |\alpha|\|v\|$, and $\|u + v\| \le \|u\| + \|v\|$. A normed space is a **Banach space** if it is complete for the metric $d(u, v) = \|u - v\|$, in the sense of Ch. 60: every Cauchy sequence converges.

The main examples:

- ℓ^p, the sequences with $\|x\|_p = (\sum_k |x_k|^p)^{1/p} < \infty$, for $1 \le p < \infty$.
- ℓ^∞, the bounded sequences with the sup norm.
- $C[a, b]$ with the sup norm.
- $L^p[a, b]$, the functions with $\int |f|^p < \infty$. Strictly, these are classes of functions that agree almost everywhere, and the integral must be Lebesgue's (§60.3).

Completeness is not automatic. $C[0, 1]$ with the L^1 norm is not complete, and its completion is L^1, just as $\mathbb{R}$ completes $\mathbb{Q}$. The fact that the L^p spaces *are* complete (the Riesz–Fischer theorem, in its general form) is the main reason for Lebesgue's integral. With Riemann's integral, limits of signals could fall out of the space.



The family tree. Each level adds structure: a length, then completeness, then angles. Most of signal processing and quantum mechanics lives in the innermost box.

In finite dimensions all norms are **equivalent**: for any two norms there are constants with $c\|v\|_a \le \|v\|_b \le C\|v\|_a$. In infinite dimensions they are not, as the x^n example shows. There $\|f_n\|_2 \to 0$ while $\|f_n\|_\infty = 1$, so no constant C can make $\|f\|_\infty \le C\|f\|_2$ hold.

Hilbert spaces: geometry with infinitely many axes

A **Hilbert space** is a Banach space whose norm comes from an inner product, $\|v\|^2 = \langle v, v\rangle$. Inner products, orthogonality and Gram–Schmidt are covered in §9.8–§9.10. The examples that matter are ℓ^2 and L^2, where $\langle f, g\rangle = \int f\,\overline{g}$. Among the ℓ^p spaces, only $p = 2$ comes from an inner product. The test is the parallelogram law $\|u + v\|^2 + \|u - v\|^2 = 2\|u\|^2 + 2\|v\|^2$, which the diamond and the square both fail.

Three facts carry over from finite dimensions, each needing completeness:

The Hilbert-space toolkit (stated)

Projection theorem. If M is a closed subspace of a Hilbert space H, every $f \in H$ has a unique closest point $Pf \in M$, and $f - Pf \perp M$. This is the infinite-dimensional version of least squares (§9.11).

Orthonormal bases. If $\{e_k\}$ is a complete orthonormal set, then $f = \sum_k \langle f, e_k\rangle e_k$, with convergence in norm, and **Parseval's identity** $\|f\|^2 = \sum_k |\langle f, e_k\rangle|^2$ holds. Fourier series are this theorem for $e_k = e^{jkt}/\sqrt{2\pi}$ (§15.8).

Riesz representation. Every continuous linear functional $\phi : H \to \mathbb{C}$ has the form $\phi(f) = \langle f, g\rangle$ for exactly one $g \in H$.

Now the first genuinely new phenomenon.

The unit ball of an infinite-dimensional Hilbert space is not compact

Let $\{e_n\}$ be an infinite orthonormal sequence. Then:

1. $\|e_m - e_n\| = \sqrt{2}$ for $m \ne n$, so no subsequence converges in norm.
2. For every fixed $f \in H$, $\langle f, e_n\rangle \to 0$.

Proof. (1) By Pythagoras, $\|e_m - e_n\|^2 = \|e_m\|^2 + \|e_n\|^2 = 2$, since $e_m \perp e_n$. A convergent subsequence would be Cauchy, but its terms all stay $\sqrt{2}$ apart.

(2) For any N, the projection of f onto $\operatorname{span}\{e_1, \dots, e_N\}$ is $\sum_{n \le N} \langle f, e_n\rangle e_n$. Its norm is at most $\|f\|$, which gives **Bessel's inequality** $\sum_{n=1}^{N} |\langle f, e_n\rangle|^2 \le \|f\|^2$. Since N is arbitrary, the series $\sum_n |\langle f, e_n\rangle|^2$ converges, so its terms tend to zero. ■

In $\mathbb{R}^n$, Bolzano–Weierstrass guarantees that every bounded sequence has a convergent subsequence. Part (1) says that in infinite dimensions this fails for the simplest bounded sequence there is. Part (2) says the sequence *does* go to zero in a weaker sense. This is the orchestra's leaking energy, made precise.

Weak convergence

$f_n \rightharpoonup f$ (**weakly**) if $\langle f_n, g\rangle \to \langle f, g\rangle$ for every $g \in H$. Norm convergence implies weak convergence, but not conversely: $e_n \rightharpoonup 0$ while $\|e_n\| = 1$.

In $L^2[0,1]$ the functions $\sqrt{2}\sin(n\pi x)$ form such a sequence. Their weak convergence to zero is the Riemann–Lebesgue lemma. Weak convergence is what rescues compactness: every bounded sequence in a Hilbert space has a *weakly* convergent subsequence. Existence proofs for PDEs and optimal controls work this way. Find a minimizing sequence, extract a weakly convergent subsequence, and show the limit is a solution.

Operators: bounded means continuous

A linear map between normed spaces is called an **operator**. Its size is the **operator norm** $\|T\| = \sup_{\|f\|\le 1}\|Tf\|$. For a matrix with the Euclidean norm this is the largest singular value (§10.7).

Bounded ⇔ continuous

A linear operator T between normed spaces is continuous if and only if it is **bounded**, meaning $\|Tf\| \le C\|f\|$ for some constant C.

Proof. If T is bounded, then $\|Tf - Tg\| = \|T(f-g)\| \le C\|f-g\|$, so T is Lipschitz and in particular continuous.

Conversely, suppose T is continuous at 0. Take $\varepsilon = 1$: there is a $\delta > 0$ such that $\|h\| \le \delta$ implies $\|Th\| \le 1$. For any $f \neq 0$, put $h = \delta f/\|f\|$, which has norm δ. By linearity,

$$\|Tf\| = \frac{\|f\|}{\delta}\,\|Th\| \le \frac{1}{\delta}\|f\|,$$

so $C = 1/\delta$ works. ∎

Every matrix is bounded. In infinite dimensions many natural operators are not. Differentiation $D = d/dx$ on smooth functions with the sup norm sends $f_n(x) = \sin(nx)$, which has $\|f_n\|_\infty = 1$, to $n\cos(nx)$, which has norm n. No constant C bounds it, so **differentiation is discontinuous**. That is the reason numerical differentiation amplifies noise (§22.7): it isn't sloppy coding, it's a theorem.

Integration is the opposite. The **Volterra operator** $(Vf)(x) = \int_0^x f(t)\,dt$ on $L^2[0,1]$ is bounded, with $\|V\| = 2/\pi \approx 0.637$. More than that, it is **compact**: it maps bounded sets to sets whose closure is compact, so it squeezes the infinite-dimensional unit ball into something essentially finite-dimensional. Its singular values are

$$\sigma_k = \frac{2}{(2k-1)\pi}, \qquad k = 1, 2, 3, \dots$$

which decay to zero. A compact operator always has singular values tending to zero. Now the inverse problem of the hook makes sense. Inverting V means dividing by the σ_k, and $1/\sigma_k \to \infty$. The inverse of a compact operator on an infinite-dimensional space is never bounded.

Dual spaces and Hahn–Banach

The **dual** V^* of a normed space is the space of its continuous linear functionals: the "measurements" you can make on its elements. Examples are evaluating a filter output at one instant, or taking an inner product with a template. Riesz says a Hilbert space is its own dual. For $1 < p < \infty$, the dual of ℓ^p is ℓ^q with $1/p + 1/q = 1$. That is why Hölder's inequality $|\sum x_k y_k| \le \|x\|_p\|y\|_q$ is everywhere.

Does a general Banach space have *enough* functionals to tell its points apart? In $\mathbb{R}^n$, separating a point from a convex set by a hyperplane was the engine of Ch. 47. Its infinite-dimensional heir is this theorem.

Hahn–Banach (stated)

A continuous linear functional defined on a subspace of a normed space extends to the whole space with the same norm. Geometric form: a closed convex set and a point outside it can always be strictly separated by a continuous linear functional, a "hyperplane" $\{\phi = c\}$.

So the walls of convex optimization survive in spaces of signals. That is why duality theory works for optimal control and for infinite linear programs. The proof needs no geometry of $\mathbb{R}^n$ at all. It uses Zorn's lemma, a form of the axiom of choice (Ch. 64).

Baire's theorem: why monsters win

The last pillar answers a question from Ch. 60.

Baire category theorem and uniform boundedness (stated)

A complete metric space is not a countable union of nowhere-dense sets. Consequence (Banach–Steinhaus): if a family of bounded operators on a Banach space is bounded at each point, $\sup_\alpha \|T_\alpha f\| < \infty$ for every f, then it is uniformly bounded, $\sup_\alpha \|T_\alpha\| < \infty$.

Banach applied this in 1931. In $C[0,1]$, the functions that have a derivative at even one point form a countable union of nowhere-dense sets, so "most" continuous functions are nowhere differentiable. Similarly, the Fourier partial-sum operators $f \mapsto S_N f(0)$ on continuous functions have norms (the Lebesgue constants) that grow like $\frac{4}{\pi^2}\ln N$. They are not uniformly bounded, so by Banach–Steinhaus some continuous function has a Fourier series that diverges at 0. In both cases the monster's existence is proved without ever building it.

Spectral theory: eigenvalues and beyond

For a symmetric matrix the spectral theorem gives an orthonormal eigenbasis (§10.5). The closest infinite-dimensional analogue is this.

Spectral theorem for compact self-adjoint operators (stated)

If T is compact and self-adjoint on a Hilbert space, then $Tf = \sum_k \lambda_k \langle f, e_k \rangle e_k$, where the e_k are orthonormal eigenvectors and the real eigenvalues $\lambda_k \to 0$.

Separation of variables for the heat and wave equations (§13.3) is this theorem in action. The inverse of $-d^2/dx^2$ with zero boundary values is a compact self-adjoint integral operator on $L^2[0,1]$ with eigenfunctions $\sin(k\pi x)$ and eigenvalues $1/(k\pi)^2$.

Without compactness, eigenvectors can vanish entirely. Define the **spectrum** $\sigma(T)$ as the set of λ for which $T - \lambda I$ has no bounded inverse. In finite dimensions that is exactly the set of eigenvalues. In infinite dimensions it can be much more:

- **Multiplication**, $(Mf)(x) = xf(x)$ on $L^2[0,1]$, is bounded and self-adjoint. It has *no eigenvalues at all*: $xf(x) = \lambda f(x)$ forces $f = 0$ almost everywhere. Yet its spectrum is the whole interval $[0,1]$. This is the position operator of quantum mechanics, and it has a *continuous spectrum*.
- **The right shift** $S(x_1, x_2, \dots) = (0, x_1, x_2, \dots)$ on ℓ^2 has no eigenvalues, preserves norms, and has spectrum equal to the closed unit disk.

Back to the hook:

Heisenberg's relation has no finite-dimensional solution

There are no $n \times n$ matrices X, P (for any $n \geq 1$) with $XP - PX = j\hbar \mathbf{I}$, $\hbar \neq 0$.

Proof. The trace satisfies $\operatorname{tr}(AB) = \operatorname{tr}(BA)$. Taking traces of both sides gives $\operatorname{tr}(XP) - \operatorname{tr}(PX) = 0$ on the left and $j\hbar \operatorname{tr} \mathbf{I} = j\hbar n \neq 0$ on the right. ∎

On $L^2(\mathbb{R})$, by contrast, take $(X\psi)(x) = x\psi(x)$ and $(P\psi)(x) = -j\hbar\,\psi'(x)$. Then

$$(XP - PX)\psi = -j\hbar\, x\psi' + j\hbar\,(x\psi)' = j\hbar\,\psi,$$

so the relation holds. The answer to the hook is that X and P are operators on an infinite-dimensional Hilbert space, and neither is a matrix. They pay a price for it: P is a differentiation and is unbounded, and on $L^2(\mathbb{R})$ the operator X is unbounded too.

? Could bounded operators have done the job?

The trace trick only rules out matrices. Infinite-dimensional operators have no trace in general. Maybe some clever pair of *bounded* operators on ℓ^2 satisfies $XP - PX = j\hbar I$, which would spare physics the problems of unbounded operators: domains, self-adjointness and convergence. The answer (Wintner 1947, Wielandt 1949) is no, and the proof is a short and beautiful spectral argument. It forces quantum theory into unbounded operators, and the Stone–von Neumann theorem then says the pair (X, P) is essentially unique. Both stories are in Ch. 92.

? Eigenvectors that aren't there

Physicists write position "eigenstates" $|x_0\rangle$ with $X|x_0\rangle = x_0|x_0\rangle$ and expand every state in them, as if M had a full set of eigenvectors. But M has *no* eigenvectors in L^2, and the would-be eigenvector is a Dirac delta, which isn't a function. What exactly replaces "a basis of eigenvectors" for an operator with continuous spectrum? The answer is spectral measures and projection-valued integrals, $T = \int \lambda\, dE(\lambda)$. That is the full spectral theorem of Ch. 90.

61.4 The algorithm

Seeing an ill-posed problem. Discretize the Volterra operator on n grid points, measure its singular values against the formula, and try to undo it on slightly noisy data:

```
import numpy as np

n = 200                                  # grid points on [0, 1]
h = 1.0 / n
x = (np.arange(n) + 0.5) * h             # midpoints
V = h * np.tril(np.ones((n, n)))         # (Vf)(x) = integral_0^x f(t) dt
V -= 0.5 * h * np.eye(n)                 # midpoint correction on the diagonal

U, s, Wt = np.linalg.svd(V)
k = np.arange(1, 6)
print("sigma_k  numeric:", np.round(s[:5], 4))
print("sigma_k  theory :", np.round(2 / ((2 * k - 1) * np.pi), 4))

f_true = np.cos(3 * np.pi * x)           # the signal we want to recover
rng = np.random.default_rng(0)
g = V @ f_true + 1e-3 * rng.standard_normal(n)   # measured, slightly noisy

f_naive = np.linalg.solve(V, g)          # exact inverse = differentiate the data
r = 20                                   # keep only r singular values
f_tsvd = Wt[:r].T @ ((U[:, :r].T @ g) / s[:r])
for name, f in [("naive", f_naive), ("TSVD r=20", f_tsvd)]:
    print(f"{name:10s} relative error = {np.linalg.norm(f - f_true) / np.linalg.norm(f_true):.3f}")
print("condition number of V:", round(s[0] / s[-1]))
```

The first five singular values match $2/((2k-1)\pi) = 0.6366,\ 0.2122,\ 0.1273,\ 0.0909,\ 0.0707$ to four digits. The matrix's condition number is about 6.5×10^4, and it grows without bound as the grid is refined, because the matrix is approximating an operator whose inverse is unbounded. With noise of only 10^{-3}, the naive solve returns a reconstruction with a relative error of 12, or 1,200%. **Truncated SVD**, which keeps only the 20 largest singular values, brings the error down to 14%.

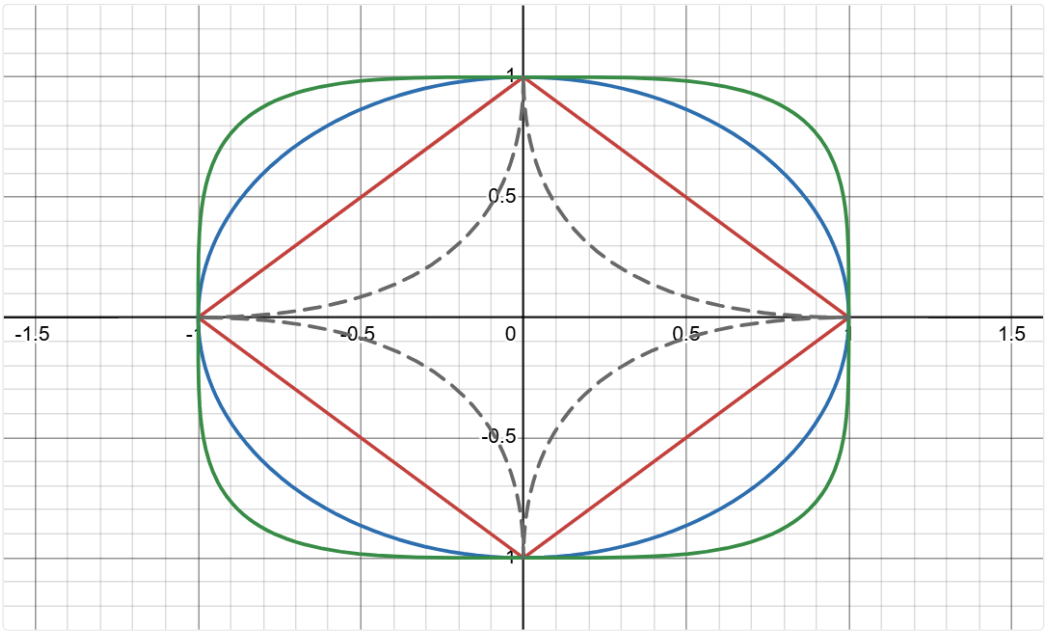
What the algorithm is doing. The data component along the k-th singular vector gets divided by σ_k. For small σ_k that component is almost pure noise, and dividing by a tiny number blows the noise up. Truncation trades a little bias (discarding fine detail) for a large cut in variance. **Tikhonov regularization** makes the same trade smoothly, replacing $1/\sigma_k$ by $\sigma_k/(\sigma_k^2 + \alpha)$.

Cost and failure modes.

- A full SVD costs $O(n^3)$. For large problems one uses iterative Krylov methods. Their iteration count itself acts as a regularizer, which is called *semi-convergence*: stop too late and the noise floods back in.
- Refining the grid does *not* fix ill-posedness. It makes the condition number worse, because a finer grid samples more of the operator's decaying spectrum.
- The best truncation level depends on the noise level and on how smooth the true signal is. Pick it from the same noisy data and you can fool yourself.

61.5 The experiment

Reshape the unit ball. Change the exponent 4 to 20 and watch the ball approach the square, which is the $p = \infty$ ball. Change 0.5 to 0.9 and then 1, and watch the star inflate to the diamond. It becomes convex exactly at $p = 1$.



Unit "balls" of $\|\cdot\|_p$ for $p = 1$ (red), 2 (blue), 4 (green) and $\frac{1}{2}$ (dashed grey, not a norm). Only $p = 2$ comes from an inner product.

Converging in energy but not in peak. This script measures the Fourier partial sums of a square wave in two norms:

```
import numpy as np

x = np.linspace(-np.pi, np.pi, 20_001)
dx = x[1] - x[0]
f = np.sign(x)                                  # square wave on one period

def partial_sum(N):
    """Fourier partial sum of the square wave, odd harmonics up to N."""
    k = np.arange(1, N + 1, 2)
    return (4 / np.pi) * (np.sin(np.outer(x, k)) / k).sum(axis=1)

print("   N    L2 error   sup error   max of S_N")
for N in [1, 5, 25, 125, 625]:
    e = partial_sum(N) - f
    l2 = np.sqrt(np.sum(e**2) * dx / (2 * np.pi))  # RMS = L2 norm / sqrt(2 pi)
    print(f"{N:4d}   {l2:8.4f}   {np.abs(e).max():8.4f}   {partial_sum(N).max():8.4f}")
```

The RMS error falls from 0.435 at $N = 1$ to 0.026 at $N = 625$, roughly halving each time N grows five-fold. The sup error stays pinned at 1.000, because a continuous partial sum can't follow a jump. The overshoot settles at 1.179, the Gibbs constant. Knobs to turn:

- Replace `np.sign(x)` by the continuous triangle wave `np.abs(x)`. Its partial sums use cosines, $\frac{\pi}{2} - \frac{4}{\pi}\sum_{k\ \text{odd}} \cos(kx)/k^2$. Watch the sup error go to zero too.
- Measure the L^1 error. Does it decay faster or slower than L^2?
- Change the exponent of `k` and see how the smoothness of a signal controls the decay rates in different norms.

61.6 The challenge

1. **Intuition.** In ℓ^2, explain without calculation why the sequence $e_1, e_2, e_3, \ldots$ "goes to zero" when measured against any fixed vector, but never gets close to zero. Then decide: does $(e_1 + \cdots + e_n)/n$ converge in norm? To what?

2. **Derivation.** Show that the Volterra operator's adjoint is $(V^*g)(x) = \int_x^1 g(t)\,dt$. Then show that the eigenfunctions of V^*V satisfy $-u'' = \lambda^{-1}u$, with $u(1) = 0$ and $u'(0) = 0$. Deduce the singular values $\sigma_k = 2/((2k-1)\pi)$, and so $\|V\| = 2/\pi$.
3. **Implementation.** Add Tikhonov regularization to the inverse-problem script. For noise levels $10^{-2}, 10^{-3}, 10^{-4}$, plot the reconstruction error against α on a log scale and find the best α for each. Then implement one rule that chooses α *without* knowing `f_true`, such as the discrepancy principle or the L-curve, and compare it with the optimum.
4. **Open investigation.** For the right shift S on ℓ^2, compute the eigenvalues of its $n \times n$ truncation (a nilpotent Jordan block), and then of slightly perturbed versions: add 10^{-10} in the corner entry $(1, n)$. Where do the eigenvalues go as n grows? Compare with the true spectrum, the closed unit disk, and look up "pseudospectra". Is there a rule that predicts which finite truncations of an infinite operator can be trusted?

61.7 Loose threads

Functional analysis turns "signal", "state" and "field" into points of a space, and "filter", "observable" and "PDE" into operators on it. This chapter set up the stage: norms, completeness, Hilbert geometry, bounded and compact operators, duality and the first spectral theorem. The plot is still to come.

> **? How much regularization is right?**
>
> Truncated SVD worked once we chose r, and Tikhonov works once we choose α, but the best choice depended on the unknown true signal. Is there a principled rule that is provably near-optimal with only the noisy data in hand? It depends on how fast the singular values decay compared with the signal's coefficients (the Picard condition). The Bayesian reading, where α is a ratio of noise variance to prior variance, gives a second answer that is in tension with the first. Both are in Ch. 91.

Further pointers. Sobolev spaces, which are Hilbert spaces of functions with square-integrable derivatives, turn PDEs into problems of projection and duality (Ch. 89). Compressed sensing exploits the pointed corners of the ℓ^1 ball from the figure, and convex duality supplies its certificates (Ch. 48). Category theory, next in this track, asks what all these "spaces with structure-preserving maps" have in common (Ch. 62).

Chapter 62 — Category Theory: Mathematics About Mathematics

> **Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on:** Ch. 1, Ch. 9, Ch. 56 · **Leads to:** Ch. 66, Ch. 99, Ch. 95 · **Related:** Ch. 58, Ch. 29, Ch. 64, Ch. 93 **Reading time:** ~30 min

62.1 The hook

A colleague hands you a compiled library function. You can't read its source. All you know is its type signature:

```
mystery : List[A] -> List[A]      # for every type A
```

It works on lists of integers, strings or circuit netlists. You run it once, `mystery([1, 2, 4])`, and get `[4, 2, 1]`. Maybe it reverses. Maybe it does something stranger on longer lists. Now take any function `f`, say `even : Int -> Bool`. Is it true that

```
mystery(map(f, xs)) == map(f, mystery(xs))      # for every list xs?
```

In words: does the order of "transform the elements" and "apply `mystery`" matter? You are being asked about code you have never seen, and yet the type seems to know. A function that must work for *every* type `A` can't look inside the elements, so it can't compare, add or print them. Is that restriction enough to settle the question?

Here is a second puzzle that looks unrelated. Write down five constructions you know:

- the Cartesian product $A \times B$ of two sets,
- the greatest common divisor $\gcd(a, b)$ of two integers,
- the minimum $\min(a, b)$ of two real numbers,
- the logical conjunction "p AND q",
- a tuple type `(A, B)` in a programming language.

They come from set theory, number theory, analysis, logic and software. Yet they are *the same construction*, done in five different worlds: not similar, the same, in a sense precise enough to prove theorems about all five at once.

Both puzzles have one answer: stop looking at what things *are*, and look at how they *connect*. That shift of attention is **category theory**. It began in 1945, when Eilenberg and Mac Lane wanted to say precisely what "natural" meant, and grew into a language that runs through algebra, logic, programming-language design and composable systems. By the end of this chapter you will have proved the `mystery` claim for a whole family of functions, and seen why gcd, min, AND, tuples and Cartesian products are one idea.

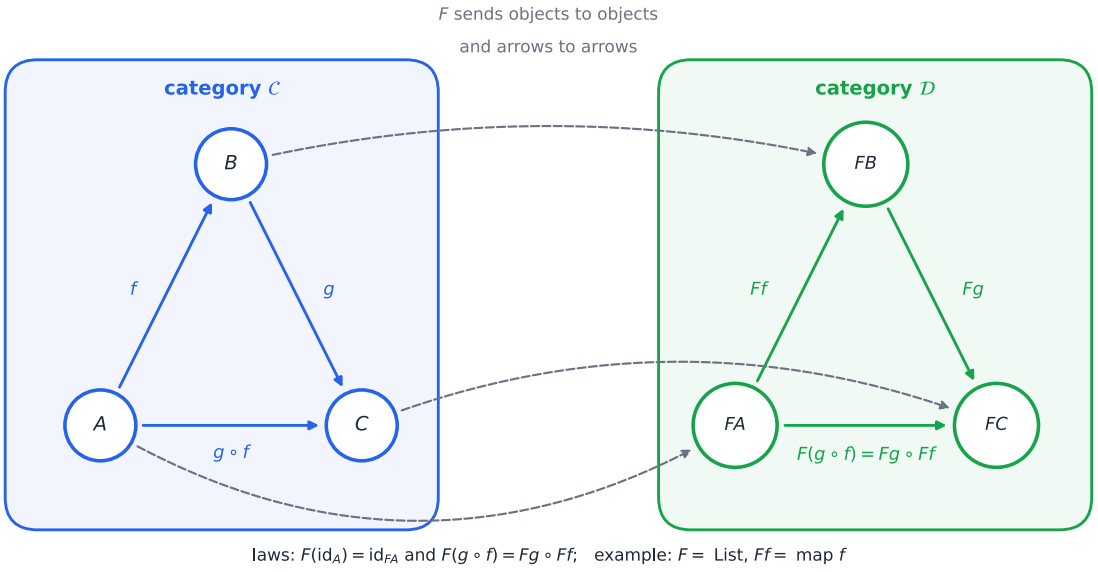
62.2 The big idea

Most of mathematics studies **objects**: numbers, sets, groups, vector spaces. Category theory studies the **arrows between them** and how arrows compose. It treats the inside of an object as off limits. Whatever you want to know about an object, you must learn by probing it with arrows.

An analogy: you could describe a person by height, address and blood type, or by their relationships, who they call and who calls them. The second description never opens the person up, and yet it largely determines them. Category theory pushes that view as far as it will go, which turns out to be very far.

Three layers build on each other.

1. A **category** is a world: objects, arrows between them, and a rule for composing arrows end to end. Sets with functions, vector spaces with linear maps (Ch. 9, §9.5), groups with homomorphisms (Ch. 56), and types with programs are all categories.
2. A **functor** is a map between worlds that respects composition. "Take the list of" is a functor: it sends a type `A` to the type `List[A]`, and a function `f` to the function `map f`.
3. A **natural transformation** is a map between functors that does the same thing "uniformly", without peeking inside. `reverse` is one: it converts lists into lists the same way for every element type.



A functor F copies the shape of one world into another: every object gets an image, every arrow gets an image, and composites go to composites. For $F = \text{List}$, the image of an arrow f is `map f`.

Above all three sits the idea that answers the second puzzle: the **universal property**. Instead of defining $A \times B$ by what is inside it (ordered pairs), define it by its relationships: the object with arrows to A and to B through which every other such pair of arrows passes in exactly one way. That never mentions elements, so it makes sense in any category: pairs in sets, the gcd among divisors, the minimum among reals.

62.3 The mathematics

Categories

Category

A **category** $\mathcal{C}$ consists of

- a collection of **objects** $A, B, C, \ldots$;
- for each pair of objects a set $\mathrm{Hom}(A, B)$ of **arrows** (morphisms) $f : A \to B$;
- a **composition** $g \circ f : A \to C$ for every $f : A \to B$ and $g : B \to C$;
- an **identity** arrow $\mathrm{id}_A : A \to A$ for every object,

such that composition is associative, $h \circ (g \circ f) = (h \circ g) \circ f$, and identities are neutral, $f \circ \mathrm{id}_A = f = \mathrm{id}_B \circ f$.

That is all. Nothing says arrows must be functions or objects must be sets. Some examples, from the familiar to the strange:

Category	Objects	Arrows $A \to B$	Composition
Set	sets	functions	usual composition
$\mathbf{Vect}_K$	vector spaces over a field K	linear maps	composition (matrix product)
Grp	groups	homomorphisms	composition
a poset $(P, \leq)$	elements of P	one arrow if $a \leq b$, none otherwise	transitivity
a monoid M	a single object $\star$	the elements of M	the monoid operation
Type	types of a language	(total) programs	piping one into the next

The poset and monoid examples show how little a category needs. In the divisibility poset there is an arrow $4 \to 12$ because 4 divides 12, and composition is the transitivity of divisibility. In a monoid all the information sits in how arrows compose.

An arrow $f : A \to B$ is an **isomorphism** if it has a two-sided inverse g, with $g \circ f = \mathrm{id}_A$ and $f \circ g = \mathrm{id}_B$: a bijection in **Set**, an invertible linear map in $\mathbf{Vect}_K$. Category theory never asks whether two objects are *equal*, only whether they are isomorphic, and *how*.

Every category has an **opposite** $\mathcal{C}^{\mathrm{op}}$ with every arrow reversed, so every theorem about all categories comes with a free dual theorem. Every definition below has a "co-" version for nothing.

Functors

Functor

A **functor** $F : \mathcal{C} \to \mathcal{D}$ assigns to each object A of $\mathcal{C}$ an object FA of $\mathcal{D}$, and to each arrow $f : A \to B$ an arrow $Ff : FA \to FB$, such that

$$F(\mathrm{id}_A) = \mathrm{id}_{FA}, \qquad F(g \circ f) = Fg \circ Ff.$$

The **List functor** sends a type A to $\mathrm{List}(A)$ and $f : A \to B$ to map f. The laws say that mapping the identity does nothing, and that mapping f then mapping g is the same as mapping $g \circ f$ once. Compilers use exactly this law to fuse two loops into one.

A **forgetful functor** $U : \mathbf{Vect}_K \to \mathbf{Set}$ forgets the linear structure. A **contravariant** functor reverses arrows: the dual space construction sends $T : V \to W$ to $T^* : W^* \to V^*$, the transpose in disguise, which is why $(\mathbf{AB})^{\mathsf{T}} = \mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$ reverses the order (Ch. 99).

The engineer's favourite functor is in hiding. Lumped linear time-invariant systems compose by **cascading**, and the transfer function sends a cascade to a product, $H_{g \circ f}(s) = H_g(s)\,H_f(s)$, and a plain wire to $H = 1$ (Ch. 14). That is the functor law: block diagrams can be "multiplied out" because the Laplace transform is functorial.

Functors **preserve isomorphisms**: if f has inverse g, then $Fg \circ Ff = F(g \circ f) = F(\mathrm{id}) = \mathrm{id}$. Read backwards, if Ff is *not* an isomorphism, f wasn't either, so a functor into a simpler world can prove something impossible in a harder one.

? A functor that proves a theorem

Topologists attach a group to every shape and a group homomorphism to every continuous map, functorially. From that plus a one-line diagram chase it follows that every continuous map of a disc to itself has a fixed point (Brouwer's theorem), a statement with no visible algebra in it. Which functor does it, and why the diagram chase is unavoidable, is the business of the fundamental group in Ch. 58.

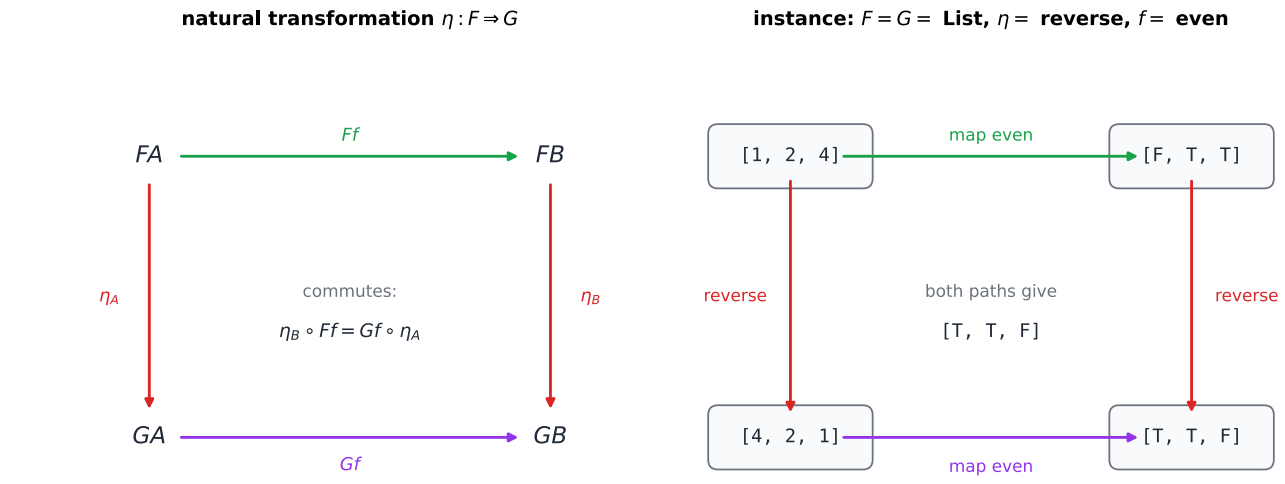
Natural transformations

Natural transformation

Given functors $F, G : \mathcal{C} \to \mathcal{D}$, a **natural transformation** $\eta : F \Rightarrow G$ is a family of arrows $\eta_A : FA \to GA$, one for each object A, such that for every arrow $f : A \to B$

$$\eta_B \circ Ff = Gf \circ \eta_A.$$

The equation is the **naturality square**: going across and then down equals going down and then across.



The naturality square. On the right, the hook's claim for `mystery = reverse` *and* `f = even`*: both routes through the square land on* `[T, T, F]`*.*

Natural transformations are what "uniform" or "canonical" means. The hook's claim is exactly that `mystery` is a natural transformation List ⇒ List. A function that can't look inside the elements can only shuffle, copy and drop them by *position*, and for that whole family we can prove it.

Position-only list functions are natural

Suppose that for each length n there is a list of indices $\sigma_n = (i_1, \ldots, i_m)$ with every $i_k \in \{1, \ldots, n\}$ (the length m may depend on n), and define, for every type A,

$$\eta_A(x_1, \ldots, x_n) = (x_{i_1}, \ldots, x_{i_m}).$$

Then η is a natural transformation List ⇒ List: for every $f : A \to B$, $\eta_B \circ \mathrm{map}\, f = \mathrm{map}\, f \circ \eta_A$.

Proof. Take $xs = (x_1, \ldots, x_n)$. Mapping first gives $(f(x_1), \ldots, f(x_n))$, which still has length n, so η_B uses the same index list σ_n and returns $(f(x_{i_1}), \ldots, f(x_{i_m}))$. Going the other way, $\eta_A(xs) = (x_{i_1}, \ldots, x_{i_m})$, and mapping f over it gives $(f(x_{i_1}), \ldots, f(x_{i_m}))$. The two lists agree entry by entry. The key step is that map f never changes the length, and η looks at nothing but the length. ■

Reverse ($\sigma_n = (n, \ldots, 1)$), "take the first two", "every other element" and "repeat each element twice" are all of this form, so all are natural. A sort is not: it chooses positions by *comparing contents*. With $f(x) = -x$, sorting $[1, 2]$ and negating gives $[-1, -2]$, but negating then sorting gives $[-2, -1]$. That is why `sort` needs an ordering on `A` in its type and can't have the plain signature `List[A] -> List[A]`.

The converse, that *every* function with the polymorphic type must be position-based, is a deeper fact called **parametricity**; §62.7 says where it is proved.

Naturality also separates constructions that merely exist from constructions that are canonical. A finite-dimensional space V is isomorphic both to its dual V^* and to its double dual V^{**}, but only one of these isomorphisms is natural.

? Two isomorphisms, one of them fake

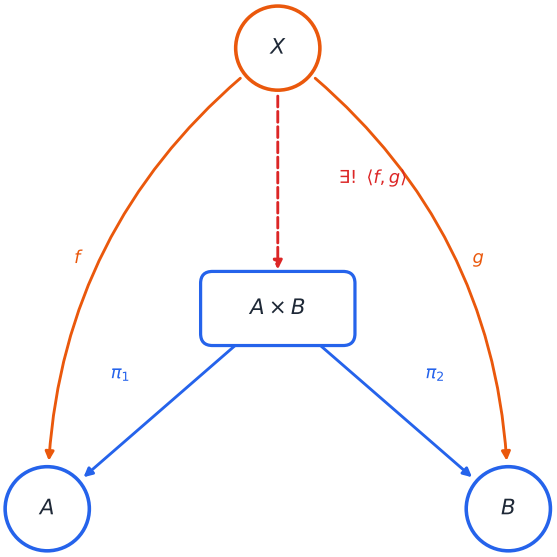
The map $V \to V^{**}$ that sends v to "evaluate at v" needs no choices and passes the naturality test for every linear map. Every isomorphism $V \to V^*$ requires picking a basis or an inner product, and *no* choice makes it natural. Why the double dual is canonical and the single dual is not, and why the double-dual map fails to be onto in infinite dimensions, is where Ch. 99 begins.

Universal properties

Now the second puzzle. Here is a definition of "product" that never mentions elements.

Product

A **product** of objects A and B is an object $A \times B$ with two arrows $\pi_1 : A \times B \to A$ and $\pi_2 : A \times B \to B$ such that for every object X and every pair $f : X \to A$, $g : X \to B$ there is **exactly one** arrow $\langle f, g \rangle : X \to A \times B$ with $\pi_1 \circ \langle f, g \rangle = f$ and $\pi_2 \circ \langle f, g \rangle = g$.



$\pi_1 \circ \langle f, g \rangle = f, \quad \pi_2 \circ \langle f, g \rangle = g$

category	product $A \times B$
Sets	pairs (a, b)
Vector spaces	direct sum $A \oplus B$
Divisibility of integers	gcd(a, b)
Real numbers with $\leq$	min(a, b)
Logic (implication)	a AND b
Program types	tuple (A, B)

one definition, six familiar constructions

$A \times B$ is the "best" object with arrows to both A and B: every rival X factors through it uniquely. Read in six categories, one diagram gives six familiar constructions.

Check it in a few worlds. In **sets**, the only function into the pairs that projects correctly is $x \mapsto (f(x), g(x))$. In a **poset** an arrow is a single fact "$x \leq y$", so for **divisibility** the definition says: p divides a and b, and every common divisor divides p. That is $\gcd(a, b)$. For **reals with** $\leq$ it is $\min(a, b)$; for **propositions ordered by implication**, $p \wedge q$. For **vector spaces** it is the direct sum $V \oplus W$, and $\langle \mathbf{F}, \mathbf{G} \rangle$ is the matrix $\mathbf{F}$ stacked on top of $\mathbf{G}$.

The definition does not promise that a product exists (the experiment in §62.5 builds a case where none does). But when one exists, it is essentially unique. The definition does not claim a product exists; it says what one must do. Sometimes none exists, and the experiment in §62.5 builds such a case. But when one exists, it is essentially unique, and this is the theorem that makes universal properties worth having.

Universal objects are unique up to unique isomorphism

If (P, π_1, π_2) and (Q, ρ_1, ρ_2) are both products of A and B, there is exactly one arrow $u : Q \to P$ compatible with the projections ($\pi_i \circ u = \rho_i$), and it is an isomorphism.

Proof. Because P is a product, the pair ρ_1, ρ_2 from Q factors through P by a unique $u : Q \to P$ with $\pi_i \circ u = \rho_i$. Because Q is a product, the pair π_1, π_2 factors through Q by a unique $v : P \to Q$ with $\rho_i \circ v = \pi_i$. Now look at $u \circ v : P \to P$. It satisfies $\pi_i \circ (u \circ v) = \rho_i \circ v = \pi_i$. But the identity id_P satisfies $\pi_i \circ \mathrm{id}_P = \pi_i$ too, and the universal property (with $X = P$, $f = \pi_1$, $g = \pi_2$) says there is only *one* arrow $P \to P$ with that property. Hence $u \circ v = \mathrm{id}_P$. The same argument in Q gives $v \circ u = \mathrm{id}_Q$. ■

Notice what the proof never used: elements, pairs, numbers. It works in every category at once: one proof, infinitely many theorems. It is also why mathematicians say "*the* product" although, as sets, $A \times B$ and $B \times A$ differ: they are uniquely isomorphic.

Turn every arrow around and you get the **coproduct** $A + B$: disjoint union in sets, lcm among divisors, max among reals, OR in logic, a **sum type** such as `Either[A, B]` in programming. In vector spaces the coproduct is the direct sum *again*, so $V \oplus W$ is both product and coproduct, a coincidence special to linear algebra that lets matrices be cut into blocks in both directions.

Limits, briefly

Products are the simplest **limits**: take a diagram of objects and arrows, and look for the best object with a compatible family of arrows into it.

- The limit of the empty diagram is a **terminal object**, with exactly one arrow into it from everywhere: a one-point set, the zero space, "true", the unit type.
- The limit of two parallel arrows $f, g : A \to B$ is the **equalizer**: $\{a : f(a) = g(a)\}$ in sets, the kernel $\ker(f - g)$ for linear maps (Ch. 9, §9.6). Solving an equation is computing an equalizer.
- The limit of $A \xrightarrow{f} C \xleftarrow{g} B$ is the **pullback** $\{(a, b) : f(a) = g(b)\}$, which database engineers call the **join** of two tables on a key.

Dually, **colimits** include initial objects, coequalizers (quotients, as in Ch. 56) and pushouts (gluing two shapes along an edge). "Solve", "intersect", "join" and "glue" are all limits or colimits.

Adjunctions

The last notion is the most powerful. For a set S, let $F(S)$ be the vector space with basis S: formal linear combinations of elements of S. Let $U(W)$ be the underlying set of a vector space W. The most-used fact of linear algebra is that **a linear map is determined by what it does to a basis, and any values on the basis are allowed** (Ch. 9, §9.5). In categorical language:

> **Free–forgetful adjunction**
>
> For every set S and vector space W there is a bijection, natural in both S and W,
>
> $$\mathrm{Hom}_{\mathbf{Vect}}\big(F(S),\, W\big) \;\cong\; \mathrm{Hom}_{\mathbf{Set}}\big(S,\, U(W)\big).$$

Proof. Send a linear map $T : F(S) \to W$ to its restriction $s \mapsto T(s)$, a function $S \to U(W)$. Conversely, send a function $\phi : S \to U(W)$ to the linear map $\hat{\phi}\big(\sum_k c_k s_k\big) = \sum_k c_k\, \phi(s_k)$; this is well defined because every element of $F(S)$ is a *unique* finite combination of basis elements. Restricting $\hat{\phi}$ recovers ϕ, and a linear map that agrees with T on a basis equals T everywhere, so the two constructions are inverse. Naturality (compatibility with maps of S and of W) is a one-line check. ∎

Whenever $\mathrm{Hom}_{\mathcal{D}}(FX, Y) \cong \mathrm{Hom}_{\mathcal{C}}(X, GY)$ naturally, F is **left adjoint** to G, written $F \dashv G$. The pattern is everywhere.

- **Free constructions.** Free groups, polynomial rings and the free monoid on an alphabet (all strings) are left adjoints of forgetful functors.
- **Currying.** $\mathrm{Hom}(A \times B, C) \cong \mathrm{Hom}(A, C^B)$: a function of two arguments is a function returning a function, so "$- \times B$" is left adjoint to "$B \to -$". Categories where this works (*cartesian closed*) are the semantics of typed functional languages.
- **Rounding.** Order the integers and reals by $\le$ and let $i : \mathbb{Z} \to \mathbb{R}$ be the inclusion. For every real x and integer n,

$$\lceil x \rceil \le n \iff x \le i(n),$$

so the ceiling function is the left adjoint of the inclusion (and the floor its right adjoint). Between posets, adjunctions are called **Galois connections**.

Adjoints obey general laws, the most useful being that **left adjoints preserve colimits and right adjoints preserve limits**. For the ceiling this predicts $\lceil \max(x, y) \rceil = \max(\lceil x \rceil, \lceil y \rceil)$, since max is a coproduct. For the free vector space it predicts $F(S \sqcup T) \cong F(S) \oplus F(T)$. Each "obvious" identity is one instance of a single theorem.

Where it pays off

Type theory and programming languages. Tuples, tagged unions, function types and the unit type are products, coproducts, exponentials and the terminal object, so their typing and pattern-matching rules follow from universal properties. Generic containers are functors, and polymorphic functions are natural transformations, which is why the hook could be answered from a type signature.

Abstract algebra. The first isomorphism theorem (Ch. 56) says a quotient has a universal property: every homomorphism that kills a normal subgroup factors uniquely through it. Free groups, polynomial rings and tensor products are defined, and proved unique, the same way.

Compositional systems. Series wiring is composition; parallel wiring is a second operation $\otimes$, and categories with both are **monoidal categories**. Their arrows are drawn as *string diagrams*, block diagrams with rigorous semantics, and signal-flow graphs, quantum circuits and electrical networks have all been treated this way.

62.4 The algorithm

Category theory is a language, not a numerical method, but it gives algorithms for one task: **checking laws**. A functor must satisfy two equations, a natural transformation one square per arrow. For finite categories these are finite checks; for infinite ones, such as all types, you test random instances, which is how property-based testing tools (QuickCheck and its descendants) catch broken `map` implementations.

Here is a naturality tester for list functions, using random arrows $f : \{0, \dots, 9\} \to \{0, \dots, 9\}$.

```
import random

def fmap(f, xs):                # the List functor on arrows
    return [f(x) for x in xs]

candidates = {
    "reverse":   lambda xs: xs[::-1],
    "first_two": lambda xs: xs[:2],
    "evens_pos": lambda xs: xs[::2],
    "doubled":   lambda xs: [x for x in xs for _ in (0, 1)],
    "sort":      lambda xs: sorted(xs),
    "dedupe":    lambda xs: list(dict.fromkeys(xs)),
}

def is_natural(eta, trials=2000, seed=1):
    rng = random.Random(seed)
    for _ in range(trials):
        xs = [rng.randrange(10) for _ in range(rng.randrange(7))]
        table = [rng.randrange(10) for _ in range(10)]
        f = lambda x: table[x]   # a random arrow int -> int
        if eta(fmap(f, xs)) != fmap(f, eta(xs)):
            return False, (xs, table)
    return True, None

for name, eta in candidates.items():
    ok, witness = is_natural(eta)
    print(f"{name:10s} natural: {ok}" + ("" if ok else f"   counterexample xs={witness[0]}"))
```

The first four pass all 2,000 trials; `sort` and `dedupe` fail, on `xs=[7, 7, 8, 3, 5, 3]` and `xs=[5, 8, 6, 8, 3]`. Each test costs $O(n)$.

Three cautions.

- **A test is not a proof.** Passing 2,000 random squares makes naturality plausible, not certain; a function could misbehave only on lists of length 1,000. The proof in §62.3 settles the position-based case.
- **`dedupe` is the instructive failure.** It looks harmless, but a non-injective f creates duplicates: deduplicating then mapping keeps them, mapping then deduplicating removes them. Equality testing is a peek inside the elements, and any peek breaks uniformity.
- **Finite categories can be checked exhaustively.** With a composition table, associativity costs $O(|\mathrm{Arr}|^3)$ checks. In a poset, testing whether a candidate is a product of two objects costs $O(|\mathrm{Obj}|)$ comparisons, as in the experiment below.

62.5 The experiment

Any poset is a category, and in a poset the universal property becomes a finite search: the product of a and b is a lower bound of both that sits above every other lower bound. The script searches for products among the divisors of N ordered by divisibility, then checks the answer against `gcd`.

```
import numpy as np

# A poset is a category: one arrow x -> y exactly when x <= y.

```

With $N = 60$ the twelve divisors $1, 2, 3, 4, 5, 6, 10, 12, 15, 20, 30, 60$ give a full 12×12 product table, every entry equals the gcd, and `coproduct(4, 6)` returns $12 = \mathrm{lcm}(4, 6)$. Nobody told the program what a gcd is. Things to change:

1. **Delete an object.** Set `removed = {6}`. Now 12 and 30 have common lower bounds $1, 2, 3$, none above the other two, so their product **does not exist**. The universal property is a demand, and the world can refuse it.
2. **Delete the bottom.** Set `removed = {1}`. Now 2 and 3 have no common lower bound at all. How many pairs lose their product?
3. **Change the order.** Replace `leq` by `lambda x, y: x <= y`. The product becomes `min` and the coproduct `max`. Same code, different category.

4. **Grow the world.** Try $N = 360$ or $N = 2^{10}$. For a power of a prime the divisors form a chain, and every product is just the smaller element.

62.6 The challenge

1. **Intuition.** In the category with one object whose arrows are the integers under addition, what is an isomorphism? In the poset of subsets of $\{1, 2, 3\}$ ordered by inclusion, what are the product and coproduct of $\{1, 2\}$ and $\{2, 3\}$, and what are the terminal and initial objects? Why does a poset have at most one isomorphism between any two objects?
2. **Derivation.** Using only the Galois connection $\lceil x \rceil \le n \iff x \le n$, prove that $\lceil \max(x, y) \rceil = \max(\lceil x \rceil, \lceil y \rceil)$ for all real x, y. Then prove the general statement it illustrates: if $F \dashv G$ between posets, then F sends every join (least upper bound) that exists to a join.
3. **Implementation.** Store a finite category as Python dictionaries (arrows with sources and targets, plus a composition table). Write a checker for the identity and associativity laws, then a brute-force search for products of two objects, now checking uniqueness of the factorising arrow. Test it on two objects joined by two parallel non-identity arrows.
4. **Open investigation.** Principal component analysis (Ch. 10, §10.7) picks a "best" basis for a data cloud. Is it natural? For which linear maps applied to every data point (rotations, uniform scalings, axis scalings, shears) does "PCA, then transform" agree with "transform, then PCA"? Explore numerically, and decide what a category of data sets would have to be for PCA to become natural.

62.7 Loose threads

This chapter built the vocabulary and stopped short of two theorems. The **Yoneda lemma** says an object is determined, up to unique isomorphism, by the functor $\mathrm{Hom}(-, A)$ recording all arrows into it: §62.2's "relationships determine the person", made exact. And the **converse of the hook**, that the type `List[A] -> List[A]` *forces* a function to be position-based, is Reynolds's parametricity theorem ("theorems for free", in Wadler's slogan), proved for typed languages in Ch. 66.

> **? Where do monads come from?**
>
> Every adjunction $F \dashv G$ produces a functor $T = G \circ F$ with two extra natural transformations, $A \to TA$ and $TTA \to TA$. For the free vector space, T sends a set to the set of formal linear combinations of its elements. Functional programmers use exactly this structure, called a **monad**, to model exceptions, state, randomness and input/output inside pure code, and probability distributions form one too. Why one structure captures all side effects, and how it relates to proofs, is taken up with type theory in Ch. 66.

Group representations are functors from a one-object category into $\mathbf{Vect}_K$, with natural transformations as intertwining maps (Ch. 95). The tensor product is defined by a universal property for bilinear maps (Ch. 93). Whether categories can replace sets as a foundation (topos theory, univalent foundations) belongs with Ch. 64 and Ch. 68.

Chapter 99 — Abstract Linear Algebra: Vectors Without Coordinates

Level 2 · Track E — The Abstract Mathematics Behind Everything Builds on: Ch. 8, Ch. 9, Ch. 10 · **Leads to:** Ch. 61, Ch. 93, Ch. 95 · **Related:** Ch. 56, Ch. 62, Ch. 79, Ch. 90 **Reading time:** ~30 min

99.1 The hook

A temperature sensor sits on a metal bar. Along the bar the temperature rises steadily, and you record two things at the sensor: a small **displacement** d (how far you moved it) and the **gradient** g (how fast temperature changes with position). Working in metres, you write $d = 2$ m and $g = 3$ K/m. The temperature change is $g\,d = 6$ K.

Your colleague works in centimetres. She writes $d = 200$ cm and $g = 0.03$ K/cm. The temperature change is still 6 K, as it must be. But look at what happened to the numbers. When you shrank the unit by a factor of 100, the displacement's component got **100 times bigger** and the gradient's component got **100 times smaller**. Both are "vectors" with one component. They respond to a change of coordinates in *opposite* ways.

In three dimensions the same thing happens with full matrices: under a change of basis $\mathbf{P}$, displacements transform with $\mathbf{P}^{-1}$ and gradients with $\mathbf{P}^{\mathsf{T}}$. Store both as columns of three numbers and the same code works in an orthonormal frame and silently breaks in a skewed one; this is why graphics code must transform surface normals, which are gradients, by the inverse transpose.

So what *is* a vector, if a list of numbers can lie about it? And here is a second, sharper question. Ch. 10 showed how to diagonalize a matrix by choosing a basis of eigenvectors. But

$$\mathbf{N} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \qquad \text{and} \qquad \mathbf{R} = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$$

refuse. $\mathbf{N}$ has only one independent eigenvector, and $\mathbf{R}$, a quarter-turn of the plane, has no real eigenvectors at all. If diagonal is impossible, what is the *simplest* form to which every linear map can be brought, over any number system? The answer turns out to need almost no matrices. It needs the right way to think about vector spaces when nobody hands you coordinates.

99.2 The big idea

The core chapters taught linear algebra through matrices, which is how you compute. This chapter turns the picture round: the **linear map** is the real object, and a matrix is a *shadow* it casts once you pick a basis. Different bases cast different shadows ($\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$, Ch. 9), and the questions worth asking are about what is the same in all of them.

An analogy: a sentence can be written in English, Bengali or French, and a grammar of its *meaning* must work in all of them. Coordinate-free linear algebra is that grammar, with four new tools.

1. **The dual space.** Gradients are not vectors at all. They are *machines that eat a vector and return a number* (the temperature change along it). Such machines form their own vector space, the dual V^*, and that is why they transform the other way.
2. **The quotient.** Sometimes you want to *ignore* a subspace: voltages up to a common ground offset, signals up to a DC component, states up to an unobservable mode. The quotient V/U makes "equal up to something in U" into a new vector space.
3. **Invariant subspaces.** A map T that cannot be diagonalized can still be *chopped*: find subspaces that T maps into themselves, and study T on each piece.
4. **Multilinear forms.** Determinants, inner products and the quadratic forms of Ch. 10 are functions of several vectors at once, linear in each. Seen without coordinates, the determinant becomes a single number attached to a map, the factor by which it scales oriented volume.

The payoff is the answer to the hook: every linear map on a finite-dimensional space, over any field, splits into a direct sum of a few standard pieces. Over $\mathbb{C}$ the pieces are **Jordan blocks**; over any field they are **companion matrices**. Both lists are complete invariants: two maps are similar exactly when their lists agree.

99.3 The mathematics

Fields and spaces

Everything in Ch. 9 works with scalars from any **field** K: a number system where you can add, subtract, multiply and divide by non-zero elements (Ch. 56). Besides $\mathbb{R}$ and $\mathbb{C}$, three fields matter in practice.

- $\mathbb{F}_2 = \{0, 1\}$ with $1 + 1 = 0$. The space $\mathbb{F}_2^3$ has just 8 vectors, and there are $(8-1)(8-2)(8-4) = 168$ invertible 3×3 matrices over $\mathbb{F}_2$. Linear codes are subspaces of $\mathbb{F}_2^n$ (Ch. 79), and every theorem below applies to them.
- $\mathbb{Q}$, the rationals. $\mathbb{R}$ is a vector space over $\mathbb{Q}$ of *infinite* dimension, since $1, \sqrt{2}, \sqrt{3}, \pi, \ldots$ are linearly independent over $\mathbb{Q}$.
- $\mathbb{C}$, whose key property is that every polynomial has a root. That single fact is why Jordan form exists over $\mathbb{C}$ and not over $\mathbb{R}$.

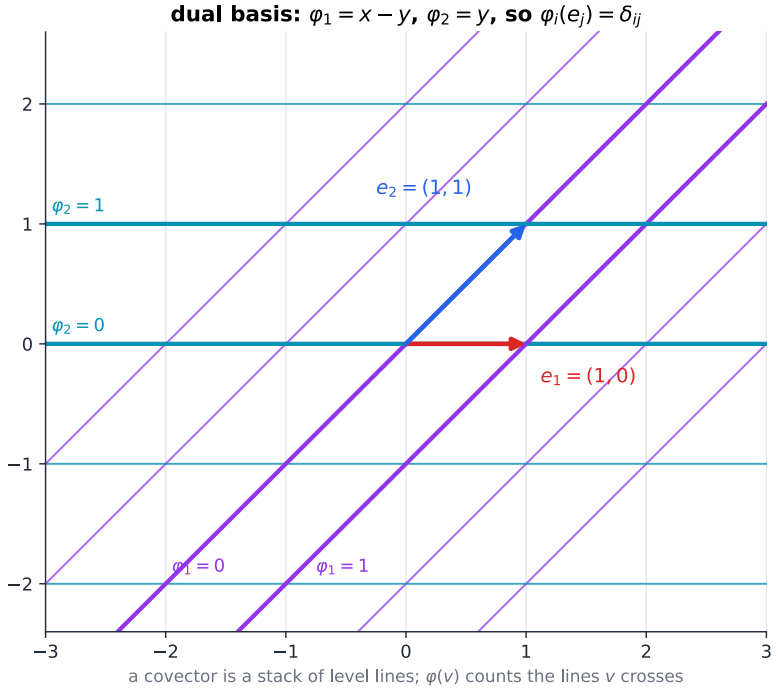
The linear maps $V \to W$ form a vector space $\mathrm{Hom}(V, W)$ of their own, of dimension $\dim V \cdot \dim W$.

Dual spaces

Dual space

The **dual** of V is $V^* = \mathrm{Hom}(V, K)$, the space of linear functionals $\varphi : V \to K$, also called **covectors**. If $e_1, \ldots, e_n$ is a basis of V, the **dual basis** $\varphi^1, \ldots, \varphi^n$ of V^* is defined by $\varphi^i(e_j) = \delta_{ij}$, so φ^i reads off the i-th coordinate.

A covector on the plane is best pictured as a family of parallel, equally spaced **level lines**: $\varphi(v)$ counts how many lines v crosses. The gradient of the hook is one: its value on a displacement is the temperature change. When the basis is not orthonormal, the dual basis does not point along the basis vectors at all.



The dual basis of $e_1 = (1, 0)$, $e_2 = (1, 1)$ is $\varphi^1 = x - y$, $\varphi^2 = y$. Each e_j crosses exactly one line of its own covector and lies along a level line of the other. Tilting e_2 would tilt the purple lines, not the teal ones.

Linear maps act on covectors *backwards*. Given $T : V \to W$, the **dual map** $T^* : W^* \to V^*$ is $T^*(\psi) = \psi \circ T$: to measure a vector of V with ψ, push it through T first. No coordinates are involved. But choose coordinates and something familiar appears.

The dual map is the transpose

Let $T : V \to W$ have matrix $\mathbf{A}$ with respect to bases (e_j) of V and (f_i) of W. Then T^* has matrix $\mathbf{A}^{\mathsf{T}}$ with respect to the dual bases (ψ^i) of W^* and (φ^j) of V^*.

Proof. The matrix of T is defined by $Te_j = \sum_i a_{ij} f_i$. To find the matrix of T^*, expand $T^*\psi^i$ in the basis φ^j; the coefficient of φ^j is $(T^*\psi^i)(e_j)$, because φ^j is the only dual basis vector that is non-zero on e_j. Compute it:

$$(T^*\psi^i)(e_j) = \psi^i(Te_j) = \psi^i\Big(\sum_k a_{kj} f_k\Big) = a_{ij}.$$

So $T^*\psi^i = \sum_j a_{ij}\varphi^j$: the entry in row j, column i of the matrix of T^* is a_{ij}. That is $\mathbf{A}^{\mathsf{T}}$. ∎

The transpose was never "flip the array". It is the matrix of the map that pulls measurements back, and $(ST)^* = T^*S^*$ reverses order because pulling back reverses order. Now the hook is explained. Under a change of basis by $\mathbf{P}$, coordinates of vectors change by $\mathbf{P}^{-1}$, so coordinates of covectors must change by $\mathbf{P}^{\mathsf{T}}$ to keep every pairing $\varphi(v)$ unchanged. Displacements are vectors, gradients are covectors, and an inner product is exactly the extra structure that lets you convert one into the other (Ch. 9, §9.8). Without an inner product the two kinds stay apart.

The double dual. Every $v \in V$ defines a functional on V^*, "evaluate at v": $\mathrm{ev}_v(\varphi) = \varphi(v)$. This gives a map $\iota : V \to V^{**}$ that uses no basis, no inner product, nothing.

Finite-dimensional spaces are their own double duals

If $\dim V = n < \infty$, then $\iota : V \to V^{**}$, $v \mapsto \mathrm{ev}_v$, is a linear isomorphism, and it is natural: $T^{**} \circ \iota_V = \iota_W \circ T$ for every linear $T : V \to W$.

Proof. Linearity: $\mathrm{ev}_{av+bw}(\varphi) = a\varphi(v) + b\varphi(w)$. Injectivity: if $v \neq 0$, extend v to a basis and let φ be the first dual basis vector; then $\mathrm{ev}_v(\varphi) = 1 \neq 0$, so the kernel is zero. Dimensions: the dual basis shows $\dim V^* = n$, hence $\dim V^{**} = n$, and an injective linear map between spaces of equal finite dimension is onto (rank–nullity, Ch. 9, §9.6). Naturality: for $\psi \in W^*$, $(T^{**}\,\mathrm{ev}_v)(\psi) = \mathrm{ev}_v(T^*\psi) = \psi(Tv) = \mathrm{ev}_{Tv}(\psi)$. ∎

Here is the point that Ch. 62 promised. V and V^* also have the same dimension, so they are isomorphic, but every isomorphism between them needs a choice (a basis, or an inner product), and none of them is natural. The double dual needs no choice. In the proof, the only place where finite dimension entered was the dimension count.

? When the double dual is bigger

In infinite dimensions $\iota : V \to V^{**}$ is still injective, but it can fail to be onto: the dual of the space of absolutely summable sequences is the space of bounded sequences, and the dual of *that* is far larger than where we started. Worse, the "algebraic" dual of a function space is so big that analysts throw most of it away and keep only the continuous functionals, among them the Dirac delta. Which functionals survive, and why the Dirac delta turns out to be a covector, is the business of Ch. 61.

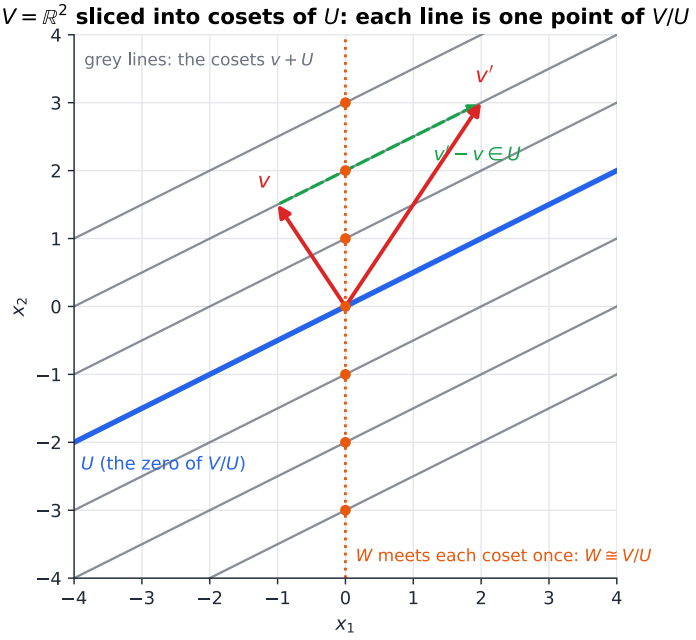
For a subspace $U \subseteq V$, the **annihilator** $U^0 = \{\varphi \in V^* : \varphi(u) = 0 \text{ for all } u \in U\}$ is the set of measurements blind to U, and $\dim U + \dim U^0 = \dim V$. A subspace of dimension k in $\mathbb{R}^n$ is cut out by exactly $n - k$ independent linear equations; the annihilator is the space of those equations.

Quotients and direct sums

Quotient space

For a subspace $U \subseteq V$, the **coset** of v is $v + U = \{v + u : u \in U\}$. The **quotient** V/U is the set of cosets, with $(v + U) + (w + U) = (v + w) + U$ and $c(v + U) = cv + U$. Its zero is U itself, and $v + U = v' + U$ exactly when $v' - v \in U$.

The operations are well defined because changing representatives changes the answer only by something in U. Geometrically, V/U collapses each translate of U to a single point.



V/U for a line U in $\mathbb{R}^2$: every grey line is one element. Any complement W meets each coset exactly once, which is why $V/U \cong W$, but the quotient itself does not depend on which W you pick.

Engineers already work in quotients. Node potentials are defined only up to a common constant, so the physical object lives in $\mathbb{R}^n/\operatorname{span}(1, \dots, 1)$, and "grounding a node" is choosing a complement (Ch. 9, §9.6). An indefinite integral is an element of a quotient by the constants.

First isomorphism theorem

For linear $T : V \to W$, the map $\bar{T} : V/\ker T \to \operatorname{im} T$, $\bar{T}(v + \ker T) = Tv$, is a well-defined linear isomorphism. In particular, if V is finite-dimensional, $\dim V = \dim \ker T + \dim \operatorname{im} T$.

Proof. Well defined: if $v + \ker T = v' + \ker T$ then $v' - v \in \ker T$, so $Tv' = Tv$. Linear: inherited from T. Onto $\operatorname{im} T$: by definition. One-to-one: $\bar{T}(v + \ker T) = 0$ means $Tv = 0$, so $v \in \ker T$, so $v + \ker T$ is the zero coset. For the dimension count, pick a basis $u_1, \dots, u_k$ of $U = \ker T$ and extend it to a basis $u_1, \dots, u_k, w_1, \dots, w_m$ of V. The cosets $w_1 + U, \dots, w_m + U$ span V/U (the u's vanish modulo U) and are independent (a relation $\sum c_i w_i \in U$ forces all $c_i = 0$ by independence of the full basis), so $\dim V/U = \dim V - \dim U$. Combine with $V/\ker T \cong \operatorname{im} T$. ∎

That is rank–nullity (Ch. 9) with the matrices removed: a linear map is "collapse the kernel, then embed isomorphically". The same theorem, word for word, holds for groups and rings (Ch. 56).

Direct sums. $V = U \oplus W$ means every v is *uniquely* $u + w$ with $u \in U$, $w \in W$; equivalently $U + W = V$ and $U \cap W = \{0\}$. Direct sums correspond exactly to **projections**: linear maps with $P^2 = P$. Given P, take $U = \operatorname{im} P$ and $W = \ker P$; given the decomposition, let $P(u + w) = u$. In a basis adapted to $U \oplus W$, a projection is $\operatorname{diag}(\mathbf{I}, \mathbf{0})$, and a map that preserves both pieces is **block diagonal**.

Invariant subspaces

A subspace U is **invariant** under $T : V \to V$ if $T(U) \subseteq U$. Eigenvector lines are the one-dimensional examples; $\ker T$, $\operatorname{im} T$ and $\ker p(T)$ for any polynomial p are others. An invariant subspace gives two smaller maps: the **restriction** $T|_U : U \to U$ and the **induced map** $\bar{T} : V/U \to V/U$, $\bar{T}(v + U) = Tv + U$ (well defined precisely because $T(U) \subseteq U$). In a basis that starts with a basis of U,

$$[T] = \begin{bmatrix} [T|_U] & * \\ \mathbf{0} & [\bar{T}] \end{bmatrix}, \qquad \chi_T(x) = \chi_{T|_U}(x)\,\chi_T(x),$$

since the determinant of a block-triangular matrix is the product of the diagonal blocks' determinants (Ch. 8, §8.3). This is the engine of every canonical form: find an invariant subspace, split off the restriction, and *recurse on the quotient*. Over $\mathbb{C}$ the engine never stalls, because every map has an eigenvalue and so a one-dimensional invariant subspace. Induction on dimension then gives **Schur's triangularization**: every operator on a finite-dimensional complex space has an upper-triangular matrix in a suitable basis. Over $\mathbb{R}$ the engine can stall: the quarter-turn $\mathbf{R}$ has no invariant line, so the smallest invariant pieces may be planes.

? Two maps at once

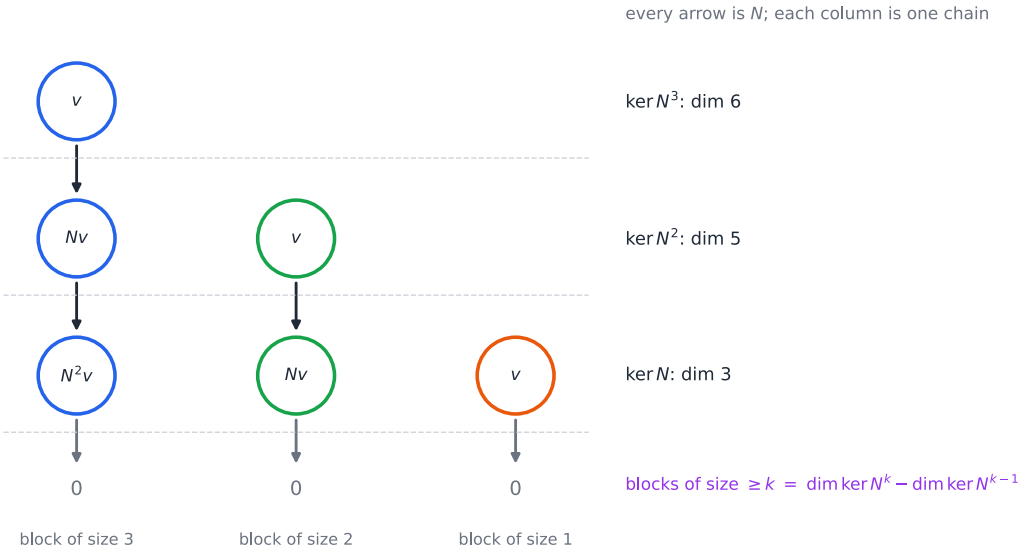
The recursion above classifies one map up to change of basis completely. Try two maps S, T on the same space, changed by the *same* basis $\mathbf{P}$ ($\mathbf{P}^{-1}\mathbf{S}\mathbf{P}$, $\mathbf{P}^{-1}\mathbf{T}\mathbf{P}$), and the problem changes character: there is no finite list of standard pieces, and a full classification of pairs would classify the modules of every finite-dimensional algebra at once. Mathematicians call such problems **wild**. Why pairs are wild while single maps are tame is one of the deep results of Ch. 95.

Jordan and rational canonical forms

Over $\mathbb{C}$ the characteristic polynomial factors as $\chi_T(x) = \prod_i (x - \lambda_i)^{m_i}$. The **generalized eigenspace** $V_\lambda = \ker(T - \lambda I)^m$ is invariant, and V is their direct sum (a consequence of Cayley–Hamilton, Ch. 10, §10.1, plus coprimality of the factors). On each V_λ, the map $N = T - \lambda I$ is **nilpotent**: some power is zero. So everything reduces to understanding nilpotent maps.

A nilpotent N moves vectors along **chains**: $v \mapsto Nv \mapsto N^2v \mapsto \cdots \mapsto 0$. The main structure theorem, which we state, says that V_λ has a basis consisting of disjoint chains. In the basis $N^{k-1}v, \ldots, Nv, v$ of one chain, N shifts each vector to the previous one, and its matrix is a **Jordan block**: zeros on the diagonal, ones just above it. Adding back λI:

$$J_k(\lambda) = \begin{bmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{bmatrix} \quad (k \times k).$$



A nilpotent map on a 6-dimensional space with chains of lengths 3, 2, 1. The bottom row spans $\ker N$*; the bottom two rows span* $\ker N^2$*; all three span* $\ker N^3$*. Counting dots row by row recovers the block sizes.*

The remarkable fact is that the chain lengths, and hence the Jordan form, are determined by numbers anyone can compute.

Counting Jordan blocks

Let N be nilpotent on V with a chain basis, and let $d_k = \dim \ker N^k$ ($d_0 = 0$). Then

$$\#\{\text{blocks of size } \geq k\} = d_k - d_{k-1}, \qquad \#\{\text{blocks of size exactly } k\} = 2d_k - d_{k-1} - d_{k+1}.$$

In particular the block sizes do not depend on which chain basis you found.

Proof. Number the vectors of a chain of length ℓ by their **height**: $N^{\ell-j}v$ has height j, so v has height ℓ and the last non-zero vector $N^{\ell-1}v$ has height 1. A basis vector of height j is sent to zero by N^k exactly when $j \leq k$, and N^k maps the basis vectors of height $j > k$ to *distinct* basis vectors of height $j - k$, which are independent. So $\ker N^k$ is spanned by the basis vectors of height at most k, and d_k counts them. Hence $d_k - d_{k-1}$ counts basis vectors of height exactly k. Each chain of length $\geq k$ has exactly one such vector, and shorter chains have none. That is the first formula; the second is the first at k minus the first at $k+1$. The d_k depend only on N, never on the basis, so neither do the block sizes. ∎

In the figure, $d_1, d_2, d_3 = 3, 5, 6$, so there are 3 blocks of size ≥ 1, 2 of size ≥ 2, 1 of size ≥ 3: sizes $3, 2, 1$. The hook's $\mathbf{N}$ is $J_2(0)$, the smallest map that no basis can diagonalize. The **Jordan form theorem** puts the pieces together: over $\mathbb{C}$, every operator is similar to a block-diagonal matrix of Jordan blocks, unique up to the order of the blocks, and two matrices are similar exactly when they have the same blocks.

Over a field where polynomials don't split, such as $\mathbb{R}$ or $\mathbb{Q}$, use a different chain. Pick v and follow $v, Tv, T^2v, \dots$ until the vectors become dependent. The span is invariant, and in the basis $v, Tv, \dots, T^{k-1}v$ the matrix of T is the **companion matrix** of the polynomial $x^k + c_{k-1}x^{k-1} + \cdots + c_0$ that expresses $T^k v$ in terms of the earlier vectors. The **rational canonical form** says every operator over every field is similar to a block-diagonal matrix of companion matrices $C(p_1), \dots, C(p_r)$ with $p_1 \mid p_2 \mid \cdots \mid p_r$, uniquely. For the quarter-turn $\mathbf{R}$, $v = e_1$ gives $Tv = e_2$ and $T^2v = -e_1$, so the polynomial is $x^2 + 1$ and $\mathbf{R}$ is already its own companion matrix. That is the honest answer to the hook over $\mathbb{R}$: the irreducible polynomial $x^2 + 1$, not a pair of imaginary eigenvalues, is the real invariant.

Multilinear forms

A **bilinear form** $B : V \times V \to K$ is linear in each slot. Inner products, the quadratic energy forms $\mathbf{x}^{\mathsf{T}}\mathbf{K}\mathbf{x}$ of Ch. 10, and the symplectic form of mechanics are examples. In a basis, $B(x, y) = \mathbf{x}^{\mathsf{T}}\mathbf{B}\mathbf{y}$, and under a change of basis $\mathbf{B} \mapsto \mathbf{P}^{\mathsf{T}}\mathbf{B}\mathbf{P}$, *not* $\mathbf{P}^{-1}\mathbf{B}\mathbf{P}$. Forms and operators are different objects that both happen to be stored as square arrays. A form eats two vectors; an operator eats one vector and returns a vector. They agree only when $\mathbf{P}^{\mathsf{T}} = \mathbf{P}^{-1}$, which is why the distinction is invisible in orthonormal coordinates. For real symmetric forms the invariant under congruence is not the eigenvalues but only their *signs*: the numbers of positive, negative and zero eigenvalues (**Sylvester's law of inertia**).

An n-linear form ω on an n-dimensional space is **alternating** if it vanishes whenever two arguments are equal (so it changes sign when two are swapped). Expanding each argument in a basis shows that ω is fixed by its single value $\omega(e_1, \dots, e_n)$, so the alternating n-forms form a **one-dimensional** space. Any operator T acts on it by $\omega \mapsto \omega(T\cdot, \dots, T\cdot)$, and a linear map on a one-dimensional space is multiplication by a scalar. That scalar *is* the determinant:

$$\omega(Tv_1, \dots, Tv_n) = (\det T)\, \omega(v_1, \dots, v_n) \quad \text{for all } \omega, v_1, \dots, v_n.$$

No matrix, no cofactor expansion, no basis. Multiplicativity is now one line: applying S after T multiplies by $\det T$, then by $\det S$, so $\det(ST) = \det S \det T$. And $\det T$ is visibly the factor by which T scales oriented volume, since ω measures oriented volume.

> **? One space for all bilinear maps**
>
> Bilinear maps $V \times W \to X$ are not linear maps on $V \times W$. Yet there is a single space $V \otimes W$ such that bilinear maps out of $V \times W$ are *exactly* linear maps out of $V \otimes W$, and the alternating forms above live in a quotient of $V \otimes \cdots \otimes V$. How that space is built, and why physicists' upper and lower indices are just vectors and covectors in disguise, is the subject of Ch. 93.

99.4 The algorithm

The counting theorem is an algorithm: to find the Jordan blocks for an eigenvalue λ, compute $d_k = \dim \ker(\mathbf{A} - \lambda\mathbf{I})^k = n - \operatorname{rank}(\mathbf{A} - \lambda\mathbf{I})^k$ until it stops growing, and read off the sizes. No chain basis is needed.

```
import numpy as np

def jordan_structure(A, lam, tol=1e-9):
    """Sizes of the Jordan blocks of A for eigenvalue lam, from kernel dimensions."""
    n = A.shape[0]
    N = A - lam * np.eye(n)
    d = [0]                                  # d[k] = dim ker N^k
    P = np.eye(n)
    while True:
        P = P @ N
        d.append(int(n - np.linalg.matrix_rank(P, tol=tol)))
        if d[-1] == d[-2]:
            break
    at_least = [d[k] - d[k - 1] for k in range(1, len(d))]   # blocks of size >= k
    sizes = []
    for k, m in enumerate(at_least, start=1):
        nxt = at_least[k] if k < len(at_least) else 0
        sizes += [k] * (m - nxt)                             # blocks of size exactly k
    return d[1:-1], sorted(sizes, reverse=True)

# A matrix with eigenvalue 2 only, disguised by a change of basis
J = np.diag([2.0] * 6) + np.diag([1, 1, 0, 1, 0], k=1)       # blocks 3, 2, 1
S = np.eye(6) + np.eye(6, k=1) + np.eye(6, k=-1)               # det S = 1
A = S @ J @ np.linalg.inv(S)
print(np.round(A, 3))
print("dim ker (A-2I)^k:", *jordan_structure(A, 2.0))
print("eigvals of A, distance from 2:", np.round(np.sort(abs(np.linalg.eigvals(A) - 2)), 8))

# the same computation after a tiny perturbation of size 1e-10
E = 1e-10 * np.random.default_rng(0).standard_normal((6, 6))
for tol in (1e-8, 1e-12):
    print(f"perturbed, tol={tol:g}:", jordan_structure(A + E, 2.0, tol))
```

The disguised matrix is an integer matrix with no visible structure, yet the script reports $d_k = 3, 5, 6$ and blocks $[3, 2, 1]$, the figure's chains exactly. Each rank costs one SVD, $O(n^3)$, and there are at most n powers, so the cost is $O(n^4)$ per eigenvalue.

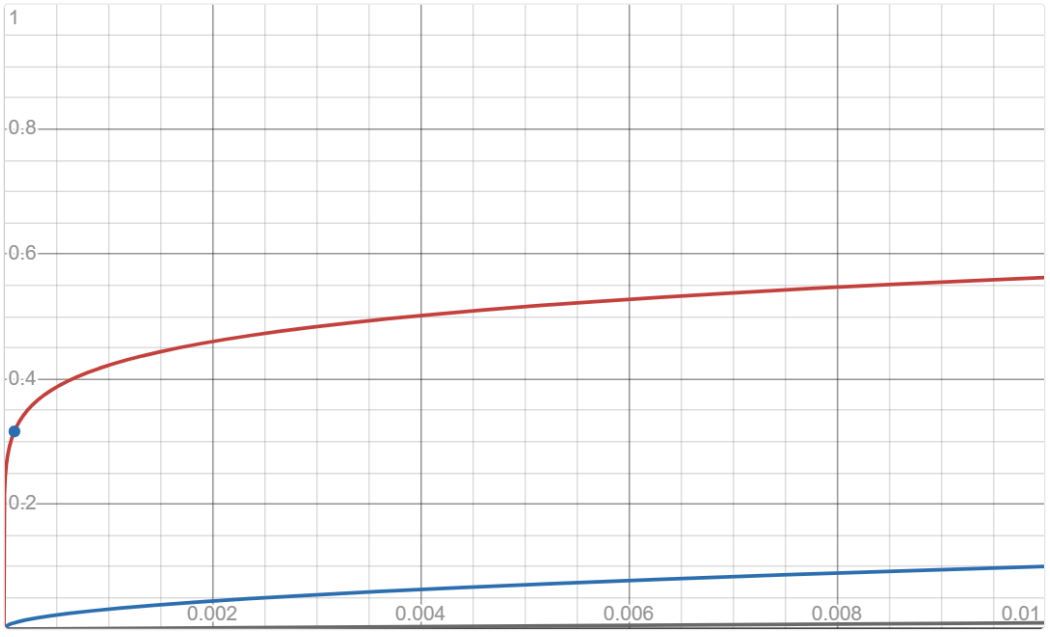
Now the warning. The same script asks `numpy` for the eigenvalues of the *exact* integer matrix $\mathbf{A}$, whose only eigenvalue is 2. It returns three of them about 3.3×10^{-6} away from 2. Rounding errors of size 10^{-16} have been amplified to 10^{-6}, roughly $(10^{-16})^{1/3}$, because a Jordan block of size 3 spreads a perturbation ε into eigenvalues at distance about $\varepsilon^{1/3}$. After a deliberate perturbation of size 10^{-10}, the rank test with tolerance 10^{-8} still finds $[3, 2, 1]$; with tolerance 10^{-12} it finds

no eigenvalue 2 at all, which is the exact truth for the perturbed matrix.

Both answers are correct. The Jordan form is a **discontinuous** function of the matrix: every non-diagonalizable matrix is a limit of diagonalizable ones. So numerical libraries compute the stable Schur form instead, and the Jordan form is asked for only in exact arithmetic over $\mathbb{Q}$ or $\mathbb{F}_p$. The tolerance is your claim about how much of the matrix is real.

99.5 The experiment

How sensitive is a Jordan block? Take the $n \times n$ block $J_n(0)$, whose only eigenvalue is 0, and put ε in the bottom-left corner. The characteristic polynomial becomes $x^n - \varepsilon$, so every eigenvalue jumps to distance $\varepsilon^{1/n}$ from 0. A diagonalizable matrix would move them by about ε.



Eigenvalue displacement against perturbation size ε: grey for a diagonalizable matrix, blue for a 2×2 Jordan block, red for an 8×8 block. Change the exponent $\frac{1}{8}$ to $\frac{1}{20}$ and watch the curve become a wall.

The script draws the eigenvalues in the complex plane. With the defaults it prints `max|lambda| = 1.000e-02` for $\varepsilon = 10^{-16}$: a perturbation at the level of rounding error moves the eigenvalues of an 8×8 block by 0.01, fourteen orders of magnitude more.

```
import numpy as np
import matplotlib.pyplot as plt

# KNOBS: block size n, perturbation sizes, and where the perturbation goes
n = 8
epsilons = [1e-16, 1e-12, 1e-8, 1e-4]
corner_only = True        # False: perturb every entry at random

J = np.diag(np.ones(n - 1), k=1)          # nilpotent Jordan block: only eigenvalue 0
rng = np.random.default_rng(1)
fig, ax = plt.subplots(figsize=(6, 6))
for eps in epsilons:
    E = np.zeros((n, n))
    if corner_only:
        E[-1, 0] = eps                    # the single entry that closes the chain
    else:
        E = eps * rng.standard_normal((n, n))
    lam = np.linalg.eigvals(J + E)
    r = np.abs(lam).max()
    print(f"eps={eps:.0e}  max|lambda|={r:.3e}  eps^(1/n)={eps ** (1 / n):.3e}")
    ax.plot(lam.real, lam.imag, "o", label=f"eps = {eps:.0e}")
ax.set_aspect("equal"); ax.grid(True); ax.legend()
ax.set_title(f"eigenvalues of a perturbed {n}x{n} Jordan block (exact answer: all 0)")
plt.show()
```

Things to try: set `n = 20` and see $\varepsilon = 10^{-16}$ produce eigenvalues of size about 0.16; set `corner_only = False` and check that random perturbations obey the same $\varepsilon^{1/n}$ law; replace `J` by a diagonal matrix and watch the effect collapse to size ε.

99.6 The challenge

1. **Intuition.** In $\mathbb{R}^3$, describe V/U when U is a line, and when U is a plane. Why is there a natural map $V \to V/U$ but no natural map $V/U \to V$? Which of the two covector families in the dual-basis figure moves if you replace e_1 by $(2, 0)$?
2. **Derivation.** Prove $\dim U + \dim U^0 = \dim V$, and show that $(\operatorname{im} T)^0 = \ker T^*$. Deduce, without matrices, that row rank equals column rank.

3. **Implementation.** Write `rational_form(A)` for integer matrices using exact `fractions.Fraction` arithmetic: grow cyclic chains $v, Av, A^2v, \dots$ until they become dependent, record the polynomial, and split off the invariant subspace. Test it on $\mathbf{R}$ (expect x^2+1) and on a 4×4 matrix with characteristic polynomial $(x^2+1)^2$.
4. **Open investigation.** For random $n \times n$ matrices $\mathbf{E}$ with independent Gaussian entries, how does the *distribution* of eigenvalues of $J_n(0) + \varepsilon \mathbf{E}$ look as n grows with ε fixed? Does it concentrate on a circle of radius $\varepsilon^{1/n}$, fill a disc, or do something else? Explore numerically and form a conjecture.

99.7 Loose threads

This chapter stated, rather than proved, the existence of chain bases and the rational canonical form. Both are one theorem in disguise: a vector space with an operator T is a module over the polynomial ring $K[x]$ (let x act as T), and the **structure theorem for finitely generated modules over a principal ideal domain** decomposes it into cyclic pieces. The same theorem classifies finite abelian groups, with $\mathbb{Z}$ in place of $K[x]$; its home is the ring theory of Ch. 56.

The numerical fragility of §99.4 also has a modern answer. Since eigenvalues of non-normal matrices are unreliable, analysts study **pseudospectra**, the sets where $\|(\mathbf{A} - z\mathbf{I})^{-1}\|$ is large, which are stable and explain transient growth in fluid flows and lasers (Ch. 90).

The three mysteries lead out of the track: continuous functionals in infinite dimensions (Ch. 61), the wildness of pairs of matrices (Ch. 95), and the tensor product (Ch. 93). Quotients by "functions that vanish almost everywhere", which turn functions into vectors of L^2, are waiting in measure theory (Ch. 97).

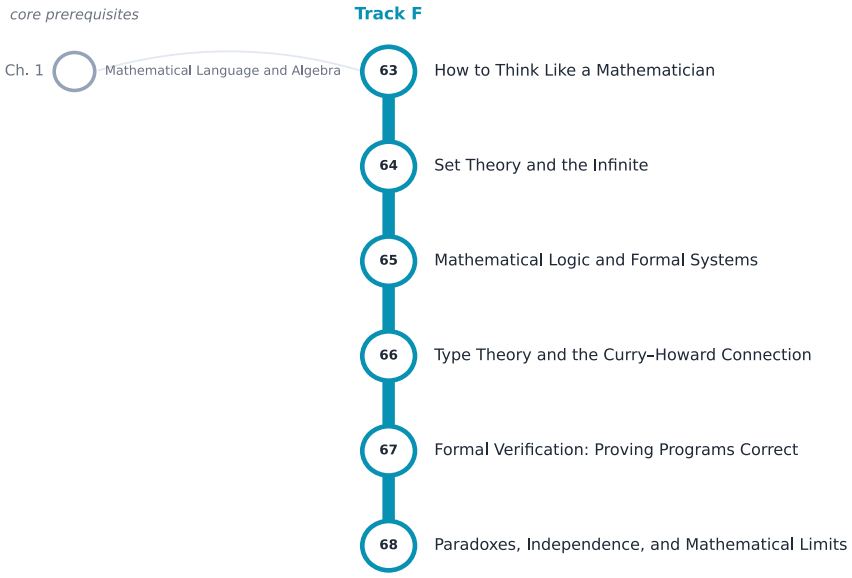
Track F — Logic, Proofs, and the Foundations of Truth

> **Level 2 — Specializations.** For writing reliable algorithms, designing programming languages, and understanding why some truths cannot be proved.



Suggested reading order for Track F. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 1 — Mathematical Language and Algebra

Chapters

Ch.	Chapter	What it explores
63	How to Think Like a Mathematician	Direct proof, contradiction, induction, construction, counterexamples.
64	Set Theory and the Infinite	Cardinality, ordinals, countability, uncountability, axioms.
65	Mathematical Logic and Formal Systems	Predicate logic, completeness, soundness, compactness, incompleteness.
66	Type Theory and the Curry–Howard Connection	Types as propositions, proofs as programs, dependent types.
67	Formal Verification: Proving Programs Correct	Hoare logic, invariants, model checking, theorem provers.
68	Paradoxes, Independence, and Mathematical Limits	Russell's paradox, Gödel's incompleteness theorems, independence results.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 63 — How to Think Like a Mathematician

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 1, Ch. 29 · **Leads to:** Ch. 64, Ch. 65, Ch. 67 · **Related:** Ch. 28, Ch. 57, Ch. 66 **Reading time:** ~25 min

63.1 The hook

Put two points on a circle and join them: the disc is cut into 2 regions. Three points, all chords drawn: 4 regions. Four points: 8. Five points: 16. Anyone who has seen the sequence $1, 2, 4, 8, 16$ knows what comes next. Draw six points (in general position, so that no three chords meet at one interior point), count carefully, and you get **31**.

Not 32. Thirty-one. The pattern was a liar, and it lied politely for five steps before it betrayed you.

It gets worse. The polynomial $n^2 + n + 41$, found by Euler, produces primes for $n = 0, 1, 2, \ldots, 39$: $41, 43, 47, 53, 61, \ldots, 1601$. Forty primes in a row. At $n = 40$ it gives $1681 = 41^2$. Euler also guessed that you need at least k k-th powers to add up to a k-th power. For two centuries nobody found an exception, until in 1966 a computer search turned up

$$27^5 + 84^5 + 110^5 + 133^5 = 144^5,$$

four fifth powers summing to a fifth power. And Fermat, perhaps the greatest pattern-spotter of all, claimed that every number $2^{2^m} + 1$ is prime. It is for $m = 0, 1, 2, 3, 4$ (giving $3, 5, 17, 257, 65537$). For $m = 5$, Euler found $2^{32} + 1 = 4294967297 = 641 \times 6700417$.

Now a puzzle with the opposite flavour. Take a $2^n \times 2^n$ chessboard and delete any one square you like. Can the rest always be tiled by L-shaped trominoes (three squares forming an L)? For $n = 1$ the board is 2×2 minus a square, which *is* an L. For $n = 2$ you can find a tiling by hand in a minute. For $n = 10$ the board has 1,048,576 squares and over a million choices of missing square, and the number of ways to place trominoes is beyond any computer. Testing is hopeless. Yet the answer is yes, for every n and every missing square, and by the end of §63.3 you will have seen why with your own eyes, in about ten lines.

So here is the question this chapter is about:

> **When a pattern has held a thousand times, how do you know it will hold the thousand-and-first time, and how do you decide which tool will tell you?**

63.2 The big idea

A **proof** is a finite argument that settles infinitely many cases at once. Testing checks cases one at a time and never finishes; a proof finds a reason that applies to all of them. The two activities are partners: testing suggests what might be true, and proof decides it. A single failed test kills a universal claim outright, while a million passed tests do not establish it.

A programmer's analogy works well. A theorem is a specification, a proof is an implementation that has been checked to meet it, and a counterexample is a failing test case. A failing test is decisive; a passing test suite is only evidence. (Ch. 29 takes this analogy literally and proves programs correct; Ch. 66 will show it is more than an analogy.)

The second idea is that the *shape of the claim* usually tells you which tool to reach for. Mathematicians are not geniuses who pull proofs out of the air; they read the logical form of the statement and pick from a small toolkit, the way an engineer reads a circuit and decides between nodal and mesh analysis.

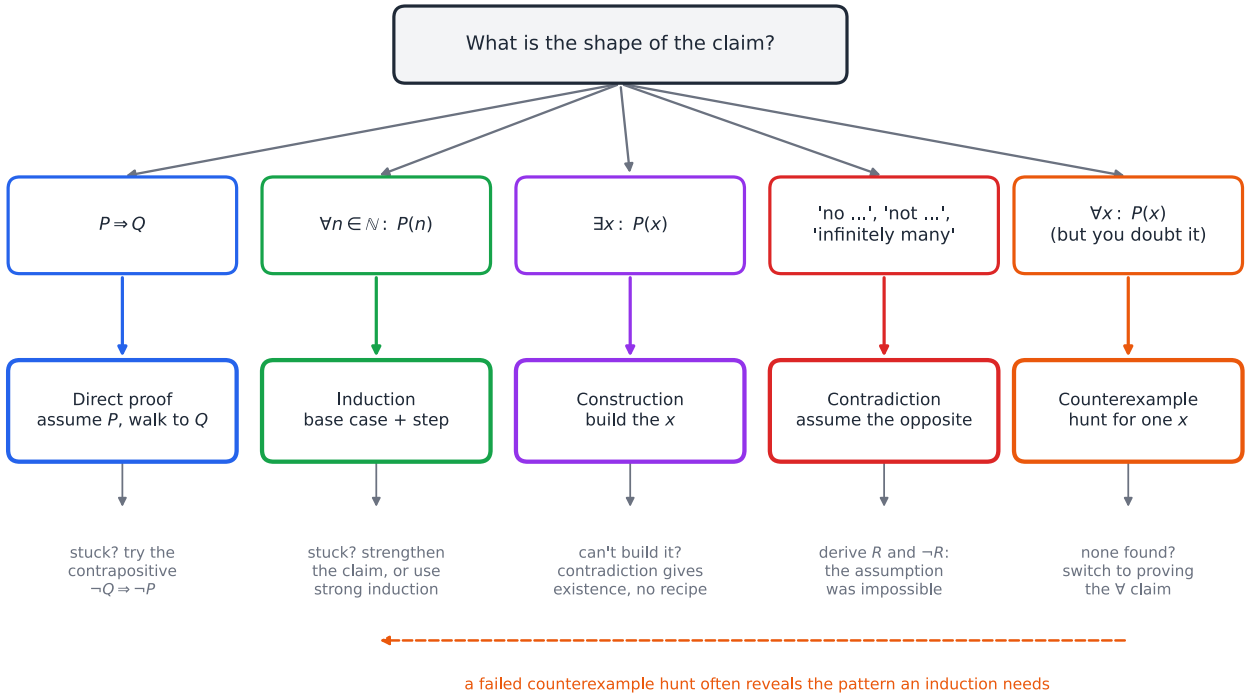


Figure 63.1 — Read the claim's logical shape, pick the matching strategy, and know the fallback when you get stuck. Hunting for counterexamples is not a separate activity: it is how you find out which box you are in.

The five boxes are the whole chapter:

- **Direct proof.** To prove $P \Rightarrow Q$, assume P and walk, step by valid step, to Q.
- **Contradiction.** To prove S, assume $\neg S$ and derive something absurd. Best for negative claims: "there is no...", "is irrational", "there are infinitely many...".
- **Induction.** To prove $P(n)$ for every natural number n, prove $P(0)$ and prove that $P(k)$ forces $P(k+1)$.
- **Construction.** To prove $\exists x\, P(x)$, build an x and check it.
- **Counterexample.** To refute $\forall x\, P(x)$, exhibit one x with $\neg P(x)$.

Ch. 1 lists the first four in §1.10, and Ch. 29 develops the variants of induction (strong induction, well-ordering, structural induction) in §29.3. This chapter is about *using* them: what each one feels like from the inside, where each one breaks, and how to choose.

63.3 The mathematics

We need one piece of vocabulary from logic, covered in Ch. 29's predicate-logic section: $P \Rightarrow Q$ is false only when P is true and Q false, and $\neg\forall x\, P(x)$ is equivalent to $\exists x\, \neg P(x)$. That last equivalence is the entire theory of counterexamples.

Direct proof and the contrapositive

> **Even, odd, divides**
>
> An integer n is **even** if $n = 2k$ for some integer k, and **odd** if $n = 2k + 1$. We write $a \mid b$ ("a divides b") if $b = ak$ for some integer k.

A direct proof unpacks definitions, manipulates, and repacks. Claim: *if $a \mid b$ and $b \mid c$ then $a \mid c$.* Assume $b = ak$ and $c = bl$. Then $c = a(kl)$, and kl is an integer, so $a \mid c$. □ Three lines, and nothing clever: the definitions did the work. Most proofs you will ever write look like this, and the skill is mostly in writing down the definitions precisely before you start.

Sometimes the forward walk has nowhere to go. Claim: *if n^2 is even then n is even.* Assume $n^2 = 2k$. Now what? Taking square roots leads nowhere. The **contrapositive** $\neg Q \Rightarrow \neg P$ is logically equivalent to $P \Rightarrow Q$ (check the four rows of a truth table), and here it is easy: if n is odd, $n = 2k + 1$, then $n^2 = 4k^2 + 4k + 1 = 2(2k^2 + 2k) + 1$ is odd. □ The lesson is general: when the hypothesis is weak and the conclusion is strong, flip the implication so that the strong statement becomes the hypothesis. This lemma is exactly the step used in the irrationality of $\sqrt{2}$ in §1.1.

Proof by contradiction

Contradiction is the most powerful and the most dangerous tool. You assume the claim is false, reason until you reach a statement and its negation, and conclude that the assumption was impossible. Its power is that you get a free hypothesis to work with. Its danger is that if you make an ordinary mistake along the way, you also "reach a contradiction", and the proof looks just as convincing.

Theorem 63.1 — Euclid: there are infinitely many primes

For every finite list of primes, there is a prime not on the list.

Proof. Suppose, for contradiction, that $p_1, p_2, \dots, p_m$ is a complete list of all primes. Let $N = p_1 p_2 \cdots p_m + 1$. Since $N \geq 3 > 1$, N has at least one prime factor q (the smallest divisor of N greater than 1 must be prime, because any proper factor of it would be a smaller divisor). By assumption q is one of the p_i. Then $q \mid p_1 \cdots p_m$ and $q \mid N$, so q divides their difference, $N - p_1 \cdots p_m = 1$. No prime divides 1. Contradiction, so no finite list contains all primes. □

A common misreading: "$p_1 \cdots p_m + 1$ is always prime." It is not. With the first six primes, $2 \cdot 3 \cdot 5 \cdot 7 \cdot 11 \cdot 13 + 1 = 30031 = 59 \times 509$. The proof never claimed N was prime, only that its prime factors were new. Read the proof again and notice that it can be rewritten *without* contradiction: given any list, N's smallest prime factor is a new prime, and that is a construction. Many proofs by contradiction hide a direct proof inside; finding it usually gives you more information.

Induction, and the art of strengthening

Ch. 29 states the principle and its variants. Figure 63.2 is the picture to keep in your head.

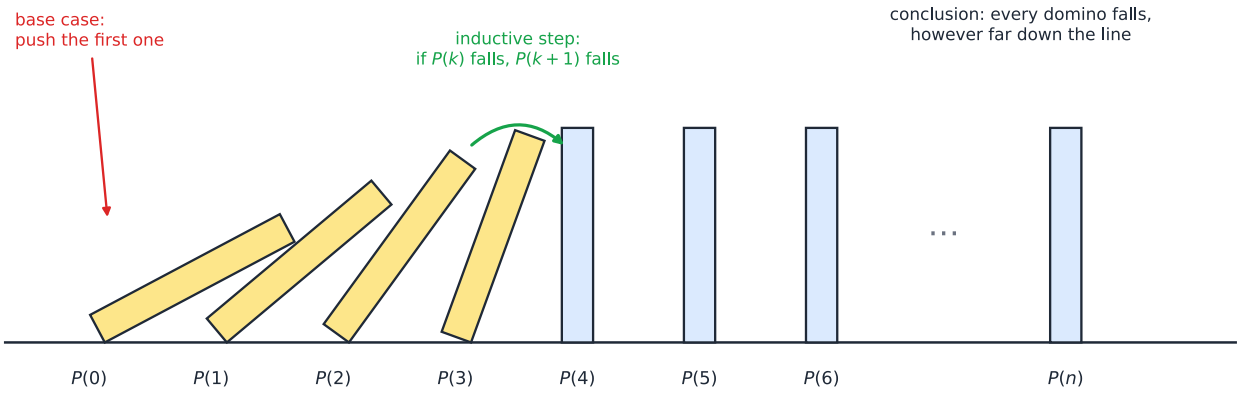

Figure 63.2 — Induction as a line of dominoes. The base case knocks over the first one; the inductive step guarantees that every falling domino knocks over the next. Neither half alone is enough: a perfect step with no push does nothing, and a push with one gap in the line stops the cascade.

The domino picture also explains the classic failure. "All horses are the same colour": in any set of $k+1$ horses, the first k share a colour and the last k share a colour, and these overlap, so all $k+1$ do. The step fails exactly from $k = 1$ to $k = 2$, where the "first one" and the "last one" do not overlap. One gap in the line of dominoes, and the whole cascade stops at the second domino.

Now the tromino puzzle from the hook. Here is the surprising lesson: the stronger claim is *easier* to prove.

Theorem 63.2 — Tromino tiling

For every $n \geq 1$ and every choice of one square to remove, the remaining $4^n - 1$ squares of a $2^n \times 2^n$ board can be tiled by L-trominoes.

Proof. By induction on n. Let $P(n)$ be the full statement, "for **every** missing square".

Base case $n = 1$. A 2×2 board minus any one square is itself an L-tromino.

Inductive step. Assume $P(k)$ and take a $2^{k+1} \times 2^{k+1}$ board with one square removed. Cut it into four $2^k \times 2^k$ quadrants. The missing square lies in one of them. Place a single tromino at the centre of the board so that it covers one square from each of the *other three* quadrants (the three central corners). Now each of the four quadrants is a $2^k \times 2^k$ board with exactly one square unavailable: the original hole in one, a square covered by the central tromino in the other three. By $P(k)$, applied four times, each quadrant can be tiled. Together with the central tromino, that tiles the whole board. □

Look at what made this work. If we had tried to prove only "the board minus a *corner* can be tiled", the inductive step would have failed: three of the four quadrants end up missing a *central* square, not a corner, and the weaker hypothesis would not apply to them. By asking for more (every missing square), we got a stronger hypothesis to use in the step. This is the single most useful trick in induction: **if the step does not go through, try proving something stronger.** It feels backwards, and it works constantly. The count also checks out: $4^n - 1$ is always divisible by 3 (it equals $1, 5, 21, 85, 341$ trominoes for $n = 1, \dots, 5$), as it must be.

The proof is also an algorithm. Follow it recursively and it *places* the trominoes; §63.4 turns it into code.

Construction: proving that something exists

To prove "there exist n consecutive composite numbers, for every n", build them. The numbers

$$(n+1)! + 2,\ (n+1)! + 3,\ \dots,\ (n+1)! + (n+1)$$

are n consecutive integers, and for each $2 \leq k \leq n+1$, k divides both $(n+1)!$ and k, so $k \mid (n+1)! + k$, which is therefore composite. For $n = 5$: $722, 723, 724, 725, 726$, divisible by $2, 3, 4, 5, 6$ respectively. So primes have arbitrarily large gaps, even though Theorem 63.1 says they never run out. The construction is crude (the gap after 113 already has length 13, far below 14!) but crude is fine: an existence proof only needs *one* witness.

Now a stranger existence proof.

Theorem 63.3 — An irrational power of an irrational can be rational

There exist irrational numbers a and b such that a^b is rational.

Proof. Consider $x = \sqrt{2}^{\sqrt{2}}$. Either x is rational or it is not. If it is, take $a = b = \sqrt{2}$, which is irrational by §1.1. If it is not, take $a = x$ and $b = \sqrt{2}$: then

$$a^b = \left(\sqrt{2}^{\sqrt{2}}\right)^{\sqrt{2}} = \sqrt{2}^{\sqrt{2}\cdot\sqrt{2}} = \sqrt{2}^{2} = 2,$$

which is rational. Either way the pair exists. □

This proof is airtight and deeply unsatisfying. It proves that a pair exists, and at the end you *still do not know which pair it is*. (It happens that $\sqrt{2}^{\sqrt{2}}$ is irrational, by the Gelfond–Schneider theorem, but the proof above did not need to know that and cannot tell you.)

? A proof that refuses to show its witness

Theorem 63.3 used the law of excluded middle, "x is rational or it is not", to prove existence without producing an example. A school of mathematicians, the intuitionists, rejects such proofs, and for programmers there is a sharp reason to care: a proof of "there exists" that does not contain a recipe cannot be *run*. What kind of logic do you get if every existence proof must carry its witness, and why does that logic turn out to be a programming language? That is the subject of Ch. 66.

Counterexamples: the cheapest proof there is

To refute "for all x, $P(x)$" you need exactly one x that fails. Every example in the hook is a counterexample, and Figure 63.3 shows the first one in full.

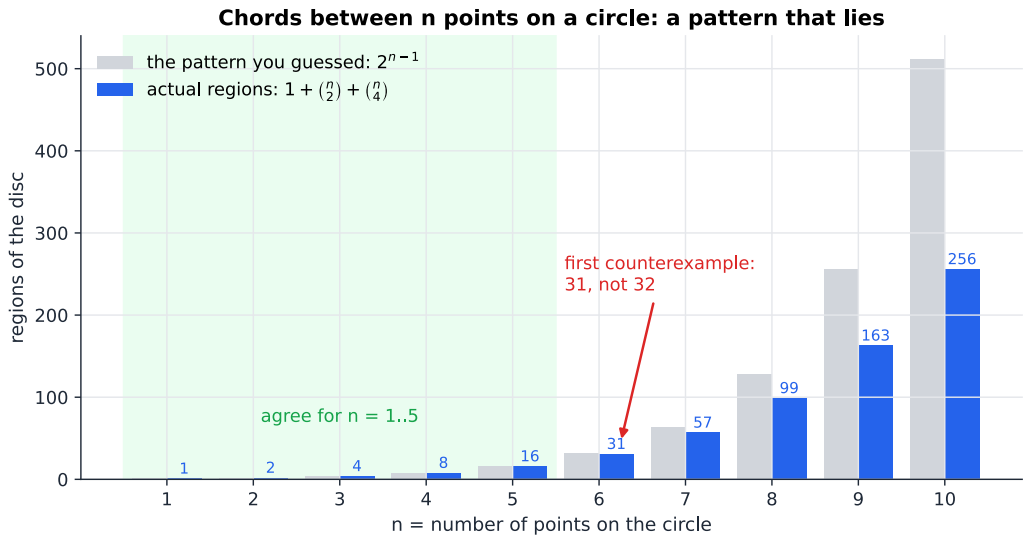

Figure 63.3 — The regions cut out by all chords between n points on a circle (blue) against the doubling pattern (grey). They agree for five values and then separate for good: the true count grows like $n^4/24$, the guess like 2^n.

Why does the true formula $1 + \binom{n}{2} + \binom{n}{4}$ fit five values of 2^{n-1}? Because $2^{n-1} = \sum_i \binom{n-1}{i}$, and for $n \le 5$ that sum and $1 + \binom{n}{2} + \binom{n}{4}$ happen to coincide (both are $\binom{n-1}{0} + \cdots + \binom{n-1}{4}$, the first five terms, by Pascal's rule). At $n = 6$ the doubling sequence picks up a sixth term, $\binom{5}{5} = 1$, and the geometric count does not. The coincidence had a reason, and so did its end. Finding *that* reason, why each new chord crossing adds one region, is what a proof of the formula does; Ch. 28 has the counting tools (Ch. 28).

Three habits make counterexample hunting effective:

1. **Try the edge cases first**: 0, 1, the empty set, negative numbers, equal inputs, degenerate shapes. "Every continuous function is differentiable" dies at $|x|$; "every bounded sequence converges" dies at $(-1)^n$.
2. **Search systematically** when the space is enumerable, and let a computer do it. Euler's conjecture fell to a computer, not to cleverness.
3. **When the hunt keeps failing, ask why.** Each near-miss is information. The reason no counterexample appears is very often the proof.

Counterexamples can hide far out

Pólya conjectured in 1919 that, below any $N \ge 2$, at least half the numbers have an odd number of prime factors. It holds for every N below 906,150,257, where it first fails. The Mertens conjecture was disproved in 1985 without anyone ever finding an explicit counterexample; the best known bound on where the first one lies is around $e^{10^{33}}$. Testing up to a billion proves nothing.

63.4 The algorithm

Two of our five strategies are algorithms in disguise: induction (the proof of Theorem 63.2 is a recursive procedure) and counterexample search (an enumeration with a check). Here is the tromino proof, executed.

```
import numpy as np

def tile(n, hole):
    """Tile a 2^n x 2^n board minus `hole` with L-trominoes (Theorem 63.2)."""
    N = 2 ** n
    board = np.zeros((N, N), dtype=int)
    board[hole] = -1
    count = [0]

    def solve(r, c, size, hr, hc):          # quadrant at (r,c), blocked cell (hr,hc)
        if size == 1:
            return
        count[0] += 1
        t, h = count[0], size // 2
        centre = [(r+h-1, c+h-1), (r+h-1, c+h), (r+h, c+h-1), (r+h, c+h)]
        corners = [(r, c), (r, c+h), (r+h, c), (r+h, c+h)]
        for (qr, qc), (cr, cc) in zip(corners, centre):
            if qr <= hr < qr+h and qc <= hc < qc+h:
                solve(qr, qc, h, hr, hc)      # quadrant with the real hole
            else:
                board[cr, cc] = t             # central tromino covers this cell
                solve(qr, qc, h, cr, cc)      # ...which is now this quadrant's hole
    solve(0, 0, N, *hole)
    return board

print(tile(3, (5, 2)))
```

Each call does constant work and makes four calls on boards a quarter of the size, so the running time satisfies $T(4^n) = 4T(4^{n-1}) + O(1)$, which is $O(4^n)$: linear in the number of squares, the best possible since every square must be covered. The recursion depth is $n = \log_2 N$, so there is no stack problem even for $N = 2^{20}$.

The **counterexample hunter** is simpler still:

```
for x in an enumeration of the domain, in order of "size":
    if not P(x): return x          # refuted
return "no counterexample up to the bound"
```

Its outputs are asymmetric. A returned x is a proof (check it by hand, and you are done forever). The message "none up to the bound" proves nothing about larger x, as the warning above shows. Two engineering points matter:

- **Order of enumeration.** Enumerate by increasing size (sum of the entries, number of nodes, length of the list). Small counterexamples are the common case and the easiest to understand, an idea Ch. 29 calls the small-scope hypothesis.
- **Check P exactly.** Floating point can manufacture a counterexample that is not there, or hide one that is. Here both sides are the 11-digit number $61{,}917{,}364{,}224$, comfortably exact in a double; push the search a little further and the sums pass $2^{53} \approx 9 \times 10^{15}$, where doubles start rounding. Use exact integers.

Finally, proof by exhaustion is legitimate when the cases are finite: the four-colour theorem (1976) and the Kepler conjecture (1998) were proved by reducing an infinite problem to finitely many cases, then checking those by computer. The infinite-to-finite reduction is the human proof; the computer only does the bookkeeping.

63.5 The experiment

The script below is a counterexample hunter with three suspects. Run it, then change the knobs.

```
import numpy as np
from math import comb, isqrt

def is_prime(n):
    return n >= 2 and all(n % p for p in range(2, isqrt(n) + 1))

# Suspect 1: a prime-generating polynomial  n^2 + A n + B
A, B = 1, 41          # knob: try (-79, 1601), (1, 17), (1, 11)
bad = next(n for n in range(10**4) if not is_prime(n*n + A*n + B))
print(f"n^2+{A}n+{B}: first composite at n={bad}, value {bad*bad + A*bad + B}")

# Suspect 2: circle regions double each time
for n in range(1, 9):
    real, guess = 1 + comb(n, 2) + comb(n, 4), 2 ** (n - 1)
    print(n, real, guess, "" if real == guess else "<-- counterexample")

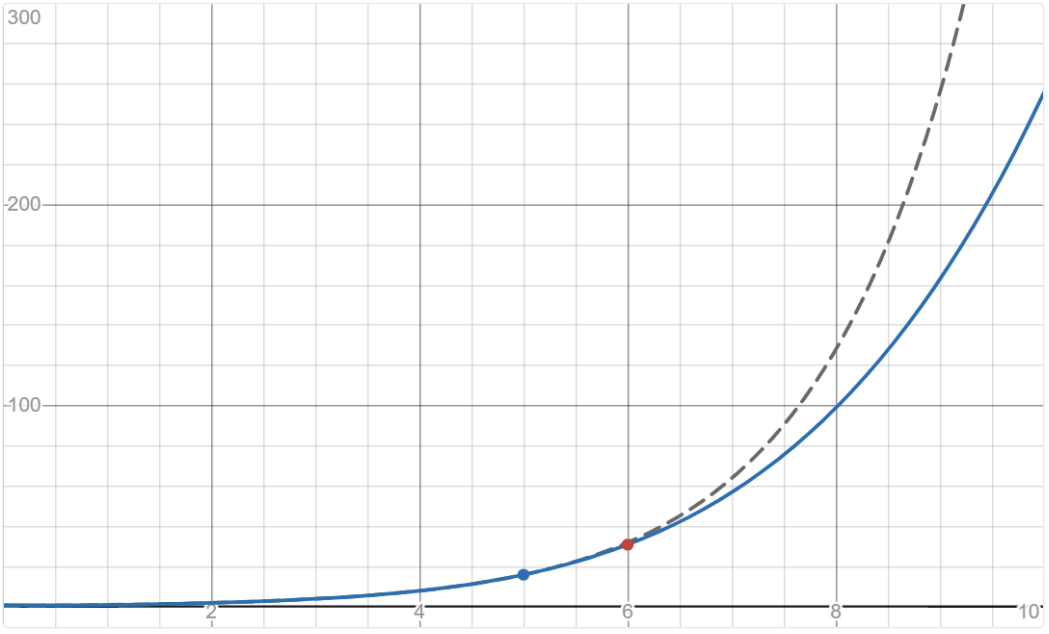
# Suspect 3: Goldbach -- every even number >= 4 is a sum of two primes
LIMIT = 20_000        # knob: raise it and watch the time grow
sieve = np.ones(LIMIT + 1, bool); sieve[:2] = False
for p in range(2, isqrt(LIMIT) + 1):
    if sieve[p]:
        sieve[p*p::p] = False
primes = np.flatnonzero(sieve)
fails = [m for m in range(4, LIMIT + 1, 2)
         if not any(sieve[m - primes[primes <= m // 2]])]
print("Goldbach failures up to", LIMIT, ":", fails)
```

With the default knobs it reports the first composite at $n = 40$ (value 1681), prints `<-- counterexample` from $n = 6$ on, and finds no Goldbach failure.

Things to try:

1. Set `(A, B) = (-79, 1601)`. This polynomial produces primes for 80 consecutive n (with repeats). Why does *no* non-constant polynomial with integer coefficients produce only primes? Hint: evaluate $f(n + k\,f(n))$ modulo $f(n)$.
2. Raise `LIMIT` to 10^6. Goldbach has been checked by computer up to 4×10^{18} and is still unproved. Count, for each even m, the number of ways to write it as a sum of two primes, and plot that count against m. The cloud of points grows; why does that make a counterexample feel ever less likely, and why is "feels unlikely" not a proof?
3. Change suspect 2 to points placed at the vertices of a *regular* hexagon. Now three chords meet at the centre. Count the regions by drawing them. Which hypothesis of the formula did you violate?

You can also watch the circle-region formula and the doubling guess separate.



The quartic $1 + \binom{x}{2} + \binom{x}{4}$ (blue) and the exponential guess (dashed) touch at $x = 1, \dots, 5$ and part ways. Change the 24 in the constant term to 25 and watch a single coefficient destroy the coincidence.

63.6 The challenge

No answers are given.

1. **Intuition.** Remove two diagonally opposite corners from an ordinary 8×8 chessboard. Can the remaining 62 squares be tiled by 1×2 dominoes? Find a one-sentence argument. Then decide whether your argument is a direct proof, a contradiction, or an invariant, and say why the label matters less than the idea.

2. **Derivation.** Prove by induction that every integer $n \geq 2$ is a product of primes. You will find ordinary induction does not work and strong induction does (§29.3). Then prove *by contradiction, using well-ordering,* that the factorisation is unique up to order, assuming the lemma "if a prime divides ab, it divides a or b".
3. **Implementation.** Extend the tromino code in §63.4 to draw the tiling with matplotlib, one colour per tromino. Then write a brute-force backtracking tiler and compare running times with the recursive one for $n = 2, 3, 4$. Where does brute force give up, and why?
4. **Open investigation.** Take any claim of the form "for all n, $f(n)$ is prime", for polynomials f of degree 2 with small coefficients. Search for the f with the longest initial run of primes. Is there an upper bound on how long the run can be for degree 2? (This touches open questions about prime-producing quadratics, related to class numbers of quadratic fields; nobody has a complete answer.)

63.7 Loose threads

We answered the hook's question, as far as it can be answered. You know a pattern holds for the thousand-and-first case only when you have a finite argument that covers every case, and the logical shape of the claim points to the argument: implications to direct proof, negations to contradiction, statements about all n to induction, existence claims to construction, and suspicious universals to a counterexample hunt. The tromino board of any size is tileable because the strengthened claim carries itself from one size to the next.

But every proof in this chapter rested on things we did not question.

- **What exactly is "valid"?** Each step was justified by "clearly" or "by definition". Could the rules of valid reasoning themselves be written down as a finite list, so precisely that a machine could check every proof? Ch. 65 does exactly that, and Ch. 67 shows engineers using such machines today.
- **What is a natural number?** Induction works on $\mathbb{N}$ because $\mathbb{N}$ has no infinite descending chain. On the integers, the rationals or the reals it fails. Why, and what is the right generalisation to infinite collections? Ch. 64 builds the infinite from sets and extends induction beyond the natural numbers.

> **? True but unprovable?**
>
> Goldbach's conjecture has survived checking up to 4×10^{18}, and the Collatz loop of Ch. 29 has survived up to about 3×10^{20}. Perhaps they are true but no proof exists at all: not hard to find, but *non-existent*, within the rules mathematicians accept. Can that happen to a perfectly ordinary statement about whole numbers? In 1931 Kurt Gödel showed that it can. How, and what it means, is the subject of Ch. 65 and Ch. 68.

> **? Can a machine find the proof for you?**
>
> Checking a written proof is mechanical. Finding one is creative, or is it? Given a statement, is there an algorithm that always finds a proof if one exists, and says "no" otherwise? The answer splits in a strange way: there is a procedure that finds every proof that exists, but it may run forever when none does. Why the "no" half is impossible connects to the halting problem of Ch. 30 and is made precise in Ch. 65.

So proofs are finite arguments about infinitely many cases. The next chapter asks what "infinitely many" means, and finds that there is more than one size of infinity.

Chapter 64 — Set Theory and the Infinite

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 1, Ch. 29, Ch. 63 · **Leads to:** Ch. 65, Ch. 68 · **Related:** Ch. 30, Ch. 60, Ch. 19 **Reading time:** ~25 min

64.1 The hook

Imagine a hotel with infinitely many rooms, numbered $1, 2, 3, \ldots$, and every room is occupied. A traveller arrives late at night and asks for a room. In any ordinary hotel the answer is "sorry, we're full". This hotel's manager, David Hilbert in the usual telling, picks up the intercom: *"Would every guest please move from room n to room $n + 1$."* Everyone moves at once, nobody is left without a room, and room 1 is now empty. The traveller checks in.

Next night a coach arrives carrying infinitely many passengers, one per seat, seats numbered $1, 2, 3, \ldots$. The hotel is full again. The manager announces: *"Guest in room n, please move to room $2n$."* All current guests now sit in the even-numbered rooms, and every odd-numbered room is free. The passenger in seat k takes room $2k - 1$. Everyone is housed.

The third night, infinitely many coaches arrive, each with infinitely many passengers. Seat k on coach c is a pair (c, k). Surely this is too much? It is not, and by §64.3 you will be able to house them all yourself.

The fourth night is different. A coach arrives with one passenger for every infinite string of 0s and 1s: one for $0000\ldots$, one for $1010\ldots$, one for every pattern you can imagine. The manager tries every trick in the book, and fails. Not because she is not clever enough. She fails because it is impossible: **however she assigns rooms, some passenger is left in the car park.** This chapter is about why, and it answers a question that sounds as if it should have no answer:

> **Is every infinity the same size, and if not, how could you possibly tell two infinities apart?**

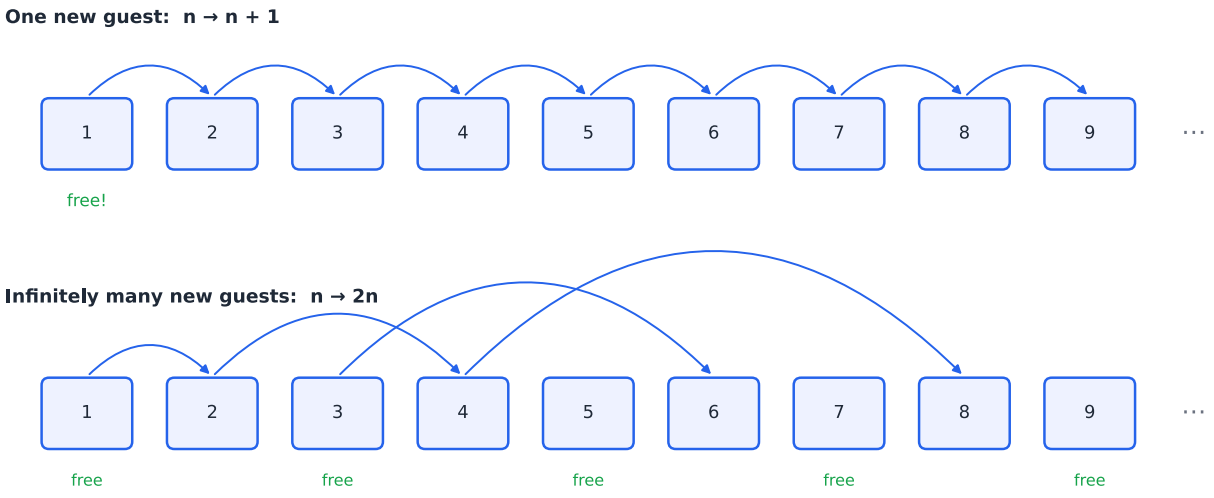

Figure 64.1 — Two of the manager's moves. Top: shifting everyone up one room frees room 1. Bottom: doubling every room number frees all the odd rooms, enough for a whole new infinity of guests. A finite hotel can do neither.

64.2 The big idea

How do you know that a room of chairs has as many chairs as people, without counting either? Ask everyone to sit down. If every person has a chair and every chair has a person, the numbers are equal. You never needed the number itself. **Matching comes before counting.**

Georg Cantor's insight in the 1870s was to take this as the *definition* of "same size", and to apply it fearlessly to infinite collections. Two sets have the same size, or **cardinality**, if their elements can be paired off perfectly, with nothing left over on either side. This one decision has two consequences that look contradictory and are not:

- An infinite set can have the same size as a part of itself. The hotel's first trick pairs $\{1, 2, 3, \ldots\}$ with $\{2, 3, 4, \ldots\}$. This is not a paradox; it is the defining feature of infinity. (Dedekind actually *defined* a set to be infinite if it can be matched with a proper part of itself.)
- Not every pair of infinite sets *can* be matched. Some infinities are strictly larger than others, and there is an infinite ladder of them.

The proof that some infinity is bigger is the **diagonal argument**, one of the most reused ideas in all of mathematics. It reappears in Ch. 30 to show that some problems cannot be solved by any program, and in Ch. 65 to show that some truths cannot be proved. Its form is always the same: *given any list, build something that differs from every entry on the list.*

64.3 The mathematics

We use sets naively for now: a set is a collection of objects, written $\{\dots\}$, with the operations $\cup, \cap, \setminus, \times$ from Ch. 29. §64.3's last part explains why "naively" will not do in the end.

Comparing sizes

Injection, surjection, bijection, cardinality

A function $f : A \to B$ is **injective** (one-to-one) if $f(a) = f(a')$ implies $a = a'$, **surjective** (onto) if every $b \in B$ equals some $f(a)$, and **bijective** if it is both. We write

- $|A| = |B|$ if there is a bijection $A \to B$;
- $|A| \le |B|$ if there is an injection $A \to B$;
- $|A| < |B|$ if $|A| \le |B|$ but $|A| \ne |B|$.

A set is **countable** if it is finite or has the same cardinality as $\mathbb{N} = \{0, 1, 2, \dots\}$. The cardinality of $\mathbb{N}$ is written $\aleph_0$ ("aleph-nought"). An infinite set that is not countable is **uncountable**.

Countable means *listable*: you can write the elements as $a_0, a_1, a_2, \dots$ so that every element appears at some finite position. Hilbert's hotel is a machine for building bijections. $n \mapsto n + 1$ shows $|\mathbb{N}| = |\mathbb{N} \setminus \{0\}|$; $n \mapsto 2n$ shows that the even numbers are exactly as numerous as all the numbers; and the map $n \mapsto n/2$ for even n, $n \mapsto -(n+1)/2$ for odd n lists the integers as $0, -1, 1, -2, 2, \dots$, so $|\mathbb{Z}| = \aleph_0$.

Is $\le$ really an ordering of sizes? If A injects into B and B injects into A, are they the same size? For finite sets obviously. For infinite sets it is true but not obvious.

Schröder–Bernstein theorem

If there are injections $A \to B$ and $B \to A$, then there is a bijection $A \to B$.

We use it without proof; the idea is to follow chains $a \mapsto f(a) \mapsto g(f(a)) \mapsto \cdots$ backwards and forwards and decide, chain by chain, which injection to use. It is a huge labour-saver: to show two sets have the same size, you only need an injection each way, which is usually much easier than a bijection.

The rationals are countable

The rationals look far more numerous than the integers. Between any two of them lies another, so they are **dense**; between 0 and 1 alone there are infinitely many. Surely they cannot be listed?

Theorem 64.1 — $\mathbb{N} \times \mathbb{N}$ and $\mathbb{Q}$ are countable

The map $\pi(p, q) = \dfrac{(p+q)(p+q+1)}{2} + q$ is a bijection $\mathbb{N} \times \mathbb{N} \to \mathbb{N}$. Consequently $|\mathbb{Q}| = \aleph_0$.

Proof. Arrange the pairs (p, q) in a grid and walk the anti-diagonals $p + q = s$ for $s = 0, 1, 2, \dots$ in turn. Diagonal s contains the $s + 1$ pairs $(s, 0), (s-1, 1), \dots, (0, s)$. Before diagonal s begins, we have used up $1 + 2 + \cdots + s = s(s+1)/2$ positions, and within diagonal s the pair (p, q) sits at offset q. So (p, q) lands at position $s(s+1)/2 + q$ with $s = p + q$, which is $\pi(p, q)$. Every position $z \in \mathbb{N}$ is reached exactly once: z lies in exactly one interval $[s(s+1)/2,\ (s+1)(s+2)/2)$, which picks out s, and then $q = z - s(s+1)/2 \in \{0, \dots, s\}$ and $p = s - q$ are forced. So π is a bijection.

For $\mathbb{Q}$: write each positive rational in lowest terms p/q and send it to $\pi(p, q)$. This is an injection from the positive rationals into $\mathbb{N}$, so they are countable; adding 0 and the negatives, as for $\mathbb{Z}$, keeps the set countable. An injection $\mathbb{N} \to \mathbb{Q}$ is obvious ($n \mapsto n$), so by Schröder–Bernstein $|\mathbb{Q}| = \aleph_0$. $\square$

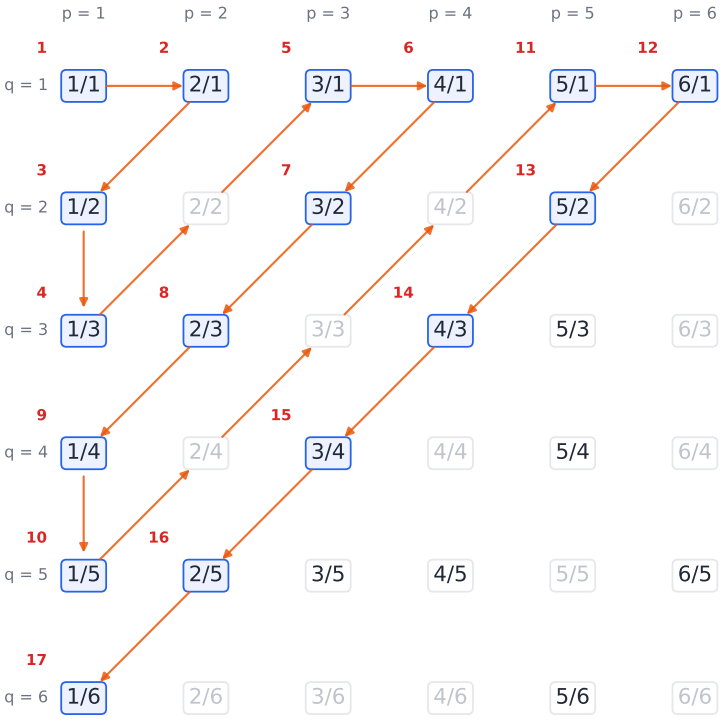

Figure 64.2 — Cantor's zig-zag through the positive fractions, with p across and q down. Each reduced fraction gets a finite position (red numbers); grey fractions such as $2/4$ are skipped because their value already appeared. Every positive rational is reached after finitely many steps.

The same proof houses the hotel's third night: call the guests already in the hotel "coach 0", number coaches and seats from 0, and put seat k of coach c in room $\pi(c, k) + 1$. More generally, a countable union of countable sets is countable, and so are $\mathbb{N}^3$, $\mathbb{N}^{17}$, the set of all finite strings over a finite alphabet, the set of all polynomials with integer coefficients, and the set of all Python programs. That last one will matter.

The diagonal argument

Now the fourth night. Let $\{0,1\}^{\mathbb{N}}$ be the set of infinite binary sequences $s = (s(0), s(1), s(2), \dots)$.

> **Theorem 64.2 — Cantor (1891): binary sequences are uncountable**
>
> No list $s_0, s_1, s_2, \dots$ of binary sequences contains every binary sequence.

Proof. Take any list. Define a new sequence d by flipping the diagonal:

$$d(k) = 1 - s_k(k) \qquad (k = 0, 1, 2, \dots).$$

For each k, d differs from s_k in position k, so $d \neq s_k$. Hence d is not on the list. □

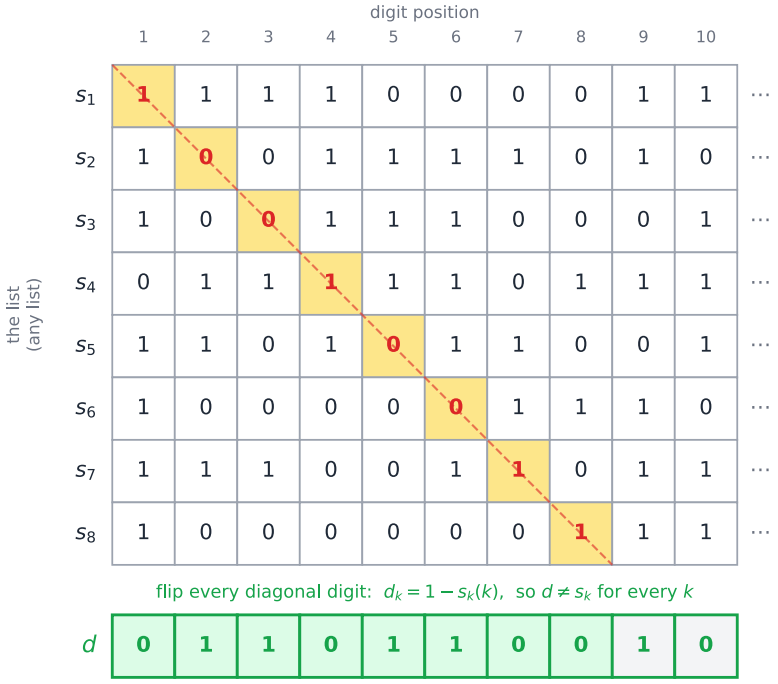

Figure 64.3 — The diagonal argument. Whatever the list, read down the diagonal and flip each digit. The result d disagrees with row k in column k, so it is not any row. The grey tail stands for the digits beyond the drawn part, also flipped from the diagonal of rows further down.

The proof is so short it can feel like a trick. Probe it. "Just add d to the front of the list." Fine: the new list has its own diagonal, and a new d' escapes it. "Then the list was infinite, so perhaps d is at position ∞." There is no such position: every entry of a list sits at a finite index k, and d has been made to differ from the entry at index k, for every k. The argument does not say any particular list is bad; it says *every* list is.

Now transfer the result to the real numbers. Each $x \in (0,1)$ has a decimal expansion $0.x_1x_2x_3\ldots$, unique if we forbid expansions ending in an infinite run of 9s. Given any list $r_1, r_2, \ldots$ of reals in $(0,1)$, define x by its digits: $x_k = 5$ if the k-th digit of r_k is not 5, and $x_k = 4$ if it is. Then x differs from r_k in the k-th digit, and because x uses only the digits 4 and 5, it has no second expansion that could secretly coincide with r_k. So x is not on the list, and:

Corollary — the reals are uncountable

$|\mathbb{N}| < |\mathbb{R}|$. In fact $|\mathbb{R}| = |(0,1)| = |\{0,1\}^{\mathbb{N}}|$, a cardinality written $2^{\aleph_0}$ or $\mathfrak{c}$ (the continuum).

The bijection $(0,1) \to \mathbb{R}$ is $x \mapsto \tan(\pi(x - \tfrac{1}{2}))$, which you can drag around in §64.5; the equality with $\{0,1\}^{\mathbb{N}}$ follows from Schröder–Bernstein using binary and decimal expansions as the two injections. A startling consequence: the rationals are countable, so "almost all" real numbers are irrational. Algebraic numbers (roots of integer polynomials, like $\sqrt{2}$) are countable too, since there are countably many polynomials and each has finitely many roots, so almost all reals are **transcendental**, even though proving that one specific number like π is transcendental is hard. Cantor's argument gives you infinitely many without naming a single one, the non-constructive style of Theorem 63.3 in Ch. 63.

? Numbers nobody can ever name

Every number you can describe, by a formula, a program that prints its digits, or a sentence in English, comes from a description, and descriptions are finite strings: there are only countably many. So all but countably many real numbers can never be specified, computed, or written down by anyone, ever. What does it mean to say such numbers *exist*? Which numbers can a machine compute, and is there a definable number that no machine can compute? Ch. 30 meets the first uncomputable objects, and Ch. 68 asks what "definable" can even mean.

A ladder of infinities

Cantor's argument generalises from $\mathbb{N}$ to any set whatsoever. Write $\mathcal{P}(A)$ for the **power set** of A, the set of all subsets of A. A binary sequence is just a subset of $\mathbb{N}$ in disguise ($s(k) = 1$ means "k is in"), so Theorem 64.2 says $|\mathbb{N}| < |\mathcal{P}(\mathbb{N})|$.

Theorem 64.3 — Cantor's theorem

For every set A, $|A| < |\mathcal{P}(A)|$.

Proof. The map $a \mapsto \{a\}$ is an injection $A \to \mathcal{P}(A)$, so $|A| \le |\mathcal{P}(A)|$. Suppose for contradiction that some $f : A \to \mathcal{P}(A)$ is a bijection; we only need that it is surjective. Define the "diagonal" set

$$D = \{a \in A : \ a \notin f(a)\}.$$

D is a subset of A, so by surjectivity $D = f(d)$ for some $d \in A$. Is $d \in D$? If $d \in D$, then by the definition of D, $d \notin f(d) = D$. If $d \notin D$, then $d \notin f(d)$, so by definition $d \in D$. Either way we contradict ourselves, so no surjection exists. □

So there is no largest infinity:

$$\aleph_0 = |\mathbb{N}| < |\mathcal{P}(\mathbb{N})| = |\mathbb{R}| < |\mathcal{P}(\mathbb{R})| < |\mathcal{P}(\mathcal{P}(\mathbb{R}))| < \cdots$$

The set of all real functions $\mathbb{R} \to \mathbb{R}$ already sits on the third rung: it has cardinality $|\mathcal{P}(\mathbb{R})|$, strictly more than the continuum. The continuous functions, by contrast, are determined by their values on the rationals, so there are only $\mathfrak{c}$ of them. Most functions are wildly discontinuous, which is one reason analysis restricts which functions it talks about (Ch. 60).

> **? The rung that might not exist**
>
> $\aleph_0 < \mathfrak{c}$. Is there any set strictly bigger than $\mathbb{N}$ but strictly smaller than $\mathbb{R}$? Cantor believed not (the **continuum hypothesis**) and spent years failing to prove it. Hilbert put it first on his famous 1900 list of problems. The eventual answer, from Gödel (1940) and Paul Cohen (1963), is one of the strangest in mathematics, and it is not "yes" and it is not "no". What else could it be? See Ch. 68.

Ordinals: counting past infinity

Cardinals answer "how many?". **Ordinals** answer "in what position?". For finite sets the two coincide, but for infinite ones they split. List the natural numbers $0, 1, 2, \ldots$ and then put one more element after all of them:

$$0,\ 1,\ 2,\ 3,\ \ldots\ ;\ \omega.$$

The new element sits at position ω, the first infinite ordinal. Keep going: $\omega + 1,\ \omega + 2,\ \ldots,\ \omega \cdot 2,\ \omega \cdot 2 + 1,\ \ldots,\ \omega \cdot 3,\ \ldots,\ \omega^2,\ \ldots,\ \omega^\omega,\ \ldots$. Each of these is the *order type* of a **well-ordering**: an ordering in which every non-empty subset has a least element. The order $0, 1, 2, \ldots\ ; \omega$ is a different shape from $0, 1, 2, \ldots$ (it has a last element; $\mathbb{N}$ does not), yet as a set it is still countable: it has cardinality $\aleph_0$. So ω and $\omega + 1$ are different ordinals with the same cardinal.

Ordinal arithmetic is arithmetic of arrangements, and it is not commutative. $1 + \omega$ means "one element, then a copy of $\mathbb{N}$", which is just a copy of $\mathbb{N}$ again, so $1 + \omega = \omega$. But $\omega + 1$ means "a copy of $\mathbb{N}$, then one more", which has a last element, so $\omega + 1 \neq \omega$. Hilbert's hotel lives in cardinals, where $1 + \aleph_0 = \aleph_0 + 1 = \aleph_0$; ordinals are what you get when the *queue order* matters.

Why care? Because well-orderings are exactly what induction needs. Ch. 29 proved termination of a loop by a variant that decreases in $\mathbb{N}$ (§29.3). Some programs need more: a process whose "remaining work" is a pair (a, b) ordered lexicographically can make b jump up arbitrarily far each time a drops by one, so no single natural number bounds the number of steps, yet the process must stop because $\omega \cdot \omega = \omega^2$ is well-ordered. **Transfinite induction** extends proof by induction along any ordinal: if a property passes from all smaller ordinals to the next one, it holds for all of them.

Why axioms?

So far a "set" has been any collection we can describe. That freedom is fatal. Consider $R = \{x : x \notin x\}$, the set of all sets that are not members of themselves. Is $R \in R$? The proof of Theorem 64.3 runs again, with f the identity, and both answers contradict themselves. This is **Russell's paradox** (1901), and it showed that "any describable collection is a set" is inconsistent. Its full story, and its cousins, are in Ch. 68.

The repair, settled by Zermelo, Fraenkel and others by the 1920s, is to say precisely which sets exist. The standard list is **ZFC** (Zermelo–Fraenkel with Choice). Roughly:

Axiom	It says
Extensionality	sets with the same elements are equal
Empty set, pairing, union	$\varnothing$, $\{a, b\}$ and $\bigcup A$ exist
Separation	for a set A and a property P, $\{x \in A : P(x)\}$ exists (only *inside* an existing set)
Power set	$\mathcal{P}(A)$ exists
Infinity	an infinite set exists (one containing $\varnothing$ and closed under $x \mapsto x \cup \{x\}$)
Replacement	the image of a set under a definable function is a set
Foundation	no infinite descending chain $\cdots \in x_2 \in x_1 \in x_0$
Choice	from any family of non-empty sets one can choose one element from each

Separation is the key restriction: you may carve a subset out of a set you already have, but not conjure $\{x : P(x)\}$ from nothing. Russell's R is never built. And from these axioms the whole of ordinary mathematics can be constructed: $0 = \varnothing$, $1 = \{0\}$, $2 = \{0, 1\}$, $n + 1 = n \cup \{n\}$, so each natural number is the set of the ones before it, and $\omega = \{0, 1, 2, \ldots\}$ is the set the axiom of infinity provides. Integers are classes of pairs of naturals, rationals classes of pairs of integers, and reals are built from rationals by Dedekind cuts or Cauchy sequences (Ch. 60). Every object in this book, from a phasor to a probability space (Ch. 19), is, at bottom, a set.

64.4 The algorithm

Countability *is* an algorithm: a set is countable exactly when you can write a procedure that, run forever, outputs every element at some finite time. Here are two enumerations of the positive rationals and a diagonaliser.

Cantor pairing and its inverse. The bijection of Theorem 64.1 can be inverted in constant time with an integer square root: given z, the diagonal is $s = \lfloor (\sqrt{8z + 1} - 1)/2 \rfloor$, then $q = z - s(s + 1)/2$, $p = s - q$. For example $\pi(3, 4) = 32$ and $\pi(4, 3) = 31$. Use `math.isqrt`, not floating `sqrt`: for z above about 10^{15} a double cannot hold $8z + 1$ exactly and the floor can land on the wrong diagonal.

The Calkin–Wilf sequence. Skipping non-reduced fractions, as in Figure 64.2, wastes work. A cleverer enumeration visits every positive rational *exactly once* with no gcd tests at all:

$$x_0 = 1, \qquad x_{n+1} = \frac{1}{2\lfloor x_n \rfloor - x_n + 1},$$

giving $1,\ \frac{1}{2},\ 2,\ \frac{1}{3},\ \frac{3}{2},\ \frac{2}{3},\ 3,\ \frac{1}{4},\ \frac{4}{3},\ \frac{3}{5},\ \frac{5}{2},\ \frac{2}{5},\ \frac{5}{3},\ \frac{3}{4},\ 4, \ldots$ (Newman's formula for the Calkin–Wilf tree). Each step costs $O(1)$ operations on exact fractions. Do it with floating point and the sequence drifts after a few dozen terms: the map is exact only on exact rationals.

A diagonaliser. Given *any* enumerator, a function `s(k, i)` returning digit i of the k-th sequence, the procedure `d(i) = 1 - s(i, i)` computes a sequence missing from the enumeration. This is an algorithm that defeats every algorithm of a given kind, and that idea is the engine of Ch. 30: feed it an enumeration of all programs and you get a function no program computes.

64.5 The experiment

The script enumerates rationals by Calkin–Wilf, checks that no value repeats and none is missed, and then diagonalises against a list of your choice.

```
from fractions import Fraction
from math import floor, gcd

N = 4100                        # knob: how many Calkin-Wilf terms to generate
M = 12                          # knob: check every p/q with p, q <= M appears

x, seen = Fraction(1), []
for _ in range(N):
    seen.append(x)
    x = 1 / (2 * floor(x) - x + 1)

print("repeats:", len(seen) - len(set(seen)))
wanted = {Fraction(p, q) for p in range(1, M + 1) for q in range(1, M + 1)}
missing = wanted - set(seen)
print(f"p/q with p,q<={M}: {len(wanted)} values, missing from first {N}: {len(missing)}")
print("first 10:", [str(f) for f in seen[:10]])

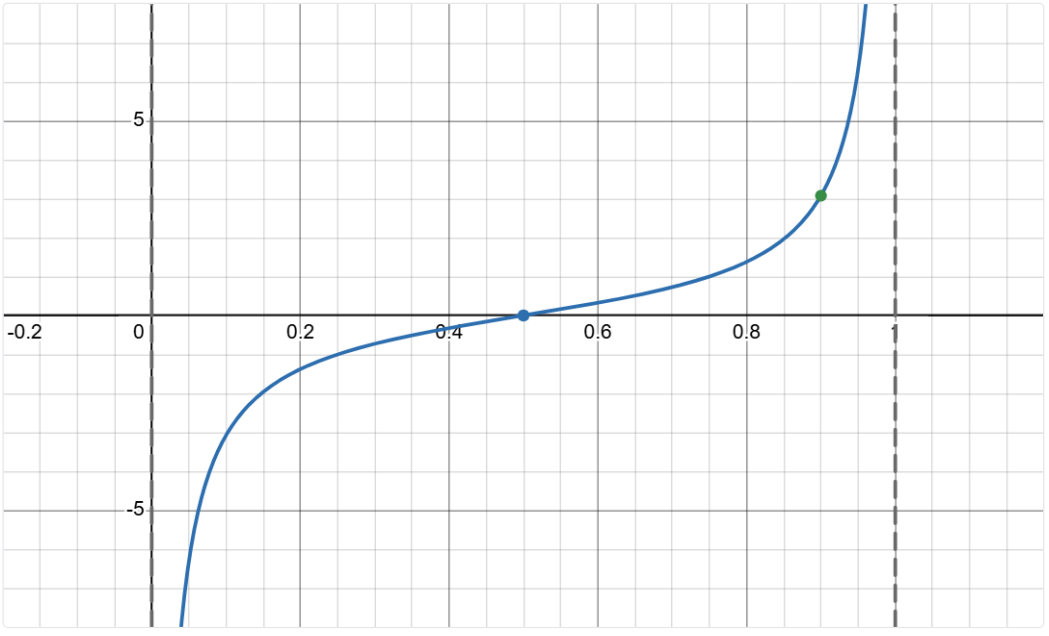
# Diagonalise: the k-th row is the binary expansion of the k-th rational in (0,1)
ROWS = 16                       # knob: size of the list we defeat
rats = [f for f in seen if f < 1][:ROWS]
def digit(f, i):                # i-th binary digit of f after the point
    return floor(f * 2 ** (i + 1)) % 2
d = [1 - digit(rats[k], k) for k in range(ROWS)]
for k, f in enumerate(rats):
    row = "".join(str(digit(f, i)) for i in range(ROWS))
    print(f"{str(f):>6}  {row}   differs from d at digit {k}")
print("     d  " + "".join(map(str, d)))
```

With the defaults it reports 0 repeats and that all 91 distinct values with $p, q \le 12$ appear among the first 4100 terms (the last to arrive is 12 itself, at position 4094), then prints 16 rows and the escaping sequence d.

Things to try:

1. Lower `N` to 2000 and count what goes missing. Which fractions with $p, q \le 12$ arrive *last*? (Print the positions of $1/M$ and M for several M.) How many terms does Calkin–Wilf need, as a function of M, to reach all of them, and what does that say about using it to enumerate "small" fractions?
2. Replace the Calkin–Wilf step with floating point, `x = 1 / (2*floor(x) - x + 1)` on a `float`. After how many terms does it produce a value that is not a fraction with small denominator, or repeat one?
3. Now the deep one: d is the binary expansion of *some* real number in $[0, 1]$. Increase `ROWS`. Is that number rational? (Is it on the full infinite list?) Explain why the answer must be no, no matter how large `ROWS` is.

The bijection between the interval $(0, 1)$ and the whole real line is easy to see:



The map $x \mapsto \tan(\pi(x - \frac{1}{2}))$ sends the short interval $(0, 1)$ onto all of $\mathbb{R}$, one-to-one. Replace $\tan(\pi(x - 0.5))$ with $\frac{x-0.5}{x(1-x)}$, an algebraic bijection: as many points in a unit interval as on the entire line.

64.6 The challenge

No answers are given.

1. **Intuition.** On the fourth night the manager tries this: "Order the passengers by how many 1s their string has, and give out rooms in that order." Find the exact point at which her plan breaks down, and explain why no repair of the same kind can work.
2. **Derivation.** Prove that $|[0, 1]| = |(0, 1)|$ by constructing an explicit bijection. (Hint: Hilbert's hotel. Pick the countable set $\{\frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \dots\}$ inside $(0, 1)$ and shift it to make room for the two endpoints.) Then prove $|\mathbb{R}^2| = |\mathbb{R}|$ by interleaving digits, and deal carefully with the two-expansion problem.
3. **Implementation.** Write a generator that enumerates every finite list of natural numbers exactly once (for example, using Cantor pairing repeatedly, or by ordering lists by "length plus sum"). Check by brute force that your first 10,000 outputs have no repeats and include every list of length ≤ 3 with entries ≤ 5. Then explain why no generator can enumerate every *infinite* list.
4. **Open investigation.** In the Calkin–Wilf sequence, let $n(p/q)$ be the position of the reduced fraction p/q. Plot $\log_2 n(p/q)$ against $p + q$ for all $p, q \leq 200$. The sequence is related to Stern's diatomic sequence and to continued fractions. Find empirically which fractions with a given $p + q$ appear earliest and latest, and try to explain the pattern in terms of the continued-fraction expansion of p/q.

64.7 Loose threads

We have answered the hook. Infinities are compared by matching, not counting. By that measure $\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Q}$ and every set of finite descriptions all have the same size $\aleph_0$, while the reals, the binary sequences and the passengers of the fourth night form a strictly larger infinity, because the diagonal argument defeats every attempted list. Cantor's theorem then builds an endless ladder of larger infinities, and ordinals let us count past ω in a well-ordered queue that supports induction.

What we have not done:

- **We used the axioms without asking whether they are safe.** ZFC was built to stop Russell's paradox. Does it stop *every* paradox? Can ZFC prove its own consistency? The answer, which Ch. 68 reveals, is a theorem about all sufficiently strong systems, and it is not the answer anyone hoped for.
- **We used the axiom of choice silently.** "A countable union of countable sets is countable" needs it: you must *choose* an enumeration of each set. Choice also proves that a solid ball can be cut into finitely many pieces and reassembled into two balls of the same size (Banach–Tarski). Should we believe it? See Ch. 68, and Ch. 60 for why the pieces cannot have a volume.
- **We never said what "proof from axioms" means.** ZFC is a list of sentences, but what are the legal moves from them? Is every true statement about sets provable from them? That is what a formal system makes precise, and it is where we go next, in Ch. 65.

A puzzle to carry forward. ZFC is written with countably many symbols and proves "$\mathbb{R}$ is uncountable". Yet logic, as the next chapter shows, guarantees that any consistent set of axioms like ZFC has a model, a mathematical world in which they are all true, whose underlying collection is *countable*. So there is a countable world in which "the reals are uncountable" is true. Is that a contradiction? It is called Skolem's paradox, and it is waiting for you in Ch. 65.

Chapter 65 — Mathematical Logic and Formal Systems

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 29, Ch. 63, Ch. 64 · **Leads to:** Ch. 66, Ch. 67, Ch. 68 · **Related:** Ch. 30, Ch. 56, Ch. 1 **Reading time:** ~25 min

65.1 The hook

Here is a game with three letters, M, I and U. You start with the string **MI**. You may apply any of four rules, as often as you like, in any order (here x and y stand for any strings, possibly empty):

Rule	From	You may write	Example
R1	xI	xIU	MI → MIU
R2	Mx	Mxx	MIU → MIUIU
R3	xIIIy	xUy	MIIII → MUI
R4	xUUy	xy	MUUI → MI

Your goal: produce the string **MU**.

Try it for five minutes before reading on. You will double strings with R2 to pile up I's, chop III into U with R3, delete pairs of U's with R4. You will get close, MUI, MUIU, MUUU, and never quite there. (This is Douglas Hofstadter's MU puzzle, from *Gödel, Escher, Bach*.)

Now imagine handing the puzzle to a computer. It can search systematically: all strings one rule away, then two rules away, and so on. If MU is reachable, the search will find it eventually. If MU is *not* reachable, the search runs forever, producing longer and longer strings, and never tells you anything. To know that MU is impossible, you need something the rules themselves do not give you: you need to *step outside the game and reason about it*.

That is the whole of mathematical logic in miniature. Around 1920, David Hilbert proposed to turn all of mathematics into a game like this one: fixed starting strings (axioms), fixed rules (logic), and theorems as whatever strings you can reach. He hoped to show that the game could reach every true statement and never reach a false one. This chapter is about what happened to that hope, and it is a story with a twist:

> **Can a finite set of rules, applied mechanically, produce every truth of mathematics, and nothing else?**

65.2 The big idea

Every formal system lives on two levels at once, and the whole subject is about the bridge between them.

- **Syntax** is symbols and rules. A proof is a finite list of strings, each one an axiom or obtained from earlier ones by a rule. Checking a proof needs no understanding at all: a machine can do it. We write $T \vdash \varphi$ ("T proves φ") when there is a proof of φ from the axioms T.
- **Semantics** is meaning. A **model** of T is a mathematical structure in which every axiom of T is true. We write $T \models \varphi$ ("φ is a consequence of T") when φ is true in *every* model of T.

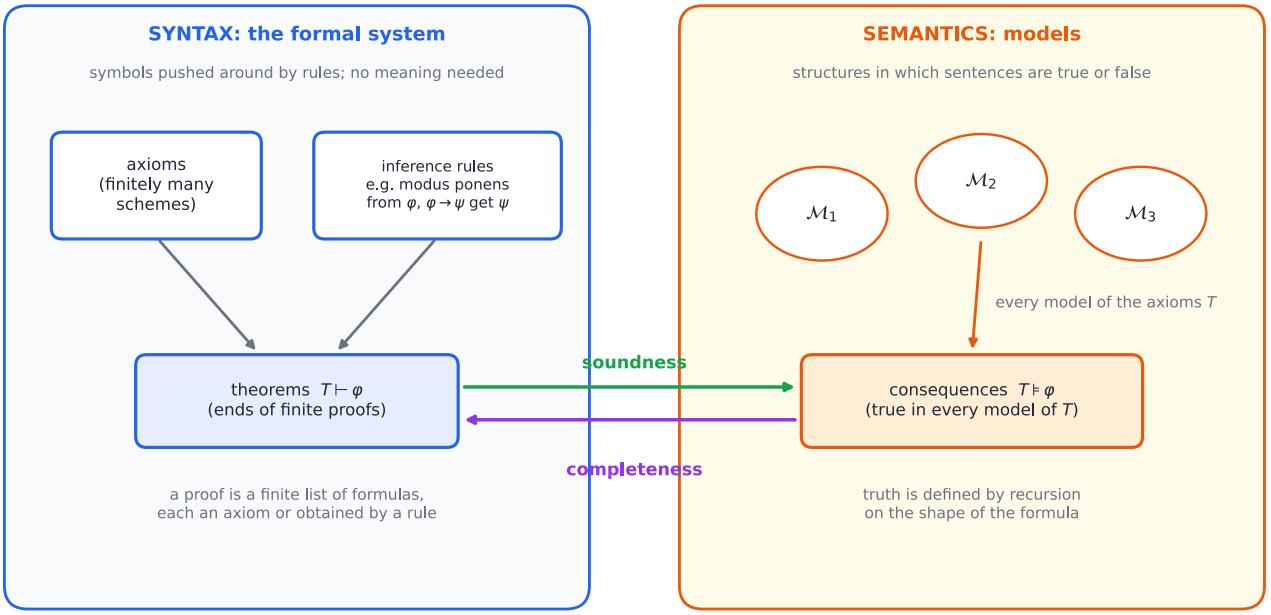

Figure 65.1 — The two worlds of logic. On the left, theorems are produced by pushing symbols; on the right, consequences are determined by truth in models. Soundness says the left never outruns the right; completeness says it always keeps up.

A programmer knows this split already. A type checker works on syntax: it inspects the program text and either accepts or rejects. What the program *does* when run is semantics. A type system is *sound* if every accepted program is safe when run (no false positives), and *complete* if every safe program is accepted (no misses). Real type checkers are sound and incomplete: they reject some perfectly good programs. Logic asks the same two questions of proof rules.

Here is the plot of the chapter in one paragraph. For **first-order logic**, the logic of "for all", "there exists", "and", "not" over any structure, the answer to both questions is yes: the rules are sound and complete, and $\vdash$ and $\models$ coincide exactly (Gödel, 1929). Strange consequences follow, including mathematical worlds with "infinitely large" natural numbers. But when you fix one specific structure, the natural numbers $\mathbb{N}$ with $+$ and $\times$, and ask for rules that prove exactly the sentences *true in* $\mathbb{N}$, the answer flips to no (Gödel again, 1931). Same logician, two years apart, opposite answers.

65.3 The mathematics

First-order languages, briefly

Ch. 29 introduced predicates and quantifiers informally (§29.3). A first-order language fixes the vocabulary.

Language, structure, satisfaction

A **language** L is a set of constant symbols, function symbols and relation symbols, each with an arity. **Terms** are built from variables and constants by applying function symbols; **formulas** are built from atomic formulas ($t_1 = t_2$, or $R(t_1, \dots, t_k)$) using $\neg$, $\to$ (and the other connectives) and $\forall x$, $\exists x$. A **sentence** is a formula with no free variables.

An L**-structure** $\mathcal{M}$ is a non-empty set M (the domain) together with an interpretation of each symbol: an element for each constant, a function $M^k \to M$ for each function symbol, a relation on M^k for each relation symbol. **Truth** $\mathcal{M} \models \varphi$ is defined by recursion on φ: $\mathcal{M} \models \neg\varphi$ iff not $\mathcal{M} \models \varphi$; $\mathcal{M} \models \forall x\, \varphi(x)$ iff $\mathcal{M} \models \varphi(a)$ for every $a \in M$; and so on. $\mathcal{M}$ is a **model** of a set of sentences T if it satisfies every sentence in T.

"First-order" means the quantifiers range over *elements* of the domain, never over subsets or functions. That restriction looks minor. It is the source of everything strange below.

An example. The language of groups has one binary function symbol $\cdot$ and one constant e. The group axioms T_{grp} say that $\cdot$ is associative, e is an identity, and inverses exist (Ch. 56 develops them). Models of T_{grp} are exactly the groups: $(\mathbb{Z}, +, 0)$, the rotations of a square, the permutations of three objects. Consider the sentence $\gamma = \forall x \forall y\ (x \cdot y = y \cdot x)$. It is true in $(\mathbb{Z}, +, 0)$ and false among permutations of three objects. So γ is neither a consequence of T_{grp} nor is $\neg\gamma$. Keep this example in mind: in a moment, soundness will turn it into a proof that γ cannot be proved from the group axioms, without examining a single proof.

A proof system

To prove anything we need rules. Many equivalent systems exist; here is the classical Hilbert system for the propositional part, with $\to$ and $\neg$ as the connectives. Its axioms are all instances (for arbitrary formulas φ, ψ, χ) of

$$\begin{aligned} &\text{A1:} && \varphi \to (\psi \to \varphi) \\ &\text{A2:} && \big(\varphi \to (\psi \to \chi)\big) \to \big((\varphi \to \psi) \to (\varphi \to \chi)\big) \\ &\text{A3:} && (\neg\psi \to \neg\varphi) \to (\varphi \to \psi) \end{aligned}$$

and its only rule is **modus ponens** (MP): from φ and $\varphi \to \psi$, infer ψ. For first-order logic one adds axioms for quantifiers and equality (for example $\forall x\, \varphi(x) \to \varphi(t)$) and the rule of generalisation; we will not need the details.

Proofs in this system are notoriously unnatural. Here is a proof of the obvious-looking $\varphi \to \varphi$:

Line	Formula	Justification
1	$\varphi \to ((\varphi \to \varphi) \to \varphi)$	A1 with $\psi := \varphi \to \varphi$
2	$\big(\varphi \to ((\varphi \to \varphi) \to \varphi)\big) \to \big((\varphi \to (\varphi \to \varphi)) \to (\varphi \to \varphi)\big)$	A2 with $\psi := \varphi \to \varphi$, $\chi := \varphi$
3	$(\varphi \to (\varphi \to \varphi)) \to (\varphi \to \varphi)$	MP from 1, 2
4	$\varphi \to (\varphi \to \varphi)$	A1 with $\psi := \varphi$
5	$\varphi \to \varphi$	MP from 4, 3

Five lines, and every line checkable by pattern-matching, with no idea what φ means. That is the point. Humans write proofs in natural language; logic shows that every such proof *could* be expanded into a list like this one, and Ch. 67 shows engineers doing exactly that with proof assistants.

Soundness: the rules never lie

Theorem 65.1 — Soundness (propositional case)

If $\vdash \varphi$ in the Hilbert system, then φ is a **tautology**: it is true under every assignment of truth values to its variables.

Proof. By strong induction on the length n of a shortest proof of φ; the claim is that every line of every proof is a tautology.

Axioms. Each instance of A1–A3 is a tautology. For A1: if $\varphi \to (\psi \to \varphi)$ were false under some assignment, then φ is true and $\psi \to \varphi$ is false, which needs φ false; contradiction. A2 and A3 are checked the same way, or by an 8-row and a 4-row truth table (the script in §65.4 does it). Substituting formulas for φ, ψ, χ does not matter, because the truth value of the instance depends only on the truth values of the substituted formulas.

Modus ponens. Suppose line k is ψ, obtained from earlier lines φ and $\varphi \to \psi$, both tautologies by the induction hypothesis. Under any assignment, φ is true and $\varphi \to \psi$ is true, so ψ is true. Hence ψ is a tautology.

Every line is an axiom or comes by MP, so every line, in particular the last, is a tautology. □

The first-order version reads: **if** $T \vdash \varphi$ **then** $T \models \varphi$, and the proof is the same induction, with one extra case per quantifier rule. Soundness is a *tool for proving unprovability*. Back to the groups: γ (commutativity) is false in a model of T_{grp}, so $T_{\text{grp}} \not\models \gamma$, so by soundness $T_{\text{grp}} \nvdash \gamma$. No proof of commutativity from the group axioms exists, and we know it without searching. The MU puzzle works the same way: an invariant (the number of I's is never divisible by 3) is a "model" in which every theorem has the property and MU does not.

Completeness: the rules never miss

The converse is the deep one.

> **Theorem 65.2 — Gödel's completeness theorem (1929)**
>
> For every set of first-order sentences T and every sentence φ: if $T \models \varphi$ then $T \vdash \varphi$. Equivalently, every **consistent** T (one that does not prove a contradiction) has a model.

We state it without full proof. The idea, due to Leon Henkin (1949), is a construction worth knowing. Start with a consistent T. Add new constant symbols as "witnesses": for every sentence $\exists x\, \psi(x)$, add a constant c_ψ and the axiom $\exists x\, \psi(x) \to \psi(c_\psi)$. Then extend T, one sentence at a time, to a maximal consistent set, deciding every sentence one way or the other. Finally build a model *out of the symbols themselves*: its elements are the closed terms (modulo provable equality), and a relation holds exactly when the set says it does. The model is made of syntax. And because the language had countably many symbols, the model is countable, which gives a theorem we will need:

> **Löwenheim–Skolem theorem (downward)**
>
> If a set of sentences in a countable language has a model, it has a countable model.

This settles the puzzle left at the end of Ch. 64. If ZFC is consistent, it has a countable model $\mathcal{M}$, and inside $\mathcal{M}$ the sentence "$\mathbb{R}$ is uncountable" is true. There is no contradiction, because "uncountable" means "there is no bijection with $\mathbb{N}$", and inside $\mathcal{M}$ that means "no bijection *that is an element of* $\mathcal{M}$". The bijection that we, outside, can see is simply not one of $\mathcal{M}$'s sets. "Countable" turns out to be relative to the world you are standing in.

Compactness: infinity from finite pieces

Proofs are finite. That trivial fact, combined with completeness, has an astonishing consequence.

> **Theorem 65.3 — Compactness**
>
> A set of first-order sentences T has a model if and only if every finite subset of T has a model.

Proof. If T has a model, so does every subset. Conversely, suppose every finite subset of T has a model, but T does not. Then T is inconsistent by the completeness theorem (in its second form), so there is a proof of a contradiction, say $\chi \wedge \neg\chi$, from T. That proof is a finite list of formulas, so it uses only finitely many axioms of T; call them T_0. Then $T_0 \vdash \chi \wedge \neg\chi$, and by soundness every model of T_0 satisfies $\chi \wedge \neg\chi$, which is impossible, so T_0 has no model. But T_0 is a finite subset of T. Contradiction. □

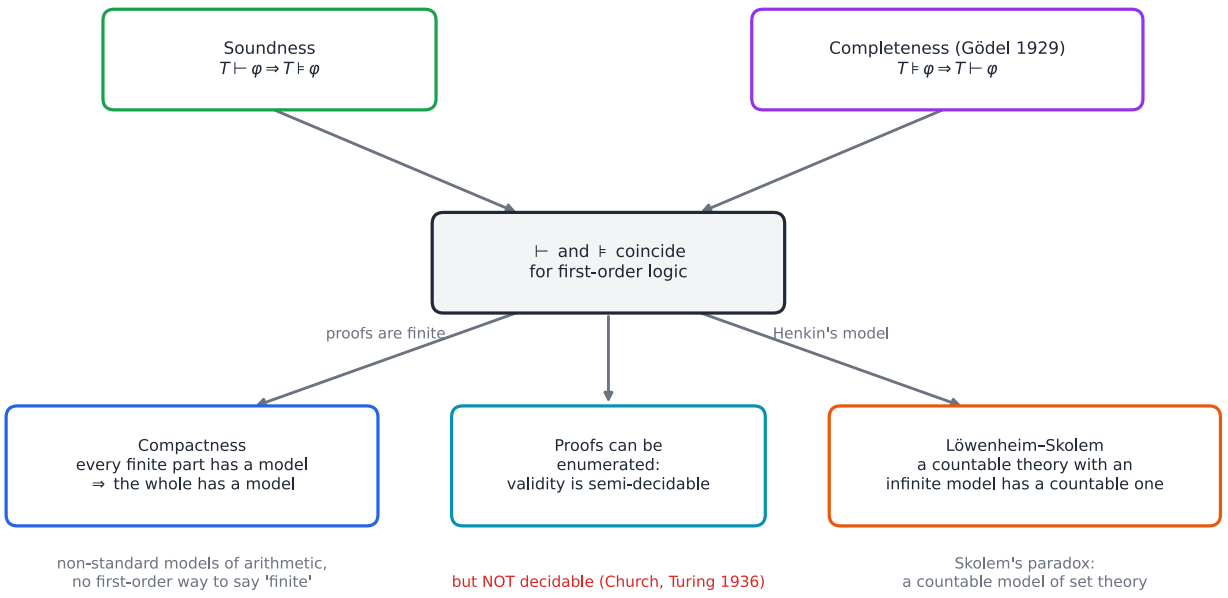

Figure 65.2 — How the big theorems of first-order logic hang together. Soundness and completeness together make provability and truth-in-all-models the same relation; compactness, Löwenheim–Skolem and the mechanical enumerability of theorems all follow, along with some very strange models.

Now watch compactness do something unsettling.

Theorem 65.4 — Non-standard models of arithmetic

Let $\mathrm{Th}(\mathbb{N})$ be the set of *all* first-order sentences in the language $\{0, S, +, \times, <\}$ that are true in the natural numbers. There is a model of $\mathrm{Th}(\mathbb{N})$ containing an element larger than every natural number.

Proof. Add a new constant symbol c, and let $\underline{n}$ be the term $S(S(\cdots S(0)))$ with n copies of S (the numeral for n). Consider

$$T = \mathrm{Th}(\mathbb{N}) \cup \{\, \underline{n} < c \;:\; n = 0, 1, 2, \dots \}.$$

Any finite subset of T mentions only finitely many of the new axioms, say up to $\underline{N} < c$. Interpret c as the number $N + 1$ in the ordinary natural numbers: every sentence of $\mathrm{Th}(\mathbb{N})$ is true there by definition, and so is $\underline{n} < c$ for every $n \le N$. So every finite subset has a model. By compactness, T has a model $\mathcal{M}$. It satisfies every true sentence of arithmetic, and its element $c^{\mathcal{M}}$ is larger than $\underline{n}^{\mathcal{M}}$ for every n. $\square$

Sit with that. $\mathcal{M}$ agrees with $\mathbb{N}$ on *every* first-order sentence: every theorem of number theory you have ever met, every statement about primes, holds in $\mathcal{M}$. Yet $\mathcal{M}$ contains an "infinite" natural number c, and with it $c + 1$, $c - 1$, $2c$, c^2, a whole galaxy of non-standard numbers beyond the standard ones. No first-order sentence can tell $\mathcal{M}$ and $\mathbb{N}$ apart. In particular, "x is a standard number" (equivalently, "the set of things below x is finite") cannot be written in first-order arithmetic at all. Induction itself is the casualty: the first-order induction *scheme* cannot pin down $\mathbb{N}$, because it can only talk about definable properties, and "standard" is not one.

Incompleteness: where the bridge breaks

Completeness says: anything true in *every* model of T is provable from T. It does not say anything is provable that is true in *one particular* model. And for arithmetic, the one model we care about is $\mathbb{N}$.

Peano arithmetic (PA) is the first-order theory with axioms saying 0 is not a successor, S is injective, $+$ and $\times$ obey their recursive definitions ($x + 0 = x$, $x + S(y) = S(x + y)$, $x \cdot 0 = 0$, $x \cdot S(y) = x \cdot y + x$), plus the induction scheme: for every formula $\psi(x)$,

$$\big(\psi(0) \wedge \forall x\, (\psi(x) \to \psi(S(x)))\big) \to \forall x\, \psi(x).$$

PA proves essentially all of elementary number theory. Hilbert hoped that it, or something like it, proves *every* true sentence about $\mathbb{N}$.

Gödel's first incompleteness theorem (1931), stated

Let T be any consistent set of axioms that can be listed by an algorithm and that includes PA (or even a weak fragment of it). Then there is a sentence G_T in the language of arithmetic such that $T \nvdash G_T$ and $T \nvdash \neg G_T$. Moreover G_T is true in $\mathbb{N}$.

The idea, which we only sketch: code formulas and proofs as numbers (**Gödel numbering**), so that "p is the code of a proof of the formula with code q" becomes an arithmetic relation between p and q, checkable by an algorithm and hence expressible in the language of PA. Then build a sentence G_T that says, in effect, "*there is no number that codes a T-proof of me*". If T proved G_T, there would be such a number, and T would prove that too, so T would be inconsistent. So T does not prove G_T, which is exactly what G_T says: it is true.

How does that square with completeness? G_T is true in $\mathbb{N}$ but not provable, so by completeness it must be *false in some other model of T*. That model is non-standard, and in it there is a non-standard number that the model "believes" codes a proof of G_T: an infinitely long proof that only a non-standard world could contain. Completeness and incompleteness are not in conflict. The gap between them is precisely the gap between $\mathbb{N}$ and the strange models of Theorem 65.4.

? The sentence that talks about itself

The sketch above leaned on a sentence that says "I am not provable". But sentences of arithmetic talk about numbers: additions, multiplications, inequalities. How can a sentence about numbers refer to *itself*, without circularity, and without falling into the liar paradox "this sentence is false"? The tool is Gödel's **diagonal lemma**, a cousin of Cantor's diagonal argument and of Turing's halting proof in Ch. 30. Its construction, and what it does to Hilbert's dream, are in Ch. 68.

65.4 The algorithm

Logic is full of algorithms, and the line between what can and cannot be automated is sharp.

Checking a proof is easy and fast: for each line, check that it matches an axiom scheme or follows by a rule from earlier lines. Time is polynomial (essentially linear) in the length of the proof. Here is a checker for the Hilbert system, which also verifies by truth tables that the axioms are tautologies, the base case of Theorem 65.1. Formulas are nested tuples: `('->', a, b)`, `('~', a)`, or a variable name.

```
from itertools import product

def imp(a, b): return ('->', a, b)
def neg(a): return ('~', a)
A1 = lambda p, q: imp(p, imp(q, p))
A2 = lambda p, q, r: imp(imp(p, imp(q, r)), imp(imp(p, q), imp(p, r)))
A3 = lambda p, q: imp(imp(neg(q), neg(p)), imp(p, q))

def value(f, env):
    if isinstance(f, str): return env[f]
    if f[0] == '~': return not value(f[1], env)
    return (not value(f[1], env)) or value(f[2], env)

def atoms(f):
    return {f} if isinstance(f, str) else set().union(*map(atoms, f[1:]))

def tautology(f):
    vs = sorted(atoms(f))
    return all(value(f, dict(zip(vs, bits))) for bits in product([False, True], repeat=len(vs)))

print("A1..A3 tautologies:", tautology(A1('p', 'q')), tautology(A2('p', 'q', 'r')), tautology(A3('p', 'q')))

def check(proof):          # each line: (formula, 'AX') or (formula, ('MP', i, j))
    for k, (f, why) in enumerate(proof):
        if why == 'AX':
            assert tautology(f), f"line {k}: not an axiom instance we trust"
        else:
            _, i, j = why
            assert i < k and j < k and proof[j][0] == imp(proof[i][0], f), f"line {k}: bad MP"
    return proof[-1][0]

p = 'p'
proof = [(A1(p, imp(p, p)), 'AX'), (A2(p, imp(p, p), p), 'AX'), (imp(A1(p, p), imp(p, p)), ('MP', 0, 1)),
         (A1(p, p), 'AX'), (imp(p, p), ('MP', 3, 2))]
print("proved:", check(proof))
```

(For brevity the checker accepts any tautology as an axiom line; a strict one would pattern-match the three schemes, as challenge 3 asks.)

Deciding truth is another matter.

- *Propositional logic* is decidable: a formula with n variables is a tautology iff all 2^n rows of its truth table say true, so `tautology` above always halts, in time $O(2^n \cdot \text{size})$. Whether one can do fundamentally better is the P versus NP question of Ch. 30.
- *First-order logic* is **semi-decidable**. Completeness means that $\models \varphi$ iff some proof of φ exists, and proofs are finite strings, so enumerate all strings in order of length and run the checker on each. If φ is valid, this finds a proof eventually. If φ is not valid, it runs forever, exactly like the search for MU. Church and Turing (1936) proved that nothing better is possible in general: validity of first-order sentences is **undecidable**, by reduction from the halting problem.
- *Truth in* $\mathbb{N}$ is worse still: it is not even semi-decidable. If it were, we could list all true sentences of arithmetic and use that list as an axiom system, which incompleteness forbids.

In practice, automated theorem provers (resolution, superposition, SMT solvers) replace blind enumeration with clever search and succeed astonishingly often. They can never succeed always.

65.5 The experiment

The script runs breadth-first search over the MIU system, the "blind enumeration of theorems" of §65.4, with a cap on string length, and compares what it finds with the invariant.

```
from collections import deque
from itertools import product

CAP = 10          # knob: longest string the search may visit (try 10, 14, 18)
TARGET = "MU"     # knob: try "MUI", "MIIU", "MUIIU", "MIIIIIIU"

def successors(s):
    if s.endswith("I"):
        yield s + "U"                                # R1
    yield "M" + s[1:] * 2                            # R2
    for i in range(1, len(s) - 2):
        if s[i:i + 3] == "III":
            yield s[:i] + "U" + s[i + 3:]            # R3
    for i in range(1, len(s) - 1):
        if s[i:i + 2] == "UU":
            yield s[:i] + s[i + 2:]                  # R4

seen, queue = {"MI": 0}, deque(["MI"])
while queue:
    s = queue.popleft()
    for t in successors(s):
        if len(t) <= CAP and t not in seen:
            seen[t] = seen[s] + 1
            queue.append(t)

print(f"theorems found with length <= {CAP}: {len(seen)}")
print(f"{TARGET}:", f"derived in {seen[TARGET]} steps" if TARGET in seen else "not found")

# The invariant: number of I's is never divisible by 3
print("invariant holds on all found:", all(s.count("I") % 3 != 0 for s in seen))

# Every short string allowed by the invariant: did the search find it?
L = 6
allowed = {"M" + "".join(w) for n in range(L) for w in product("IU", repeat=n)
           if "".join(w).count("I") % 3 != 0}
found = {s for s in seen if len(s) <= L}
print(f"strings of length <= {L} allowed by invariant: {len(allowed)}, found: {len(found)}")
```

With `CAP = 10` it finds 87 theorems, does not find MU, confirms the invariant, and finds only 32 of the 42 short strings the invariant permits.

Things to try:

1. Raise `CAP` to 14. Now all 42 short strings appear (634 theorems in all). Why did some *short* theorems need *long* intermediate strings? Find one and trace its derivation.
2. Set `TARGET = "MIIU"`, then `"MUIIU"`. Record the number of steps. Then raise `CAP` to 18 and check whether the step counts change: the search might find shorter derivations through longer strings.
3. The experiment suggests a conjecture: *a string is a theorem if and only if it is M followed by I's and U's with the number of I's not divisible by 3.* The "only if" half is the invariant. Can you see how to prove the "if" half? (It is true. Think about how R2 doubles the I-count modulo 3, and how R3 and R4 tidy up.)

Notice the asymmetry: raising `CAP` can only *add* theorems, so no run of the search ever establishes that MU is missing. That proof came from outside, from arithmetic modulo 3.

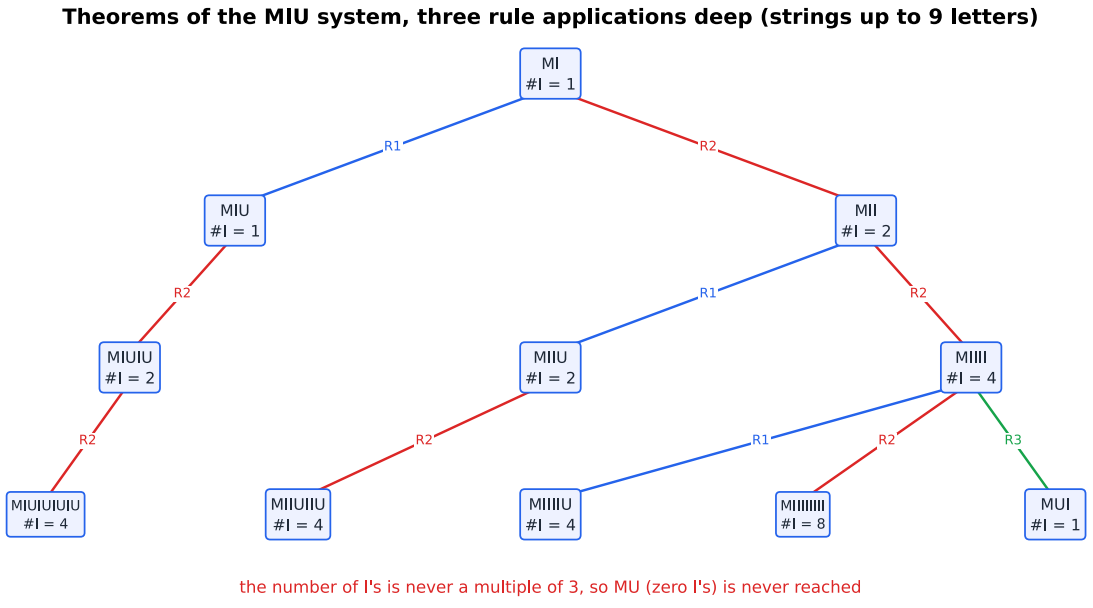

Figure 65.3 — The first three levels of the MIU search tree, coloured by rule, with the count of I's in each box. R2 doubles the count, R3 subtracts 3, R1 and R4 leave it unchanged. Modulo 3, doubling swaps 1 and 2 and subtracting 3 changes nothing, so a count that starts at 1 can never become a multiple of 3.

65.6 The challenge

No answers are given.

1. **Intuition.** In the language with one binary relation $<$, write first-order axioms for a strict linear order (irreflexive, transitive, any two distinct elements comparable). Which of $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$, $(\mathbb{Q}, <)$, $(\mathbb{R}, <)$ are models? Use soundness to show that neither "there is a least element" nor "between any two elements lies a third" can be proved from your axioms, and that neither of their negations can be proved either.
2. **Derivation.** Using compactness, prove that if a first-order theory has arbitrarily large finite models, then it has an infinite model. (Hint: add sentences λ_n saying "there are at least n distinct elements".) Deduce that no set of first-order sentences in the language of groups has exactly the finite groups as its models.
3. **Implementation.** Extend the checker in §65.4 so that axiom lines must match one of the schemes A1, A2, A3 exactly (write a pattern matcher that recovers φ, ψ, χ). Then write out and machine-check a Hilbert-style proof of $\neg\neg p \to p$. Expect it to be long, and record how many lines you needed.
4. **Open investigation.** Let $d(s)$ be the length of the shortest derivation of the MIU theorem s. Using the experiment with a generous `CAP`, tabulate $d(s)$ for all theorems of length ≤ 8. How does the worst case grow with length? Is the cap you need to find the shortest derivation of a length-n string bounded by a simple function of n? (There is no standard answer; you are mapping new ground.)

65.7 Loose threads

We can now answer the hook, and the answer has two halves. For first-order logic in general, **yes**: the Hilbert rules are sound (Theorem 65.1) and complete (Theorem 65.2), so a finite set of mechanical rules produces exactly the sentences true in every model, and nothing else. For the truths of one particular structure, the natural numbers, **no**: every consistent, algorithmically listable axiom system leaves some true sentence unproved (Gödel's first incompleteness theorem). Compactness explains why the two answers can coexist: first-order axioms never pin down $\mathbb{N}$ uniquely, and the unprovable truths are exactly those that fail in some non-standard twin of $\mathbb{N}$.

Three questions remain open, and each one leads onward.

> **? Can mathematics vouch for itself?**
>
> Hilbert's second hope was a proof, inside a system like PA or ZFC, that the system never proves a contradiction. Gödel's *second* incompleteness theorem says what happens if you try, and it is not good news. If our foundations cannot certify their own consistency, what exactly is our confidence in mathematics based on? See Ch. 68, along with the independence of the continuum hypothesis promised in Ch. 64.

> **? What is a proof, computationally?**
>
> Our proof system was classical: it proves $\neg\neg p \to p$ and, with it, existence claims that give no witness, like Theorem 63.3 in Ch. 63. Drop that law, and something remarkable happens: proofs of $\varphi \to \psi$ become *functions* turning evidence for φ into evidence for ψ, and the five-line proof of $\varphi \to \varphi$ in §65.3 becomes the identity function. Why, and how far does the correspondence go? Ch. 66 tells the story.

- **Proof checking is mechanical; can verification of real software be?** Proof assistants such as Lean, Coq and Isabelle are proof checkers like ours, scaled up by decades of engineering. Ch. 67 shows how they are used to prove that compilers, operating-system kernels and cryptographic code meet their specifications.

The MU puzzle had an answer that the rules could not find but a mathematician could. Gödel showed that arithmetic has statements of the same kind, and that a mathematician who writes down new rules to capture them just produces a new system with new unreachable truths. No finite set of rules ever reaches all of them.

Chapter 66 — Type Theory and the Curry–Howard Connection

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 1, Ch. 29, Ch. 63, Ch. 65 · **Leads to:** Ch. 67, Ch. 68 · **Related:** Ch. 30, Ch. 62, Ch. 64 **Reading time:** ~25 min

66.1 The hook

Here is a programming puzzle with an unusual rule. You may write only `lambda`, variables and function calls: no numbers, `if`, loops, exceptions or `None`. And `A`, `B`, `C` are unknown types: integers, images, bank accounts.

Puzzle 1. Write a function with the type

```
(A -> B) -> (B -> C) -> (A -> C)
```

That is easy. Take `f`, take `g`, take `x`, and return `g(f(x))`. It is function composition (Ch. 1, §1.9).

Puzzle 2. Write one of type `A -> (B -> A)`. Also easy: `lambda a: lambda b: a`.

Puzzle 3. Write a function with the type

```
((A -> B) -> A) -> A
```

Try it before you read on. You are handed `h`, which turns "a way to get from `A` to `B`" into an `A`. To call `h` you must supply a function `A -> B`, but you have no `B` and no way to make one. You have no `A` either: getting one is the whole point. Every attempt goes round in a circle.

Now read the three types as statements of logic, with `->` meaning "implies". Puzzle 1 says that if A implies B and B implies C, then A implies C. Puzzle 2 says that if A is true, then B implies A. Puzzle 3 is **Peirce's law**, $((A \to B) \to A) \to A$. Check its truth table (Ch. 29): it is true for every assignment of true and false to A and B. All three are tautologies.

So two tautologies have programs, and one does not, and this is no accident of Python: in any language whose functions always return, no program of type `((A -> B) -> A) -> A` exists for unknown `A` and `B`. This chapter explains why, by showing that "this type has a program" and "this statement has a proof" are the same thing. The missing program is a missing proof, in a logic slightly more demanding than the one you learned at school.

66.2 The big idea

Think of a type as a promise. A value of type `int` is evidence that an integer exists. A value of type `A -> B` is a machine that turns any evidence for `A` into evidence for `B`. That is exactly what a proof of "A implies B" does in everyday mathematics: *assume* A, then reason your way to B.

Push the analogy row by row and nothing breaks. Evidence for "A and B" is a **pair** `(a, b)`. Evidence for "A or B" is one of them *plus a label saying which*, a **tagged union** such as `Left(a)`. "False" has no evidence at all: it is the **empty type**, and a function out of it exists vacuously, so from False anything follows. "Not A" is a function `A -> Empty`.

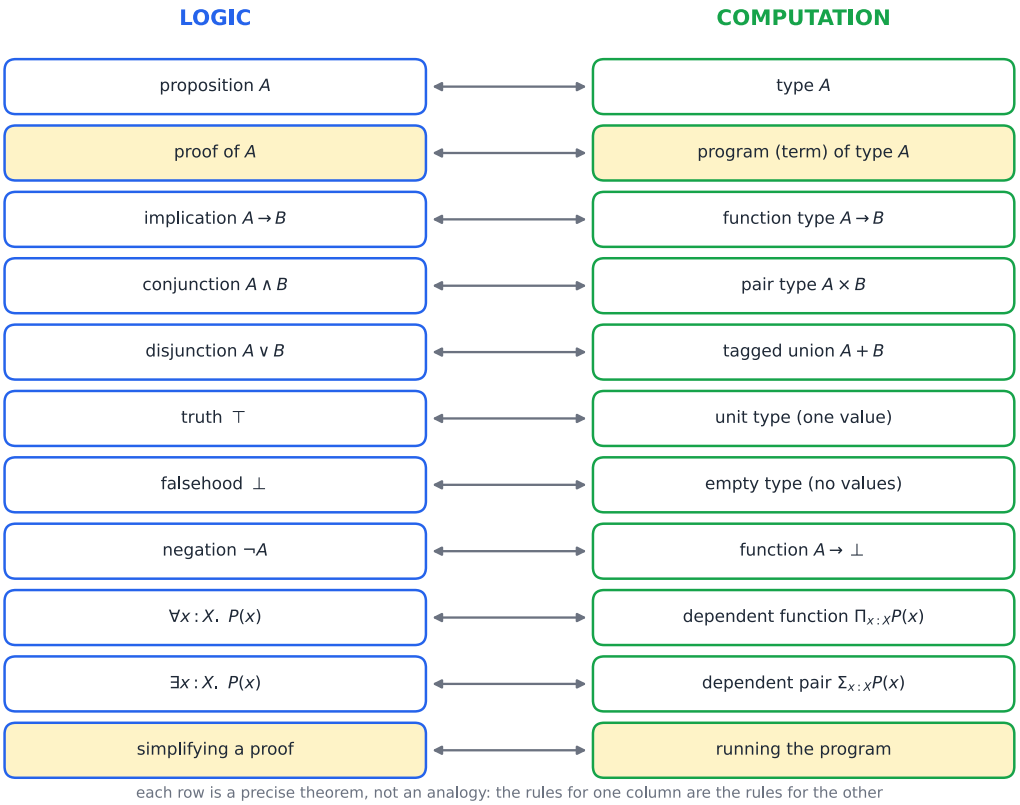

Figure 66.1 — The Curry–Howard dictionary. Propositions are types; a proof is a program of that type; and simplifying a proof is running the program. The last two rows, for quantifiers, need the dependent types of §66.3.

Haskell Curry noticed the first rows in 1934; William Howard wrote the full correspondence down in a manuscript of 1969, published in 1980.

Why does Peirce's law fail? Look at the "or" row. Evidence for $A \vee \neg A$ must say *which* side holds, and for an unknown A you cannot. Truth tables quietly assume every statement already is true or false; evidence does not. The logic you get by insisting that every proof carry its evidence is called **intuitionistic** (or constructive) logic. It is the logic hinted at in Ch. 63, where an existence proof by excluded middle failed to produce its witness. Peirce's law is a disguised form of excluded middle, so it is a classical tautology with no constructive proof.

The analogy has a second half. A proof that proves a lemma $A \to B$, proves A, then applies the lemma, contains a detour: you could have plugged the proof of A straight into the lemma's proof. In programming, that simplification is **running the code**, replacing a call by the function's body with the argument plugged in. Proof simplification and evaluation are one process.

66.3 The mathematics

The simply typed lambda calculus

We need a tiny programming language, small enough to reason about completely. Its **types** are built from atomic types $A, B, C, \ldots$ (unknowns) by

$$T ::= A \mid T_1 \to T_2 \mid T_1 \times T_2 \mid T_1 + T_2 \mid \mathbf{1} \mid \mathbf{0}.$$

Its **terms** are variables x, functions $\lambda x{:}T.\, t$, applications $t\,u$, pairs $\langle t, u\rangle$ with projections $\pi_1 t$, $\pi_2 t$, injections $\mathrm{inl}\, t$, $\mathrm{inr}\, t$ with case analysis $\mathrm{case}\, t$ of $\mathrm{inl}\, x \Rightarrow u \mid \mathrm{inr}\, y \Rightarrow v$, the unit value $\star$, and absurd t, which turns a value of the empty type into anything. We usually drop the annotation on λ.

A **context** $\Gamma = x_1{:}T_1, \ldots, x_n{:}T_n$ lists the variables in scope and their types. A **typing judgement** $\Gamma \vdash t : T$ says that in context Γ, term t has type T. Judgements are derived by rules: premises above a line, conclusion below. The rules for functions are

$$\frac{x{:}T \in \Gamma}{\Gamma \vdash x : T}\ (\mathrm{var}) \qquad \frac{\Gamma,\, x{:}A \vdash t : B}{\Gamma \vdash \lambda x.\, t : A \to B}\ (\mathrm{abs}) \qquad \frac{\Gamma \vdash t : A \to B \qquad \Gamma \vdash u : A}{\Gamma \vdash t\,u : B}\ (\mathrm{app})$$

and for pairs, sums and the empty type

$$\frac{\Gamma \vdash t : A \quad \Gamma \vdash u : B}{\Gamma \vdash \langle t, u\rangle : A \times B} \qquad \frac{\Gamma \vdash t : A \times B}{\Gamma \vdash \pi_1 t : A} \qquad \frac{\Gamma \vdash t : A}{\Gamma \vdash \mathrm{inl}\, t : A + B} \qquad \frac{\Gamma \vdash t : \mathbf{0}}{\Gamma \vdash \mathrm{absurd}\, t : C}$$

with the obvious companions for π_2, inr, $\star : \mathbf{1}$ and case (if $t : A + B$, and $u : C$ assuming $x{:}A$, and $v : C$ assuming $y{:}B$, then the case expression has type C).

Now delete every term and keep only the types. Var becomes "a hypothesis may be used". Abs becomes "if assuming A you can derive B, conclude $A \to B$ and discharge the assumption". App becomes *modus ponens*. Pairing and projection are $\wedge$-introduction and elimination, the injections are $\vee$-introduction, case is proof by cases, and absurd is *ex falso quodlibet*. These are exactly Gentzen's rules of **natural deduction** for intuitionistic logic (Ch. 65), reading $\times, +, \mathbf{1}, \mathbf{0}$ as $\wedge, \vee, \top, \bot$.

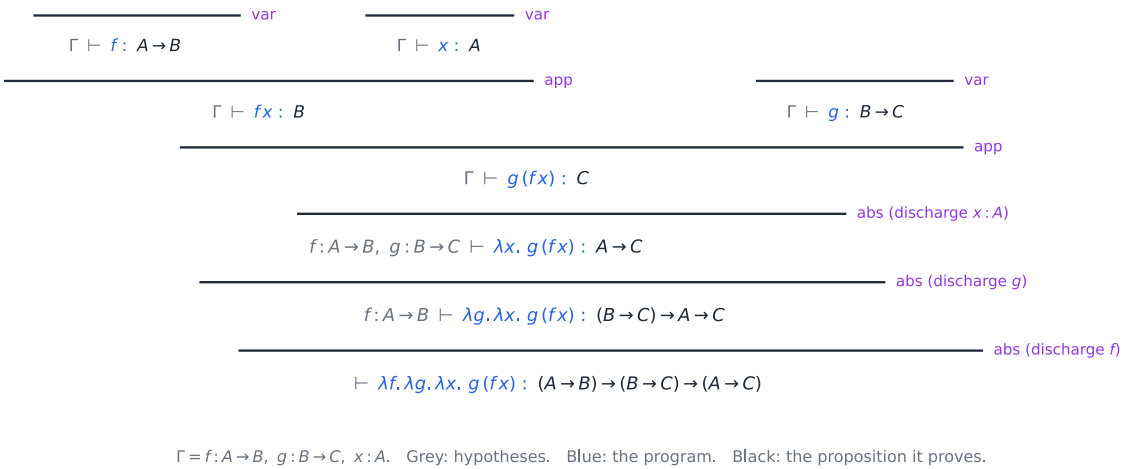

Figure 66.2 — The derivation that gives composition its type. Read upward, it is a type checker's work. Read with the blue terms erased, it is a proof in natural deduction: from $A \to B$, $B \to C$ and A, two uses of modus ponens give C, and three discharges give the theorem.

Theorem 66.1 — Curry–Howard correspondence

Let $\Gamma = x_1{:}A_1, \dots, x_n{:}A_n$. There is a term t with $\Gamma \vdash t : B$ if and only if B is provable from the hypotheses $A_1, \dots, A_n$ in intuitionistic natural deduction. Moreover, typing derivations of t and natural-deduction proofs correspond one to one.

Proof. ($\Rightarrow$) Induction on the typing derivation. Each typing rule, with terms erased, is an instance of a natural-deduction rule with the same premises and conclusion. Erasing terms from a whole derivation therefore leaves a proof.

($\Leftarrow$) Induction on the natural-deduction proof, building t as we go. A hypothesis A_i becomes the variable x_i. If the last step is $\to$-introduction from a proof of B under the extra hypothesis A, the induction hypothesis gives $\Gamma, x{:}A \vdash s : B$ for a fresh x, and abs gives $\lambda x.\, s : A \to B$. If the last step is modus ponens from proofs of $A \to B$ and A, the induction hypothesis gives terms s and u for them, and $s\,u : B$. The other connectives go the same way, one rule at a time. Each step is forced, so the two constructions are inverse to each other. □

So the hook's third puzzle is a question about provability.

Running a program simplifies a proof

Computation in this language is **β-reduction**: a function applied to an argument steps to the body with the argument substituted,

$$(\lambda x.\, t)\, u \;\longrightarrow\; t[u/x],$$

and likewise $\pi_1 \langle t, u \rangle \longrightarrow t$, and a case on $\mathrm{inl}\, u$ steps to its left branch with $x := u$. On the logic side each redex is a **detour**: an introduction rule immediately followed by the matching elimination. For this to make sense, reduction must not change what is being proved.

Theorem 66.2 — Subject reduction (types are preserved by evaluation)

If $\Gamma \vdash t : T$ and $t \longrightarrow t'$, then $\Gamma \vdash t' : T$.

Proof. The heart of it is a **substitution lemma**: if $\Gamma, x{:}A \vdash t : B$ and $\Gamma \vdash u : A$, then $\Gamma \vdash t[u/x] : B$. We prove the lemma by induction on the derivation of t, showing only the function rules.

- t is a variable. If $t = x$, then $B = A$ and $t[u/x] = u$, which has type A. If $t = y \neq x$, the substitution does nothing, and $y{:}B$ is already in Γ.
- $t = t_1\, t_2$ with $t_1 : C \to B$ and $t_2 : C$. By induction $t_1[u/x] : C \to B$ and $t_2[u/x] : C$, so app gives $(t_1 t_2)[u/x] = t_1[u/x]\, t_2[u/x] : B$.
- $t = \lambda y.\, s$ with $B = C \to D$ and $\Gamma, x{:}A, y{:}C \vdash s : D$. Rename y if needed so that it does not occur in u. Adding the unused hypothesis $y{:}C$ to $\Gamma \vdash u : A$ is harmless, so induction gives $\Gamma, y{:}C \vdash s[u/x] : D$, and abs gives $\lambda y.\, s[u/x] : C \to D$.

Now the theorem. If the step is at the top, $t = (\lambda x.\, s)\, u$ with T its type. Its derivation must end with app, whose premises are $\Gamma \vdash \lambda x.s : A \to T$ and $\Gamma \vdash u : A$. The first must come from abs, so $\Gamma, x{:}A \vdash s : T$. The lemma gives $\Gamma \vdash s[u/x] : T$. If the step happens inside a subterm, induction on the derivation applies the same argument there. Pairs and cases are similar. □

In logical terms: removing a detour leaves a proof of the same theorem. Prawitz proved this for natural deduction in 1965, and Gentzen's cut elimination of 1935 is its sequent-calculus cousin.

A term with no redex left is in **normal form**. The next fact is the deep one, and we state it without proof.

Theorem 66.3 — Strong normalization (Tait's method, 1967)

In the simply typed lambda calculus, every well-typed term reaches a normal form, whatever order the reductions are performed in. In particular, every program terminates.

The reason this needs a clever argument is that substitution can make a term *bigger*: $(\lambda x.\ f\ x\ x)\ u$ copies u twice, and the copies may contain new redexes. Untyped, the term $(\lambda x.\ x\ x)(\lambda x.\ x\ x)$ reduces to itself forever. Types forbid $x\ x$, because x would need a type A equal to $A \to B$.

? Why does every typed program halt?

Tait's proof does not count steps; it defines a set of "reducible" terms for each type and shows by induction on types that every well-typed term is reducible. For Girard's System F, where functions can take *types* as arguments, the idea still works, but the proof needs more strength than the system has: normalization of System F implies the consistency of second-order arithmetic. Why a system can never certify its own termination, or its own consistency, is Gödel's second incompleteness theorem, in Ch. 68.

Why excluded middle has no program

Normal forms have a rigid shape, and that shape is what lets us prove a negative. A normal term is either an **introduction** ($\lambda x.\ t$, a pair, $\mathrm{inl}\ t$, $\mathrm{inr}\ t$, $\star$) or **neutral**: a variable with a chain of eliminations applied to it, such as $x\ u_1\ u_2$, $\pi_1(x\ u)$ or $\mathrm{case}\ x\ \ldots$. (If an elimination were applied to an introduction, that would be a redex.) A neutral term has a free variable at its head, so a *closed* normal term, typed in the empty context, must be an introduction.

Theorem 66.4 — Excluded middle is not constructively provable

Let A be an atomic type. There is no closed term of type $A + (A \to \mathbf{0})$. Equivalently, $A \vee \neg A$ has no proof in intuitionistic logic.

Proof. Suppose $\vdash t : A + (A \to \mathbf{0})$. By Theorems 66.2 and 66.3 we may replace t by its normal form, which has the same type and is closed, hence an introduction. For a sum type the only introductions are inl and inr.

Case $t = \mathrm{inl}\ s$ with $\vdash s : A$. Then s is a closed normal term of an atomic type. No introduction rule produces an atomic type, and closed normal terms are not neutral. So no such s exists.

Case $t = \mathrm{inr}\ s$ with $\vdash s : A \to \mathbf{0}$. Then s is an introduction of a function type, $s = \lambda x.\ r$ with $x{:}A \vdash r : \mathbf{0}$ and r normal. No introduction has type $\mathbf{0}$, so r is neutral, and its head variable must be x, the only one in scope. But x has atomic type A: it cannot be applied, projected, case-analysed or passed to absurd, because each of those needs a function, pair, sum or empty type. So $r = x$, whose type is A, not $\mathbf{0}$. Contradiction. □

The proof reasons about what a program *could* look like once it has finished computing. Peirce's law fares the same, because any program for it that works at every type could be turned into a program for excluded middle (challenge problem 2 asks you to write the conversion).

This is the logic keeping a promise. A constructive proof of "A or not A" would be a program that *decides* A, and for "this Turing machine halts" no such program exists (Ch. 30).

Classical reasoning is not lost, only relocated. A program of type $\neg\neg(A \vee \neg A)$, that is $((A + (A \to \mathbf{0})) \to \mathbf{0}) \to \mathbf{0}$, does exist:

$$\lambda k.\ k\ (\mathrm{inr}\ (\lambda a.\ k\ (\mathrm{inl}\ a))).$$

Read it as a con trick. Handed a refutation k of the disjunction, it first claims "not A". If k ever calls that bluff by producing an $a{:}A$, the program rewinds and offers $\mathrm{inl}\ a$ instead. Glivenko showed in 1929 that every classical propositional tautology becomes intuitionistically provable once you put $\neg\neg$ in front of it. In programming, $(A \to R) \to R$ is the **continuation monad**: instead of returning an A, a value takes a callback that consumes one. That answers the question Ch. 62 left about monads and proofs: a monad is a *modality*, "A holds, possibly after some effect", and the effect behind classical logic is the ability to jump back in time.

Dependent types: quantifiers become functions

So far a type cannot mention a value, so we cannot say "for every n, $n + 0 = n$". **Dependent types** lift that restriction. A *type family* $P(x)$ is a type that depends on a value $x{:}X$: for example $\mathrm{Vec}(n)$, the type of lists of length exactly n, or $n + 0 = n$, the type of proofs that this particular equation holds.

- The **dependent function type** $\Pi_{x:X} P(x)$ contains functions sending each $x{:}X$ to something of type $P(x)$. It is $\forall x{:}X.\ P(x)$: a proof of a universal statement is a function from instances to proofs.
- The **dependent pair type** $\Sigma_{x:X} P(x)$ contains pairs $\langle x, p\rangle$ with $p : P(x)$. It is $\exists x{:}X.\ P(x)$: a proof of existence *is* a witness plus evidence that it works.

When P does not depend on x, Π collapses to $X \to P$ and Σ to $X \times P$, recovering the simple types. Induction becomes recursion. Here is a proof assistant (Lean 4) proving that $0 + n = n$ for every natural number, given that addition is defined by recursion on its second argument:

```
theorem zero_add' : ∀ n : Nat, 0 + n = n
  | 0     => rfl                              -- 0 + 0 reduces to 0
  | n + 1 => congrArg Nat.succ (zero_add' n)  -- use the proof for n
```

The second line is a recursive call: the proof for $n + 1$ is built from the proof for n. That this recursion is legal, and that it terminates because n shrinks, is induction on $\mathbb{N}$ (Ch. 29), seen as a program.

One consequence startles set theorists. In type theory the **axiom of choice**, in the form "if for every x there is a y with $R(x, y)$, then there is a function f with $R(x, f(x))$ for every x", is a *theorem*. The proof is one line: given $h : \Pi_x \Sigma_y R(x, y)$, take $f(x) = \pi_1(h\ x)$, and the evidence is $\pi_2(h\ x)$. The existential already contained the choice. In set theory, where existence carries no witness, choice is an independent axiom (Ch. 64, Ch. 68).

Dependent types power modern proof assistants. Coq checked the four colour theorem in 2005 and the Feit–Thompson theorem in 2012; there, "the proof is correct" means "the program type-checks".

66.4 The algorithm

Checking a proof is type checking

Because proofs are programs, a proof checker is a type checker, and a type checker for the simple language of §66.3 fits on a screen. Types are atoms (strings) or tuples `('->', A, B)`; terms are tagged tuples, with λ carrying its argument's type.

```
def typeof(t, ctx):
    tag = t[0]
    if tag == 'var':
        return ctx[t[1]]                              # rule var
    if tag == 'lam':                                  # ('lam', x, A, body): rule abs
        _, x, A, body = t
        return ('->', A, typeof(body, {**ctx, x: A}))
    if tag == 'app':                                  # rule app
        f, a = typeof(t[1], ctx), typeof(t[2], ctx)
        if f[0] != '->' or f[1] != a:
            raise TypeError(f"cannot apply {f} to {a}")
        return f[2]
    raise ValueError(f"unknown term {tag}")           # pairs, sums: challenge 3
```

Feed it composition and it returns `('->', ('->', 'A', 'B'), ('->', ('->', 'B', 'C'), ('->', 'A', 'C')))`, the theorem of Figure 66.2. Feed it the self-application `lam x:A. x x` and it raises `cannot apply A to A`: the term that looped forever in §66.3 is rejected before it runs.

Each branch is one typing rule read upward, and each subterm is visited once, so checking costs about the term size times the size of the largest type. This is the heart of the **de Bruijn criterion** that proof assistants follow: however clever the tools that *find* a proof, the result is checked by a small kernel like this one, so trust rests on a few hundred lines of code rather than on the search.

Finding a proof is finding a program

The reverse direction, **type inhabitation** ("given T, find a t with $\vdash t : T$"), is proof search. It is harder, and how much harder depends on the logic.

Problem	Logic	Status
check that t has type T	any of the systems here	decidable, roughly linear time
infer the type of an unannotated t	ML-style polymorphism (Hindley–Milner)	decidable; worst case exponential, fast in practice
decide whether T is inhabited	intuitionistic propositional logic	decidable, PSPACE-complete (Statman, 1979)
decide whether T is inhabited	first-order or dependent types	undecidable, only semi-decidable

The undecidable row is the theorem of Ch. 65 and Ch. 30 in new clothes: if we could always decide whether a proof exists, we could decide the halting problem. Proof assistants therefore make the human supply the hard steps and automate the rest. The propositional case is decidable because a goal-directed search only ever needs subformulas of the goal, and there are finitely many. The experiment below implements that search.

Failure cases: how a type system stops being a logic

Every type in the correspondence must be honest: an inhabitant must be real evidence. Three features of everyday languages break this.

- **General recursion.** `def loop(): return loop()` can be annotated with any return type. Under Curry–Howard that proves every proposition, including $\bot$. Languages used as logics (Coq, Agda, Lean) accept only recursion they can see terminating, such as structural recursion in `zero_add'`. Since termination is undecidable, such a check must reject some programs that do terminate.
- **Exceptions and null.** `raise` and `None` inhabit every type, so they too "prove" anything.
- **Types of types.** Dependent types need a type of types, so that Vec can map $\mathbb{N}$ to types. The obvious choice, a `Type` that contains every type including itself, is fatal.

> **? The type of all types**
>
> In 1972 Jean-Yves Girard showed that a type theory with `Type` : `Type` is inconsistent: there is a closed term of the empty type, a program that claims to prove False and runs forever. Every proof assistant now uses an infinite tower of universes, $\mathsf{Type}_0 : \mathsf{Type}_1 : \mathsf{Type}_2 : \cdots$, so that no universe contains itself. Why does a universe that contains itself collapse? It is the same trap that destroyed Frege's set theory in 1902, and it is sprung in Ch. 68.

66.5 The experiment

The script checks formulas of implicational logic twice, with `F` for falsehood: **classically** by truth table, and **constructively** by searching for a Python program of that type built from `lambda`, calls and `absurd`. For a goal $A \to B$ it writes a `lambda` and seeks B; for an atomic goal it tries each hypothesis ending in that atom (or in `F`). A loop check makes the search finite, and it finds a program whenever one exists.

```
import itertools

def I(*ts):                     # I(A, B, C) means A -> B -> C (arrows associate right)

        if all(s is not None for s in subs):
            r = v + ''.join('(%s)' % s for s in subs)
            return r if t == goal else 'absurd(%s)' % r
    return None

# KNOBS: add your own formulas. 'F' plays the role of falsehood.
tests = {'compose': I(I('A', 'B'), I('B', 'C'), 'A', 'C'),
         'K': I('A', 'B', 'A'),
         'Peirce': I(I(I('A', 'B'), 'A'), 'A'),
         'not-not-intro': I('A', I('A', 'F'), 'F'),
         'not-not-elim': I(I(I('A', 'F'), 'F'), 'A'),
         'not-not-Peirce': I(I(I(I(I('A', 'B'), 'A'), 'A'), 'F'), 'F')}
for name, t in tests.items():
    print(f"{name:14s} {show(t):34s} tautology={tautology(t)!s:5s} program={prove([], t)}")
```

All six are tautologies. Composition, `K` and $A \to \neg\neg A$ get programs; for composition the machine finds `lambda x0: lambda x1: lambda x2: x1(x0(x2))`, the hook's answer. Peirce's law and $\neg\neg A \to A$ get `None`. But put $\neg\neg$ in front of Peirce's law and a program appears, a little time machine of nested callbacks, as Glivenko promised.

Things to change:

1. Add the formula $(A \to B \to C) \to (B \to A \to C)$ (swap the arguments) and predict the program before running.
2. Add **contraposition** $(A \to B) \to (\neg B \to \neg A)$ and its converse $(\neg B \to \neg A) \to (A \to B)$. One of them has a program. Which, and why does the other need classical logic?
3. Delete the `'F'` in `if t not in (goal, 'F')`. You now have **minimal logic**, without *ex falso*. Watch what happens to the double-negated Peirce law.

66.6 The challenge

No answers are given.

1. **Intuition.** The empty type $\mathbf{0}$ has no values, so a function $\mathbf{0} \to C$ "exists" for every C. Explain in plain words why this matches *ex falso quodlibet*. Then explain why a language that lets you write `def f() -> Empty: return f()` cannot be used as a logic, and what that has to do with Theorem 66.3.
2. **Derivation.** Write closed terms for currying, $(A \times B \to C) \to (A \to B \to C)$ and its converse, and for $\neg(A \vee B) \to (\neg A \times \neg B)$. Then show that Peirce's law, assumed for *every* pair of types, yields excluded middle: write a term of type $\neg(A \vee \neg A) \to (A \vee \neg A)$, and use Peirce's law with A replaced by $A \vee \neg A$ and B by $\mathbf{0}$. Why does this, together with Theorem 66.4, show that no polymorphic program for Peirce's law exists?
3. **Implementation.** Extend `typeof` with sums (`inl`, `inr`, `case`) and `absurd`, then extend `prove` from the experiment to conjunction and disjunction. Confirm that $\neg\neg(A \vee \neg A)$ is inhabited and $A \vee \neg A$ is not. Then write a β-reducer and test Theorem 66.2 by re-checking the type after every step.
4. **Open investigation.** The type $(A \to A) \to A \to A$ has infinitely many normal inhabitants: $\lambda f.\lambda x.\, x$, $\lambda f.\lambda x.\, f\, x$, $\lambda f.\lambda x.\, f\,(f\, x)$, and so on, the **Church numerals**. Others have one, finitely many, or none. Write a program that counts normal inhabitants up to a given size, and explore. Can you predict finite versus infinite from the shape of the type alone?

66.7 Loose threads

The hook's third puzzle has no program because Peirce's law has no constructive proof, and Theorem 66.4 shows why from the shape of normal forms: a closed program must commit to an answer, and for an unknown proposition it has nothing to commit to. Proofs are programs, propositions are types, checking is type checking, and dependent types stretch the dictionary to quantifiers.

What we did not tell you:

- **Why typed programs terminate.** Theorem 66.3 was stated, not proved, and its stronger forms cannot be proved inside the systems they describe (Ch. 68).
- **Why universes must be stacked.** Girard's paradox descends from Russell's, which opens Ch. 68.

- **How to use this on real code.** Most software is not written in Lean. How do engineers prove a C loop correct, or a protocol free of deadlock? That is Ch. 67.

? When are two types the same?

A proof of $x = y$ is itself a value, an element of an *identity type*. Can there be two *different* proofs that $x = y$? Around 2006–2009 Vladimir Voevodsky and others saw that identity types behave like paths in a space. His **univalence axiom** says that equivalent types are equal, turning "isomorphic structures are interchangeable" into a rule of logic. Cubical type theory (from 2015) gives univalence a computational meaning, but whether homotopy type theory can serve as a practical foundation for all of mathematics is an open research question.

Chapter 67 — Formal Verification: Proving Programs Correct

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 24, Ch. 29, Ch. 30, Ch. 65, Ch. 66 · **Leads to:** Ch. 68 · **Related:** Ch. 27, Ch. 34, Ch. 77 **Reading time:** ~25 min

67.1 The hook

In October 1994 a mathematics professor, Thomas Nicely, noticed that his new Pentium computer was getting some divisions wrong. The cleanest example became famous:

$$\frac{4195835}{3145727} = 1.333820449\ldots \quad \text{but the chip said} \quad 1.333739068\ldots$$

The error was in the fourth significant digit. The cause was five missing entries in a lookup table of 1,066 used by the division circuit. Intel had tested the chip intensively, but by its own estimate a random division hit the bad entries about once in nine billion tries. The replacement programme cost the company 475 million US dollars.

Count what exhaustive testing would have needed. A double-precision divider takes two 64-bit inputs, so there are $2^{128} \approx 3.4 \times 10^{38}$ input pairs. At a billion tests a second, checking them all would take about 10^{22} years, a trillion times the age of the universe. Testing samples a vanishing fraction of the input space. It can find bugs, but it cannot show their absence.

Two years later, on 4 June 1996, the first Ariane 5 rocket veered off course about 37 seconds after lift-off and destroyed itself. A 64-bit floating-point velocity had been converted into a 16-bit integer. On the slower Ariane 4, where the code came from, the value always fitted. On Ariane 5 it did not, and the overflow shut down both inertial reference computers, which ran identical software.

Both failures were in components that had been tested and had worked. The question this chapter asks is the one an engineer asks after a disaster: **can we prove, once and for all inputs, that a program or a circuit does what it should?** After 1994 Intel began proving its floating-point units correct with theorem provers. Today Amazon checks its distributed protocols with model checkers, an operating-system kernel and a C compiler have been proved correct line by line, and avionics software is analysed for overflow before it flies. This chapter shows how.

67.2 The big idea

A proof of correctness needs two things that testing does not: a **specification** written as a logical formula, and a way of reasoning about *every* execution at once.

There are three main ways to get the second.

1. **Deductive verification.** Attach logical assertions to points in the program, and prove that each statement carries a true assertion before it to a true assertion after it. Loops are handled by an **invariant**, exactly as in Ch. 29. The proof obligations are ordinary formulas of arithmetic that a solver or a human can discharge. This is **Hoare logic**.
2. **Model checking.** If the system has finitely many states, as a circuit or a protocol does, just explore all of them. A graph search visits every reachable state and either certifies that no bad state is reachable or returns the exact sequence of steps that reaches one.
3. **Interactive theorem proving.** Write the program, its specification and its proof in a proof assistant whose kernel checks every step, using the proofs-as-programs machinery of Ch. 66.

An analogy: testing is spot-checking a bridge by driving trucks over it. Deductive verification is the structural calculation that shows every beam carries its load. Model checking is a stress simulation of every possible load pattern, feasible only because the bridge has finitely many joints. Theorem proving is having the calculation audited by an inspector who accepts nothing on trust.

All three run into the same wall. By Rice's theorem (Ch. 30), no algorithm decides whether an arbitrary program meets an arbitrary specification. Each method gives something up: deductive methods need a human or a heuristic to supply invariants, model checking needs a finite state space, and theorem proving needs human effort.

67.3 The mathematics

Hoare triples

Fix a small imperative language: assignments `x := e`, sequencing `S1; S2`, conditionals `if b then S1 else S2` and loops `while b do S`. A **state** σ gives every variable an integer value. Assertions are formulas of predicate logic about the variables (Ch. 29).

> **Hoare triple**
>
> The triple $\{P\}\ S\ \{Q\}$ holds (in the sense of **partial correctness**) if, whenever S starts in a state satisfying the **precondition** P and terminates, the final state satisfies the **postcondition** Q. It holds in the sense of **total correctness** if, in addition, S always terminates from such states.

Partial correctness says nothing about termination. $\{\top\}$ `while true do skip` $\{\bot\}$ is a valid partial-correctness triple, because the loop never finishes and so never delivers a bad state. Termination is proved separately with a variant, as in Ch. 29.

In 1969 Tony Hoare gave rules that derive valid triples, one per construct:

$$\{Q[e/x]\}\ x := e\ \{Q\}\ \text{(assign)} \qquad \frac{\{P\}\ S_1\ \{R\} \qquad \{R\}\ S_2\ \{Q\}}{\{P\}\ S_1; S_2\ \{Q\}}\ \text{(seq)}$$

$$\frac{\{P \wedge b\}\, S_1\, \{Q\} \qquad \{P \wedge \neg b\}\, S_2\, \{Q\}}{\{P\}\ \texttt{if}\ b\ \texttt{then}\ S_1\ \texttt{else}\ S_2\ \{Q\}}\ (\text{if}) \qquad \frac{\{I \wedge b\}\, S\, \{I\}}{\{I\}\ \texttt{while}\ b\ \texttt{do}\ S\ \{I \wedge \neg b\}}\ (\text{while})$$

$$\frac{P \Rightarrow P' \qquad \{P'\}\, S\, \{Q'\} \qquad Q' \Rightarrow Q}{\{P\}\ S\ \{Q\}}\ (\text{consequence})$$

Here $Q[e/x]$ means Q with every free x replaced by the expression e. The while rule is the loop-invariant principle in compact form: if one pass of the body preserves I, then I survives any number of passes, and on exit the guard is false. The consequence rule is the only place where ordinary mathematics enters: it lets us strengthen a precondition or weaken a postcondition by proving an implication.

The assignment rule runs backwards

The assignment rule looks back to front. To know what must be true *before* `x := x + 1` so that $x > 5$ holds *after*, substitute: $(x > 5)[x + 1/x]$ is $x + 1 > 5$, that is $x > 4$. Reasoning flows from the goal backwards, and the next theorem says this backward step loses nothing.

Weakest precondition

$\mathrm{wp}(S, Q)$ is the assertion satisfied by exactly those states from which S terminates in a state satisfying Q. It is the weakest P for which $\{P\}\ S\ \{Q\}$ holds totally: any valid precondition implies it.

Theorem 67.1 — Assignment is exact

For every assertion Q, $\mathrm{wp}(x := e,\ Q) = Q[e/x]$. In particular the assignment rule is sound, and no weaker precondition would do.

Proof. Write $\sigma[x \mapsto v]$ for the state σ with x changed to v, and $\sigma(e)$ for the value of e in σ. Running $x := e$ from σ always terminates, in $\sigma[x \mapsto \sigma(e)]$. So σ is in $\mathrm{wp}(x := e, Q)$ exactly when $\sigma[x \mapsto \sigma(e)] \models Q$.

It remains to show the **substitution lemma**: $\sigma \models Q[e/x]$ if and only if $\sigma[x \mapsto \sigma(e)] \models Q$. Argue by induction on the structure of Q. For a term t, evaluating $t[e/x]$ in σ gives the same value as evaluating t in $\sigma[x \mapsto \sigma(e)]$: every occurrence of x is replaced by e, whose value in σ is precisely what x holds in the updated state, and the other variables are unchanged. So atomic formulas such as $t_1 < t_2$ agree. The connectives $\neg, \wedge, \vee, \Rightarrow$ preserve agreement directly. For a quantifier $\forall y.\ R$, rename y so that it is neither x nor a variable of e; then substitution passes inside, and the induction hypothesis applies for each value of y. $\square$

Sequencing composes: $\mathrm{wp}(S_1; S_2, Q) = \mathrm{wp}(S_1, \mathrm{wp}(S_2, Q))$, and for conditionals $\mathrm{wp} = (b \Rightarrow \mathrm{wp}(S_1, Q)) \wedge (\neg b \Rightarrow \mathrm{wp}(S_2, Q))$. Straight-line code can therefore be verified mechanically, by computing the weakest precondition and checking one implication. Loops are where this stops. The weakest precondition of a loop is a limit of infinitely many unrollings, and in general no algorithm can write it down. Instead, someone supplies an invariant, and the loop becomes three implications.

A proof of division

Hoare's 1969 paper verified a program that divides x by y using only subtraction:

```
q := 0; r := x;
while r >= y do
    r := r - y; q := q + 1
```

Theorem 67.2 — Division by repeated subtraction is correct

$\{x \geq 0 \wedge y > 0\}$ the program above $\{x = q\,y + r \wedge 0 \leq r < y\}$ holds with total correctness.

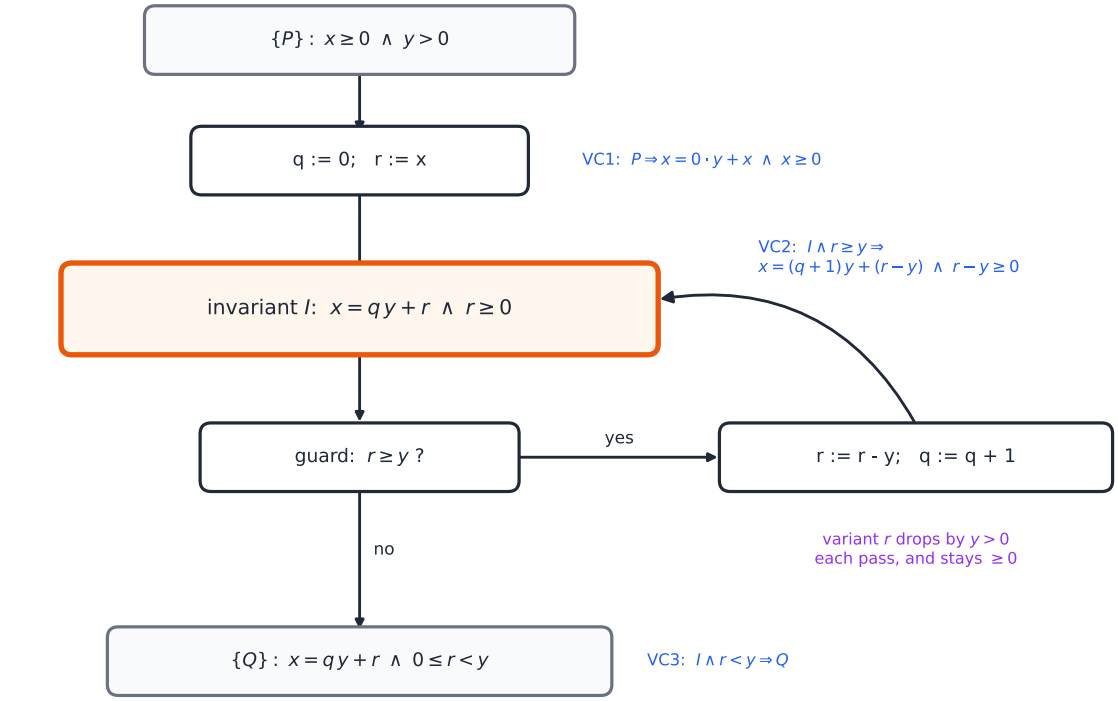
Proof. Take the invariant $I:\ x = q\,y + r \wedge r \geq 0$. Three verification conditions remain, each an implication about integers (Figure 67.1).

VC1, initialisation. By the assignment rule twice, the precondition of `q := 0; r := x` for I is $I[x/r][0/q]$, which is $x = 0 \cdot y + x \wedge x \geq 0$. This follows from $x \geq 0$.

VC2, maintenance. The precondition of the body for I is $I[q + 1/q][r - y/r]$, that is $x = (q + 1)\,y + (r - y) \wedge r - y \geq 0$. Assume I and the guard $r \geq y$. Then $(q + 1)y + (r - y) = qy + r = x$, and $r - y \geq 0$ is the guard. So $\{I \wedge r \geq y\}$ body $\{I\}$, and the while rule gives $\{I\}$ loop $\{I \wedge r < y\}$.

VC3, exit. $I \wedge r < y$ is $x = qy + r \wedge r \geq 0 \wedge r < y$, which is the postcondition word for word.

Termination. Use the variant r. While the guard holds, $r \geq y > 0$, and each pass replaces r by $r - y < r$ with $r - y \geq 0$. A non-negative integer cannot decrease forever (the argument of Ch. 29), so the loop stops. The consequence and sequencing rules stitch the pieces together. $\square$



Three implications of ordinary arithmetic replace infinitely many test runs.

Figure 67.1 — Hoare logic on the division loop. Every path through the program begins and ends at an assertion; the invariant (orange) cuts the loop open so that each path is finite. The three blue verification conditions are all that must be proved. Note how $y > 0$ is used: without it the variant would not decrease.

Notice what has happened. A claim about infinitely many runs, one for each (x, y), has become three facts of high-school algebra. A program called an **SMT solver** (satisfiability modulo theories) can check such facts automatically: it tries to find values making the negation true, and when the search space is exhausted, the implication is proved.

? Is Hoare logic complete?

Every triple derived by Hoare's rules is valid. Is every *valid* triple derivable? Stephen Cook proved in 1978 that it is, *relative* to an oracle for the consequence rule, one that can tell which implications of arithmetic are true. But no proof system can play that oracle. Why there are true statements of integer arithmetic that no consistent, mechanically checkable set of axioms proves is Gödel's first incompleteness theorem, in Ch. 68.

Model checking: search instead of proof

For a system with finitely many states, we can skip invariants and look everywhere.

Transition system and safety

A **transition system** is a finite set of states S, a set of initial states $S_0 \subseteq S$, and a transition relation $\to \subseteq S \times S$. A state is **reachable** if some path $s_0 \to s_1 \to \cdots \to s_k$ leads to it from S_0. A **safety property** names a set of bad states B and asserts that no reachable state is in B. In temporal-logic notation it is written $\mathbf{G}\,\neg \mathit{bad}$, "globally, never bad".

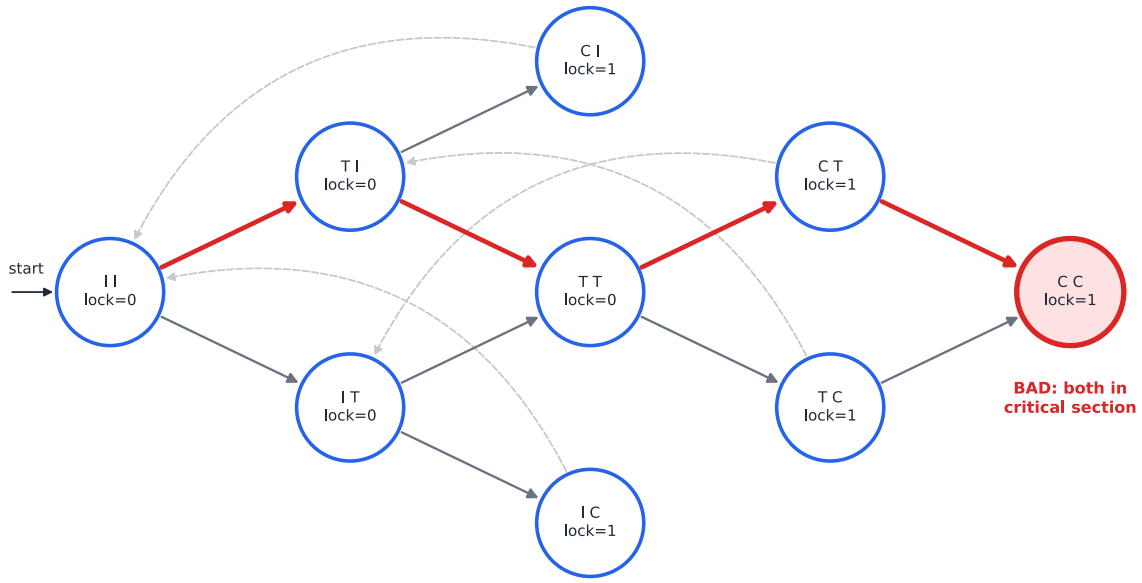
Safety says nothing bad ever happens. Its partner, **liveness**, says something good eventually happens, written $\mathbf{F}\,\mathit{good}$: every request is eventually served, or the system never deadlocks forever. Temporal logics such as LTL and CTL combine $\mathbf{G}$, $\mathbf{F}$ and "until" into a specification language, and Clarke, Emerson and Sifakis shared the 2007 Turing Award for the algorithms that check them.

Theorem 67.3 — Safety checking is a graph search

For a finite transition system, whether some bad state is reachable can be decided in time $O(|S| + |{\to}|)$. If one is reachable, breadth-first search returns a shortest path to it.

Proof. Breadth-first search from S_0 (Ch. 27) visits every reachable state exactly once and examines every transition out of a visited state once, which gives the time bound. It visits states in order of their distance from S_0: the queue always holds states of distance d followed by states of distance $d+1$, by induction on the number of steps. So the first bad state dequeued is a closest one, and following the recorded parent pointers back to S_0 gives a shortest path. If the search ends without dequeuing a bad state, every reachable state has been visited and none is bad. □

The shortest path is the most useful output of all: a **counterexample trace**, a step-by-step replay of the bug. For concurrent programs, which fail only under rare interleavings, it is the difference between a heisenbug and a fix. Figure 67.2 shows a lock that two processes implement by first *testing* a shared flag and then *setting* it. The search finds the four-step trace in which both test before either sets.



I = idle, T = has seen lock free, C = critical. Red: the shortest counterexample found by breadth-first search. Dashed: release steps.

Figure 67.2 — Model checking a test-then-set lock. Each node is a global state: the program counters of both processes and the shared lock bit. Breadth-first search reaches the bad state, both processes in the critical section, in four steps. Four further states beyond the bad one are not drawn.

67.4 The algorithm

Generating verification conditions

Deductive verifiers such as Dafny, Why3 and Frama-C turn an annotated program into formulas by running the weakest-precondition rules backwards, then hand the formulas to an SMT solver. The core fits in a few lines of pseudocode:

```
vcgen(S, Q):                    # returns (precondition, side conditions)
  case S of
    x := e          : return (Q[e/x], [])
    S1; S2          : (P2, C2) = vcgen(S2, Q); (P1, C1) = vcgen(S1, P2)
                      return (P1, C1 + C2)
    if b S1 else S2: (P1, C1) = vcgen(S1, Q); (P2, C2) = vcgen(S2, Q)
                      return ((b => P1) and (not b => P2), C1 + C2)
    while b inv I S: (PB, CB) = vcgen(S, I)
                      return (I, CB + [I and b => PB, I and not b => Q])

verify(Pre, S, Post):
  (P, C) = vcgen(S, Post)
  for each formula F in [Pre => P] + C:  ask the solver whether F is valid
```

Run on the division program, it produces exactly VC1 to VC3 of Theorem 67.2. The cost is linear in the program for straight-line code with care, but naive substitution through a chain of k conditionals can duplicate Q at each branch, giving formulas of size 2^k. Practical tools introduce fresh names for intermediate values to keep the formulas small. The solver's job, deciding whether a formula of arithmetic is valid, is decidable for linear integer arithmetic and undecidable once multiplication of variables is allowed, so the solver may answer "valid", "invalid, here is a counterexample", or "unknown".

Where the invariants come from

The algorithm takes the invariant `I` as input. Ch. 29 asked whether a program could find invariants on its own, and Ch. 30 proved that no program can always succeed. Real tools succeed often anyway, in three ways.

- **The programmer writes them.** Languages like Dafny make `invariant` a keyword, and the verifier checks each one as it is typed. It feels like a type checker that understands arithmetic.
- **Abstract interpretation.** Run the program on *sets* of values instead of values, for example intervals $[a, b]$ for each variable. A loop is iterated until the intervals stop growing, with a "widening" step that jumps to infinity if they would grow forever. The result is an invariant guaranteed to hold, though it may be too weak to prove what you want. The analyser Astrée used this to prove the absence of run-time errors, including overflows of the Ariane kind, in the flight-control software of Airbus aircraft.
- **Learning from failure.** Guess a weak invariant, let the solver produce a counterexample, and refine the guess to exclude it. Techniques called CEGAR and IC3 automate this loop, and they power the hardware model checkers used at chip companies today.

Explicit-state model checking and the state explosion

Theorem 67.3 is the whole algorithm for safety: breadth-first search with a visited set and parent pointers, linear in the size of the state graph. The trouble is that size. A system of n processes, each with k local states, can have up to k^n global states before counting shared variables. Ten processes with ten states each give 10^{10}, and one 32-bit variable multiplies that by four billion. This **state explosion** is the central enemy of model checking, and three ideas fight it.

- **Symbolic model checking** represents sets of states as compact Boolean formulas (binary decision diagrams) and computes the reachable set by manipulating formulas, never listing states. In 1992 this handled systems with more than 10^{20} states.
- **Bounded model checking** asks a SAT solver whether a bad state is reachable within k steps, by unrolling the transition relation k times into one big formula.
- **Partial-order reduction** notices that independent steps of different processes commute, so only one ordering of them needs exploring.

> **? Why does SAT solving work at all?**
>
> Bounded model checking turns verification into Boolean satisfiability, which is NP-complete (Ch. 30). In theory that should be hopeless. In practice, modern solvers routinely settle industrial formulas with millions of variables, and the whole hardware-verification industry rests on this. Why real-world formulas are so much easier than the worst case is not understood. Explaining the success of conflict-driven clause learning on structured instances is an open problem.

Failure cases

A verified system can still fail, and the ways it fails are instructive.

- **The specification is wrong.** A proof shows that the code meets the specification, not that the specification says what you meant. Ariane 5's code met the Ariane 4 assumptions perfectly.
- **The model is not the machine.** Theorem 67.2 used exact integers. On a machine, `q + 1` can overflow. The binary search bug of Ch. 29 and floating-point rounding (Ch. 24) are the same mistake.
- **The trusted base is buggy.** The compiler, the operating system and the hardware are assumed correct. That is why verifying them matters. The seL4 microkernel (2009) is about 8,700 lines of C with roughly 200,000 lines of machine-checked proof. The CompCert C compiler is proved in Coq to preserve the meaning of programs; when researchers bombarded compilers with random programs in 2011, they found hundreds of bugs in GCC and LLVM and none in CompCert's verified core.

67.5 The experiment

The script below is a complete explicit-state model checker in under 40 lines. It explores every interleaving of two processes and either reports how many states it explored and that the property holds (`None`), or prints the shortest trace to a bad state. Two protocols are included: the naive test-then-set lock of Figure 67.2 and **Peterson's algorithm** (1981), which achieves mutual exclusion with two flags and a `turn` variable.

```
from collections import deque

# A state is (pc0, pc1, shared...). Each protocol says what process i may do next.
def naive(s, i):                      # shared: lock. pc: 0 idle, 1 saw lock free, 2 critical
    pc, lock = list(s[:2]), s[2]
    if pc[i] == 0 and lock == 0: pc[i] = 1                # test the lock...
    elif pc[i] == 1: pc[i], lock = 2, 1                   # ...then set it (not atomic!)
    elif pc[i] == 2: pc[i], lock = 0, 0                   # leave, release
    else: return None                                     # blocked
    return (*pc, lock)

def peterson(s, i):                   # shared: flag0, flag1, turn. pc 3 = critical
    pc, flag, turn, j = list(s[:2]), list(s[2:4]), s[4], 1 - i
    if pc[i] == 0: flag[i], pc[i] = 1, 1                  # I want to enter
    elif pc[i] == 1: turn, pc[i] = j, 2                   # but you go first
    elif pc[i] == 2:
        if flag[j] == 0 or turn == i: pc[i] = 3           # enter if you don't want to, or it's my turn
        else: return None                                 # busy-wait
    elif pc[i] == 3: flag[i], pc[i] = 0, 0                # leave
    return (*pc, *flag, turn)

def check(step, start, bad):          # breadth-first search over every interleaving
    parent, queue = {start: None}, deque([start])
    while queue:
        s = queue.popleft()
        if bad(s):                                        # rebuild the shortest path to s
            trace = []
            while s is not None: trace.append(s); s = parent[s]
            return len(parent), trace[::-1]
        for i in (0, 1):
            t = step(s, i)
            if t is not None and t not in parent:
                parent[t] = s; queue.append(t)
    return len(parent), None

# KNOBS: switch protocol; try changing turn = j to turn = i in peterson.
print(check(naive, (0, 0, 0), lambda s: s[0] == 2 and s[1] == 2))
print(check(peterson, (0, 0, 0, 0, 0), lambda s: s[0] == 3 and s[1] == 3))
```

The naive lock fails with the trace `(0,0,0) → (1,0,0) → (1,1,0) → (2,1,1) → (2,2,1)`: process 0 sees the lock free, process 1 sees it free, both enter. Peterson's algorithm explores all 20 of its reachable states and reports `None`: mutual exclusion is *proved* for every interleaving, not tested on some.

Things to change:

1. In `peterson`, replace `turn, pc[i] = j, 2` by `turn, pc[i] = i, 2`, so that each process politely insists on its *own* turn. The checker finds a six-step counterexample among 26 states. Read the trace and explain it in words.

2. Swap the order of the first two steps of Peterson's algorithm (set `turn` before raising the flag). Is it still safe?
3. Add a check for **deadlock**: a reachable state in which neither process can move. Does either protocol have one?

67.6 The challenge

No answers are given.

1. **Intuition.** A bug strikes one random division in nine billion. A test campaign runs a billion random divisions. Estimate the chance that it finds the bug, and then explain why the triple $\{\top\}$ `while true do skip` $\{\bot\}$ is valid. Which of these two facts is more worrying for an engineer, and why?
2. **Derivation.** Prove, with an invariant and a variant, that this program computes a^n for integers a and $n \geq 0$: `p := 1; b := a; k := n; while k > 0 do (if k odd then p := p*b); b := b*b; k := k div 2`. Then compute wp of `x := x + y; y := x - y; x := x - y` for the postcondition $x = Y \wedge y = X$, and say what the result proves.
3. **Implementation.** Generalise `check` to n processes and implement the **filter lock**, Peterson's algorithm for n processes. Measure the number of reachable states for $n = 2, 3, 4$ and fit the growth. How large an n can your laptop verify?
4. **Open investigation.** Run the division program on many random inputs and record (x, y, q, r) at the loop head. From these samples, guess candidate invariants of the form $c_1 x + c_2 q\, y + c_3 r = 0$ or simple inequalities, keeping those that no sample violates (the idea behind the tool Daikon). How often is a guessed invariant actually *inductive*, preserved by one pass of the body? Try other small loops. Is there a reliable way to tell, from samples alone, which guesses will survive a proof?

67.7 Loose threads

The hook asked whether we can prove a program correct for every input. For a large and growing class of programs, yes. Hoare logic turns a loop into three implications once someone supplies the invariant, the weakest-precondition calculus makes the rest mechanical, and model checking settles finite systems outright, with a counterexample when it fails. Proof assistants close the remaining gaps by hand, and kernels, compilers and flight software have been verified that way. What no method does is decide correctness for *all* programs: Rice's theorem forbids it, and every tool is a negotiated settlement with that fact.

What we did not tell you:

- **Where completeness breaks.** The first mystery said Hoare logic is only as complete as arithmetic. Why arithmetic itself cannot be completely axiomatised is Ch. 68.
- **Why the hard problem is easy.** SAT-based verification works far better than complexity theory predicts, an open problem.
- **What happens when the system flips coins.** Every transition in this chapter was certain.

> **? Verifying a coin-flipping protocol**
>
> Ethernet's backoff, randomised consensus protocols and quantum key distribution all make random choices. For them, "a bad state is never reached" is the wrong question; the right one is "with what probability is a bad state reached?" Probabilistic model checkers such as PRISM answer it, and the answer comes from turning the state graph into a Markov chain and solving a linear system for that probability. Where the linear system comes from, and why it has a unique solution, is the first-step analysis of Ch. 34.

Verification also has an adversarial cousin. A cryptographic protocol must be correct not against random inputs but against an attacker who chooses the worst ones, and proving such protocols secure is the work of Ch. 77.

Chapter 68 — Paradoxes, Independence, and Mathematical Limits

> **Level 2 · Track F — Logic, Proofs, and the Foundations of Truth Builds on:** Ch. 30, Ch. 64, Ch. 65, Ch. 66 · **Leads to:** Ch. 98, Ch. 62 · **Related:** Ch. 29, Ch. 63, Ch. 67 **Reading time:** ~25 min

68.1 The hook

On 16 June 1902 a young Bertrand Russell wrote a short, polite letter to the logician Gottlob Frege. Frege had spent two decades building arithmetic on pure logic, and the second volume of his masterpiece was at the printer. Russell's letter pointed out, in a few lines, that Frege's system could prove a contradiction. Frege added an appendix to the volume, admitting that the foundation of his building had given way.

The contradiction concerned a single set: the set of all sets that are not members of themselves. Ask whether it is a member of itself, and either answer forces the other.

Thirty years later Kurt Gödel found that the trouble was not confined to careless foundations. Here is a game that shows how strange things got. Take a number, say 4, and write it in "hereditary base 2", where even the exponents are written in base 2:

$$4 = 2^2.$$

Now replace every 2 by a 3, and subtract 1: $3^3 - 1 = 26$. Write 26 in hereditary base 3, $26 = 2 \cdot 3^2 + 2 \cdot 3 + 2$, replace every 3 by a 4, and subtract 1: $2 \cdot 4^2 + 2 \cdot 4 + 2 - 1 = 41$. Keep going, raising the base by one each time:

$$4,\ 26,\ 41,\ 60,\ 83,\ 109,\ 139,\ 173,\ 211,\ 253,\ \ldots$$

The numbers climb. After 2,000 steps the sequence stands at about four million, and it is still climbing. Yet in 1944 Reuben Goodstein proved that **every such sequence, from every starting number, eventually reaches 0**. The one starting at 4 gets there after about $3 \cdot 2^{402653211}$ steps, a number with some 121 million digits.

Here is the twist. In 1982 Laurence Kirby and Jeff Paris proved that Goodstein's theorem, a statement purely about whole numbers, additions and powers, **cannot be proved** from the standard axioms of arithmetic. It is true, and the axioms that every number theorist uses are powerless to show it.

How can a statement about whole numbers be true but unprovable? Which "true" do we mean, if not "provable"? And if the standard axioms miss Goodstein's theorem, what else do they miss? This chapter is about those questions, and about why the answers all go back to Russell's letter.

68.2 The big idea

Every paradox in this chapter has the same skeleton: **an object that talks about itself, with a negation.** "This sentence is false." "The set of all sets not containing themselves." "The program that does the opposite of whatever the halting decider predicts it will do" (Ch. 30). Cantor's proof that the reals are uncountable (Ch. 64) is the same move. List the objects, look down the diagonal, and flip it.

In ordinary language, self-reference produces nonsense. In a precise system it produces a theorem: some object you thought existed cannot exist. Russell's set cannot exist. The halting decider cannot exist. And, in Gödel's version, **a formal system that is consistent, mechanically checkable and strong enough for arithmetic cannot prove every true arithmetic statement.**

Picture a formal system as a machine that prints theorems: it starts from axioms and applies inference rules, forever, printing everything it can derive. We want the machine to be

1. **consistent**: it never prints both a sentence and its negation;
2. **complete**: for every sentence, it eventually prints either the sentence or its negation;
3. **effective**: there is an algorithm to check whether a string is an axiom, so that the machine really is a machine.

For simple subjects all three are possible. For arithmetic of addition alone, Presburger found such a system in 1929. Gödel showed that once multiplication is in, you can have at most two. Since nobody wants an inconsistent or uncheckable system, completeness goes.

A sentence that the system can neither prove nor refute is **independent** of it. Independence is not a vague "too hard". It is a theorem about the system, as definite as any other.

68.3 The mathematics

Russell's paradox and the end of naive sets

Frege's system, like the intuitive set theory most of us carry around, included the principle of **unrestricted comprehension**: for any property $\varphi(x)$, there is a set $\{x : \varphi(x)\}$ of all things with that property.

> **Theorem 68.1 — Russell's paradox**
>
> (a) Unrestricted comprehension is inconsistent. (b) In Zermelo–Fraenkel set theory, for every set A the set $R_A = \{x \in A : x \notin x\}$ is not a member of A. Hence there is no set of all sets.

Proof. (a) Apply comprehension to $\varphi(x) = x \notin x$, giving a set R with $x \in R \iff x \notin x$ for every x. Take $x = R$: then $R \in R \iff R \notin R$. A statement equivalent to its own negation yields a contradiction whichever truth value it has.

(b) Zermelo's **separation** axiom allows only $\{x \in A : \varphi(x)\}$, carving a subset out of a set A that already exists. So R_A exists, and $x \in R_A \iff (x \in A \wedge x \notin x)$. Suppose $R_A \in A$. Then for $x = R_A$ we get $R_A \in R_A \iff R_A \notin R_A$, the same contradiction. So $R_A \notin A$. If there were a set V of all sets, R_V would be a set not in V, which is absurd. □

Part (b) is the repair that became modern set theory (Ch. 64): sets are built in stages from sets already available, and no stage contains everything. The universe of type theory in Ch. 66 is stratified for the same reason, and Girard's paradox about Type : Type is Russell's argument rebuilt with types.

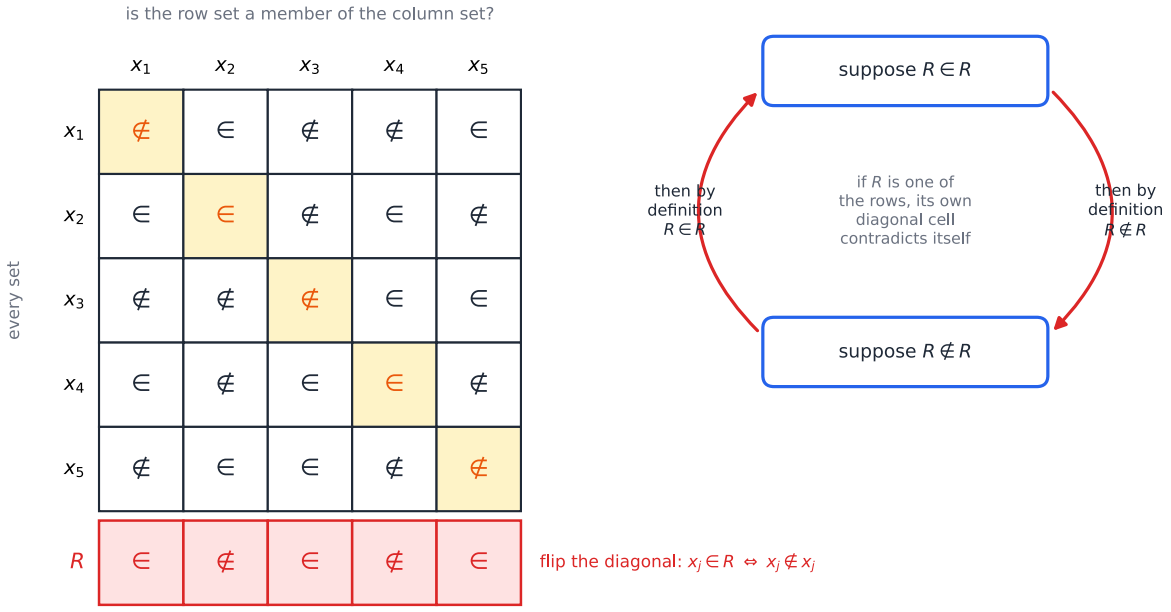

Figure 68.1 — Russell's set is a flipped diagonal. Row x_i, column x_j records whether $x_i \in x_j$. Russell's R contains x_j exactly when the diagonal cell says $x_j \notin x_j$, so R differs from every column on the diagonal. If R were itself one of the sets, its own diagonal cell would have to equal its own negation.

? One theorem behind every diagonal?

Cantor's uncountability proof, Russell's paradox, Turing's halting problem and Gödel's theorem all flip a diagonal. Is that a family resemblance, or a single theorem? In 1969 William Lawvere showed it is one theorem, about functions $A \to (A \to B)$ in a cartesian closed category: if some map $B \to B$ has no fixed point, then no such function can hit every map $A \to B$. Every diagonal argument in this book is an instance, and the language that makes this precise is Ch. 62.

Formal systems, truth and provability

Let T be a theory in the language of arithmetic (symbols 0, S for successor, $+$, $\times$, $<$ and the usual logic). Its standard example is **Peano arithmetic** (PA): basic axioms such as $x + 0 = x$ and $x + S(y) = S(x + y)$, plus the induction schema. T is

- **effectively axiomatised** if an algorithm recognises its axioms. Then its theorems can be listed by a program that enumerates all finite strings and prints those that are correct proofs;
- **consistent** if it proves no sentence together with its negation;
- **sound** if every theorem is *true* in the standard model $\mathbb{N} = \{0, 1, 2, \dots\}$;
- **complete** (or negation-complete) if for every sentence σ it proves σ or $\neg\sigma$.

Do not confuse the last with Gödel's *completeness* theorem of Ch. 65, which says that a sentence true in *every* model of T is provable. Here we ask about truth in the one model we care about, $\mathbb{N}$.

We need one fact from the arithmetisation of computation, which we state without proof. Turing machines and their inputs can be coded by numbers, and "machine M halts on input w" can be written as an arithmetic sentence $H_{M,w}$ of the form $\exists s\, \theta(s)$, where θ says "s codes a halting computation of M on w" and can be checked by bounded search. The sentence is true in $\mathbb{N}$ exactly when M halts on w.

Theorem 68.2 — Incompleteness from the halting problem

Let T be sound and effectively axiomatised. Then there are M and w such that M does not halt on w, but T proves neither $\neg H_{M,w}$ nor $H_{M,w}$. So $\neg H_{M,w}$ is a true sentence that T cannot decide.

Proof. Suppose instead that T proves $\neg H_{M,w}$ for *every* pair (M, w) with M not halting on w. Here is an algorithm for the halting problem. Given (M, w), run two processes side by side, one step of each in turn:

1. simulate M on w; if the simulation halts, answer **halts**;
2. enumerate the theorems of T; if $\neg H_{M,w}$ appears, answer **does not halt**.

The procedure always stops: if M halts, process 1 stops; if not, $\neg H_{M,w}$ is true, so by our assumption T proves it and process 2 finds it. The answer is always correct: process 1 is never wrong, and if process 2 answers, T proved $\neg H_{M,w}$, which is then true by soundness, so M really does not halt. That decides the halting problem, contradicting Theorem 30.2.

So some non-halting pair (M, w) has $T \nvdash \neg H_{M,w}$. And $T \nvdash H_{M,w}$, because $H_{M,w}$ is false and T is sound. □

The proof never wrote the unprovable sentence down. It showed that a complete, sound, effective theory would be a halting decider, and no halting decider exists. Gödel did better: he built the sentence explicitly, and he needed only consistency, not soundness.

Gödel's sentence

Gödel coded formulas as numbers, writing $\ulcorner \varphi \urcorner$ for the code of φ. Checking a proof is mechanical, so there is an arithmetic formula $\mathrm{Prov}_T(x)$ that says "x is the code of a theorem of T". Two standard facts, stated without proof, do the heavy lifting.

- **Representability.** If $T \vdash \varphi$, then $T \vdash \mathrm{Prov}_T(\ulcorner \varphi \urcorner)$: when a proof exists, T can verify it by checking it step by step.
- **The diagonal lemma.** For every formula $\psi(x)$ there is a sentence G with $T \vdash G \leftrightarrow \psi(\ulcorner G \urcorner)$. It is the logical version of a program that prints its own source code (§68.4).

Apply the lemma to $\psi(x) = \neg\,\mathrm{Prov}_T(x)$. The result is a sentence G that T proves equivalent to "G is not provable in T".

Theorem 68.3 — Gödel's first incompleteness theorem (1931)

Let T be consistent, effectively axiomatised and strong enough for representability and the diagonal lemma (Peano arithmetic is more than enough). Then $T \nvdash G$. If T is also sound, G is true and $T \nvdash \neg G$.

Proof. Suppose $T \vdash G$. By representability, $T \vdash \mathrm{Prov}_T(\ulcorner G \urcorner)$. But G is equivalent in T to $\neg\,\mathrm{Prov}_T(\ulcorner G \urcorner)$, so $T \vdash \neg\,\mathrm{Prov}_T(\ulcorner G \urcorner)$ as well. That is a sentence and its negation, contradicting consistency. Hence $T \nvdash G$.

That is exactly what G asserts, so G is true. If T is sound it proves only true sentences, so it cannot prove the false $\neg G$. □

In 1936 Barkley Rosser modified the sentence ("if I am provable, then a shorter refutation of me exists") so that consistency alone shows that neither it nor its negation is provable. Either way, **adding G as a new axiom does not help**: the stronger theory $T + G$ is still consistent and effective, so it has its own Gödel sentence G'.

The second theorem: no system vouches for itself

Let Con_T be the arithmetic sentence $\neg\,\mathrm{Prov}_T(\ulcorner 0 = 1 \urcorner)$, "$T$ does not prove $0 = 1$".

Theorem 68.4 — Gödel's second incompleteness theorem (1931)

If T is consistent, effectively axiomatised and contains Peano arithmetic, then $T \nvdash \mathrm{Con}_T$.

Sketch. The proof of Theorem 68.3 showed, informally, "if T is consistent then G is not provable". Every step of that argument is elementary reasoning about proofs and codes, and with considerable effort one checks that T itself can carry it out. So $T \vdash \mathrm{Con}_T \to \neg\,\mathrm{Prov}_T(\ulcorner G \urcorner)$, that is, $T \vdash \mathrm{Con}_T \to G$. If T proved Con_T, it would prove G, contradicting Theorem 68.3. □

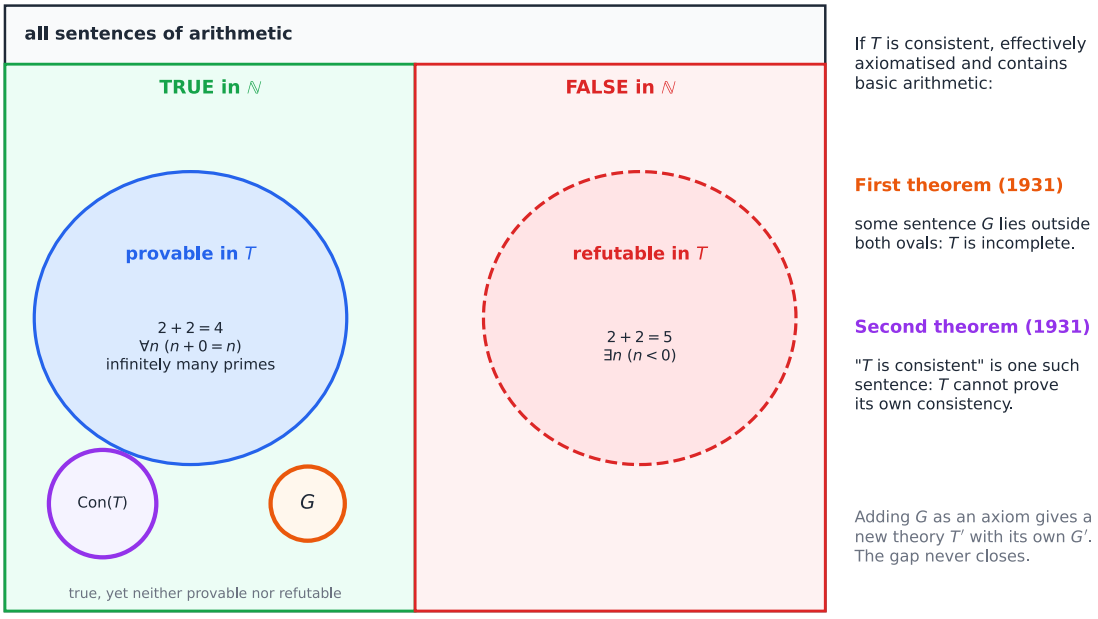

Figure 68.2 — What Gödel's theorems say about a formal system T. Provable sentences (if T is sound) are true, refutable ones are false, but the two ovals never cover everything. The first theorem puts G in the gap; the second puts $\mathrm{Con}(T)$ there too.

This ended Hilbert's programme of the 1920s, which hoped to prove the consistency of all of mathematics by finite, uncontroversial means. Any such proof, formalised in a system T, would be a proof of Con_T inside T. It also explains the first mystery of Ch. 66: proving that every program of System F halts implies the consistency of second-order arithmetic, so that proof can never be carried out *inside* second-order arithmetic.

Independence in the wild

Gödel's G is artificial, built only to say "I am unprovable". The shock of the following decades was that natural questions turned out to be independent too. The method is always the same, and it comes from soundness: if $T \vdash \varphi$, every model of T satisfies φ. So to show $T \nvdash \varphi$, build a model of T in which φ is false. To show independence, build two models, one for each answer. Non-Euclidean geometry proved the parallel postulate independent of Euclid's other axioms in exactly this way, decades before Gödel.

- **Goodstein's theorem** is independent of Peano arithmetic (Kirby and Paris, 1982), though it is provable in set theory. The proof replaces each base by the infinite ordinal ω, so that the sequence becomes a strictly *decreasing* sequence of ordinals below $\varepsilon_0 = \omega^{\omega^{\omega^{\cdots}}}$, which must stop because ordinals are well-ordered (Ch. 64). Peano arithmetic cannot prove that such ordinal descents terminate; in 1936 Gentzen showed that this very fact suffices to prove PA consistent, which by Theorem 68.4 PA cannot do itself.
- **The continuum hypothesis** (CH), Cantor's guess that no set has size strictly between $\mathbb{N}$ and $\mathbb{R}$, is independent of the standard axioms of set theory, ZFC. Gödel built a model of ZFC in which CH holds (1938–40); Paul Cohen invented *forcing* to build one in which it fails (1963), and won the Fields Medal for it.
- **Busy beavers.** The values $\mathrm{BB}(n)$ of Ch. 30 are definite numbers. But in 2016 Adam Yedidia and Scott Aaronson built a 7,918-state Turing machine that halts if and only if ZFC is inconsistent, so ZFC cannot determine its behaviour. Later work cut the size to under 750 states. Somewhere below that, the value of $\mathrm{BB}(n)$ escapes the axioms of all of mathematics.

> **? Is the continuum hypothesis true?**
>
> CH is independent of ZFC, so the axioms do not settle it. Is it then meaningless, or is there a fact of the matter that the axioms simply fail to capture? Set theorists split. Some search for new, natural axioms that decide it: W. Hugh Woodin argued for years that CH is false, then developed an "ultimate L" programme that would make it true. Others hold that there is a *multiverse* of equally good set-theoretic worlds. Which view is right, and whether any new axiom will win acceptance, is an open problem at the foundations of mathematics.

68.4 The algorithm

Self-reference is a programming technique

The diagonal lemma sounds like a logician's trick. It is really an algorithm, and the cleanest way to see it is a program that prints its own source code, a **quine**:

```
s = 's = %r\nprint(s %% s)'
print(s % s)
```

Run it and it prints exactly those two lines. The string `s` is a *template* with a hole; `%r` fills the hole with a quoted copy of the template itself. The diagonal lemma works the same way. Given $\psi(x)$, form the template "ψ(the code of the result of substituting this template into itself)", then substitute the template into itself. The result is a sentence that talks about its own code. Kleene's recursion theorem (1938) says every programming language can do this: any program can be given access to its own source. That is why the halting argument of Ch. 30 works without hand-waving: the machine D really can ask the decider about itself.

Enumerating theorems

The "theorem-printing machine" of §68.2 is an honest algorithm:

```
for n = 1, 2, 3, ...:
    for each string p of length at most n:
        if p is a correctly formed proof in T (check every step against axioms and rules):
            print the last line of p
```

Checking a proof is fast, roughly linear in its length for a well-designed system. The search is hopeless in practice, exponential in the length of the proof sought. But in principle it prints every theorem of T, and only theorems. Theorems of an effective theory are therefore **recursively enumerable**: a machine can list them. Theorem 68.2 used exactly this machine. Incompleteness then says: for arithmetic, the list of theorems can never coincide with the list of true sentences, because the second list cannot be produced by any machine at all.

Computing Goodstein sequences

The bump step in the hook is a recursive algorithm, because exponents must themselves be written in the base:

```
bump(n, b):                         # hereditary base b, then replace b by b+1
    result = 0; power = 0
    while n > 0:
        n, digit = divmod(n, b)
        result = result + digit * (b+1) ^ bump(power, b)
        power = power + 1
    return result
```

Each call handles one level of the hereditary representation, and exponents are tiny compared with n, so one step costs a few big-integer operations. The difficulty is not the cost per step but the number of steps. A program that runs the sequence until it reaches 0 is a program whose termination is Goodstein's theorem, so Peano arithmetic cannot prove that the program halts, even though it does. Such programs are where the independence phenomena of this chapter meet the verification problems of Ch. 67: a verifier built on Peano arithmetic would be unable to certify this loop terminates, whatever invariant you handed it.

Failure cases

- **Self-reference does not always paradox.** "This sentence has five words" is self-referential and simply true. The trouble needs negation, a diagonal that flips.

- **Incompleteness needs strength.** Presburger arithmetic (no multiplication), the theory of real closed fields (Tarski) and plane Euclidean geometry are complete and decidable. Gödel's theorem bites only once a system can encode its own proofs.
- **It is not "everything is unknowable".** Incompleteness says no single effective system captures all arithmetic truth. It does not say any particular open problem is independent, and most never turn out to be.

68.5 The experiment

The script computes a Goodstein sequence, prints the first terms and the term after `STEPS` steps, and plots the number of digits. Set `HEREDITARY = False` to get the **weak Goodstein sequence**, where only the base itself is bumped and the exponents stay as they were.

```
import numpy as np
import matplotlib.pyplot as plt

START, STEPS = 4, 2000      # KNOBS: try START = 3, 5, 6; more STEPS
HEREDITARY = True           # False gives the "weak" Goodstein sequence (exponents not bumped)

def bump(n, b):
    """Write n in base b (hereditarily, if asked), replace every b by b+1, return the value."""
    result, power = 0, 0
    while n:
        n, digit = divmod(n, b)
        exponent = bump(power, b) if HEREDITARY else power
        result += digit * (b + 1) ** exponent
        power += 1
    return result

n, base, values = START, 2, [START]
while n > 0 and len(values) <= STEPS:
    n = bump(n, base) - 1          # bump the base, then subtract one
    base += 1
    values.append(n)

print("first terms:", values[:8])
print("after", len(values) - 1, "steps the value is", values[-1] if values[-1] < 10**12
      else f"a {len(str(values[-1]))}-digit number", "in base", base)
digits = [np.log10(v) if v > 0 else 0 for v in values]
plt.plot(digits)
plt.xlabel("step k"); plt.ylabel("log10 of the term")
plt.title(f"Goodstein sequence from {START} (hereditary={HEREDITARY})")
plt.show()
```

From 3, the sequence is `3, 3, 3, 2, 1, 0`. From 4 it climbs past four million in 2,000 steps, and the plot rises steadily with no sign of turning. Now set `HEREDITARY = False`: from 4, the weak sequence reaches 0 after only 21 steps. The difference between the two versions is exactly the difference between what Peano arithmetic can prove and what it cannot. Weak Goodstein sequences always terminate, and PA proves it.

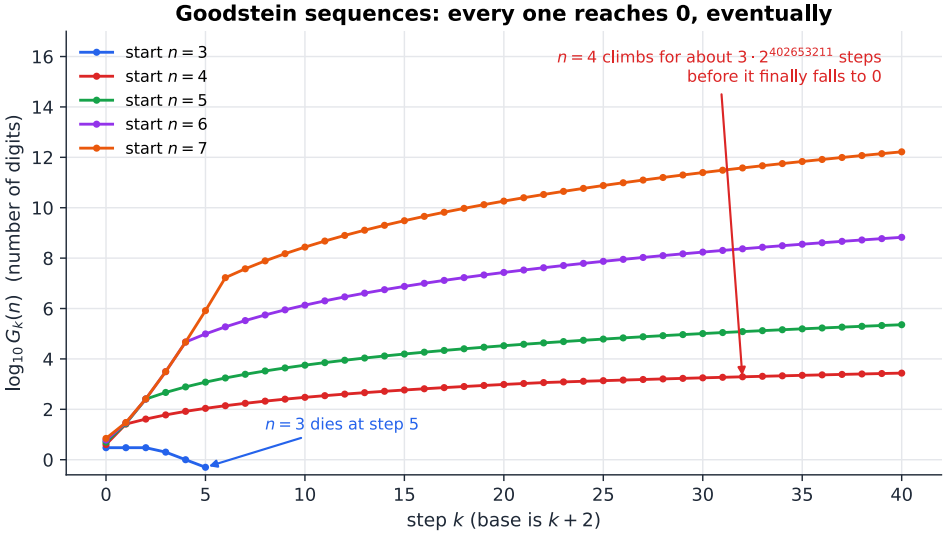

Figure 68.3 — Digits of $G_k(n)$ for the first 40 steps. Only $n = 3$ visibly dies. The others climb, the steeper the larger the start, and every one of them will eventually come back to 0, a fact Peano arithmetic cannot prove.

Things to change:

1. Run `START = 5` and `START = 6` for a few hundred steps. How fast do the digit counts grow? Do not try to run them to the end.
2. With `HEREDITARY = False`, record how many steps the weak sequence takes from $n = 1, \ldots, 8$. Does the step count grow like a polynomial, an exponential, or something worse?
3. Change "subtract one" to "subtract two". Does every sequence still reach 0? Does your reason survive?

68.6 The challenge

No answers are given.

1. **Intuition.** Call an adjective *heterological* if it does not describe itself: "long" is heterological, "short" is not. Is "heterological" heterological? Compare this with the barber who shaves exactly those who do not shave themselves. Why does the barber puzzle merely show that no such barber exists, while Russell's paradox destroyed a whole theory?
2. **Derivation.** Using Theorem 68.4, show that if PA is consistent, then so is the theory $\mathrm{PA} + \neg\,\mathrm{Con}_{\mathrm{PA}}$, which "believes" itself inconsistent. Then explain why this strange theory is consistent but not sound, and what its models must contain that $\mathbb{N}$ does not.
3. **Implementation.** Write a quine in a language other than Python. Then write a Python program that takes a function `halts(src)` as a parameter, reads its own source code using the quine trick, and does the opposite of whatever `halts` predicts about it. Test it against three different (necessarily wrong) `halts` functions and record how each one fails.
4. **Open investigation.** In the **hydra game** of Kirby and Paris, Hercules cuts a head off a tree-shaped hydra, and the hydra regrows copies of the wounded branch, more copies at each step. Every strategy kills every hydra, and this too is unprovable in PA. Simulate it. Investigate how the number of steps depends on Hercules's strategy (always cut the leftmost head, the rightmost, a random one) and on the shape of the starting tree. Is there a strategy that is reliably fastest?

68.7 Loose threads

The hook asked how a statement about whole numbers can be true but unprovable. Now we know. Provability is relative to a formal system, a theorem-printing machine, and Gödel showed that any consistent, effective machine strong enough for arithmetic misses some truths, including the truth of its own consistency. Goodstein's theorem is one of them for Peano arithmetic. It is provable in a stronger system, which has its own blind spots in turn. Russell's paradox started this story by showing that naive self-reference destroys a theory. Gödel finished it by showing that careful self-reference, inside any sufficiently rich theory, reveals limits that cannot be engineered away.

What we did not tell you:

- **How the independence of CH is proved.** Forcing builds new models of set theory by adding a "generic" object to an old one, and it is among the most powerful techniques in logic. We stated Cohen's result without even a sketch.
- **Why the diagonal keeps appearing.** The first mystery points to Lawvere's fixed-point theorem in Ch. 62.
- **What working mathematicians do about it.** Almost nothing, usually, and the reasons are part of how research proceeds: see Ch. 98.

> **? Could P versus NP be independent?**
>
> Ch. 30 left P versus NP open. Could it be open because it is independent of ZFC, like the continuum hypothesis? Some researchers have taken the possibility seriously, and it is known that certain *weak* systems of arithmetic cannot prove some lower bounds of the kind needed. But no one knows how to prove that P versus NP is independent of ZFC, or even of Peano arithmetic, and most experts expect a proof one way or the other to exist. Whether the most famous problem in computer science lies beyond the reach of mathematics itself is an open problem.

Track G — Mathematics for Computer Graphics, Games, and Simulation

> **Level 2 — Specializations.** The geometry, algebra and numerics that turn equations into worlds on a screen.

Suggested reading order for Track G. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 2 — Complex Numbers and Engineering Representation
- Ch. 3 — Trigonometry and Periodic Functions
- Ch. 7 — Vector Calculus
- Ch. 8 — Matrices and Linear Systems
- Ch. 10 — Eigenvalues and Eigenvectors
- Ch. 16 — Fourier Transforms
- Ch. 22 — Numerical Methods

Chapters

Ch.	Chapter	What it explores
69	The Mathematics of 3D Worlds	Coordinate systems, affine transformations, homogeneous coordinates, projections.
70	Quaternions and the Geometry of Rotation	Rotation groups, quaternion algebra, interpolation, rigid-body transforms.
71	Ray Tracing: The Geometry of Light	Rays, intersections, reflection, refraction, sampling, rendering equations.
72	Numerical Simulation and Physics Engines	Numerical integration, collision detection, constraints, stability, error.
73	Fractals: Infinite Complexity from Simple Rules	Iterated functions, self-similarity, fractal dimensions, chaotic sets.
74	Procedural Generation: Creating Worlds with Rules	Noise functions, random fields, cellular automata, grammars, spatial structures.
75	Computational Geometry: Algorithms for Shapes	Convex hulls, triangulation, Voronoi diagrams, spatial indexing.
76	Signal Processing for Audio and Visual Computing	Sampling, filtering, convolution, transforms, spectral analysis.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 69 — The Mathematics of 3D Worlds

> **Level 2 · Track G — Mathematics for Computer Graphics, Games, and Simulation Builds on:** Ch. 8, Ch. 9, Ch. 7 · **Leads to:** Ch. 70, Ch. 71, Ch. 75 · **Related:** Ch. 22, Ch. 58, Ch. 59 **Reading time:** ~25 min

69.1 The hook

A first-year game programmer is building a toy solar system. She wants the Earth to spin on its axis and also sit 10 units from the Sun. She writes two lines: "rotate the Earth by the day angle" and "move the Earth 10 units out". It runs, and the Earth does something nobody asked for: instead of spinning in place, it swings around the Sun once a day like a stone on a string. She swaps the two lines, and now it spins in place. Same two operations, same numbers, opposite worlds.

Meanwhile her graphics card is doing something that should be impossible. Every frame, sixty times a second, it takes several million corners of triangles, each given as three numbers in the coordinates of its own little model, and lands each one on a pixel of your screen. Along the way every point must be

- **rotated** (the model faces some direction),
- **translated** (the model sits somewhere in the world, the camera sits somewhere else),
- **scaled** (the model was built in centimetres, the world is in metres),
- and **projected**, which means dividing by its distance from the eye, so that far things look small.

Here is the puzzle. A matrix is a *linear* map (see Ch. 9 §9.5): it always sends the zero vector to zero. A translation moves the origin, so no 3×3 matrix can translate anything. And projection divides by depth, which is not even close to linear. Yet the hardware does all of it with one 4×4 matrix per object and a single division per vertex.

How can a matrix with an extra row and column carry a whole world onto a flat screen? And why did swapping two lines move the Earth?

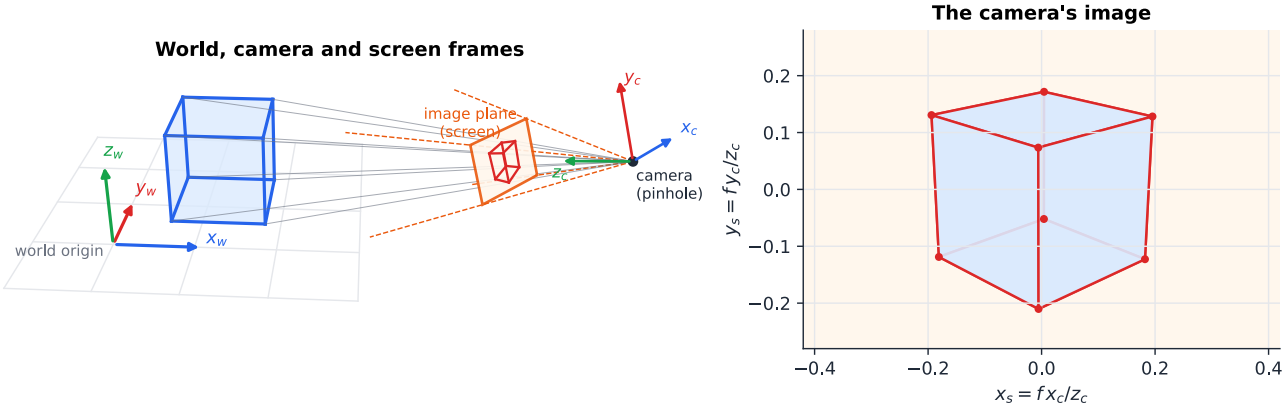
69.2 The big idea

Three ideas do almost all of the work.

Every coordinate is relative to a frame. "The cup is at $(2, 0, 1)$" means nothing until you say *measured from where, along which directions*. A frame is an origin plus three axes. A game has many: each model's own frame (where the artist built it), the world frame, the camera frame, and finally the screen. Rendering is nothing but a chain of changes of frame. The solar-system bug is a question of which frame each operation happens in: rotating *after* moving the Earth out swings it about the Sun's origin; rotating *before* spins it about its own centre.

Add one coordinate, and translation becomes linear. Write a 3-D point as $(x, y, z, 1)$. In four dimensions, the 3-D world is a flat slice at height $w = 1$, and a translation of that slice is a *shear* of 4-D space, which is linear. Directions get $w = 0$, so the shear leaves them alone, exactly as it should: moving a ship does not change which way its nose points.

A camera is a box with a hole. Light from a point passes through a pinhole and hits a screen. By similar triangles the image height is the true height divided by the distance. With the fourth coordinate in hand, we can make a matrix *copy* the depth into w; the hardware's final step "divide by w" then performs the projection.



Three frames in one picture. The world frame sits at the origin; the camera frame (x_c right, y_c up, z_c along the line of sight) sits at the pinhole. Each ray from a cube corner to the pinhole pierces the image plane, and the pierce points (red) form the picture on the right. The left panel was itself drawn by the same projection, from a second camera.

The analogy to hold onto: the GPU is a factory with one machine, "multiply by a 4×4 matrix", and one finishing step, "divide by the last number". Every trick in this chapter is a way of disguising a non-linear wish as a matrix.

69.3 The mathematics

Points, vectors and frames

There are two kinds of 3-D objects, and confusing them causes real bugs. A **point** is a location. A **vector** is a displacement: the arrow from one point to another. Their algebra is different: point minus point is a vector, point plus vector is a point, vector plus vector is a vector, but "point plus point" means nothing (what is Paris plus Tokyo?).

> **Frame**
>
> A **frame** $(\mathbf{o};\ \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ is an origin point $\mathbf{o}$ and a basis $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ of vectors. The coordinates of a point $\mathbf{p}$ in this frame are the unique numbers (x, y, z) with $\mathbf{p} = \mathbf{o} + x\mathbf{e}_1 + y\mathbf{e}_2 + z\mathbf{e}_3$. The coordinates of a vector $\mathbf{v}$ are the numbers with $\mathbf{v} = x\mathbf{e}_1 + y\mathbf{e}_2 + z\mathbf{e}_3$; the origin plays no part.

When the basis is orthonormal, coordinates are just dot products: $x = (\mathbf{p} - \mathbf{o}) \cdot \mathbf{e}_1$ and so on. For a camera at $\mathbf{c}$ with orthonormal axes $\hat{\mathbf{r}}$ (right), $\hat{\mathbf{u}}$ (up), $\hat{\mathbf{f}}$ (forward), a world point has camera coordinates

$$x_c = (\mathbf{p} - \mathbf{c}) \cdot \hat{\mathbf{r}}, \qquad y_c = (\mathbf{p} - \mathbf{c}) \cdot \hat{\mathbf{u}}, \qquad z_c = (\mathbf{p} - \mathbf{c}) \cdot \hat{\mathbf{f}}.$$

This is a change of basis followed by a shift of origin; the change-of-basis part is Ch. 9 §9.4, and the fact that the inverse of an orthogonal matrix is its transpose is Ch. 9 §9.7. How do we build $\hat{\mathbf{r}}, \hat{\mathbf{u}}, \hat{\mathbf{f}}$ from "camera at $\mathbf{c}$, looking at $\mathbf{t}$, world up is $\hat{\mathbf{z}}$"? Normalise $\mathbf{t} - \mathbf{c}$ to get $\hat{\mathbf{f}}$; then $\hat{\mathbf{r}} = \hat{\mathbf{f}} \times \hat{\mathbf{z}} / \|\hat{\mathbf{f}} \times \hat{\mathbf{z}}\|$ and $\hat{\mathbf{u}} = \hat{\mathbf{r}} \times \hat{\mathbf{f}}$. Two cross products (Ch. 7 §7.2) and you have a camera. (Notice the failure case already: if you look straight up, $\hat{\mathbf{f}} \times \hat{\mathbf{z}} = \mathbf{0}$ and the camera has no idea which way is right.)

Affine maps

> **Affine map**
>
> A map $T : \mathbb{R}^3 \to \mathbb{R}^3$ is **affine** if $T(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{t}$ for some 3×3 matrix $\mathbf{A}$ and vector $\mathbf{t}$. Rotations, scalings, shears, reflections and translations are all affine. It is **rigid** if $\mathbf{A}$ is a rotation ($\mathbf{A}^{\mathsf{T}}\mathbf{A} = \mathbf{I}$, $\det \mathbf{A} = 1$).

Affine maps are not linear (unless $\mathbf{t} = \mathbf{0}$), but they preserve something almost as good. Call $\sum_i \lambda_i \mathbf{p}_i$ an **affine combination** of points if the weights sum to one, $\sum_i \lambda_i = 1$. Only these combinations make sense for points: $\frac{1}{2}\mathbf{p} + \frac{1}{2}\mathbf{q}$ is the midpoint, wherever the origin is, while $\mathbf{p} + \mathbf{q}$ depends on the arbitrary choice of origin.

> **Result 1: affine maps preserve affine combinations**
>
> If $T(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{t}$ and $\sum_i \lambda_i = 1$, then $T\left(\sum_i \lambda_i \mathbf{p}_i\right) = \sum_i \lambda_i\, T(\mathbf{p}_i)$.

Proof. Using linearity of $\mathbf{A}$ and then $\sum_i \lambda_i = 1$ to write $\mathbf{t} = \sum_i \lambda_i \mathbf{t}$:

$$T\Big(\sum_i \lambda_i \mathbf{p}_i\Big) = \sum_i \lambda_i \mathbf{A}\mathbf{p}_i + \mathbf{t} = \sum_i \lambda_i \mathbf{A}\mathbf{p}_i + \sum_i \lambda_i \mathbf{t} = \sum_i \lambda_i \left(\mathbf{A}\mathbf{p}_i + \mathbf{t}\right) = \sum_i \lambda_i T(\mathbf{p}_i).$$

The step that used $\sum \lambda_i = 1$ is exactly where a non-affine combination would leave a stray $\mathbf{t}$. $\square$

The consequences are what make 3-D graphics cheap. The segment $\{(1-s)\mathbf{p} + s\mathbf{q}\}$ maps to the segment between $T(\mathbf{p})$ and $T(\mathbf{q})$, so **lines map to lines** and you only ever transform the endpoints. Midpoints map to midpoints, parallel lines stay parallel, and a point inside a triangle with barycentric coordinates $(\lambda_1, \lambda_2, \lambda_3)$ keeps them. A whole triangle with a million interior points is described by three corners. Remember this; projection will break it.

Homogeneous coordinates

Now the trick from §69.2. Attach a fourth coordinate: a point $\mathbf{p}$ becomes $(\mathbf{p}, 1)$ and a vector $\mathbf{v}$ becomes $(\mathbf{v}, 0)$. Then

$$\begin{bmatrix} \mathbf{A} & \mathbf{t} \\ \mathbf{0}^{\mathsf{T}} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{p} \\ 1 \end{bmatrix} = \begin{bmatrix} \mathbf{A}\mathbf{p} + \mathbf{t} \\ 1 \end{bmatrix}, \qquad \begin{bmatrix} \mathbf{A} & \mathbf{t} \\ \mathbf{0}^{\mathsf{T}} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ 0 \end{bmatrix} = \begin{bmatrix} \mathbf{A}\mathbf{v} \\ 0 \end{bmatrix}.$$

A 4×4 matrix in this block form performs an affine map on points and its linear part on vectors, with no special cases. The bookkeeping rules for points and vectors fall out of the last coordinate: point minus point has $w = 1 - 1 = 0$ (a vector), point plus vector has $w = 1$ (a point), and point plus point would have $w = 2$, which is not on the slice $w = 1$, the algebra's way of saying "meaningless".

Composition is now matrix multiplication (Ch. 8 §8.2). Applying $T_1(\mathbf{x}) = \mathbf{A}_1\mathbf{x} + \mathbf{t}_1$ and then T_2 gives

$$\begin{bmatrix} \mathbf{A}_2 & \mathbf{t}_2 \\ \mathbf{0}^{\mathsf{T}} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{A}_1 & \mathbf{t}_1 \\ \mathbf{0}^{\mathsf{T}} & 1 \end{bmatrix} = \begin{bmatrix} \mathbf{A}_2\mathbf{A}_1 & \mathbf{A}_2\mathbf{t}_1 + \mathbf{t}_2 \\ \mathbf{0}^{\mathsf{T}} & 1 \end{bmatrix}.$$

Look at the top-right block: the second map *rotates the first map's translation*. That is the solar-system bug, in one formula. Let $\mathbf{R}$ be a rotation by 90° about z and $\mathbf{T}$ a translation by $(10, 0, 0)$. Apply both to the Earth's centre, which starts at the origin:

- **rotate, then translate ($\mathbf{TR}$)**: the centre stays at the origin under $\mathbf{R}$, then moves to $(10, 0, 0)$. The Earth spins in place, out where it belongs.
- **translate, then rotate ($\mathbf{RT}$)**: the centre moves to $(10, 0, 0)$, then the rotation about the Sun's origin carries it to $(0, 10, 0)$. A quarter-day later, the Earth is a quarter of the way around its orbit.

Our programmer's first version applied the day rotation last. The rule of thumb, "matrices act right to left, the rightmost acts first, in the object's own frame", saves more debugging hours in graphics than any other sentence.

Inverting a rigid transform never needs a general inverse. If $\mathbf{x}' = \mathbf{R}\mathbf{x} + \mathbf{t}$, then $\mathbf{x} = \mathbf{R}^{\mathsf{T}}(\mathbf{x}' - \mathbf{t})$, so

$$\begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}^\mathsf{T} & 1 \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{R}^\mathsf{T} & -\mathbf{R}^\mathsf{T}\mathbf{t} \\ \mathbf{0}^\mathsf{T} & 1 \end{bmatrix}.$$

The **view matrix** of a camera is exactly this: the camera's own placement in the world is a rigid transform $(\mathbf{R}_c, \mathbf{c})$ whose rotation has columns $\hat{\mathbf{r}}, \hat{\mathbf{u}}, \hat{\mathbf{f}}$; the view matrix is its inverse, with rows $\hat{\mathbf{r}}^\mathsf{T}, \hat{\mathbf{u}}^\mathsf{T}, \hat{\mathbf{f}}^\mathsf{T}$, which reproduces the dot-product formulas for x_c, y_c, z_c above. Moving the camera left is the same as moving the world right.

Normals do not transform like points

Here is a trap that catches professionals. A surface's **normal** $\mathbf{n}$ is a vector perpendicular to it, used for lighting. Since normals are vectors, surely they transform by $\mathbf{A}$? Try a non-uniform stretch $\mathbf{A} = \operatorname{diag}(2, 1, 1)$ on the plane $x + y = 0$, which has tangent $\mathbf{s} = (1, -1, 0)$ and normal $\mathbf{n} = (1, 1, 0)$. After stretching, the tangent is $\mathbf{A}\mathbf{s} = (2, -1, 0)$, and the naive normal $\mathbf{A}\mathbf{n} = (2, 1, 0)$ has dot product $4 - 1 = 3$ with it. The lighting is now computed with a normal that is not normal.

> **Result 2: normals transform by the inverse transpose**
>
> If tangent vectors transform by an invertible $\mathbf{A}$, then $\mathbf{n}' = \mathbf{A}^{-\mathsf{T}}\mathbf{n}$ is perpendicular to every transformed tangent.

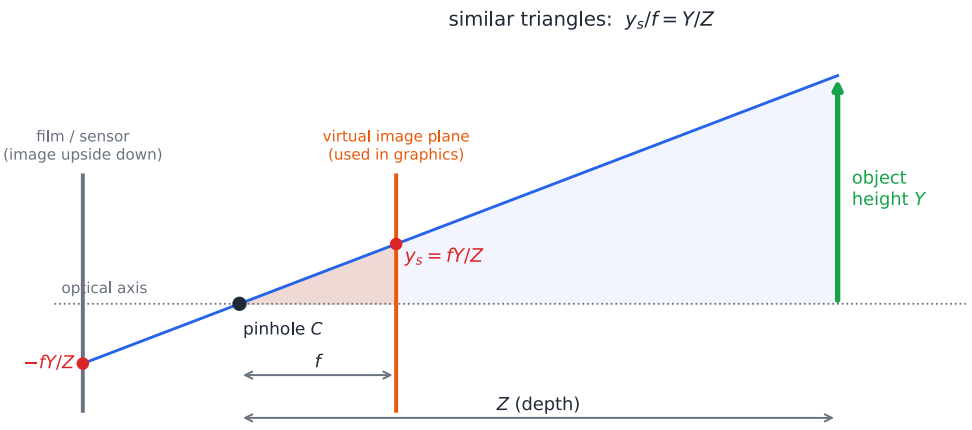
Proof. Perpendicularity is $\mathbf{n}^\mathsf{T}\mathbf{s} = 0$ for every tangent $\mathbf{s}$. Insert $\mathbf{I} = \mathbf{A}^{-1}\mathbf{A}$:

$$0 = \mathbf{n}^\mathsf{T}\mathbf{s} = \mathbf{n}^\mathsf{T}\mathbf{A}^{-1}\mathbf{A}\mathbf{s} = \left(\mathbf{A}^{-\mathsf{T}}\mathbf{n}\right)^\mathsf{T}(\mathbf{A}\mathbf{s}).$$

So $\mathbf{A}^{-\mathsf{T}}\mathbf{n}$ is perpendicular to every transformed tangent $\mathbf{A}\mathbf{s}$. □

In the example, $\mathbf{A}^{-\mathsf{T}}\mathbf{n} = (0.5, 1, 0)$ and $(0.5, 1, 0) \cdot (2, -1, 0) = 1 - 1 = 0$. For a rotation, $\mathbf{R}^{-\mathsf{T}} = \mathbf{R}$, which is why the bug hides until someone scales a model unevenly. The deeper lesson: tangents and normals are different kinds of object. Tangents are vectors; normals are really *covectors*, linear functions that eat vectors, and covectors transform "the other way".

The pinhole and the projection matrix



The pinhole camera. The small shaded triangle (pinhole, f, y_s) and the large one (pinhole, Z, Y) are similar, so $y_s = fY/Z$. A real camera's film sits behind the hole and sees the world upside down; graphics puts a virtual screen in front, which gives the same picture the right way up.

In camera coordinates (looking along $+z_c$), the similar triangles give the **perspective projection**

$$x_s = \frac{f\,x_c}{z_c}, \qquad y_s = \frac{f\,y_c}{z_c}.$$

A point at $(2, 1, 4)$ with $f = 1$ lands at $(0.5, 0.25)$; move it twice as far, to $(4, 2, 8)$, and it lands at the same place: every point on a ray through the pinhole has the same image. That is the geometric content of projection, and it is the same as the defining property of homogeneous coordinates: (x, y, z, w) and $(\lambda x, \lambda y, \lambda z, \lambda w)$ for $\lambda \neq 0$ name the same point $(x/w, y/w, z/w)$. So we let a matrix put z_c into the last slot and let the divide do the rest:

$$\begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & a & b \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} = \begin{bmatrix} f x_c \\ f y_c \\ a z_c + b \\ z_c \end{bmatrix} \xrightarrow{\div w} \left(\frac{f x_c}{z_c},\ \frac{f y_c}{z_c},\ a + \frac{b}{z_c} \right).$$

The third row keeps a **depth** value for deciding which surface is in front. Choosing a and b so that the near plane $z_c = n$ maps to depth 0 and the far plane $z_c = F$ to depth 1 gives $a = F/(F - n)$ and $b = -nF/(F - n)$. (Conventions differ: OpenGL looks down $-z$ and maps depth to $[-1, 1]$; the mathematics is the same.)

The matrix made the projection look linear, but the divide is not. What survives?

> **Result 3: perspective maps lines to lines, but not midpoints to midpoints**
>
> For points in front of the camera ($z_c > 0$), the projection of a segment is a segment. Ratios along the segment are not preserved.

Proof. Let the 3-D segment be $\mathbf{p}(s) = (1 - s)\mathbf{p}_0 + s\mathbf{p}_1$ with depths $z_0, z_1 > 0$. Its screen image is $\boldsymbol{\sigma}(s) = f\,(x(s), y(s))/z(s)$. Write $\boldsymbol{\sigma}_0, \boldsymbol{\sigma}_1$ for the endpoint images, so $f(x_i, y_i) = z_i\boldsymbol{\sigma}_i$. Then

$$\boldsymbol{\sigma}(s) = \frac{(1-s)z_0\,\boldsymbol{\sigma}_0 + s\,z_1\,\boldsymbol{\sigma}_1}{(1-s)z_0 + s z_1} = (1-u)\,\boldsymbol{\sigma}_0 + u\,\boldsymbol{\sigma}_1, \qquad u = \frac{s z_1}{(1-s)z_0 + s z_1}.$$

As s runs from 0 to 1, u runs monotonically from 0 to 1 (both weights stay positive), so the image is exactly the screen segment from $\boldsymbol{\sigma}_0$ to $\boldsymbol{\sigma}_1$. But $u \neq s$ unless $z_0 = z_1$. $\square$

Take $\mathbf{p}_0 = (-1, 0, 2)$ and $\mathbf{p}_1 = (1, 0, 6)$ with $f = 1$. The endpoints land at $x_s = -0.5$ and $x_s = 1/6$. The 3-D midpoint $(0, 0, 4)$ lands at $x_s = 0$, but the screen midpoint is $-1/6$. The near half of the segment takes up three quarters of its screen length. This is foreshortening, and it is why a texture painted on a floor must not be interpolated linearly across the screen: some mid-1990s game consoles did exactly that, and their floor tiles visibly wobble and swim as you walk.

69.4 The algorithm

Every rasterising renderer, from a phone game to a film previsualisation tool, runs this pipeline on every vertex:

```
for each object:
    M  = model matrix          (object frame  -> world frame; scale, rotate, translate)
    V  = view matrix           (world frame   -> camera frame; inverse of camera placement)
    P  = projection matrix     (camera frame  -> clip space; copies depth into w)
    MVP = P @ V @ M            (compose ONCE per object, 64 multiplies)
    for each vertex v = (x, y, z, 1):
        c = MVP @ v            (16 multiplies, 12 adds)
        clip triangles against the near plane (where w would approach 0)
        ndc = c.xyz / c.w      (the perspective divide)
        pixel = viewport(ndc)  (scale and shift to the window)
    normals: transform by inverse-transpose of the upper-left 3x3 of V @ M
```

Complexity. Composing three matrices costs a few hundred flops once per object; each vertex then costs one matrix–vector product. Precomposing is the whole point: the alternative, applying model, view and projection separately, triples the per-vertex work. With 10^6 vertices at 60 frames per second, that is the difference between 10^9 and 3×10^9 flops per second for this step alone.

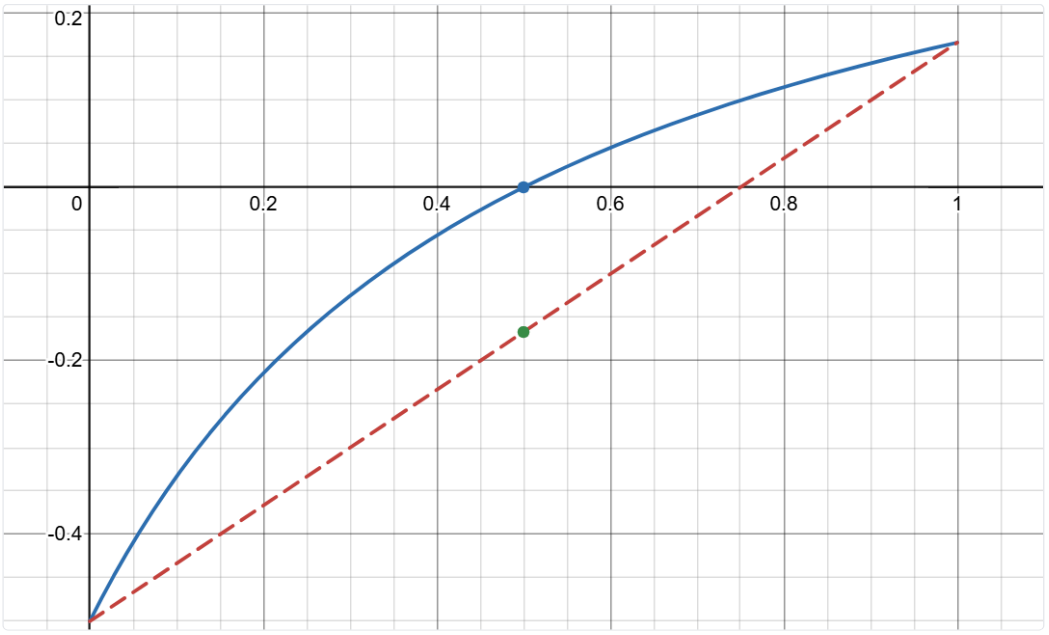
Failure cases.

- *Points behind the eye.* For $z_c < 0$ the divide flips the sign, and a vertex behind you appears in front, upside down. A triangle with one corner behind the camera would be smeared across the whole screen. This is why triangles are **clipped** against the near plane *before* the divide, in homogeneous coordinates where nothing has blown up yet.
- *Degenerate look-at.* Looking straight along "world up" makes $\hat{\mathbf{f}} \times \hat{\mathbf{z}} = \mathbf{0}$. Flight and space games cannot use a fixed world-up vector at all; they need a better description of orientation (Ch. 70).
- *Matrix drift.* An object rotated a little every frame, $\mathbf{R} \leftarrow \mathbf{R}\,\Delta\mathbf{R}$, slowly stops being a rotation in floating point: its columns lose length and orthogonality, and the model visibly shears. The repair (re-orthonormalising, Gram–Schmidt from Ch. 9 §9.7) is a patch; Ch. 70 offers a cure.
- *Depth precision.* The stored depth $a + b/z_c$ is a function of $1/z_c$, not z_c. With $n = 0.1$ and $F = 1000$, depth already reaches 0.50005 at $z_c = 0.2$: half the whole depth range is spent on the first 10 cm in front of your nose. With a 24-bit depth buffer, two surfaces near $z_c = 1000$ must be about 0.6 units apart to be told apart (at $z_c = 100$, about 0.006). Closer than that, they flicker through each other, a defect called **z-fighting**.

> **? The clue we're holding back**
>
> Pushing the near plane out helps z-fighting, but cuts off things close to the eye. Modern engines do something stranger: they flip the depth mapping so the *far* plane is 0 and the near plane is 1, store it as a floating-point number, and the precision problem nearly vanishes. Why does reversing a number line fix it? The answer lies in how floating-point numbers are spaced, in Ch. 22 §22.1.

69.5 The experiment

First, see foreshortening as a graph. A point slides along the 3-D segment from $(-1, 0, 2)$ to $(1, 0, 6)$; the horizontal axis is the 3-D parameter s (here called x) and the curve is its screen position $x_s = (-1 + 2s)/(2 + 4s)$. The dashed line is what naive linear interpolation on the screen would give.



Screen position (blue) against position along the 3-D segment. The blue curve bends: equal steps in the world are unequal on the screen. Change the depth slope `4` in the denominator to `0` (the segment is now parallel to the screen) and the curve becomes the straight line; make it `20` and watch the far half crowd into a sliver.

Second, the whole pipeline in under forty lines. Two wireframe cubes, one near and one far, are carried by a single composed matrix and a perspective divide.

```
import numpy as np
import matplotlib.pyplot as plt

DIST = 6.0          # KNOB: camera distance from the near cube's front face
FOCAL = 0.5 * DIST  # KNOB: focal length; FOCAL proportional to DIST = "dolly zoom"
YAW = 30.0          # KNOB: rotate both cubes about the vertical axis (degrees)
ORTHO = False       # KNOB: True = orthographic (no division by depth)

V = np.array([[x, y, z, 1.0] for x in (-1, 1) for y in (-1, 1) for z in (-1, 1)])
E = [(a, b) for a in range(8) for b in range(a + 1, 8) if np.sum(V[a] != V[b]) == 1]

def T(tx, ty, tz):                      # homogeneous translation
    M = np.eye(4); M[:3, 3] = (tx, ty, tz); return M

def Ry(deg):                            # rotation about the vertical (y) axis
    c, s = np.cos(np.radians(deg)), np.sin(np.radians(deg))
    return np.array([[c, 0, s, 0], [0, 1, 0, 0], [-s, 0, c, 0], [0, 0, 0, 1]])

P = np.array([[FOCAL, 0, 0, 0],         # perspective: w' = z, then divide
              [0, FOCAL, 0, 0],
              [0, 0, 1, 0],
              [0, 0, 1, 0]])
if ORTHO:
    P = np.diag([FOCAL / DIST, FOCAL / DIST, 1.0, 1.0])

view = T(0, 0, DIST + 1)                # camera at origin looking down +z
cubes = {"near cube": T(0, 0, 0) @ Ry(YAW), "far cube": T(2.5, 0, 8) @ Ry(YAW)}
fig, ax = plt.subplots(figsize=(6, 4))
for (name, model), c in zip(cubes.items(), ["tab:blue", "tab:red"]):
    clip = (P @ view @ model @ V.T).T   # one matrix product carries every vertex
    s = clip[:, :2] / clip[:, 3:4]      # the perspective divide
    for a, b in E:
        ax.plot(s[[a, b], 0], s[[a, b], 1], color=c)
    ax.plot([], [], color=c, label=name)
ax.set_aspect("equal"); ax.set_xlim(-1.5, 1.5); ax.set_ylim(-1, 1)
ax.legend(); ax.set_title(f"DIST={DIST}, FOCAL={FOCAL:.2f}, ortho={ORTHO}")
plt.show()
```

Things to try:

- **The dolly zoom.** Because `FOCAL` is tied to `DIST`, the near cube's front face always has half-height 0.5 on screen. Set `DIST = 2.0`: the far cube's front face shrinks to half-height 0.1. Set `DIST = 20.0`: it grows to about 0.36. The subject stays put while the background breathes. Hitchcock used this in *Vertigo* (1958) to make a staircase lurch.
- **Swap the order.** Replace `T(2.5, 0, 8) @ Ry(YAW)` by `Ry(YAW) @ T(2.5, 0, 8)` and vary `YAW`. The far cube now swings around the near cube (the world origin) instead of turning in place: the solar-system bug, reproduced.
- **Go orthographic.** Set `ORTHO = True`. Parallel edges stay parallel and the two cubes are the same size: an engineering drawing, not a photograph.
- **Walk through the eye.** Set `DIST = -1.0` and `FOCAL = 1.0`, so the near cube straddles the camera. Vertices behind the eye get negative w and the drawing explodes. That is the clipping problem of §69.4, in your hands.

69.6 The challenge

1. **Intuition.** Railway tracks are parallel in the world, yet in a photograph they meet at a *vanishing point*. Using Result 3 and the fact that all lines with direction $\mathbf{d}$ share the homogeneous "point" $(\mathbf{d}, 0)$, explain where the vanishing point is on the screen. Why do lines parallel to the image plane have no vanishing point? Where do all the vanishing points of horizontal lines lie?
2. **Derivation.** Show that $1/z_c$ is an *affine* function of the screen coordinates (x_s, y_s) across the image of any planar triangle (start from the plane equation $\alpha x_c + \beta y_c + \gamma z_c = \delta$). Deduce that a texture coordinate q is interpolated correctly on the screen by interpolating q/z_c and $1/z_c$ linearly and dividing.
3. **Implementation.** Extend the experiment script into a tiny **rasteriser**: fill each face of the cube with a flat colour, resolve visibility with a per-pixel depth buffer on a 160×120 grid instead of drawing faces in order, and compute flat shading from face normals transformed by the inverse transpose. Add a non-uniform scale to the model matrix and confirm that the wrong (non-inverse-transpose) normals visibly break the shading.
4. **Open investigation.** Real lenses are not pinholes. Wide-angle lenses bend straight lines near the edges (barrel distortion), often modelled by $r_d = r(1 + k_1 r^2 + k_2 r^4)$ in screen radius r. Distort your rasteriser's output with this model and then try to *undo* it from a photo of a checkerboard, estimating k_1, k_2 by least squares. How many squares do you need? How does the error behave near the corners? Camera calibration is a field in its own right; see how far you get with only this chapter.

69.7 Loose threads

The programmer's Earth now spins in place, because she knows that matrices act right to left and that the rightmost one acts in the object's own frame. The GPU's impossible trick has a name: homogeneous coordinates turn translation into a 4-D shear and projection into "copy depth into w, then divide". Three theorems carry the load: affine maps preserve affine combinations, normals transform by the inverse transpose, and perspective keeps lines straight while distorting distances along them.

What we did not tell you:

- **Rotation is the weak link.** We stored orientation as nine numbers in a matrix, though a rotation has only three degrees of freedom. Nine numbers drift, cannot be averaged, and give no sensible way to turn smoothly from one orientation to another.

> **? Halfway between two orientations**
>
> A camera faces north; a second later it must face straight up and slightly east. Average the two rotation matrices entrywise and you do not get a rotation at all: the result shrinks and shears the world. What *is* halfway between two orientations, and why does the honest answer need a four-dimensional number system invented on a Dublin bridge in 1843? That is Ch. 70.

- **Points at infinity.** The homogeneous points with $w = 0$ behave like genuine points: parallel lines meet there, and a projective transformation can move them into view as vanishing points. Adding them turns 3-D space into *projective space*, where every two distinct lines in a plane meet in exactly one point.

> **? A world with one side**
>
> Collapse each line through the origin of $\mathbb{R}^3$ to a single point and you get the *real projective plane*: the world of homogeneous coordinates (x, y, w) up to scale. It is a closed surface that cannot be built in ordinary 3-D space without crossing itself, and it has only one side. Why, and what does that mean for a creature living on it? The answer is in Ch. 58.

- **The inverse problem.** Projection throws away depth. Recovering it from two or more photographs (stereo, structure from motion) is an inverse problem with its own geometry, the *epipolar* constraint, and its own instabilities; see Ch. 91.
- **The other way to draw.** The pipeline here pushes triangles toward the eye. The opposite approach pulls light backward from the eye into the scene, one ray per pixel, and gets shadows, mirrors and glass almost for free: Ch. 71. Clipping, culling and finding what a ray hits quickly are algorithms on shapes, in Ch. 75.

70.1 The hook

July 1969. Apollo 11 is on its way to the Moon, and the spacecraft's sense of direction lives in a gyroscope-stabilised platform held inside three nested rings, or **gimbals**. Each gimbal lets the spacecraft turn about one axis while the platform stays fixed relative to the stars. Three rings, three angles: yaw, pitch, roll. It sounds complete.

It is not. If the spacecraft turns so that the middle ring is at 90°, the outer and inner rings line up, and their two axes become the same axis. The platform has lost one of its three directions of freedom. A turn in the missing direction now drags the platform with it, and the guidance computer's picture of "which way is up" is gone, to be rebuilt by hand from star sightings. This is **gimbal lock**. The crew were trained to steer clear of it, and the command module pilot, Michael Collins, is often quoted as asking mission control, half joking, for a fourth gimbal for Christmas.

Fifty years later every 3-D game, drone, phone and VR headset faces the same problem in software. Store an orientation as three angles, and there is some orientation where the angles jam. Store it as a 3×3 rotation matrix, as in Ch. 69, and you carry nine numbers for three degrees of freedom; they drift in floating point, and there is no honest way to say what orientation lies *halfway* between two others. A camera that must swing smoothly from "facing north" to "facing straight up" has no good recipe.

The cure was found 126 years before Apollo, on 16 October 1843, by a man walking along a canal in Dublin. William Rowan Hamilton had spent years trying to multiply triples of numbers the way complex numbers multiply pairs. In a flash he saw that triples would never work, but *quadruples* would, and he carved the rule into the stone of Broom Bridge:

$$\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1.$$

Why should rotating a 3-D world need a 4-D number? And why does the answer involve *half* the rotation angle?

70.2 The big idea

Start with something you already know. In the plane, multiplying by the unit complex number $e^{j\theta}$ rotates every point by θ (Ch. 2 §2.7). Rotations of the plane *are* unit complex numbers; composing rotations is multiplying them; and the halfway point between two orientations is just the point halfway along the arc of the unit circle. One number, no jamming, perfect interpolation.

Quaternions do the same for space, with two twists.

Rotations have axes. Whatever tangle of turns you apply to a rigid body, the net result is a single turn by some angle θ about some fixed axis $\hat{\mathbf{n}}$ (Euler's rotation theorem, proved below). So an orientation is really "an axis and an angle": four numbers with one constraint, which is exactly what a unit quaternion is. The unit quaternions form a 3-D sphere sitting in 4-D space, and **every point on that sphere is an orientation**. There are no poles, no special angles, no place where the coordinates jam.

The angle is halved, and every rotation appears twice. A unit quaternion q does not rotate a vector by multiplying it once; it *sandwiches* it, $\mathbf{v} \mapsto q\mathbf{v}q^{*}$. Each factor contributes half the turn, so q must carry $\theta/2$. The price is that q and $-q$ give the same rotation: the sphere of quaternions wraps twice around the space of rotations.

Interpolation then becomes geometry on that sphere. To swing from orientation q_0 to q_1, walk along the great circle between them at constant speed. That walk is **SLERP**, and it is the reason a game camera can glide where Euler angles would lurch.

The analogy: Euler angles are like describing a location on Earth by latitude and longitude. They work almost everywhere, but at the North Pole longitude is meaningless and a small step can change it by 180°. Quaternions are like describing the location by a point in 3-D space on the globe's surface: no special places at all.

70.3 The mathematics

Rotations and their axes

A **rotation** of space is a 3×3 matrix $\mathbf{R}$ that preserves lengths and handedness: $\mathbf{R}^{\mathsf{T}}\mathbf{R} = \mathbf{I}$ and $\det \mathbf{R} = 1$ (orthogonal matrices are Ch. 9 §9.7). The set of all of them is called $SO(3)$, the *special orthogonal group*. It is a group: products and inverses of rotations are rotations, and $\mathbf{R}^{-1} = \mathbf{R}^{\mathsf{T}}$. It is not commutative: tip a book forward and then turn it left, versus left then forward, and the book ends up in two different poses.

> **Result 1: Euler's rotation theorem**
>
> Every rotation $\mathbf{R} \in SO(3)$ fixes some unit vector $\hat{\mathbf{n}}$: $\mathbf{R}\hat{\mathbf{n}} = \hat{\mathbf{n}}$. So every rotation is a turn about an axis.

Proof. We need 1 to be an eigenvalue of $\mathbf{R}$ (Ch. 10 §10.2), that is, $\det(\mathbf{R} - \mathbf{I}) = 0$. Using $\mathbf{R}\mathbf{R}^{\mathsf{T}} = \mathbf{I}$, $\det \mathbf{R} = 1$ and $\det \mathbf{M}^{\mathsf{T}} = \det \mathbf{M}$:

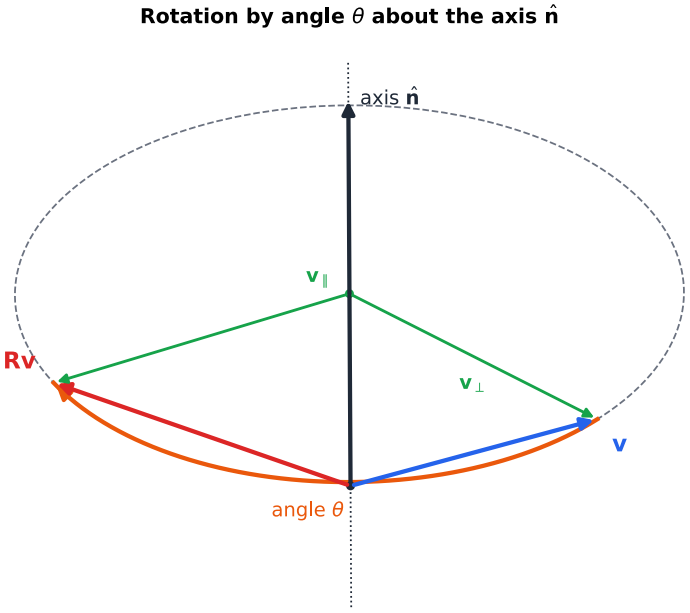
$$\det(\mathbf{R} - \mathbf{I}) = \det\left(\mathbf{R}(\mathbf{I} - \mathbf{R}^{\mathsf{T}})\right) = \det \mathbf{R}\, \det\left((\mathbf{I} - \mathbf{R})^{\mathsf{T}}\right) = \det(\mathbf{I} - \mathbf{R}) = (-1)^3 \det(\mathbf{R} - \mathbf{I}).$$

A number equal to its own negative is zero. The factor $(-1)^3$ is where three dimensions matter: in the plane, $(-1)^2 = 1$ and the argument (rightly) fails, since a planar rotation fixes no direction. □

The axis $\hat{\mathbf{n}}$ is the eigenvector for eigenvalue 1. The other two eigenvalues are $e^{\pm j\theta}$, and θ is the angle of turn; since the trace is the sum of the eigenvalues, $\operatorname{tr}\mathbf{R} = 1 + 2\cos\theta$. Conversely, the rotation by θ about $\hat{\mathbf{n}}$ is given by **Rodrigues' formula**,

$$\mathbf{R}\mathbf{v} = \mathbf{v}\cos\theta + (\hat{\mathbf{n}} \times \mathbf{v})\sin\theta + \hat{\mathbf{n}}(\hat{\mathbf{n}} \cdot \mathbf{v})(1 - \cos\theta),$$

which you can read straight off the figure: split $\mathbf{v}$ into its part along the axis, which does not move, and its part perpendicular to the axis, which turns by θ in the plane spanned by $\mathbf{v}_\perp$ and $\hat{\mathbf{n}} \times \mathbf{v}$.



Rotation about an axis. The component $\mathbf{v}_\parallel$ along $\hat{\mathbf{n}}$ stays put; the component $\mathbf{v}_\perp$ swings by θ around the circle. Every rotation of space looks like this, for some axis (Result 1).

Euler angles and gimbal lock

The most popular way to write a rotation is as three turns about fixed coordinate axes, for example

$$\mathbf{R}(\alpha, \beta, \gamma) = \mathbf{R}_z(\alpha)\,\mathbf{R}_y(\beta)\,\mathbf{R}_x(\gamma),$$

with yaw α, pitch β and roll γ. Three numbers that a human can read: an excellent user interface. As a data structure, it has a hole.

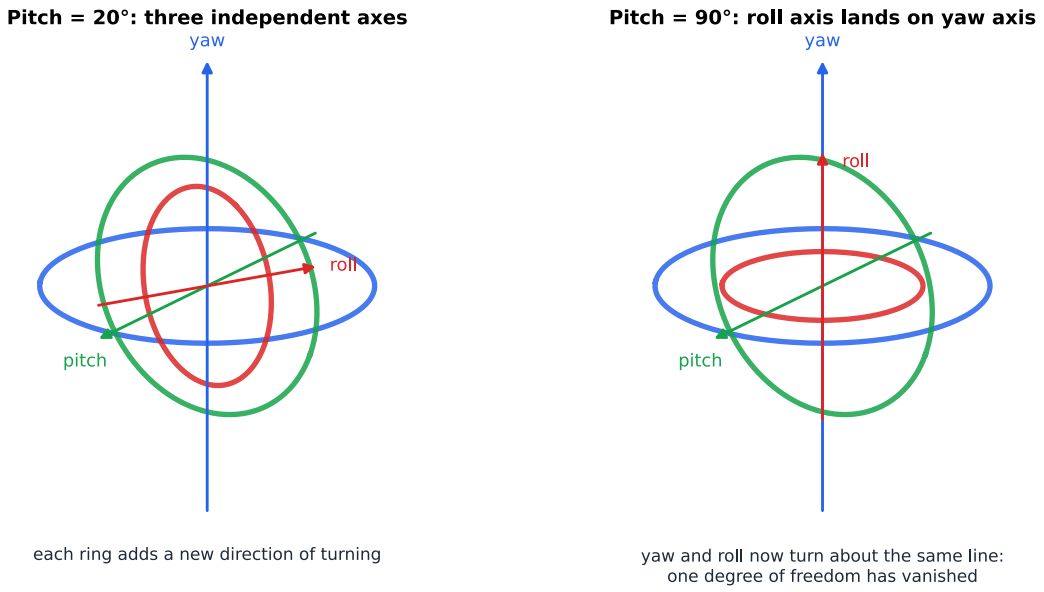
Result 2: gimbal lock

At pitch $\beta = 90°$, the rotation depends only on $\alpha - \gamma$:

$$\mathbf{R}_z(\alpha)\,\mathbf{R}_y(90°)\,\mathbf{R}_x(\gamma) = \mathbf{R}_z(\alpha - \gamma)\,\mathbf{R}_y(90°).$$

Proof. For any rotation $\mathbf{Q}$, the conjugate $\mathbf{Q}\mathbf{R}_{\hat{\mathbf{a}}}(\gamma)\mathbf{Q}^{-1}$ is the rotation by γ about the turned axis $\mathbf{Q}\hat{\mathbf{a}}$ (turn the axis into place, rotate, turn back). Take $\mathbf{Q} = \mathbf{R}_y(90°)$, which sends $\hat{\mathbf{x}}$ to $-\hat{\mathbf{z}}$. Then $\mathbf{R}_y(90°)\mathbf{R}_x(\gamma)\mathbf{R}_y(90°)^{-1}$ is a turn by γ about $-\hat{\mathbf{z}}$, which is $\mathbf{R}_z(-\gamma)$. Hence $\mathbf{R}_y(90°)\mathbf{R}_x(\gamma) = \mathbf{R}_z(-\gamma)\mathbf{R}_y(90°)$, and multiplying on the left by $\mathbf{R}_z(\alpha)$ gives the claim. □

So at that pitch, changing yaw and changing roll do *the same thing*. The map from three angles to rotations, which is smooth and three-to-three almost everywhere, collapses to two dimensions there: its Jacobian (Ch. 6) drops rank. In a mechanical gimbal, that is the moment two rings become coplanar. In software, it shows up as a camera that suddenly spins wildly when it tries to follow a target passing overhead: a small change of orientation demands a huge change of yaw and roll.



Gimbal lock. Each ring turns about its own axis. At 90° of pitch the roll axis lands on the yaw axis, so two rings produce the same motion and no ring can produce the third.

The hole is not a flaw of this particular choice. Any description of all rotations by three smooth angles has such a place somewhere; the reason is topological (see §70.7). The escape is to use more numbers, but cleverly.

Quaternion algebra

Quaternions

A **quaternion** is $q = w + x\mathbf{i} + y\mathbf{j} + z\mathbf{k}$ with real w, x, y, z, multiplied using Hamilton's rule $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -1$, which implies $\mathbf{ij} = \mathbf{k} = -\mathbf{ji}$, $\mathbf{jk} = \mathbf{i} = -\mathbf{kj}$, $\mathbf{ki} = \mathbf{j} = -\mathbf{ik}$. Write $q = (w, \mathbf{v})$ with scalar part w and vector part $\mathbf{v} = (x, y, z)$. The **conjugate** is $q^* = (w, -\mathbf{v})$ and the **norm** is $\|q\| = \sqrt{w^2 + x^2 + y^2 + z^2}$.

(The book's imaginary unit is j; the quaternion units are written bold, $\mathbf{i}, \mathbf{j}, \mathbf{k}$, and each of them squares to -1 like j does. The complex numbers sit inside the quaternions as $w + x\mathbf{i}$.)

Multiplying out with the table and collecting terms gives the whole algebra in one line:

$$(w_1, \mathbf{v}_1)(w_2, \mathbf{v}_2) = \big(w_1 w_2 - \mathbf{v}_1 \cdot \mathbf{v}_2,\ \ w_1\mathbf{v}_2 + w_2\mathbf{v}_1 + \mathbf{v}_1 \times \mathbf{v}_2\big).$$

Both 3-D products appear, the dot and the cross. Hamilton's algebra is in fact where they came from: physicists later split quaternion multiplication into these two pieces and called the result vector analysis. The cross product is why quaternions do not commute, matching the fact that rotations do not.

Three facts follow quickly. $qq^* = (\|q\|^2, \mathbf{0})$, so every non-zero quaternion has an inverse $q^{-1} = q^*/\|q\|^2$. Conjugation reverses products, $(pq)^* = q^*p^*$. And the norm is multiplicative, $\|pq\| = \|p\|\,\|q\|$, since $\|pq\|^2 = pq(pq)^* = p\,qq^*\,p^* = \|q\|^2\,pp^*$. So **products of unit quaternions are unit quaternions**: the unit sphere S^3 in 4-D space is closed under multiplication, just as the unit circle is for complex numbers.

The sandwich

Identify a 3-D vector $\mathbf{v}$ with the "pure" quaternion $(0, \mathbf{v})$.

Result 3: unit quaternions rotate by sandwiching

Let $q = \big(\cos\frac{\theta}{2},\ \sin\frac{\theta}{2}\,\hat{\mathbf{n}}\big)$ with $\hat{\mathbf{n}}$ a unit vector. Then $q\,\mathbf{v}\,q^*$ is a pure quaternion, and it equals the rotation of $\mathbf{v}$ by angle θ about $\hat{\mathbf{n}}$.

Proof. Write $c = \cos\frac{\theta}{2}$, $s = \sin\frac{\theta}{2}$, and split $\mathbf{v} = \mathbf{v}_\parallel + \mathbf{v}_\perp$ along and across $\hat{\mathbf{n}}$. The map $\mathbf{v} \mapsto q\mathbf{v}q^*$ is linear, so treat the two parts separately.

Parallel part. $\mathbf{v}_\parallel = a\hat{\mathbf{n}}$ is a multiple of q's own vector part, so it commutes with q (the cross product term vanishes). Hence $q\mathbf{v}_\parallel q^* = \mathbf{v}_\parallel qq^* = \mathbf{v}_\parallel$: the axis does not move.

Perpendicular part. With $\hat{\mathbf{n}} \cdot \mathbf{v}_\perp = 0$, the product rule gives

$$q\,\mathbf{v}_\perp = (c, s\hat{\mathbf{n}})(0, \mathbf{v}_\perp) = \big(-s\,\hat{\mathbf{n}} \cdot \mathbf{v}_\perp,\ c\,\mathbf{v}_\perp + s\,\hat{\mathbf{n}} \times \mathbf{v}_\perp\big) = \big(0,\ c\,\mathbf{v}_\perp + s\,\hat{\mathbf{n}} \times \mathbf{v}_\perp\big),$$

and the same computation shows $\mathbf{v}_\perp q^* = (0,\ c\,\mathbf{v}_\perp + s\,\hat{\mathbf{n}} \times \mathbf{v}_\perp) = q\mathbf{v}_\perp$. So $q\mathbf{v}_\perp q^* = q\,(q\mathbf{v}_\perp) = q^2\mathbf{v}_\perp$. Now $q^2 = (c^2 - s^2,\ 2cs\,\hat{\mathbf{n}}) = (\cos\theta,\ \sin\theta\,\hat{\mathbf{n}})$ by the double-angle formulas, so applying the first computation again with θ in place of $\theta/2$:

$$q\,\mathbf{v}_\perp\,q^* = \big(0,\ \mathbf{v}_\perp\cos\theta + (\hat{\mathbf{n}} \times \mathbf{v}_\perp)\sin\theta\big).$$

That is $\mathbf{v}_\perp$ turned by θ in its plane. Adding the unmoved $\mathbf{v}_\parallel$ gives exactly Rodrigues' formula. □

Now the half angle is no mystery: one factor q on each side, each turning the perpendicular part by $\theta/2$. A check: rotate $\mathbf{v} = \hat{\mathbf{x}}$ by $90°$ about $\hat{\mathbf{z}}$. Here $q = (\frac{1}{\sqrt{2}}, 0, 0, \frac{1}{\sqrt{2}})$, and two applications of the product rule give $q\hat{\mathbf{x}}q^* = (0, 0, 1, 0)$, the vector $\hat{\mathbf{y}}$. Correct.

Because the sandwich respects products, $(pq)\mathbf{v}(pq)^* = p\,(q\mathbf{v}q^*)\,p^*$, so **composing rotations is multiplying quaternions**, with the rightmost acting first as for matrices. A turn of 90° about $\hat{\mathbf{x}}$ followed by 90° about $\hat{\mathbf{y}}$ is

$$q_y\,q_x = \left(\tfrac{1}{\sqrt{2}},0,\tfrac{1}{\sqrt{2}},0\right)\left(\tfrac{1}{\sqrt{2}},\tfrac{1}{\sqrt{2}},0,0\right) = \left(\tfrac{1}{2},\tfrac{1}{2},\tfrac{1}{2},-\tfrac{1}{2}\right),$$

whose scalar part $\cos\frac{\theta}{2} = \frac{1}{2}$ says $\theta = 120^\circ$, about the axis $(1,1,-1)/\sqrt{3}$. Two quarter-turns about perpendicular axes make a third of a turn about a diagonal: try it with a book.

Finally, since $(-q)\mathbf{v}(-q)^* = q\mathbf{v}q^*$, the antipodal points q and $-q$ on S^3 are the same rotation. Unit quaternions **double cover** $SO(3)$. Rotating by 360° about any axis gives $q = (\cos 180^\circ, \mathbf{0}) = -1$: the identity rotation, but not the identity quaternion. You must turn by 720° to get back to $q = 1$.

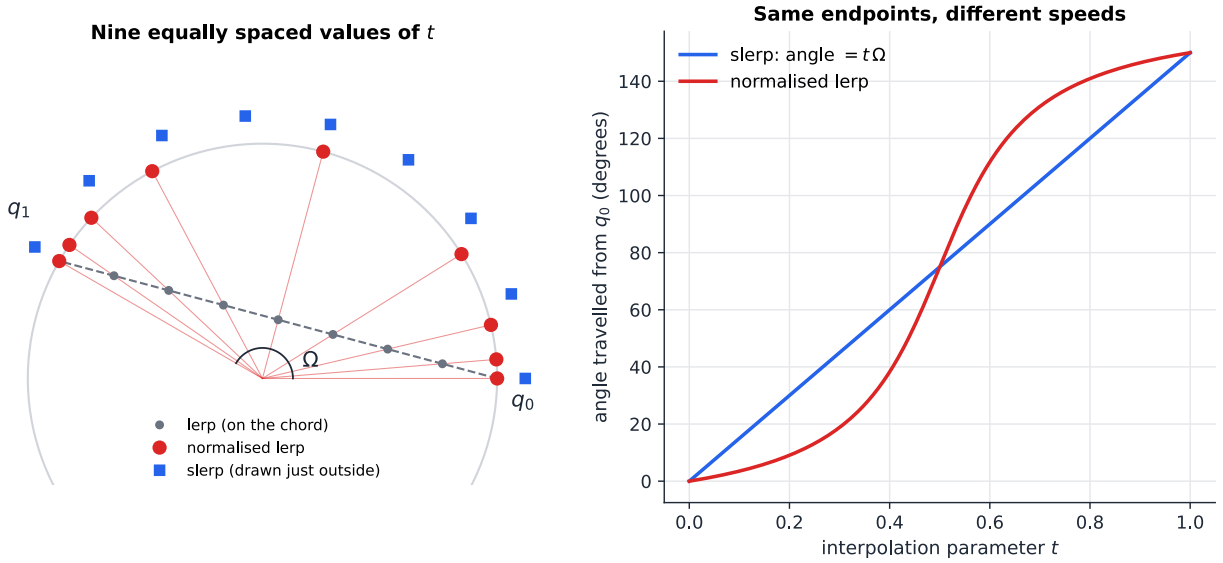
Interpolation: SLERP

Given orientations q_0, q_1 (unit quaternions), what is "the orientation a fraction t of the way from q_0 to q_1"? The natural answer is the point a fraction t of the way along the shortest great-circle arc between them on S^3. Let $\cos\Omega = q_0 \cdot q_1$ (the 4-D dot product). The arc lies in the plane spanned by q_0 and q_1; in that plane, take the unit vector $q_\perp = (q_1 - q_0\cos\Omega)/\sin\Omega$ orthogonal to q_0, so the arc is $q_0\cos(t\Omega) + q_\perp\sin(t\Omega)$. Substituting and using $\sin\Omega\cos t\Omega - \cos\Omega\sin t\Omega = \sin\big((1-t)\Omega\big)$ gives

$$\operatorname{slerp}(q_0,q_1;t) = \frac{\sin\big((1-t)\Omega\big)}{\sin\Omega}\,q_0 + \frac{\sin(t\Omega)}{\sin\Omega}\,q_1.$$

It moves at constant angular speed, and the physical rotation turns at the constant rate 2Ω per unit t about a fixed axis. One detail matters: q_1 and $-q_1$ are the same orientation but different points, and the arc to one is longer than to the other. If $q_0 \cdot q_1 < 0$, replace q_1 by $-q_1$ first, or the camera goes "the long way round".

The cheap alternative, **normalised lerp**, draws the straight chord $(1-t)q_0 + tq_1$ and pushes each point back onto the sphere. It follows the same path but at the wrong speed: slow at the ends, fast in the middle.



SLERP against normalised lerp, on a circle (the 2-D slice of S^3 containing q_0 and q_1), with the angle exaggerated to 150°. Evenly spaced points on the chord project to unevenly spaced points on the arc; at this angle the projected point moves at 2.85 times the slerp speed in the middle and 0.19 times at the ends.

70.4 The algorithm

The core toolkit fits on a page.

```
qmul((w1,v1),(w2,v2)) = (w1*w2 − v1.v2,  w1*v2 + w2*v1 + v1 x v2)   # 16 mul, 12 add
from_axis_angle(n, th) = (cos(th/2), sin(th/2) * n)                  # n must be unit
rotate(q, v)          = vector part of qmul(qmul(q, (0,v)), conj(q))
to_matrix(q)          = 3x3 matrix with entries 1−2(y^2+z^2), 2(xy−wz), ...   # for bulk use
slerp(q0, q1, t):
    d = dot(q0, q1)
    if d < 0: q1, d = −q1, −d            # take the short way round
    if d > 0.9995: return normalize((1−t)*q0 + t*q1)   # nearly equal: avoid 0/0
    W = acos(d)
    return (sin((1−t)*W)*q0 + sin(t*W)*q1) / sin(W)
```

Cost. Composing two rotations costs 16 multiplications as quaternions against 27 as matrices, and a quaternion is 4 numbers against 9. But rotating *one vector* by the sandwich costs more than a matrix–vector product (9 multiplies). So engines store and compose orientations as quaternions, then convert once to a matrix per object per frame before transforming thousands of vertices, exactly as in the pipeline of Ch. 69 §69.4.

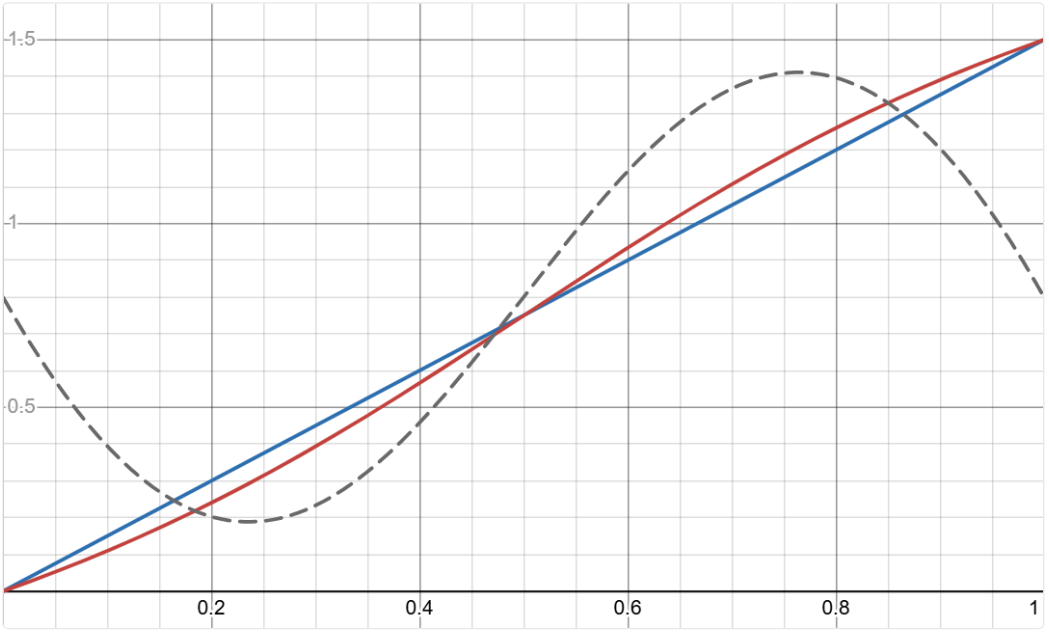
Rigid bodies. A full pose is a rotation and a position, $\mathbf{x} \mapsto q\mathbf{x}q^* + \mathbf{t}$. Poses compose like the block matrices of Ch. 69: $(q_2,\mathbf{t}_2)\circ(q_1,\mathbf{t}_1) = (q_2q_1,\ q_2\mathbf{t}_1q_2^* + \mathbf{t}_2)$, where again the second pose rotates the first one's translation. Skeletal animation stores each bone as such a pair relative to its parent and multiplies down the chain from hip to fingertip. (Blending poses by blending the pairs separately makes twisting joints collapse like a candy wrapper, which is why animators use *dual quaternions*, a variant that interpolates rotation and translation together.)

Failure cases.

- *Drift.* Repeated multiplication in floating point slowly moves q off the unit sphere, and a non-unit q also scales whatever it rotates. The fix is one line, $q \leftarrow q/\|q\|$. A drifting matrix needs a full Gram–Schmidt re-orthonormalisation instead, and you must decide which column to trust.
- *Near-equal endpoints.* In SLERP, $\sin\Omega \to 0$ as $q_0 \to q_1$; switch to normalised lerp, which is then accurate.
- *Sign flips.* Data from sensors or animation files may jump between q and $-q$ from frame to frame. Both are right, but averaging or filtering them naively gives nonsense near zero. Always align signs (by the dot product test) before blending.
- *Conventions.* Some libraries store (x, y, z, w), some (w, x, y, z); some multiply in the opposite order. Most quaternion bugs are convention bugs.

70.5 The experiment

First, see how uneven normalised lerp is. For two quaternions at angle Ω apart, the angle reached by normalised lerp at parameter t (here x) is $\arctan\bigl(t\sin\Omega/(1-t+t\cos\Omega)\bigr)$; slerp reaches $t\Omega$. The graph uses $\Omega = 1.5$ rad, close to the largest angle you meet after the sign test (a rotation of about $172°$).



Angle travelled by slerp (blue) and normalised lerp (red) for $\Omega = 1.5$; the dashed curve is their difference magnified ten times (centred at 0.8). Replace every `1.5` by `0.5`: the curves nearly coincide, which is why games often get away with lerp for small steps. Keep Ω below about 1.57 so the denominator stays positive.

At $\Omega = 1.5$ the red curve starts at 0.665 times the slerp speed and reaches 1.24 times it in the middle; the largest angle error is about $3.5°$, visible as a stutter in a slow camera move.

Second, watch numbers drift. The script below spins a body at constant angular velocity for 10^5 small steps, once by multiplying rotation matrices and once by multiplying quaternions, and measures how far each has wandered from being a true rotation.

```
import numpy as np

```

With the defaults (single precision, no renormalisation) both drift by about 10^{-3} after 10^5 steps: the matrix error is 8.6×10^{-4} and the quaternion error 1.8×10^{-3}. Quaternions are *not* magically immune to rounding. The difference is what the repair costs. Now:

- Set `RENORM_EVERY = 100`. One square root and four divisions every hundred frames, and the quaternion error is gone, while the matrix keeps shearing.
- Set `DTYPE = np.float64`. Both errors drop to about 10^{-11}. Simulators can afford this; GPUs and phone sensors often cannot.
- Raise `DT` to `0.05` and compare the final orientations of the two methods. They agree with each other, because each step is an exact rotation. But is each step the *right* rotation when $\boldsymbol{\omega}$ itself changes over time? That question belongs to physics engines.

70.6 The challenge

1. **Intuition.** Hold a cup of water flat on your palm and rotate your hand a full 360° about the vertical, keeping the cup level (your arm will end up twisted). Keep going another 360° in the same direction. What happens to your arm? Relate this to the fact that the rotation by 360° is the quaternion -1, not $+1$.
2. **Derivation.** Show that $\operatorname{tr}\mathbf{R} = 1 + 2\cos\theta$ for the rotation matrix built from $q = (\cos\frac{\theta}{2}, \sin\frac{\theta}{2}\hat{\mathbf{n}})$, and use it to derive a formula recovering q from $\mathbf{R}$ when $w = \cos\frac{\theta}{2}$ is not small. Which entries of $\mathbf{R}$ should you use instead when θ is close to 180°, and why does the naive formula then lose accuracy?
3. **Implementation.** Write a function that converts Euler angles (α, β, γ) to a quaternion and back. Feed it a camera that tracks an aircraft flying straight over your head, and plot the recovered yaw and roll against time. Watch them blow up near pitch 90°, then animate the same flight with SLERP between keyframe quaternions and confirm it stays smooth.
4. **Open investigation.** You have N noisy measurements of the same orientation, as unit quaternions (some with flipped signs). What is their "average"? Try: (a) align signs and normalise the plain sum; (b) take the eigenvector for the largest eigenvalue of $\sum_i q_i q_i^{\mathsf{T}}$ (a 4×4 matrix); (c) iterate "average in the tangent space, then step along the sphere". Compare them as the noise grows from 1° to 90°. When do they disagree, and which one would you trust in a drone?

70.7 Loose threads

Apollo's problem has an answer. Three angles always have a place where they jam (Result 2 shows where for one convention). Rotation matrices never jam but carry nine numbers. Unit quaternions carry four, compose with 16 multiplications, repair their drift with one division, and turn interpolation into walking along a great circle. Rotations have axes (Result 1), and the half-angle is the signature of the sandwich (Result 3).

What we did not tell you:

> **? Why the sphere wraps twice**
>
> Every rotation appears twice on the quaternion sphere, as q and $-q$. That is not a defect of quaternions but a fact about rotations themselves: a full 360° turn traces a loop in $SO(3)$ that cannot be shrunk to nothing, yet going round it *twice* can be (the cup-and-arm trick of challenge 1 is a physical demonstration). This is also why no three smooth angles can describe every rotation without a jam. The tools that make "loops that cannot be shrunk" precise are in Ch. 58.

? Why four, and not three?

Hamilton spent a decade trying to multiply triples and failed. It was not lack of imagination: a number system in which you can multiply, divide and keep the norm multiplicative exists only in dimensions 1, 2, 4 and 8 (the reals, complexes, quaternions and the strange non-associative *octonions*). Why exactly those four dimensions? The algebraic side of the story starts in Ch. 56.

? Rotations that change in time

A spinning body has an angular velocity $\boldsymbol{\omega}(t)$, and its orientation obeys $\dot{q} = \frac{1}{2}(0, \boldsymbol{\omega})\, q$. Integrate that with a textbook method and q leaves the unit sphere; renormalise and you may still get the wrong spin, and a tumbling brick in a game can gain energy from nowhere. Which integrators respect the sphere and the physics is a question for Ch. 72.

- **Lie groups.** $SO(3)$ and S^3 are curved spaces that are also groups. The "tangent space average" of challenge 4 and the exponential map $\boldsymbol{\omega} \mapsto e^{(0,\boldsymbol{\omega})/2}$ are the first steps of Lie theory, the geometry of continuous symmetry; see Ch. 59.
- **Smooth paths through many keys.** SLERP joins two orientations, but a path through five keyframes made of four SLERPs has kinks at the joins. Spherical splines (such as SQUAD) smooth them; making "curvature" meaningful on a sphere is again differential geometry.
- **Light.** We have placed objects and cameras in the world and turned them smoothly. Now the world needs illumination: Ch. 71 follows rays of light, and rotations reappear every time a ray reflects.

Chapter 71 — Ray Tracing: The Geometry of Light

> **Level 2 · Track G — Mathematics for Computer Graphics, Games, and Simulation Builds on:** Ch. 7, Ch. 5, Ch. 19, Ch. 69 · **Leads to:** Ch. 72, Ch. 75, Ch. 76 · **Related:** Ch. 38, Ch. 61, Ch. 22 **Reading time:** ~25 min

71.1 The hook

In 1980 an engineer at Bell Labs named Turner Whitted published a picture of a few spheres floating over a checkerboard, one of them made of glass. The checkerboard is visible *through* the glass sphere, bent and flipped. Another sphere is a mirror, and the board, the sky and its neighbour appear on its surface, curved. Every shadow falls exactly where it should. The image is small and the colours are crude, yet people who saw it knew they were looking at something new: a computer had not been told what a reflection looks like; it had *worked it out*. The picture took well over an hour to compute.

Today a game console does the same kind of computation for two million pixels sixty times a second, and film studios spend thousands of processor-hours on a single frame. Behind both is one question, asked once for every pixel:

> *What light arrives at this point of the camera, from this direction?*

Answering it means following light backward from the eye into the world, finding the first thing it hits, asking what light reaches *that* point, which means following more rays, which hit more things... A mirror sends you on one more bounce. Glass splits your ray in two. A sheet of paper scatters light into every direction at once, so the "one more ray" becomes an integral over a whole hemisphere of directions, each of which needs its own answer.

How can a finite computer evaluate an infinite cascade of bounces? And why is it allowed to trace light backward, from the eye to the lamp, when light really travels the other way?

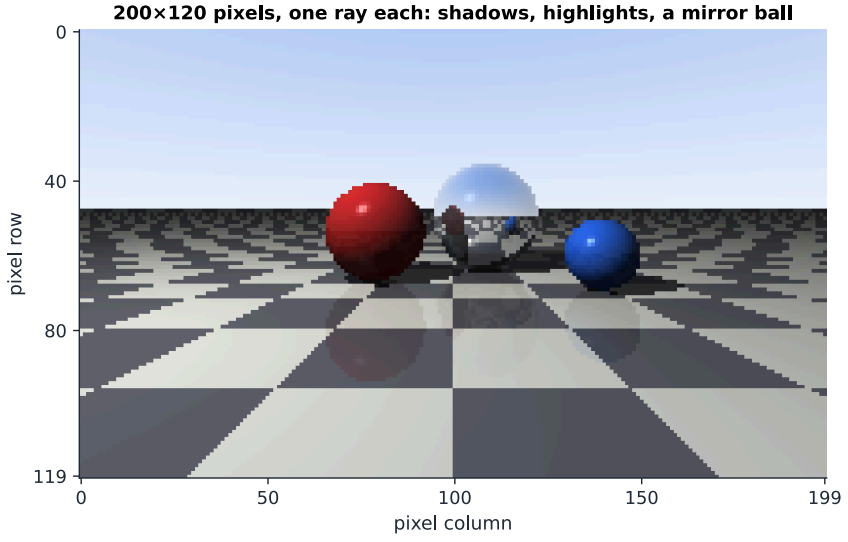
71.2 The big idea

A pixel is a question, a ray is how you ask it. From the camera's pinhole (Ch. 69 §69.3), draw the line through the centre of a pixel and out into the scene. Whatever that line hits first is what the pixel shows. Rasterisation, the method of Ch. 69, asks "where on the screen does this triangle land?"; ray tracing asks "what does this pixel see?". Same geometry, opposite loop order.

Light paths can be run in reverse. The laws of reflection and refraction are symmetric: if light can go from A to B by some path, it can go from B to A by the same path. So instead of firing trillions of photons from the lamp and waiting for the few that happen to land in the camera, we start at the camera and walk backward. When a reverse ray reaches a surface, we ask a second question: can this point see the light? Fire a **shadow ray** toward the lamp. If anything blocks it, the point is in shadow.

Every bounce is high-school geometry plus a rule. Hitting a sphere is solving a quadratic. Bouncing off a mirror is reflecting a vector across the normal. Entering glass is Snell's law. Each rule turns one ray into one or two new rays, and recursion does the rest.

Rough surfaces turn the recursion into an integral, and the integral into dice. A matte surface gathers light from all directions. The colour is an integral over the hemisphere above the point, and we estimate it the way a pollster estimates an election: sample a few random directions and average. The answer is noisy, and the noise falls like $1/\sqrt{N}$ with N samples.



Rendered by this chapter's own tracer (the figure script is about a hundred lines of NumPy): one ray per pixel, a shadow ray to one point light, highlights, and two levels of mirror reflection. The jagged edges are what one sample per pixel looks like.

71.3 The mathematics

Rays and the first hit

Ray

A **ray** is the half-line $\mathbf{p}(t) = \mathbf{o} + t\hat{\mathbf{d}}$, $t > 0$, with origin $\mathbf{o}$ and unit direction $\hat{\mathbf{d}}$. Because $\hat{\mathbf{d}}$ has unit length, t is the distance travelled. Intersecting a ray with a surface means finding the smallest $t > 0$ at which $\mathbf{p}(t)$ lies on the surface.

For a primary ray through pixel (i, j) of a $W \times H$ image, $\mathbf{o}$ is the eye and $\hat{\mathbf{d}}$ is the normalised direction to the pixel's centre on the image plane, built from the camera frame of Ch. 69.

Planes. A plane through $\mathbf{q}$ with normal $\hat{\mathbf{n}}$ is $\{\mathbf{x} : (\mathbf{x} - \mathbf{q}) \cdot \hat{\mathbf{n}} = 0\}$. Substituting the ray gives one linear equation:

$$t = \frac{(\mathbf{q} - \mathbf{o}) \cdot \hat{\mathbf{n}}}{\hat{\mathbf{d}} \cdot \hat{\mathbf{n}}},$$

with no hit if $\hat{\mathbf{d}} \cdot \hat{\mathbf{n}} = 0$ (the ray runs parallel) or $t \le 0$ (the plane is behind). **Triangles**, the workhorse of real scenes, are planes with a test: write the hit point as an affine combination $\lambda_1\mathbf{a} + \lambda_2\mathbf{b} + \lambda_3\mathbf{c}$ (Result 1 of Ch. 69) and accept it when all three barycentric weights are non-negative. The Möller–Trumbore algorithm solves for t and two of the weights at once, as a 3×3 linear system.

Spheres are where the geometry becomes satisfying.

Result 1: ray–sphere intersection

Let the sphere have centre $\mathbf{c}$ and radius r, and put $b = (\mathbf{o} - \mathbf{c}) \cdot \hat{\mathbf{d}}$ and $k = \|\mathbf{o} - \mathbf{c}\|^2 - r^2$. The ray meets the sphere at

$$t_{0,1} = -b \mp \sqrt{b^2 - k},$$

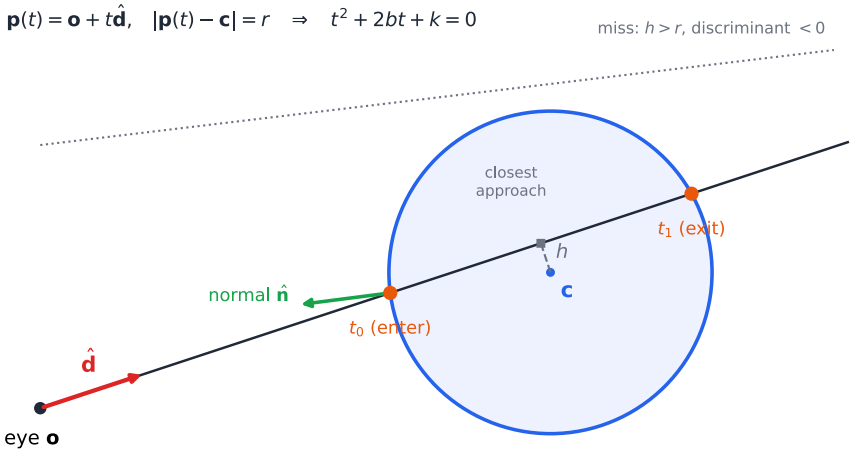
two points if $b^2 > k$, a tangent point if $b^2 = k$, and none if $b^2 < k$.

Proof. The point $\mathbf{p}(t)$ is on the sphere when $\|\mathbf{o} + t\hat{\mathbf{d}} - \mathbf{c}\|^2 = r^2$. Write $\mathbf{m} = \mathbf{o} - \mathbf{c}$ and expand the dot product, using $\hat{\mathbf{d}} \cdot \hat{\mathbf{d}} = 1$:

$$(\mathbf{m} + t\hat{\mathbf{d}}) \cdot (\mathbf{m} + t\hat{\mathbf{d}}) = r^2 \iff t^2 + 2(\mathbf{m} \cdot \hat{\mathbf{d}})\,t + \left(\mathbf{m} \cdot \mathbf{m} - r^2\right) = 0 \iff t^2 + 2bt + k = 0.$$

Completing the square, $(t + b)^2 = b^2 - k$, which gives the roots and the three cases. □

The discriminant has a geometric meaning. The point of the line closest to the centre is at $t = -b$, and its squared distance from $\mathbf{c}$ is $h^2 = \|\mathbf{m}\|^2 - b^2$ (Pythagoras). So $b^2 - k = r^2 - h^2$: the ray hits exactly when it passes within r of the centre, and $\sqrt{r^2 - h^2}$ is half the chord. Example: from $\mathbf{o} = \mathbf{0}$ along $\hat{\mathbf{d}} = \hat{\mathbf{z}}$ to a unit sphere at $(0, 0, 5)$, $b = -5$ and $k = 24$, so $t = 5 \mp 1$: the ray enters at distance 4 and leaves at 6. The surface **normal** at a hit is $\hat{\mathbf{n}} = (\mathbf{p} - \mathbf{c})/r$, free of charge.



Ray–sphere intersection. The ray enters at t_0 and exits at t_1; their midpoint is the closest approach, at distance h from the centre. A ray with $h > r$ misses, and the discriminant $b^2 - k = r^2 - h^2$ is negative.

Reflection

Let $\hat{\mathbf{n}}$ be the unit normal at the hit point and $\hat{\mathbf{d}}$ the incoming direction. A perfect mirror keeps the part of $\hat{\mathbf{d}}$ along the surface and reverses the part along the normal.

Result 2: the mirror direction

The reflected direction is $\hat{\mathbf{r}} = \hat{\mathbf{d}} - 2(\hat{\mathbf{d}} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}$. It is a unit vector, and it makes the same angle with the normal as the incoming ray (angle of incidence equals angle of reflection).

Proof. Split $\hat{\mathbf{d}} = \mathbf{d}_n + \mathbf{d}_t$ with $\mathbf{d}_n = (\hat{\mathbf{d}} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}$ along the normal and $\mathbf{d}_t = \hat{\mathbf{d}} - \mathbf{d}_n$ in the surface. The mirror rule "keep $\mathbf{d}_t$, flip $\mathbf{d}_n$" gives $\hat{\mathbf{r}} = \mathbf{d}_t - \mathbf{d}_n = \hat{\mathbf{d}} - 2\mathbf{d}_n$. Since $\mathbf{d}_t \perp \mathbf{d}_n$, $\|\hat{\mathbf{r}}\|^2 = \|\mathbf{d}_t\|^2 + \|\mathbf{d}_n\|^2 = \|\hat{\mathbf{d}}\|^2 = 1$, and $\hat{\mathbf{r}} \cdot \hat{\mathbf{n}} = -\hat{\mathbf{d}} \cdot \hat{\mathbf{n}}$: the outgoing ray has the same cosine with the normal as the incoming one, on the other side. □

The map $\hat{\mathbf{d}} \mapsto \hat{\mathbf{d}} - 2(\hat{\mathbf{d}} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}$ is the Householder reflection $\mathbf{I} - 2\hat{\mathbf{n}}\hat{\mathbf{n}}^{\mathsf{T}}$, an orthogonal matrix with determinant -1. Two reflections in a row make a rotation: the link back to Ch. 70. The same formula with the light direction in place of $\hat{\mathbf{d}}$ gives the **specular highlight**: a shiny point is bright when the mirror direction of the light points nearly at the eye, and the Phong model raises $\max(0, \hat{\mathbf{r}} \cdot \hat{\mathbf{v}})$ to a power (60 in the figure) to make the highlight tight.

Refraction and Snell's law

When light crosses from a medium of refractive index n_1 (air, $n \approx 1$) into one of index n_2 (glass, about 1.5), it bends according to **Snell's law**,

$$n_1 \sin\theta_1 = n_2 \sin\theta_2,$$

where the angles are measured from the normal. (It follows from Fermat's principle, that light takes the path of least time; a Lagrange-multiplier exercise in the spirit of Ch. 6.) A renderer needs a *direction*, not an angle.

Result 3: the refracted direction

Let $\hat{\mathbf{n}}$ point toward the incoming side, so $c_1 = -\hat{\mathbf{d}} \cdot \hat{\mathbf{n}} = \cos\theta_1 > 0$, and let $\eta = n_1/n_2$. If $1 - \eta^2(1 - c_1^2) \geq 0$, the transmitted direction is

$$\hat{\mathbf{t}} = \eta\,\hat{\mathbf{d}} + \big(\eta c_1 - c_2\big)\hat{\mathbf{n}}, \qquad c_2 = \sqrt{1 - \eta^2\,(1 - c_1^2)} = \cos\theta_2.$$

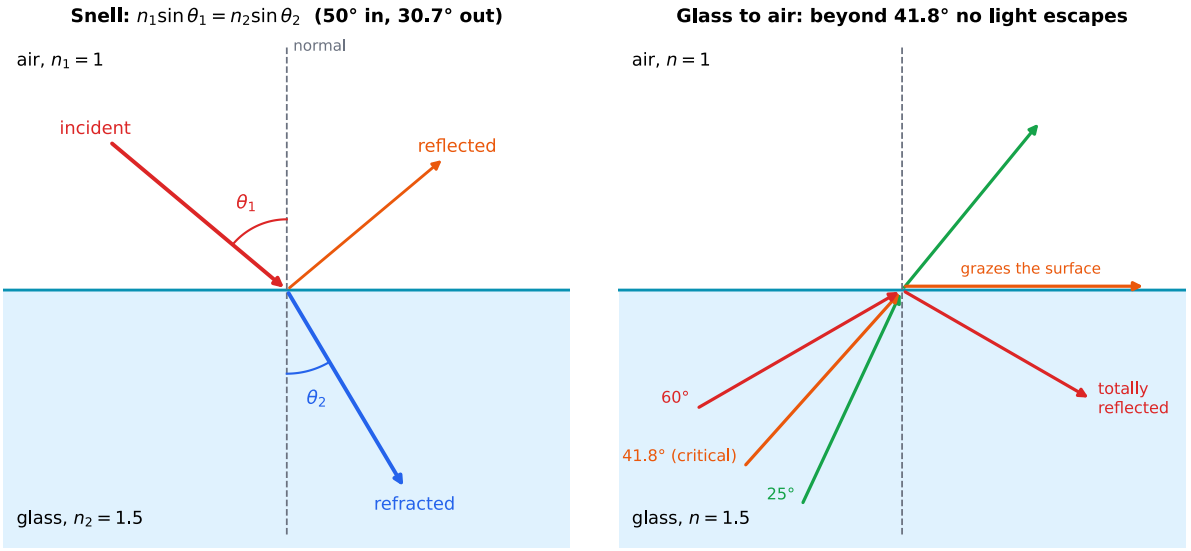
If $1 - \eta^2(1 - c_1^2) < 0$, there is no transmitted ray: **total internal reflection**.

Proof. Split $\hat{\mathbf{d}}$ into its tangential part $\mathbf{d}_t = \hat{\mathbf{d}} + c_1\hat{\mathbf{n}}$ (length $\sin\theta_1$) and its normal part $-c_1\hat{\mathbf{n}}$. The refracted ray stays in the plane of $\hat{\mathbf{d}}$ and $\hat{\mathbf{n}}$, so its tangential part points along $\mathbf{d}_t$; Snell's law fixes its length at $\sin\theta_2 = \eta\sin\theta_1$, so the tangential part is exactly $\eta\,\mathbf{d}_t$. Its normal part points into the second medium, $-\cos\theta_2\,\hat{\mathbf{n}}$, with $\cos\theta_2 = \sqrt{1 - \sin^2\theta_2} = \sqrt{1 - \eta^2(1 - c_1^2)} = c_2$. Adding the parts,

$$\hat{\mathbf{t}} = \eta\big(\hat{\mathbf{d}} + c_1\hat{\mathbf{n}}\big) - c_2\hat{\mathbf{n}} = \eta\hat{\mathbf{d}} + (\eta c_1 - c_2)\hat{\mathbf{n}},$$

a unit vector since $\sin^2\theta_2 + \cos^2\theta_2 = 1$. If $\eta\sin\theta_1 > 1$, no real θ_2 exists and the square root fails: the light cannot leave, and the surface acts as a perfect mirror. □

Numbers: a ray entering glass ($\eta = 1/1.5$) at 50° continues at 30.7°. Going the other way, from glass to air ($\eta = 1.5$), any ray steeper than the **critical angle** $\arcsin(1/1.5) = 41.8°$ is trapped (for water, 48.8°). That is how optical fibres carry light around corners, and why a diamond, with $n \approx 2.4$ and a critical angle under 25°, traps light and sparkles.



Left: reflection and refraction at an air–glass surface. Right: from inside the glass, rays beyond the critical angle of 41.8° cannot get out; the square root in Result 3 has gone negative.

How much light reflects and how much passes through? The exact answer (the Fresnel equations, from electromagnetism) is well approximated by **Schlick's formula** $R(\theta) \approx R_0 + (1 - R_0)(1 - \cos\theta)^5$, with $R_0 = \big((n_1 - n_2)/(n_1 + n_2)\big)^2$. For glass, $R_0 = 0.04$: looking straight at a window, 4% of the light reflects. At 80° the fraction is about 41%, which is why a lake mirrors the far shore but lets you see the stones at your feet.

From rays to the rendering equation

Mirrors and glass send a ray in one or two definite directions. Most surfaces do not: paper, skin, concrete and cloth scatter incoming light over every outgoing direction. The simplest model is the **Lambertian** surface, which looks equally bright from every angle and whose brightness is proportional to $\cos\theta$, the cosine between the normal and the light. (A beam of cross-section A hitting a surface at angle θ spreads over area $A/\cos\theta$.) In our tracer, that is the factor $\max(0, \hat{\mathbf{n}} \cdot \hat{\mathbf{L}})$.

But a matte surface is lit not only by the lamp. Light bouncing off the red sphere tints the floor beside it pink, a ceiling lit by a floor lamp lights the whole room. Accounting for all of it gives the **rendering equation** (Kajiya, 1986): the radiance L_o leaving point $\mathbf{x}$ in direction ω_o is

$$L_o(\mathbf{x}, \omega_o) = L_e(\mathbf{x}, \omega_o) + \int_\Omega f_r(\mathbf{x}, \omega_i, \omega_o)\, L_i(\mathbf{x}, \omega_i)\, \cos\theta_i \, d\omega_i .$$

In words: light leaving = light emitted + light arriving from every direction ω_i in the hemisphere Ω above the surface, weighted by the cosine and by the surface's **BRDF** f_r (how much light from ω_i it sends toward ω_o; for a Lambertian surface of albedo ρ, $f_r = \rho/\pi$). The catch is hidden in L_i: the light arriving at $\mathbf{x}$ from direction ω_i is the light *leaving* some other point in the scene. The unknown function appears on both sides. It is an integral equation, and every bounce of light is one more turn of it.

Integrals over a hemisphere are what Monte Carlo was made for (Ch. 19 §19.9). Draw N random directions ω_k from a density $p(\omega)$ and average:

$$\int_\Omega g(\omega)\, d\omega \;\approx\; \frac{1}{N}\sum_{k=1}^{N} \frac{g(\omega_k)}{p(\omega_k)} .$$

The estimator is **unbiased**, because $E\big[g(\omega)/p(\omega)\big] = \int_\Omega \frac{g}{p}\, p\, d\omega = \int_\Omega g\, d\omega$, and its standard deviation falls as $\sigma/\sqrt{N}$, where σ is the spread of a single sample. A test case: a patch under a uniform white sky of radiance 1 receives $\int_\Omega \cos\theta \, d\omega = \pi$. Sampling directions uniformly ($p = 1/2\pi$) gives single-sample spread $\sigma = 2\pi/\sqrt{12} \approx 1.81$; with 16 samples the estimate has standard error about 0.45, about 14% of π. Quadruple the samples and the error only halves. That $\sqrt{N}$ is why film frames take hours, and why early path-traced images look as if they were printed on sandpaper.

71.4 The algorithm

A Whitted-style tracer (mirrors, glass, shadows) is a short recursion.

```
trace(ray, depth):
    hit = nearest intersection of ray with every object       # Result 1, planes, triangles
    if no hit: return sky(ray.direction)
    p, n, material = hit.point, hit.normal, hit.material
    colour = ambient
    for each light:
        if nearest hit along ray(p + eps*n -> light) is beyond the light:   # shadow ray
            colour += lambert(n, light) + phong(n, light, ray)
    if depth > 0 and material.mirror > 0:
        colour = mix(colour, trace(reflect(ray, n), depth-1), material.mirror)   # Result 2
    if depth > 0 and material.glass:
        R = schlick(cos theta)
        colour = R * trace(reflect) + (1 - R) * trace(refract(ray, n, eta), depth-1)  # Result 3
    return colour
```

A **path tracer** replaces the fixed bounce directions by one random direction per bounce, drawn from the BRDF, and averages many such paths per pixel. It solves the rendering equation; the Whitted tracer only solves the special case of perfect mirrors and point lights.

Complexity. With P pixels, S samples per pixel, D bounces and N objects, a brute-force tracer tests about $PSDN$ intersections. For a modest 1920×1080 frame, one sample, three bounces and a million triangles, that is about 6×10^{12} tests. No hardware does that per frame. Real tracers wrap objects in a hierarchy of bounding boxes, so a ray discards whole groups of objects with one test, and the cost per ray drops from N to roughly $\log N$.

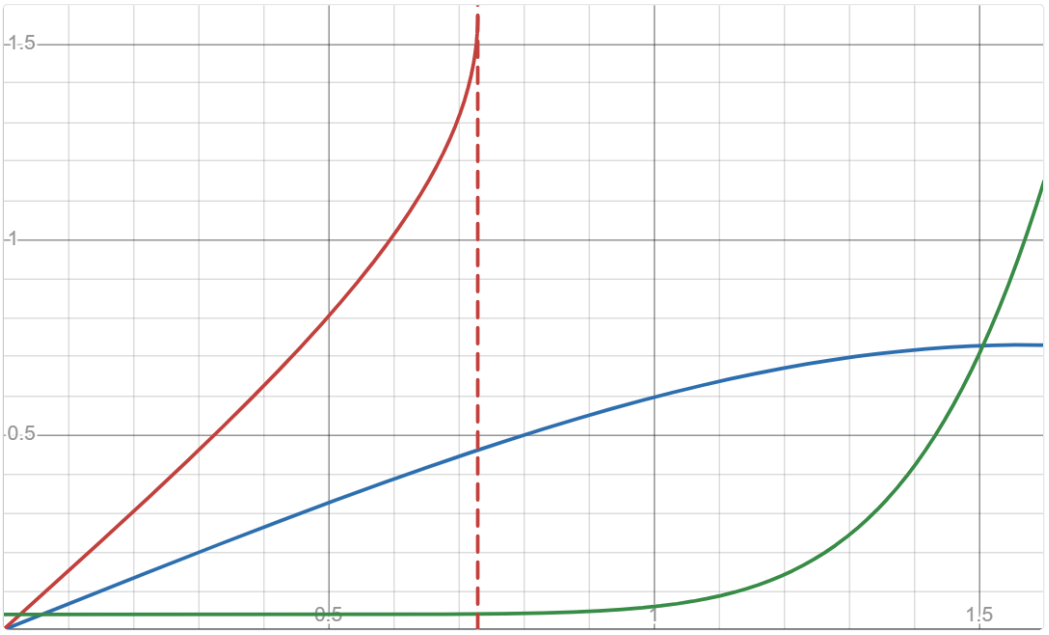
Numerical failure cases.

- *Shadow acne.* A shadow ray starts exactly on the surface; rounding error places its origin slightly *inside*, and it immediately hits the surface it came from. The result is a speckle of false shadow. The fix is to push the origin off the surface by a small ε along the normal, but too large an ε detaches shadows from their objects ("peter-panning"). There is no universally right ε.
- *Cancellation in the quadratic.* When $b^2 \gg k$ (a small or distant sphere), $-b + \sqrt{b^2 - k}$ subtracts two nearly equal numbers and loses digits; compute the larger-magnitude root first and the other from the product of the roots, $t_0 t_1 = k$ (Ch. 22 §22.2).
- *Infinite recursion.* Two facing mirrors bounce a ray forever. A depth limit stops it, which silently darkens the infinite corridor; path tracers instead stop paths at random ("Russian roulette") and reweight the survivors so that the estimate stays unbiased.
- *Aliasing.* One ray per pixel through the pixel centre makes staircase edges, and fine textures in the distance turn into shimmering moiré. More rays per pixel help; *where* inside the pixel you aim them matters more than you would think.

> **? The clue we're holding back**
>
> For the sky-lit patch above, uniform sampling gives a 14% error with 16 rays. A cleverer choice of the density $p(\omega)$ in the same estimator makes the error *exactly zero*, with a single ray. In a real scene the perfect density is unknowable, because it depends on the very answer you are computing, yet renderers get tantalisingly close. How do you choose p, and why is the perfect choice always out of reach? That is importance sampling, in Ch. 38.

71.5 The experiment

First, play with light at a surface. The graph shows, as functions of the incidence angle x in radians, the refracted angle entering glass, the refracted angle *leaving* glass (it stops at the critical angle) and Schlick's reflectance.



Blue: air into glass. Red: glass into air, which ends at the critical angle 0.7297 *rad* $(41.8°$*, dashed). Green: fraction reflected (Schlick). Change* `1.5` *to* `2.4` *(diamond) in both arcsines and watch the red curve end much sooner; the dashed line should move to* $\arcsin(1/2.4) \approx 0.430$*. For the green curve, a diamond's* R_0 *is* $\left(1.4/3.4\right)^2 \approx 0.17$*.*

Second, a complete ray tracer in forty lines. It renders a red ball and a mirror ball on a checkerboard, with a shadow ray per hit and recursive reflections.

```
import numpy as np
import matplotlib.pyplot as plt

```

Every ray in the image is processed at once as a row of a NumPy array, so the whole picture takes about a second. Things to try:

- **Move the light.** Set `LIGHT = [3, 2, 2]`: long shadows to the left. Put the light *below* the floor (`y = -1`): everything is in shadow, because every shadow ray hits the floor.
- **Break the epsilon.** Change the offset `1e-4 * n` in `p = ...` to `0.3 * n`: the shadows shrink and come loose from the balls (peter-panning). Then set it, and the `ts < 1e-4` test, to `0`. This little scene is forgiving (double precision, exact spheres, a floor test that ignores upward rays), so look closely for speckle; real renderers working with single-precision triangles are not so lucky.
- **Hall of mirrors.** Set `MIRROR = 1.0` and `BOUNCES = 0, 1, 2, 6`. The reflection of the red ball appears at depth 1; reflections of reflections need more bounces.

- **Antialiasing.** Set `SPP = 4`, then `16`. The staircase edges and the moiré on the distant checkerboard soften: each pixel now averages several jittered rays. Compare the cost with the improvement.

71.6 The challenge

1. **Intuition.** Stand facing a still lake. Using Schlick's formula, explain why the far shore appears mirrored in the water while near your feet you see the bottom. Then explain, with the critical angle of water (48.8°), what a fish looking upward sees: why does the whole sky above it appear squeezed into a circle (Snell's window), and what lies outside that circle?
2. **Derivation.** A triangle has vertices $\mathbf{a}, \mathbf{b}, \mathbf{c}$. Write the hit point as $\mathbf{a} + u(\mathbf{b} - \mathbf{a}) + v(\mathbf{c} - \mathbf{a})$ and equate it to $\mathbf{o} + t\hat{\mathbf{d}}$. Solve the resulting 3×3 system for (t, u, v) with Cramer's rule (Ch. 8 §8.3), and rewrite each determinant as a scalar triple product. This is the Möller–Trumbore algorithm. State the conditions on t, u, v for a hit, and say what happens geometrically when the main determinant is zero.
3. **Implementation.** Add a glass sphere to the experiment script. You will need the refraction direction of Result 3, a sign flip of $\hat{\mathbf{n}}$ and η when the ray is *leaving* the sphere, the far root t_1 for rays that start inside, total internal reflection, and Schlick's weight between the reflected and refracted contributions. Check your result: the checkerboard seen through the ball should appear upside down.
4. **Open investigation.** Replace the shadow ray to a point light by shadow rays to random points on a *disc* light of radius ρ, and render with N samples per pixel. The shadows grow soft edges (penumbras). Measure the pixel noise in the penumbra as a function of N and check the $1/\sqrt{N}$ law. Then try *stratified* sampling: split the disc into $\sqrt{N} \times \sqrt{N}$ cells and take one random point per cell. Does the noise now fall faster than $1/\sqrt{N}$? How fast, and does it depend on how the shadow edge is oriented?

71.7 Loose threads

Whitted's picture is no longer mysterious. Each pixel fires a ray; the first hit is a quadratic (Result 1); the mirror bounce is a reflection across the normal (Result 2); glass is Snell's law in vector form, with total internal reflection where the square root fails (Result 3); shadows are one more ray toward the light. Tracing backward is legitimate because light paths are reversible. And the full problem, light bouncing endlessly between rough surfaces, is an integral equation that we attack with random samples, at the price of noise that fades only as $1/\sqrt{N}$.

What we did not tell you:

> **? Jaggies, moiré and the right place to aim**
>
> One ray per pixel is a *sample* of a continuous image, and a checkerboard receding to the horizon contains detail finer than any pixel. The result is moiré: false, large-scale patterns that are not in the scene. Jittering the rays turns the moiré into noise, which the eye forgives. Why does randomness trade one error for a better-looking one, and what does the spectrum of a sampling pattern have to do with it? The answer is the sampling theorem and its consequences, in Ch. 76.

> **? A million triangles in twenty tests**
>
> Our tracer tests every ray against every object. With a hierarchy of bounding volumes, a ray can find its first hit among a million triangles in a few dozen box tests. How do you build the hierarchy, what makes one tree better than another, and can you prove that log N is the best you can hope for? That is Ch. 75.

- **Solving the integral equation.** Substituting the rendering equation into itself expands light into a sum over paths of 0, 1, 2, ... bounces, a *Neumann series*. When does such a series converge, and how fast? Integral equations of this kind live in the world of Ch. 61.
- **Light that is not a ray.** Ray optics ignores wavelength, so it cannot make rainbows from a thin soap film, or the colours of a peacock's feather. Those need waves and interference, and the wave equation of Ch. 13.
- **Moving worlds.** Every image so far is frozen. Make the balls fall, bounce and roll, and you need to integrate equations of motion without the world exploding: Ch. 72.

72.1 The hook

Every game programmer has a version of this story. You write a tiny space game: one sun, one planet, Newton's law of gravity. The planet's state is a position and a velocity, and each frame you do the obvious thing:

```
position += velocity * dt
velocity += acceleration(position) * dt
```

You press play. The planet goes round. It is beautiful. You leave it running while you make coffee, and when you come back the planet is gone. Not crashed into the sun: *gone*, flung into the dark on a widening spiral, as if someone had been quietly feeding it fuel.

Nobody fed it anything. The physics has no engine, no friction, no external force. The real system conserves energy exactly. Your code has manufactured energy out of nothing, a little on every frame.

Now the strange part. Swap the two lines:

```
velocity += acceleration(position) * dt
position += velocity * dt
```

Same cost. Same step size. Same "accuracy" in the textbook sense: both are first-order methods. And now the planet orbits forever. Run it for a million frames and the orbit wobbles a little, but it never spirals out.

The same ghost haunts every game engine. Ragdolls that "explode" when a character falls into a corner. A stack of crates that jitters, then leaps into the air. A bullet that passes through a wall without touching it. A rope that slowly stretches until it is twice its length. None of these are bugs in the usual sense. They are mathematics: the gap between a differential equation and the arithmetic a computer does sixty times per second.

So here is the question this chapter answers:

Why does the obvious update rule create energy from nothing, why does swapping two lines cure it, and what else must a physics engine get right to keep a virtual world from tearing itself apart?

72.2 The big idea

A game is a map, not a flow

The laws of motion are a *flow*: a rule that moves the state continuously in time,

$$\dot{\mathbf{x}} = \mathbf{v}, \qquad \dot{\mathbf{v}} = \mathbf{a}(\mathbf{x}).$$

A game never sees the flow. It sees a **map**: a function Φ_h that takes the state at frame n to the state at frame $n+1$, with h a fixed time step (typically $1/60$ s). Whatever the true physics does between frames is invisible. The only thing that matters is what the map does when it is applied ten thousand times in a row.

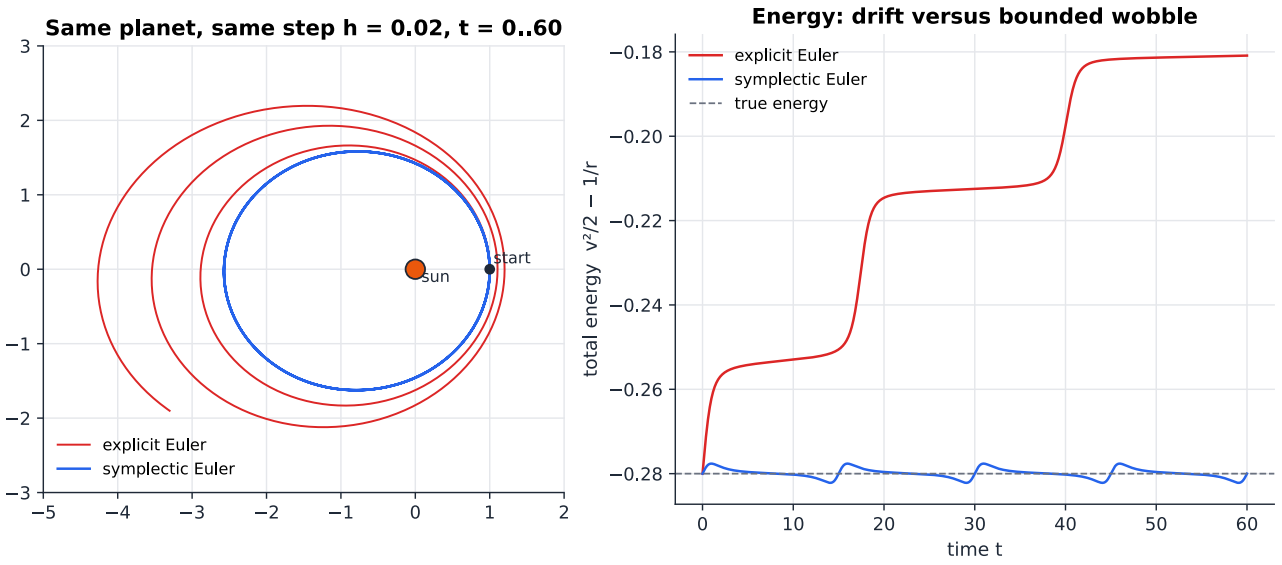
That reframing is the whole chapter. The textbook question about an integrator is "how close is one step to the truth?" (local error, order of accuracy: Ch. 22, §22.9). The game-engine question is "what does the map do *forever*?" A first-order method with the right *structure* beats a fourth-order method with the wrong one, if you run it long enough.

Two lines, two geometries

Think of a frictionless spring, the simplest oscillator. Its state lives in the **phase plane**, position on one axis and velocity on the other, and the true motion goes round an ellipse of constant energy.

Explicit Euler looks at the current state, reads off the tangent to the ellipse, and steps along it. A tangent to a convex curve always points slightly *outside* the curve. So every step lands on a slightly bigger ellipse. Outward, outward, outward: a spiral.

Semi-implicit (symplectic) Euler updates the velocity first and then moves the position using the *new* velocity. The two half-updates err in opposite directions: one pushes outward, the other inward. They do not cancel exactly, but they cancel in a precise geometric sense we will prove: the map preserves **area** in the phase plane. A map that preserves area cannot spiral outward forever, because a spiral would have to sweep a blob of initial conditions into an ever larger region.



The same planet, the same step $h = 0.02$, the same cost per step. Explicit Euler gains energy at each close pass of the sun (from -0.280 to -0.181 in four orbits) and spirals away. Symplectic Euler's energy wobbles near -0.280 and comes back, orbit after orbit.

The three jobs of a physics engine

Integration is one job. A real engine has three, run every frame:

1. **Integrate**: move every body forward by h under forces.
2. **Detect**: find which bodies now touch or overlap, among thousands, in well under a millisecond.
3. **Resolve**: fix the contacts and constraints (bounce, stop, stay attached) without creating or destroying energy you did not intend.

Each job has its own way to fail, and the failures interact.

72.3 The mathematics

The test oscillator

Stability analysis for game physics starts, as in Ch. 22, §22.9, with a linear test problem. Here it is the frictionless spring of angular frequency ω:

$$\dot{x} = v, \qquad \dot{v} = -\omega^2 x, \qquad E = \tfrac{1}{2}\left(v^2 + \omega^2 x^2\right).$$

Every stiff spring, vibrating joint or pendulum near the bottom of its swing looks like this locally, with ω^2 the local stiffness.

Explicit Euler is $x_{n+1} = x_n + h v_n$, $v_{n+1} = v_n - h\omega^2 x_n$. Then

$$v_{n+1}^2 + \omega^2 x_{n+1}^2 = (v_n - h\omega^2 x_n)^2 + \omega^2 (x_n + h v_n)^2 = (1 + h^2\omega^2)\left(v_n^2 + \omega^2 x_n^2\right),$$

because the cross terms $-2h\omega^2 x_n v_n$ and $+2h\omega^2 x_n v_n$ cancel. Energy is multiplied by exactly $1 + h^2\omega^2$ on every step, whatever the state. After time $t = nh$ the factor is $(1 + h^2\omega^2)^{t/h} \approx e^{h\omega^2 t}$. With $\omega = 1$ and $h = 0.1$ that is a factor of 1.85 per period and about 517 after ten periods. Ch. 22 already showed this in its stability-region picture: the eigenvalues $\pm j\omega$ of a lossless oscillator sit on the imaginary axis, outside explicit Euler's region. Making h smaller slows the growth, but never stops it.

Symplectic Euler preserves area

Symplectic (semi-implicit) Euler updates velocity first:

$$v_{n+1} = v_n - h\omega^2 x_n, \qquad x_{n+1} = x_n + h\, v_{n+1}.$$

Substituting the first line into the second gives a linear map $(x_n, v_n) \mapsto (x_{n+1}, v_{n+1})$ with matrix

$$\mathbf{M} = \begin{pmatrix} 1 - h^2\omega^2 & h \\ -h\omega^2 & 1 \end{pmatrix}, \qquad \det \mathbf{M} = (1 - h^2\omega^2) + h^2\omega^2 = 1.$$

Area preservation

Symplectic Euler maps every region of the phase plane to a region of the same area. Explicit Euler multiplies every area by $1 + h^2\omega^2$.

Proof. A linear map multiplies areas by $|\det \mathbf{M}|$. For symplectic Euler $\det \mathbf{M} = 1$, computed above. Explicit Euler's matrix is $\begin{pmatrix} 1 & h \\ -h\omega^2 & 1 \end{pmatrix}$, with determinant $1 + h^2\omega^2$. ∎

For nonlinear forces the same holds with the Jacobian matrix in place of $\mathbf{M}$: the velocity kick $\mathbf{v} \mapsto \mathbf{v} + h\,\mathbf{a}(\mathbf{x})$ is a shear (it changes $\mathbf{v}$ by an amount depending only on $\mathbf{x}$), the drift $\mathbf{x} \mapsto \mathbf{x} + h\mathbf{v}$ is another shear, and shears have determinant 1. The true flow of any Hamiltonian system also preserves phase-space volume (Liouville's theorem). Symplectic Euler is a composition of two exactly solvable sub-flows, and so it inherits that geometry. This is what "symplectic" means at the

level of this chapter.

Area preservation alone forbids an outward spiral, but it does not tell us how big the energy error is. For the oscillator we can do better and find what the method conserves *exactly*.

A conserved "shadow energy"

Under symplectic Euler, the quantity

$$\tilde{E} = \tfrac{1}{2}\left(v^2 + \omega^2 x^2 - h\omega^2\, xv\right)$$

is exactly conserved, and for $h\omega < 2$ the true energy E stays within the band

$$\frac{\tilde{E}_0}{1 + h\omega/2} \le E_n \le \frac{\tilde{E}_0}{1 - h\omega/2}.$$

Proof. Write $x' = x + hv'$ and $v' = v - h\omega^2 x$. First,

$$\begin{aligned} v'^2 + \omega^2 x'^2 - h\omega^2 x'v' &= v'^2 + \omega^2(x^2 + 2hxv' + h^2 v'^2) - h\omega^2(x + hv')v' \\ &= v'^2 + \omega^2 x^2 + h\omega^2 xv'. \end{aligned}$$

Now substitute $v' = v - h\omega^2 x$: $v'^2 = v^2 - 2h\omega^2 xv + h^2\omega^4 x^2$ and $h\omega^2 xv' = h\omega^2 xv - h^2\omega^4 x^2$. Adding, the $h^2\omega^4 x^2$ terms cancel and we are left with $v^2 + \omega^2 x^2 - h\omega^2 xv$. So $\tilde{E}' = \tilde{E}$.

For the band, use $|\omega xv| \le \tfrac{1}{2}(v^2 + \omega^2 x^2) = E$ (the AM–GM inequality). Then $h\omega^2|xv| = h\omega|\omega xv| \le h\omega E$, so $(1 - h\omega/2)E \le \tilde{E} \le (1 + h\omega/2)E$. Since $\tilde{E} = \tilde{E}_0$ for all n, rearranging gives the band. ∎

With $\omega = 1$, $h = 0.1$, $x_0 = 1$, $v_0 = 0$ we get $\tilde{E}_0 = 0.5$, so E must stay between $0.5/1.05 = 0.476$ and $0.5/0.95 = 0.526$. A simulation of 10^4 steps hits 0.4762 and 0.5263: the bound is sharp. The energy error is $O(h)$, as expected for a first-order method, but it is *bounded forever* instead of compounding.

The theorem also gives the stability limit. $\mathbf{M}$ has determinant 1 and trace $2 - h^2\omega^2$, so its eigenvalues are $e^{\pm j\theta}$ (on the unit circle) exactly when $|2 - h^2\omega^2| < 2$, that is when $h\omega < 2$. Beyond that, one eigenvalue leaves the unit circle and the method explodes. For a game: a 1 kg body on a spring of stiffness $k = 10^4$ N/m has $\omega = \sqrt{k/m} = 100$ rad/s, so it needs $h < 0.02$ s. At 60 Hz ($h = 0.0167$ s) it is stable. Drop the physics rate to 30 Hz ($h = 0.033$ s) and the same spring detonates. This is the most common reason a ragdoll explodes: a stiff joint and a long frame.

? The energy the planet secretly conserves

For the linear spring we found the conserved shadow energy $\tilde{E}$ by hand. The planet in the figure obeys a nonlinear force, yet its energy also wobbles and returns, for as long as anyone has run it. Is there a shadow energy for *every* symplectic method and *every* Hamiltonian? Almost: the method exactly follows the flow of a slightly modified Hamiltonian, up to an error that is exponentially small in $1/h$. Why that is true, and what "symplectic" really means as geometry rather than as a determinant, is the story of backward error analysis in Ch. 92.

Verlet: the integrator games actually ship

Add the Taylor expansions of $x(t + h)$ and $x(t - h)$:

$$x(t \pm h) = x \pm h\dot{x} + \tfrac{h^2}{2}\ddot{x} \pm \tfrac{h^3}{6}\dddot{x} + O(h^4).$$

The odd terms cancel, leaving the **Störmer–Verlet** rule

$$x_{n+1} = 2x_n - x_{n-1} + h^2 a(x_n),$$

with local error $O(h^4)$ and global error $O(h^2)$. It has no velocity at all: velocity is implied by the last two positions, $v_n \approx (x_{n+1} - x_{n-1})/(2h)$. That sounds like a flaw and is in fact the feature games love. If a collision or a constraint *moves* a particle, the velocity changes automatically and consistently with the move; there is no separate velocity to forget to fix.

Verlet is also **time-reversible**: swap x_{n+1} and x_{n-1} and the rule is unchanged. Its velocity form, *velocity Verlet* (half kick, full drift, half kick), is symplectic Euler composed with its mirror image, which is why it gains an order of accuracy for free. Runge–Kutta 4 is more accurate per step but neither symplectic nor reversible: its energy drifts, only slowly.

Collision detection: geometry under a deadline

With n bodies there are $n(n-1)/2$ pairs: for 1000 bodies, 499,500 pairs every frame. Engines split detection into a cheap **broad phase** that discards most pairs and an exact **narrow phase** for the survivors.

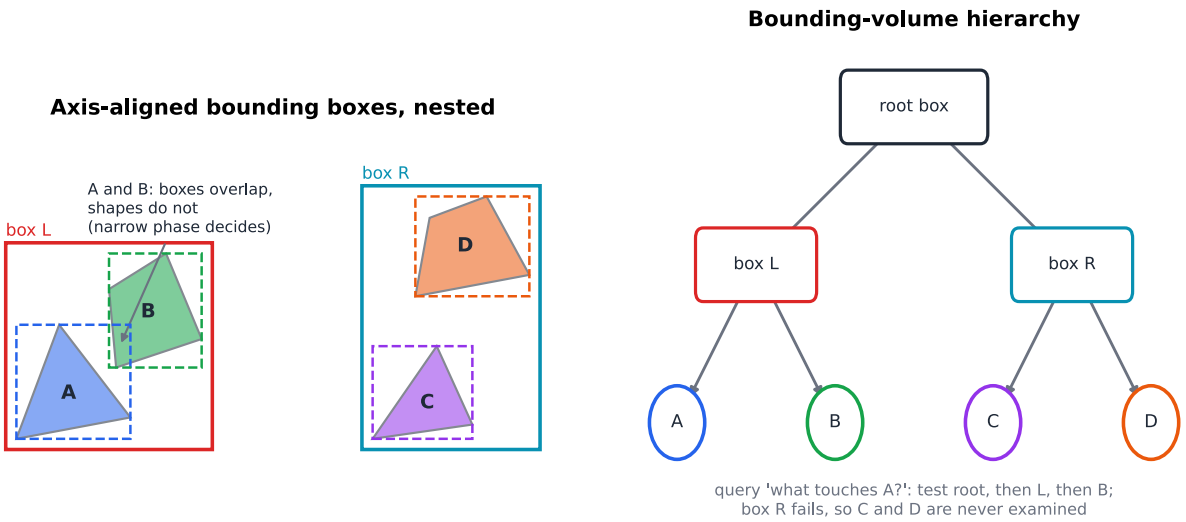
The broad phase wraps each body in a **bounding volume**, usually an axis-aligned bounding box (AABB): the smallest box, with sides parallel to the axes, containing the body.

The AABB overlap test

Two closed intervals $[a_0, a_1]$ and $[b_0, b_1]$ intersect if and only if $a_0 \le b_1$ and $b_0 \le a_1$. Two axis-aligned boxes intersect if and only if their projections onto every coordinate axis intersect.

Proof. If the intervals share a point p, then $a_0 \le p \le b_1$ and $b_0 \le p \le a_1$. Conversely, if both inequalities hold, let $p = \max(a_0, b_0)$. Then $p \le a_1$ (since $a_0 \le a_1$ and $b_0 \le a_1$) and $p \le b_1$ similarly, so p lies in both. For boxes, a box is the Cartesian product of its interval projections; a point $\mathbf{p}$ lies in both boxes exactly when each coordinate p_i lies in both i-th intervals, and such coordinates can be chosen independently axis by axis. ∎

So the test costs six comparisons in 3-D and can exit on the first failure. Boxes are conservative: overlapping boxes do not mean overlapping shapes, only "worth checking".

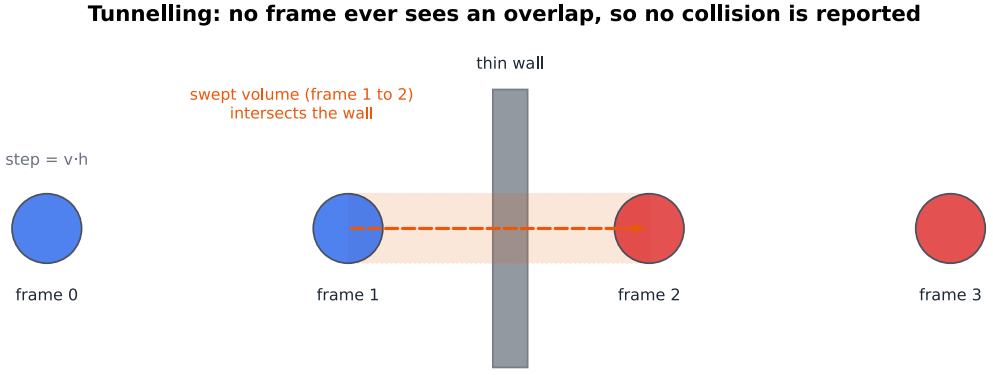


*Bounding boxes nest into a **bounding-volume hierarchy** (BVH). A query descends only into boxes it overlaps, so a body far from everything is rejected after a handful of tests. The overlapping boxes of A and B are a false positive that the narrow phase must reject.*

For the narrow phase on convex shapes, the workhorse is the **separating axis theorem**: two convex polygons (or polyhedra) are disjoint if and only if there is a line onto which their projections are disjoint, and it suffices to try the edge normals of both shapes (plus edge–edge cross products in 3-D). The AABB theorem above is the special case in which the only candidate axes are the coordinate axes. We state the general theorem without proof; it is a consequence of the separating hyperplane theorem for convex sets (Ch. 47).

Tunnelling

Detection that only looks at frames has a blind spot. A ball of radius r moving at speed v jumps vh per frame; if $vh > 2r + w$, where w is the thickness of a wall, there can be a frame before the wall and a frame after it with no overlap in between.



Tunnelling. Each frame's overlap test passes, so no collision is ever reported. Testing the swept volume, the region the body occupies during the step, catches the crossing.

A bullet at 900 m/s simulated at 60 Hz moves 15 m per frame. Engines therefore use **continuous collision detection** for fast objects: solve for the first time $t \in [0, h]$ at which the moving shapes touch. For a sphere against a plane that is a linear equation in t; for two moving spheres it is a quadratic.

Collision response: the impulse

When two bodies touch, the engine changes their velocities instantly with an **impulse** $j\,\hat{\mathbf{n}}$ along the contact normal $\hat{\mathbf{n}}$ (pointing from body 2 to body 1). Body 1 receives $+j\hat{\mathbf{n}}$ and body 2 receives $-j\hat{\mathbf{n}}$, so momentum is conserved automatically.

The collision impulse

Let the relative normal velocity before contact be $u_n = (\mathbf{v}_1 - \mathbf{v}_2)\cdot\hat{\mathbf{n}} < 0$ (approaching), and let the coefficient of restitution $e \in [0,1]$ require $u_n' = -e\,u_n$ afterwards. Then

$$j = \frac{-(1+e)\,u_n}{1/m_1 + 1/m_2}.$$

Proof. After the impulse, $\mathbf{v}_1' = \mathbf{v}_1 + (j/m_1)\hat{\mathbf{n}}$ and $\mathbf{v}_2' = \mathbf{v}_2 - (j/m_2)\hat{\mathbf{n}}$. Dot the difference with $\hat{\mathbf{n}}$ (a unit vector): $u_n' = u_n + j\,(1/m_1 + 1/m_2)$. Setting $u_n' = -eu_n$ gives $j(1/m_1 + 1/m_2) = -(1+e)u_n$. ■

Example: a 1 kg ball at 4 m/s hits a resting 3 kg ball head-on, with $e = 0.5$. Then $u_n = -4$ and $j = 1.5 \times 4/(4/3) = 4.5$ N·s. The first ball rebounds at -0.5 m/s, the second leaves at 1.5 m/s; momentum stays 4 kg·m/s, and kinetic energy falls from 8 J to 3.5 J. With $e = 1$ kinetic energy is conserved exactly; with $e > 1$ the engine would create energy, which is exactly what goes wrong when overlapping bodies are pushed apart too hard.

Constraints: projecting back onto the rules

A rope, a ragdoll limb or a cloth is a set of particles linked by **constraints** such as $C(\mathbf{p}_1, \mathbf{p}_2) = \|\mathbf{p}_1 - \mathbf{p}_2\| - L = 0$. Integration breaks them a little every step; the engine then repairs them. **Position-based dynamics** repairs a violated constraint by the smallest mass-weighted move, which is a Lagrange-multiplier problem (Ch. 6): minimise $\sum_i m_i \|\Delta \mathbf{p}_i\|^2$ subject to the linearised constraint $C + \nabla C \cdot \Delta \mathbf{p} = 0$. The solution moves each particle along the constraint gradient, in proportion to its inverse mass $w_i = 1/m_i$. For the distance constraint, with $\hat{\mathbf{n}} = (\mathbf{p}_1 - \mathbf{p}_2)/\|\mathbf{p}_1 - \mathbf{p}_2\|$,

$$\Delta \mathbf{p}_1 = -\frac{w_1}{w_1 + w_2}\, C\, \hat{\mathbf{n}}, \qquad \Delta \mathbf{p}_2 = +\frac{w_2}{w_1 + w_2}\, C\, \hat{\mathbf{n}}.$$

Two checks. The new separation is $\|\mathbf{p}_1 - \mathbf{p}_2\| - C = L$ exactly. And $m_1 \Delta \mathbf{p}_1 + m_2 \Delta \mathbf{p}_2 = \frac{C\hat{\mathbf{n}}}{w_1 + w_2}(-1 + 1) = \mathbf{0}$: the correction does not move the centre of mass, so it creates no net momentum. A fixed anchor is a particle with $w = 0$; it never moves.

With many constraints, fixing one breaks its neighbours. Engines simply sweep through them a few times per frame (Gauss–Seidel relaxation, the iteration of Ch. 8), accepting a small residual. That residual is why a cheap rope stretches under load, and why adding iterations makes it stiffer.

72.4 The algorithm

The fixed-timestep loop

Rendering rates vary; physics must not, because the stability limit $h\omega < 2$ depends on h. The standard pattern decouples them with an accumulator:

```
h = 1/60                      # physics step: fixed, chosen for stability
acc = 0.0
while running:
    acc += min(frame_time(), 0.25)   # clamp: avoid the "spiral of death"
    while acc >= h:
        integrate(h)          # symplectic Euler or velocity Verlet
        detect_collisions()   # broad phase (BVH or sort-and-sweep), then narrow phase
        resolve(iterations=8)  # impulses and constraint projections
        acc -= h
    render(interpolate(acc / h))     # blend last two physics states for smooth display
```

The clamp matters. If one frame takes too long, the loop runs several physics steps to catch up, which makes the next frame longer still; without a cap, the game freezes.

Verlet with constraints

The particle engine popularised for ragdolls and cloth is a dozen lines:

```
def step(x, x_prev, a, h, constraints, iters=8):
    x_new = 2*x - x_prev + h*h*a            # Verlet: velocity is implicit in x - x_prev
    for _ in range(iters):
        for (i, k, L, wi, wk) in constraints:
            d = x_new[i] - x_new[k]
            dist = np.linalg.norm(d)
            C = dist - L
            n = d / dist
            x_new[i] -= wi/(wi + wk) * C * n
            x_new[k] += wk/(wi + wk) * C * n
        x_new = np.maximum(x_new, floor)    # collision with the ground: project out
    return x_new, x
```

Note the last line inside the loop: collision with the ground is handled as just another constraint (stay above the floor), and because Verlet derives velocity from positions, the bounce is automatic.

Costs and failure modes

Stage	Method	Cost per frame	Typical failure
integrate	symplectic Euler, Verlet	$O(n)$	explodes if $h\omega > 2$ for the stiffest spring
broad phase	brute force	$O(n^2)$	too slow beyond a few hundred bodies
broad phase	sort-and-sweep, BVH	about $O(n \log n + k)$ for k overlapping pairs	degrades when everything is piled together
narrow phase	separating axes	$O(\text{edges})$ per pair	misses fast objects (tunnelling)
resolve	impulses + relaxation	$O(\text{iterations} \times \text{contacts})$	jitter, stretching, stacks that creep

Sort-and-sweep exploits time coherence: bodies barely move between frames, so the sorted list of box endpoints is nearly sorted already, and insertion sort fixes it in close to linear time.

Energy enters through the side door

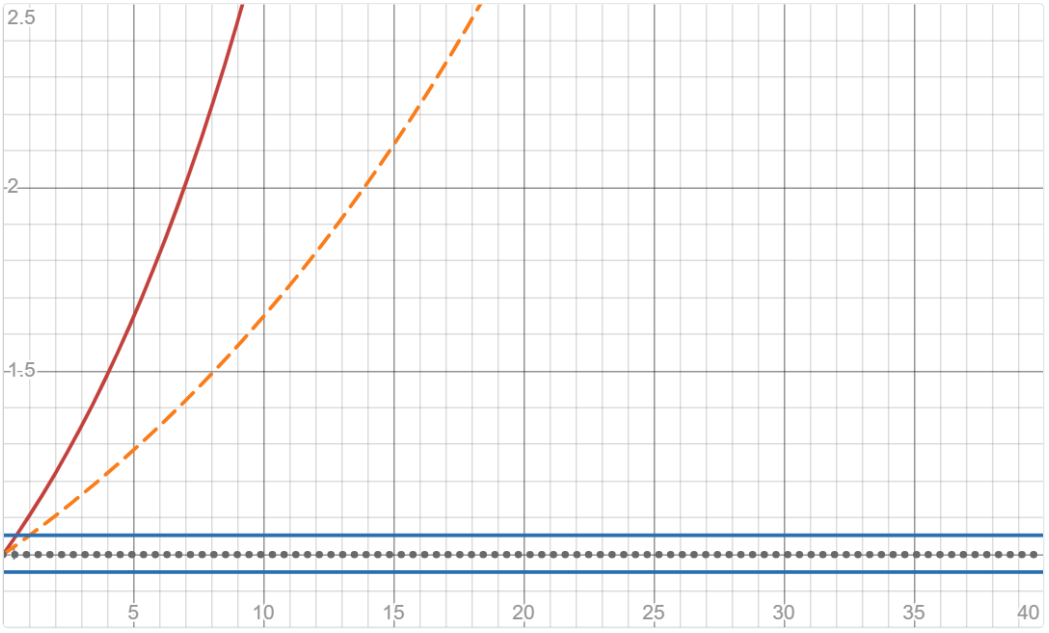
A perfect symplectic integrator still gains energy if collision response shoves overlapping bodies apart too hard. Most "explosions" in shipped games come from resolution, not integration. Plot total energy every frame: it is the cheapest error detector a physics engine has.

? Why a stack of boxes is hard

A single bounce is one impulse. A stack of ten boxes resting on each other is a different problem: every contact must push (never pull), push only when touching, and stop touching only when the push is zero. These "either-or" conditions turn resolution into a **complementarity problem**, and sequential impulses are just one slow way to solve it. Why these conditions are the KKT conditions of an optimisation problem in disguise, and what duality says about solving them, is in Ch. 48.

72.5 The experiment

First, the energy factors themselves. The red curve is explicit Euler's energy, $(1+h^2)^{t/h}$ with $\omega = 1$ and $h = 0.1$, written as 1.01^{10x}. The blue lines are the band that symplectic Euler can never leave, $1/(1 \pm h/2)$ times the shadow energy.



Energy relative to its start, against time. Red: explicit Euler with $h = 0.1$. Orange dashed: explicit Euler with $h = 0.05$, written 1.0025^{20x}, which grows more slowly but still without limit. Blue: the band that bounds symplectic Euler with $h = 0.1$. Change 0.1 to 0.2 (red: 1.04^{5x}; blue: $1/0.9$ and $1/1.1$) and watch the band widen while staying a band.

Now a script. It simulates a nonlinear pendulum, $\ddot{\theta} = -(g/\ell)\sin\theta$, with three integrators and plots the energy of each. Nothing here is linear, so the shadow-energy theorem does not apply directly: you are testing whether its message survives.

```
import numpy as np
import matplotlib.pyplot as plt

g_over_l = 9.81      # (g/l) in 1/s^2: a 1 m pendulum
h = 0.05             # time step in s: try 0.01, 0.1, 0.3, 0.6
T = 60.0             # total time in s
theta0 = 2.5         # starting angle in rad (2.5 is a wild swing; try 0.1)

def acc(th):
    return -g_over_l * np.sin(th)

def energy(th, om):
    return 0.5 * om**2 + g_over_l * (1 - np.cos(th))

def simulate(method):
    th, om = theta0, 0.0
    E = []
    for _ in range(int(T / h)):
        if method == "explicit":
            th, om = th + h * om, om + h * acc(th)
        elif method == "symplectic":
            om = om + h * acc(th)
            th = th + h * om
        else:                                   # velocity Verlet
            om_half = om + 0.5 * h * acc(th)
            th = th + h * om_half
            om = om_half + 0.5 * h * acc(th)
        E.append(energy(th, om))
    return np.array(E)

t = np.arange(int(T / h)) * h
for m in ["explicit", "symplectic", "verlet"]:
    plt.plot(t, simulate(m) / energy(theta0, 0.0), label=m)
plt.ylim(0, 3)
plt.xlabel("time (s)"); plt.ylabel("energy / initial energy")
plt.legend(); plt.show()
```

Things to try. With `h = 0.05` and `theta0 = 2.5` explicit Euler's pendulum gains energy until it goes over the top and spins; the other two hold steady. Shrink `h` to `0.01` and Verlet's wobble shrinks by a factor of about 25 (second order) while symplectic Euler's shrinks by about 5 (first order). Raise `h` until even Verlet fails: the small-angle stability limit is $h\sqrt{g/\ell} < 2$, about $h < 0.64$ s, but the wild swing fails sooner. Find out how much sooner.

72.6 The challenge

1. **Intuition.** A designer complains that springs in your engine "lose bounce" over time and asks you to switch from symplectic Euler to explicit Euler, because she read that explicit Euler "adds energy". Explain, using the phase-plane picture, why that is a bad fix even if it seems to cancel her damping, and suggest where the lost bounce is more likely to be coming from.

2. **Derivation.** For **backward (implicit) Euler** on the oscillator, $x_{n+1} = x_n + hv_{n+1}$, $v_{n+1} = v_n - h\omega^2 x_{n+1}$, find the matrix of the map, show that its determinant is $1/(1+h^2\omega^2)$, and conclude what happens to energy. Then show that alternating one explicit Euler step with one backward Euler step does not give an area-preserving method, but that a half step of each, composed, gives the trapezoidal rule. Is the trapezoidal rule symplectic for this problem?

3. **Implementation.** Build a rope of 20 particles with distance constraints, the top one pinned ($w = 0$), using the Verlet-with-constraints code above. Measure the rope's total length after it settles as a function of the number of relaxation iterations (1, 2, 4, 8, 16, 32). Plot the stretch against iterations on a log–log plot. What power law do you see, and how does it change with the number of particles?

4. **Open investigation.** Stack N identical boxes (in 2-D is fine) using sequential impulses with a fixed number of iterations per frame. For each N, find the minimum number of iterations at which the stack stands still for 60 seconds instead of creeping or collapsing. How does that number grow with N? Try warm starting (reusing last frame's impulses as the first guess) and see whether it changes the growth law. Real engines rely on heuristics here; there is no known clean formula.

72.7 Loose threads

The hook asked why the obvious update creates energy and why swapping two lines cures it. Explicit Euler multiplies every phase-space area, and the oscillator's energy, by $1 + h^2\omega^2$ per step. Symplectic Euler is a composition of two shears, preserves area exactly, and conserves a shadow energy $\tilde{E}$ that pins the true energy inside a band of width $O(h)$ forever. Around the integrator sit bounding volumes, continuous detection, impulses and constraint projection, each with its own way to inject energy.

What the chapter did not tell you:

- **The shadow Hamiltonian in general.** The first mystery: why every symplectic integrator follows a nearby energy-conserving system almost exactly, for exponentially long times. That is backward error analysis and symplectic geometry, in Ch. 92; the geometry of phase space as a manifold starts in Ch. 59.
- **Contact as optimisation.** The second mystery: resting contact and friction form a complementarity problem whose structure is duality, in Ch. 48.
- **Rotation.** Every body here was a point. Rigid bodies also spin, and integrating an orientation without it slowly ceasing to be a rotation needs the quaternions of Ch. 70.
- **Faster broad phases.** Building and updating the BVH, and the alternatives (uniform grids, k-d trees, sweep structures), belong to Ch. 75.
- **Stiffness.** Cloth and stiff joints want large k and large h together, which explicit and symplectic methods cannot deliver. Implicit methods, discussed in Ch. 22, §22.9 under stiffness, buy stability with a linear solve per step.

? Can a simulation of chaos be trusted at all?

A double pendulum is chaotic: two starting states differing by 10^{-12} end up completely different within seconds, and every step of your integrator makes an error far bigger than that. So after a minute your simulated pendulum is certainly not following the true trajectory from its starting point. Yet the motion *looks* right, and its statistics are right. Is the computed orbit following some *other* true trajectory, from a slightly different start? Sometimes provably yes, and the theorem that says when is the shadowing lemma of Ch. 84.

73.1 The hook

How long is the coast of Britain?

It sounds like a question with an answer you could look up. In the 1950s the physicist and meteorologist Lewis Fry Richardson tried to look it up, for a study of whether the length of a border between two countries affects how likely they are to go to war. He found that the published figures disagreed wildly. Spain and Portugal quoted their shared border as 987 km and 1214 km. The Netherlands and Belgium disagreed by a similar margin.

Nobody had made an arithmetic mistake. Richardson worked out what was going on by doing the measurement himself, with a pair of dividers on a map. Set the dividers to 100 km and walk them along the coast: you get some total. Set them to 50 km: the dividers now follow bays and headlands the 100 km setting stepped across, and the total goes *up*. Set them to 10 km: up again. Halving the ruler did not converge to a limit. It kept adding length, by roughly the same *factor* each time.

Richardson found that the measured length L followed a power law in the ruler length ε,

$$L(\varepsilon) \approx C\,\varepsilon^{1-D},$$

with an exponent D that was a property of the coastline: about 1.25 for the west coast of Britain, close to 1.0 for the smooth coast of South Africa. A smooth curve has $D = 1$, and then L stops changing as $\varepsilon \to 0$, which is what calculus says should happen (arc length, Ch. 7). The British coast does not.

In 1967 Benoît Mandelbrot read Richardson's forgotten paper and asked the question that founded a field. What if the exponent D is not a nuisance but a *dimension*: a coastline is more than a line and less than an area, and 1.25 measures exactly how much more?

What could it mean for a shape to have dimension 1.25, and how do we compute it?

The answer takes us through a snowflake with infinite perimeter and finite area, a two-line program that draws the most complicated object in mathematics, and a definition of dimension that a ruler can measure.

73.2 The big idea

Rules, not shapes

A smooth curve looks straighter and straighter as you zoom in: that is what having a tangent line means. A **fractal** is a shape that does not simplify under zooming. Zoom into the British coastline and you see bays within bays. Zoom into a fern and you see the same fern.

The deep idea is that such shapes are usually easy to *generate* even though they are hard to *describe*. You do not draw a fern; you write a rule and apply it forever. Three kinds of rule dominate:

- **Replacement rules.** Take a segment, replace it with a bent copy of four smaller segments, and repeat (the Koch curve).
- **Iterated function systems.** Take a set of contracting maps, apply all of them to a picture, overlay the results, and repeat (the Sierpinski triangle, Barnsley's fern).
- **Escape-time rules.** Iterate a simple map like $z \mapsto z^2 + c$ and colour each starting point by what its orbit does (the Mandelbrot and Julia sets).

Each rule is a **feedback loop**: output becomes input. That is why fractals are the natural shapes of iteration, and why they turn up wherever there is feedback: turbulence, river networks, lungs, galaxies, and the chaotic systems of Ch. 84.

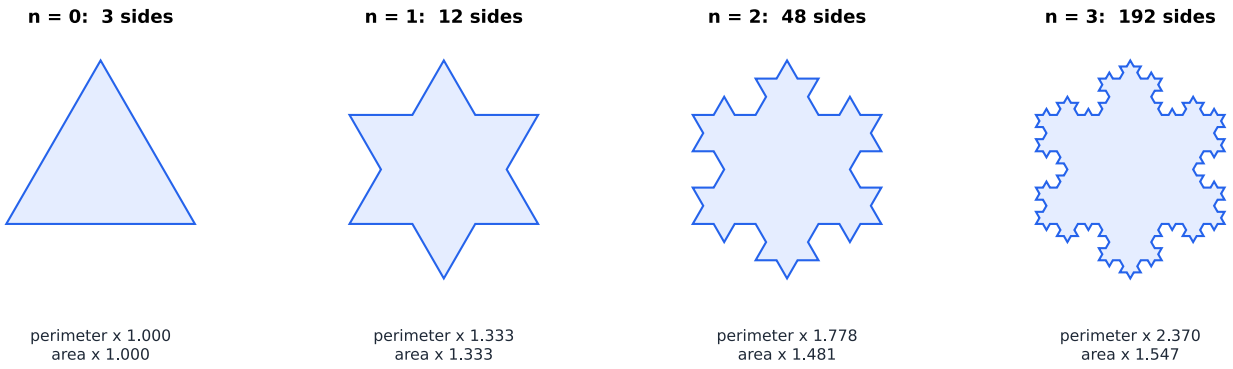
Dimension as a scaling law

Here is the analogy that unlocks fractal dimension. Cut a line segment into pieces scaled by $1/3$: you get 3 pieces. Do it to a square: 9 pieces. To a cube: 27. The number of pieces is 3^D, where D is the dimension. Dimension is the exponent in "how many small copies do I need?"

The Koch curve is built from 4 copies of itself, each scaled by $1/3$. So $3^D = 4$, and

$$D = \frac{\log 4}{\log 3} \approx 1.262.$$

That is the whole idea, and it is not a metaphor: it is a number you can measure with a ruler, exactly as Richardson did, by counting how the number of small boxes needed to cover a shape grows as the boxes shrink.



Koch snowflake, stages 0 to 3. Each stage multiplies the perimeter by $4/3$, so it grows without bound, while the area creeps toward a limit of $8/5$ of the original triangle.

73.3 The mathematics

The Koch snowflake: infinite perimeter, finite area

Start from an equilateral triangle with side s, perimeter $P_0 = 3s$ and area A_0. At each stage, replace every side by four sides one third as long: cut out the middle third and put two sides of a small outward-pointing equilateral triangle in its place.

The Koch snowflake

After n stages the snowflake has $3 \cdot 4^n$ sides, perimeter $P_n = 3s\,(4/3)^n$ and area

$$A_n = A_0 \left(1 + \frac{3}{5}\left(1 - \left(\frac{4}{9}\right)^n\right)\right).$$

So $P_n \to \infty$ while $A_n \to \frac{8}{5}A_0$.

Proof. Each side becomes 4 sides, each a third as long, so the side count is multiplied by 4 and the perimeter by $4/3$ at every stage. For the area: at stage $k \geq 1$ a new small triangle is added on each of the $3 \cdot 4^{k-1}$ sides of stage $k-1$. Its side is $s/3^k$, so its area is $A_0/9^k$ (area scales as length squared). The area added at stage k is

$$3 \cdot 4^{k-1} \cdot \frac{A_0}{9^k} = \frac{3}{4}A_0 \left(\frac{4}{9}\right)^k.$$

Summing the geometric series for $k = 1, \ldots, n$:

$$A_n = A_0 + \frac{3}{4}A_0 \cdot \frac{(4/9)\,(1 - (4/9)^n)}{1 - 4/9} = A_0 \left(1 + \frac{3}{5}\left(1 - \left(\frac{4}{9}\right)^n\right)\right).$$

As $n \to \infty$, $(4/9)^n \to 0$ and $A_n \to A_0(1 + 3/5) = \frac{8}{5}A_0$. ∎

You could paint the snowflake with a finite can of paint, but never fence it. And notice the *reason*: perimeter grows by $4/3 > 1$ per stage, area by additions that shrink like $(4/9)^k$. Length and area scale with different powers of the zoom factor, and a fractal sits between them.

Similarity dimension

Self-similar set and similarity dimension

A set F is **strictly self-similar** if it is the union of N copies of itself, each scaled by the same ratio $r < 1$, that overlap at most in negligible pieces (single points or edges). Its **similarity dimension** is the number D with $N r^D = 1$:

$$D = \frac{\log N}{\log(1/r)}.$$

The formula reproduces ordinary dimensions: a segment is N copies at ratio $1/N$, so $D = 1$; a square is N^2 copies at ratio $1/N$, so $D = 2$. And it gives new ones:

Set	Copies N	Ratio r	$D = \log N / \log(1/r)$
Cantor set (keep outer thirds of $[0,1]$, repeat)	2	$1/3$	0.631
Koch curve	4	$1/3$	1.262
Sierpinski triangle	3	$1/2$	1.585
Sierpinski carpet	8	$1/3$	1.893
Menger sponge	20	$1/3$	2.727

The Cantor set is a good warm-up for the strangeness. It has total length zero (we remove $1/3$, then $2/9$, then $4/27$, ..., which sums to 1), yet it has as many points as the whole interval (Ch. 64). Dimension 0.631 sits between "countable dust" (dimension 0) and "a line" (dimension 1).

When the copies have different ratios $r_1, \dots, r_N$, the same reasoning gives the **Moran equation** $\sum_i r_i^D = 1$, which has exactly one solution because the left side decreases strictly in D.

Box-counting dimension

Most fractals, coastlines above all, are not exactly self-similar. The measurable version of the idea counts boxes.

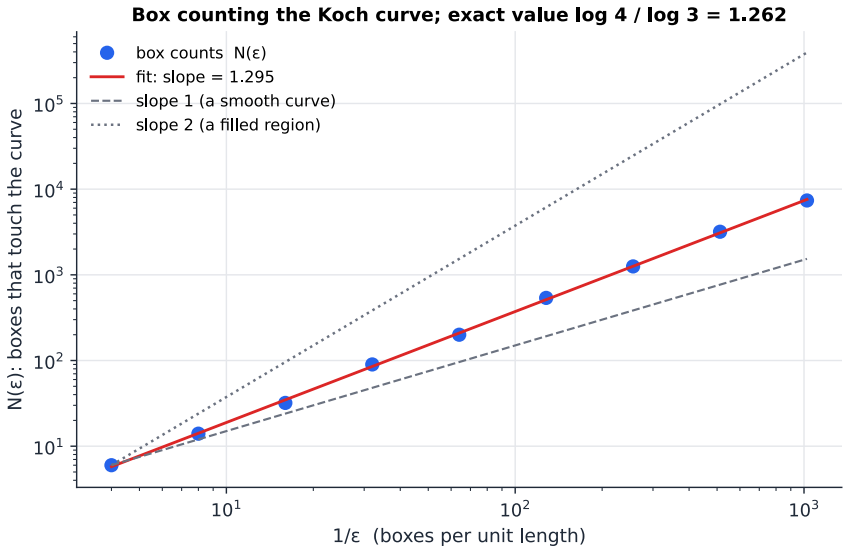
Box-counting dimension

Cover the plane with a grid of squares of side ε and let $N(\varepsilon)$ be the number of squares that meet the set F. If $N(\varepsilon) \approx C\varepsilon^{-D}$ as $\varepsilon \to 0$, then D is the **box-counting dimension**:

$$D = \lim_{\varepsilon \to 0} \frac{\log N(\varepsilon)}{\log(1/\varepsilon)}.$$

In practice, D is the slope of $\log N$ against $\log(1/\varepsilon)$.

For a smooth curve of length L, $N(\varepsilon) \approx L/\varepsilon$ (slope 1); for a region of area A, $N \approx A/\varepsilon^2$ (slope 2). Richardson's dividers are the same thing in disguise: the measured length is (number of steps) $\times\, \varepsilon \approx C\varepsilon^{-D} \cdot \varepsilon = C\varepsilon^{1-D}$, which is exactly his law. The exponent he measured on the British coast was the box-counting dimension.



Box counting the Koch curve with dyadic boxes from $\varepsilon = 1/4$ to $1/1024$. The least-squares slope is 1.295, about 3% above the exact $\log 4/\log 3 = 1.262$. The limit is approached slowly, and the coarse scales bias the fit.

A slope is not a limit

Box counting gives a dimension only in the limit $\varepsilon \to 0$, and every real data set has a smallest scale (pixels, grains of sand, atoms). Fits over a decade or two can be biased by several percent; the local slope between consecutive scales wobbles. Report the range of scales you fitted over, and be suspicious of three significant figures.

Iterated function systems

The Sierpinski triangle is the set left fixed by three maps of the plane. With corners $\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3$, let

$$f_i(\mathbf{x}) = \mathbf{p}_i + \tfrac{1}{2}(\mathbf{x} - \mathbf{p}_i), \qquad i = 1, 2, 3,$$

each a contraction by $1/2$ toward a corner. The triangle S satisfies $S = f_1(S) \cup f_2(S) \cup f_3(S)$: it is three half-size copies of itself.

A family of contractions like this is an **iterated function system** (IFS). Its key property is a fixed-point theorem, the same idea as fixed-point iteration in Ch. 22, §22.3, but where the "points" are whole compact sets and distance between sets is measured by the Hausdorff metric (the largest distance from a point of either set to the other set).

Hutchinson's theorem (stated)

If $f_1, \dots, f_N$ are contractions of the plane, the map on compact sets $\mathcal{H}(K) = f_1(K) \cup \cdots \cup f_N(K)$ is itself a contraction in the Hausdorff metric. So it has exactly one fixed compact set F, the **attractor**, and iterating $\mathcal{H}$ from *any* starting compact set converges to F.

Two consequences matter for computing. First, the starting picture is irrelevant: start from a square, a dot or a photograph of a cat, and the iterates converge to the same Sierpinski triangle. Second, there is a randomized shortcut, the **chaos game**: start at any point, and repeatedly apply one of the f_i chosen at random. After a few steps the point is within a pixel of the attractor and stays there, and the points it visits fill it out. We will use it in the experiment.

The Mandelbrot set

Now the most famous rule of all. Fix a complex number c (Ch. 2) and iterate

$$z_{n+1} = z_n^2 + c, \qquad z_0 = 0.$$

The orbit $0,\ c,\ c^2+c,\ \ldots$ either stays bounded forever or runs off to infinity. The **Mandelbrot set** M is the set of c for which it stays bounded. For $c = 0$ the orbit is $0, 0, 0, \ldots$: in M. For $c = -1$ it is $0, -1, 0, -1, \ldots$: in M. For $c = 1$ it is $0, 1, 2, 5, 26, \ldots$: not in M.

To compute M we need to know when we can stop iterating and declare escape. The answer is a short, exact theorem.

The escape radius

If $|z_n| > 2$ for some n, then $|z_n| \to \infty$. Consequently M lies inside the disc $|c| \le 2$.

Proof. First suppose $|c| > 2$. Then $z_1 = c$ already has $|z_1| > 2$ and $|z_1| \ge |c|$. Otherwise $|c| \le 2$, and any z_n with $|z_n| > 2$ also satisfies $|z_n| > |c|$. So in either case we have some $z = z_n$ with $|z| > 2$ and $|z| \ge |c|$. By the reverse triangle inequality,

$$|z^2 + c| \ge |z|^2 - |c| \ge |z|^2 - |z| = |z|\,(|z| - 1)\,.$$

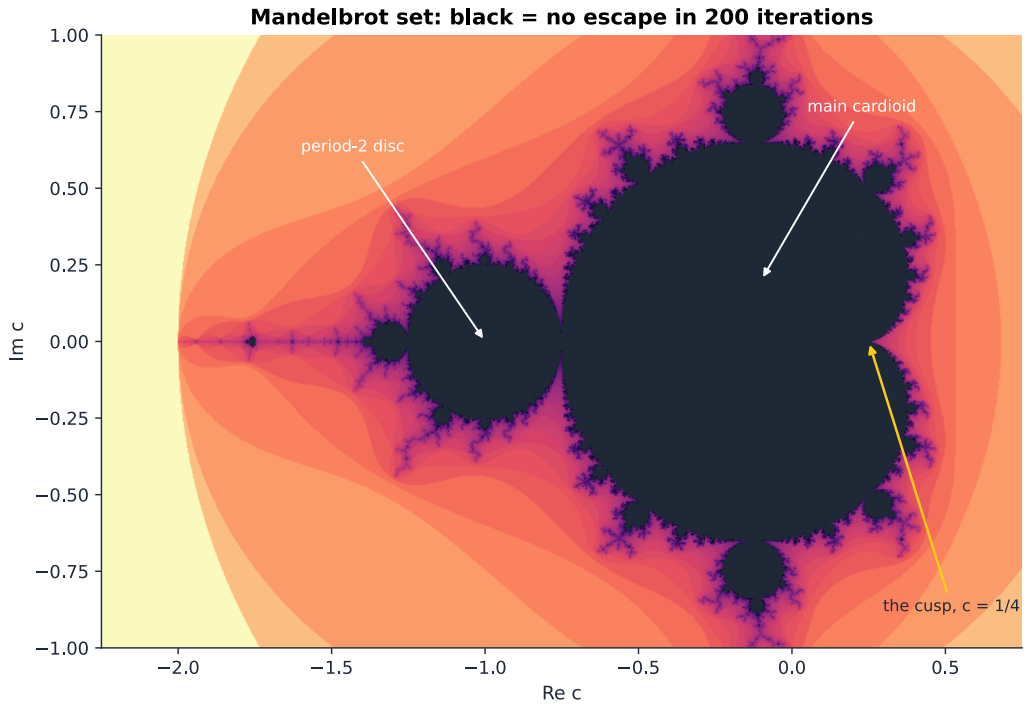
Write $|z| = 2 + \delta$ with $\delta > 0$. Then $|z_{n+1}| \ge (1+\delta)|z_n|$, and $|z_{n+1}| > 2 + \delta$, so the same bound holds at the next step with the same (or larger) δ. By induction $|z_{n+k}| \ge (1+\delta)^k |z_n| \to \infty$. ∎

So a computer can decide escape in finite time for every c outside M: iterate until $|z| > 2$. What it can never do is certify, in finite time, that a point is *inside*: an orbit that has stayed bounded for 200 iterations might escape at iteration 201. Every picture of M is an approximation from outside.

Some of the structure can be derived by hand. The big heart-shaped body, the **main cardioid**, is the set of c for which the map has an attracting fixed point. A fixed point satisfies $z^* = (z^*)^2 + c$, and it attracts when the derivative $|2z^*| < 1$. On the boundary, $2z^* = e^{j\theta}$, and then $c = z^* - (z^*)^2$ gives

$$c(\theta) = \frac{e^{j\theta}}{2} - \frac{e^{2j\theta}}{4},$$

a cardioid with its cusp at $c(0) = 1/4$ and its leftmost point at $c(\pi) = -3/4$. There the fixed point loses stability and an attracting cycle of period 2 takes over; that cycle attracts for $|c + 1| < 1/4$, the disc attached at $-3/4$. Then period 4, period 8, …



The Mandelbrot set computed by the escape-time algorithm of §73.4: 900 × 600 pixels, at most 200 iterations each, coloured by the logarithm of the escape count. The black region never exceeded $|z| = 2$.

? Is the Mandelbrot set in one piece?

Douady and Hubbard proved in 1982 that M is connected: it does not fall apart into islands, even though pictures show apparent islands (they are joined by filaments too thin to render). A much stronger statement, that M is *locally connected* (every point has arbitrarily small connected neighbourhoods), is the **MLC conjecture**. If true, it would give a complete combinatorial description of M and settle whether the hyperbolic components are dense. It is one of the central open problems of complex dynamics; how such problems are attacked is the subject of Ch. 98.

73.4 The algorithm

Escape time, vectorised

The whole Mandelbrot figure above comes from this loop, run on all pixels at once with NumPy:

```
import numpy as np

def mandelbrot(xmin, xmax, ymin, ymax, W=900, H=600, max_iter=200):
    c = np.linspace(xmin, xmax, W)[None, :] + 1j * np.linspace(ymin, ymax, H)[:, None]
    z = np.zeros_like(c)
    count = np.full(c.shape, max_iter)          # max_iter means "never escaped"
    alive = np.ones(c.shape, dtype=bool)
    for n in range(max_iter):
        z[alive] = z[alive]**2 + c[alive]
        escaped = alive & (np.abs(z) > 2)       # the escape-radius theorem
        count[escaped] = n
        alive &= ~escaped
    return count
```

Cost. $O(WHI)$ in the worst case, with I the iteration budget `max_iter`, dominated by points inside M, which never escape and run the full budget. Two cheap tests reject most of the interior before iterating: c is in the main cardioid if $q(q+(x-\tfrac14)) \le \tfrac14 y^2$ with $q=(x-\tfrac14)^2+y^2$, and in the period-2 disc if $(x+1)^2+y^2 \le \tfrac{1}{16}$. Points near the boundary escape slowly, so zooming in demands more iterations: the budget must grow as you zoom.

Smooth colouring. Integer escape counts produce visible bands. Replacing n by $n+1-\log_2\log|z_n|$ (using a large escape radius) gives a continuous value, because for large $|z|$ the map is essentially $z\mapsto z^2$ and $\log\log|z|$ grows by $\log 2$ per step.

Precision. Double-precision numbers have about 16 significant digits. A zoom to a width of 10^{-13} leaves only a few digits to distinguish neighbouring pixels, and the picture dissolves into blocks. Deep-zoom software computes one reference orbit in arbitrary precision and the other pixels as small *perturbations* of it in ordinary floating point: Ch. 22, §22.1 is the reason this is necessary.

The chaos game

```
z = 0j
for i in range(n_points):
    corner = corners[rng.integers(len(corners))]
    z = corner + r * (z - corner)      # apply a random contraction from the IFS
    plot(z)                            # skip the first few points (transient)
```

Cost $O(1)$ per point. The randomness is only a device for visiting the attractor; any sequence of maps that contains every finite pattern of choices works.

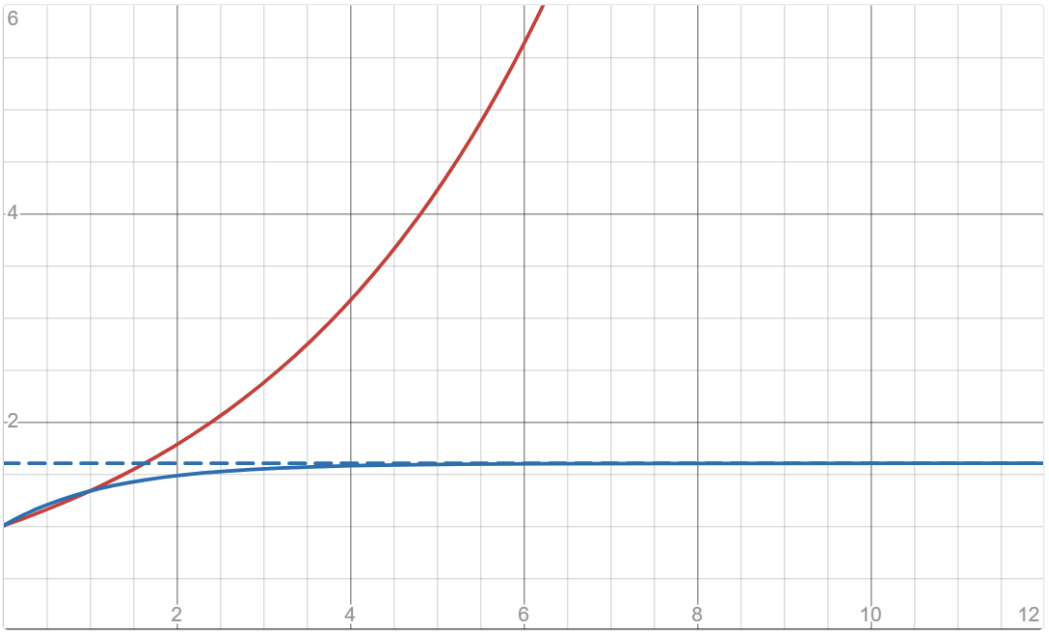
Box counting

```
def box_count(points, eps):
    cells = np.floor(np.column_stack([points.real, points.imag]) / eps)
    return len(np.unique(cells, axis=0))          # number of occupied eps-boxes
# D is the slope of log(box_count) against log(1/eps), over a range of eps
```

Two failure cases. If ε is smaller than the spacing between your sample points, the count saturates at the number of points and the slope falls toward 0. If ε is comparable to the whole set, the count is dominated by its overall shape. The usable range lies between, and it is often only a decade or two wide.

73.5 The experiment

First, the snowflake's two diverging fates. With the stage n on the horizontal axis, the red curve is the perimeter ratio $(4/3)^n$ and the blue curve is the area ratio, which flattens out under its limit $8/5$.



Perimeter (red) and area (blue) of the Koch snowflake relative to the starting triangle. Change the 4 and 3 in the red curve to N and $1/r$ for another replacement rule (try $\frac{5}{3}$ for a rule with five pieces of a third), and ask what happens to the area in that case.

Now play the chaos game and measure the dimension of what it draws. The script uses k corners of a regular polygon and contracts by r toward a random corner each step; then it box-counts the result.

```
import numpy as np
import matplotlib.pyplot as plt

rng = np.random.default_rng(1)
k = 3            # number of corners: try 4, 5, 6
r = 0.5          # contraction ratio toward the chosen corner: try 0.4, 0.6, 1/3
n_pts = 200_000  # points in the chaos game

corners = np.exp(2j * np.pi * np.arange(k) / k + 0.5j * np.pi)
z = 0j
pts = np.empty(n_pts, dtype=complex)
for i in range(n_pts):
    c = corners[rng.integers(k)]
    z = c + r * (z - c)          # jump a fraction (1 - r) of the way toward a random corner
    pts[i] = z
pts = pts[100:]                  # discard the transient

# box counting: how many eps-boxes contain at least one point?
eps = 2.0 ** -np.arange(2, 9)
N = [len(np.unique(np.floor(np.column_stack([pts.real, pts.imag]) / e), axis=0)) for e in eps]
D_fit = np.polyfit(np.log(1 / eps), np.log(N), 1)[0]
print(f"box-counting estimate D = {D_fit:.3f};  similarity dimension log k / log(1/r) = {np.log(k) / np.log(1 / r):.3f}")

fig, (a1, a2) = plt.subplots(1, 2, figsize=(10, 4.5))
a1.plot(pts.real, pts.imag, ",", color="navy"); a1.set_aspect("equal"); a1.set_title(f"chaos game, k={k}, r={r}")
a2.loglog(1 / eps, N, "o-"); a2.set_xlabel("1/eps"); a2.set_ylabel("N(eps)"); a2.set_title(f"slope = {D_fit:.3f}")
plt.show()
```

As written ($k = 3, r = 0.5$) it draws the Sierpinski triangle and estimates $D \approx 1.571$ against the exact 1.585. Things to try:

- $k = 4, r = 0.5$: the four copies tile the square exactly, the attractor is the filled square, and the formula says $D = 2$. The estimate is lower (1.914). Is that the fit or the number of points? Raise `n_pts` and find out.
- $k = 3, r = 0.4$: the copies no longer touch; you get a dust of dimension $\log 3 / \log 2.5 = 1.199$. The estimate (1.222) is close.
- $k = 5, r = 0.4$: the formula says 1.756 and the estimate says 1.691. Look at the picture closely, near where neighbouring copies meet. Something in the definition of similarity dimension has been violated. What?

73.6 The challenge

1. **Intuition.** A friend argues: "The Koch curve is made of line segments at every stage, so in the limit it is still a curve, and a curve has dimension 1." Find the flaw. Which property of the limit shape do the finite stages fail to predict, and why does box counting at a fixed ε not care how many stages you drew once the stage's segments are shorter than ε?

2. **Derivation.** The **Vicsek fractal** keeps the centre square and the four corner squares of a 3×3 grid, and repeats. Compute its similarity dimension. Then compute the area remaining after n stages, and the perimeter after n stages, and decide which of them tends to 0, which to infinity, and which to a finite limit.

3. **Implementation.** Extend the Mandelbrot code to draw the **Julia set** of $z \mapsto z^2 + c$ for a fixed c: now c is constant and the *starting point* z_0 varies over the pixels. Draw it for $c = -1$, $c = -0.123 + 0.745j$, and $c = 0.3$. One of these Julia sets is connected and one is a disconnected dust. Check, using your Mandelbrot code, whether each c lies in M, and formulate a conjecture relating the two pictures.

4. **Open investigation.** Box-count a real coastline. Take any outline you can get as a list of coordinates (a country border from an open map data set, or a coastline you trace by hand from a satellite image at several zoom levels), and estimate D over as many scales as the data allow. How stable is your estimate when you shift the grid by half a box, rotate it, or change the range of ε you fit over? Is there a scale range over which the coastline is truly "fractal", or does D drift? Researchers still argue about how to answer this for real data.

73.7 Loose threads

The hook asked what dimension 1.25 could mean. Now we know: a set has dimension D when the number of ε-boxes needed to cover it grows like ε^{-D}, and Richardson's ruler law $L \approx C\varepsilon^{1-D}$ is that statement in disguise. For exactly self-similar sets, $D = \log N / \log(1/r)$; the Koch curve has $D = 1.262$, and its snowflake has infinite perimeter around a finite area. Iterated function systems generate such sets as unique fixed points of a contraction on shapes, and the escape-time rule $z \mapsto z^2 + c$ generates the Mandelbrot set, whose outside a computer can certify and whose inside it never can.

What the chapter left open:

- **Is M locally connected?** The first mystery is the MLC conjecture, still open.
- **The right definition of dimension.** Box counting is easy to compute but has defects: the set of rational numbers in $[0, 1]$ is countable, yet every box meets it, so its box-counting dimension is 1. The **Hausdorff dimension** repairs this using measure theory; see the mystery below.
- **Where the strange attractor's dimension comes from.** Chaotic systems trace out fractal sets, and their dimension is linked to how fast nearby trajectories separate. See the last mystery.
- **Universal numbers.** Along the real axis of M, the period-doubling discs shrink by a ratio that tends to $4.669\ldots$, Feigenbaum's constant. The same number appears in dripping taps and convection cells. Why a single number governs so many unrelated systems is a story about bifurcations and renormalisation, begun in Ch. 85.
- **Fractals as worlds.** Fractal mountains, clouds and coastlines in games are built not from exact self-similarity but from *statistical* self-similarity: noise summed over octaves. That is the subject of Ch. 74.

? A curve of dimension two

The boundary of the Mandelbrot set looks like a curve: it has no interior, it is "one-dimensional" topologically. Yet in 1998 Mitsuhiro Shishikura proved that its Hausdorff dimension is exactly 2, as large as a curve in the plane can possibly be. What is Hausdorff dimension, why can it disagree with box counting, and what does it mean for a boundary to be two-dimensional when nobody yet knows whether it has any area at all? The answer requires building a theory of size for wild sets, which is measure theory, in Ch. 97.

? Where chaos keeps its fractals

Iterate the Hénon map $x_{n+1} = 1 - 1.4x_n^2 + y_n$, $y_{n+1} = 0.3x_n$ from almost any start, and the points settle onto a thin, layered set of box-counting dimension about 1.26, a fractal made by a dynamical system no one designed to make one. Why do chaotic systems produce fractal attractors, and why can their dimension be predicted from the rates at which nearby orbits stretch and fold (the Lyapunov exponents)? That is the Kaplan–Yorke story, in Ch. 84.

Chapter 74 — Procedural Generation: Creating Worlds with Rules

> **Level 2 · Track G — Mathematics for Computer Graphics, Games, and Simulation Builds on:** Ch. 21 (random processes, power spectral density), Ch. 10 (dominant eigenvalues), Ch. 22 (§22.5 interpolation), Ch. 73 · **Leads to:** Ch. 75, Ch. 76, Ch. 86 · **Related:** Ch. 81, Ch. 30, Ch. 29 **Reading time:** ~30 min

74.1 The hook

In 1984 two Cambridge undergraduates, David Braben and Ian Bell, released *Elite*, a space-trading game for the BBC Micro. The machine had 32 kilobytes of memory, shared between the program, the screen and everything else. The game contained eight galaxies of 256 star systems each: 2048 worlds, every one with a name, a position, a government, an economy, a population and a short description. Written out as text, that catalogue alone would not have fitted in the machine.

It was never written out. Each galaxy was a few bytes of **seed**. A short, deterministic scrambling routine turned the seed into the next seed, and the bits of each seed were read off as the properties of the next planet. Fly away from Lave and come back, and Lave is still there, with the same name and the same economy, because it is recomputed from the same seed every time.

Thirty-two years later *No Man's Sky* did the same thing at a larger scale: a 64-bit seed space, $2^{64} \approx 1.8 \times 10^{19}$ planets, each with continents, caves, weather and creatures, generated only when a player arrives. Minecraft does it for terrain: give it a seed, and an effectively endless landscape unrolls as you walk, identical for every player who types the same seed.

There is a paradox here. A world worth exploring has to look *designed*: mountains that rise smoothly into ridges, rivers that run downhill, caves that connect, trees that look like trees. Randomness alone gives static, the snow on an untuned television. Order alone gives a chessboard. And whatever you make has to be *reproducible*: the mountain you saw yesterday must still be there today, even though you never stored it.

How can a few bytes and a set of rules produce a world that is random enough to surprise, structured enough to believe, and deterministic enough to revisit?

74.2 The big idea

Replace storage with functions

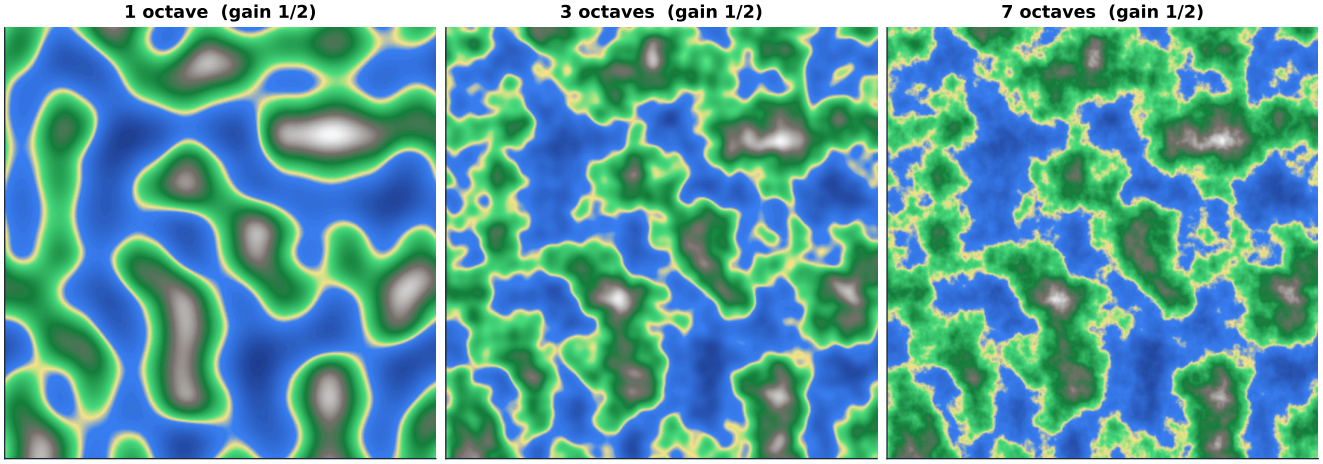
The central trick is to stop thinking of a world as data and start thinking of it as a **function of position**. The height of the terrain at (x, y) is not looked up in a table; it is computed by a function $h(x, y)$ whenever it is needed. If h is a pure function (same input, same output, no hidden state) then the world is automatically consistent. Two players, or the same player on two days, evaluating $h(1000, 2000)$ get the same mountain. Nothing outside the player's view ever needs to exist.

The seed is just one more argument: $h(x, y; \text{seed})$. And the randomness inside h comes from a **hash function**: a deterministic scramble that maps integers to values that look independent, so that `hash(1000, 2000, seed)` and `hash(1001, 2000, seed)` appear unrelated. How a deterministic function can look random enough is a deep question of its own (Ch. 81); here we just use it.

Random, but smooth: noise

Hashing each pixel independently gives television static: every point unrelated to its neighbour. Real terrain is **correlated**: the height a metre away is nearly the same as here, the height a kilometre away is unrelated. In the language of Ch. 21, we want a random field with a chosen autocorrelation, or equivalently a chosen power spectrum.

Ken Perlin's answer, devised in 1983 after he had worked on the film *Tron* and later honoured with an Academy Award for technical achievement, is beautifully cheap. Put random values only at the corners of an integer grid, and interpolate smoothly in between. The result is a hilly landscape with features about one grid cell across. To get features of every size at once, add copies at doubled frequency and halved amplitude, a sum of **octaves**, and the result has the statistical self-similarity of the fractal coastlines of Ch. 73.



Gradient noise summed over 1, 3 and 7 octaves, each octave at double the frequency and half the amplitude of the last, on the same 6×6 grid of lattice cells with the same seed. The large-scale continents are fixed by the first octave; later octaves only add detail.

Three more kinds of rule

Noise makes landscapes. Other structures need other rules, and procedural generation is a toolbox of them:

- **Cellular automata**: a grid where each cell updates from its neighbours by a local rule. A few steps of "become wall if most of your neighbours are walls" turn random static into caves.
- **Grammars**: rewriting rules on strings, like $F \to FF$, whose output is read as drawing instructions. They grow plants, buildings and road networks.
- **Spatial structures**: ways of scattering points so that they are random but not clumped (trees in a forest, stars in a sky), and of carving space into regions around them (biomes, kingdoms).

Each is a small machine for turning a seed into structure. The mathematics is about controlling what comes out.

74.3 The mathematics

Value noise and the fade curve

In one dimension, attach a pseudo-random value a_i to every integer i. For x between i and $i+1$, let $t = x - i \in [0, 1)$ and interpolate:

$$n(x) = a_i + f(t)\,(a_{i+1} - a_i),$$

where f is a **fade curve** with $f(0) = 0$ and $f(1) = 1$. With $f(t) = t$ this is linear interpolation (Ch. 22, §22.5), and the result has corners at every integer: the derivative jumps. For terrain that is fatal, because lighting depends on the surface normal, which depends on the derivative: every kink shows up as a visible crease.

How smooth does f need to be? At an integer the curve from the left cell ends with slope $(a_i - a_{i-1})f'(1)$ and the curve on the right starts with slope $(a_{i+1} - a_i)f'(0)$. These generally differ unless both are zero. The same argument applies to every derivative.

The quintic fade curve

The polynomial of lowest degree with $f(0) = 0$, $f(1) = 1$ and $f'(0) = f'(1) = f''(0) = f''(1) = 0$ is

$$f(t) = 6t^5 - 15t^4 + 10t^3.$$

Interpolating with it makes noise whose first and second derivatives are continuous everywhere.

Proof. We need f' to vanish to first order at $t = 0$ and at $t = 1$ (so that f' and f'' are both zero there). The lowest-degree polynomial with double roots at 0 and 1 is $f'(t) = c\,t^2(1-t)^2$. Integrating from 0,

$$f(t) = c\left(\frac{t^3}{3} - \frac{t^4}{2} + \frac{t^5}{5}\right),$$

and $f(1) = c\,(\tfrac{1}{3} - \tfrac{1}{2} + \tfrac{1}{5}) = c/30$, so $c = 30$, giving $f(t) = 10t^3 - 15t^4 + 6t^5$. Any lower-degree candidate would make f' of degree at most 3 with two double roots, which forces $f' \equiv 0$ and contradicts $f(1) = 1$. Since every cell's interpolant has zero first and second derivatives at both ends, they match across cell boundaries. ∎

Perlin's original 1985 noise used the cubic **smoothstep** $3t^2 - 2t^3$, which has $f'(0) = f'(1) = 0$ but $f''(0) = 6$ and $f''(1) = -6$. The second derivative jumps at every grid line, and on shaded terrain the grid shows through. Perlin switched to the quintic in 2002. You can compare the two curves in the experiment.

Gradient noise

Value noise has a subtler flaw: its features line up with the grid, because the extreme values sit at lattice points. **Gradient noise**, which is what "Perlin noise" usually means, attaches a random *slope* g_i to each lattice point instead of a random value, and blends the linear functions $g_i(x - i)$:

$$n(x) = \big(1 - f(t)\big)\, g_i\, t + f(t)\, g_{i+1}\,(t - 1).$$

At $t = 0$ this is 0, and its derivative there is g_i (because $f(0) = f'(0) = 0$). So gradient noise is *zero at every lattice point* with a random slope through it. The peaks and valleys fall between lattice points, which hides the grid, and the noise has no tendency to drift away from zero over large distances: almost no power at very low frequencies. In 2-D, the slopes become random unit vectors $\mathbf{g}_{ij}$, the linear functions become dot products $\mathbf{g}_{ij} \cdot (\mathbf{x} - \mathbf{x}_{ij})$ at the four corners of the cell, and the blending is the fade curve applied separately in x and y.

Fractal sums of octaves

A single layer of noise has features of one size. Terrain has all sizes. **Fractional Brownian motion** (fBm), in the procedural sense, sums octaves:

$$F(\mathbf{x}) = \sum_{k=0}^{K-1} g^k\, n(2^k \mathbf{x}),$$

with **gain** (or persistence) $g < 1$ and **lacunarity** 2. Two facts make this controllable.

It is bounded. If $|n| \le B$, then $|F| \le B \sum_k g^k = B\,(1 - g^K)/(1 - g) < B/(1-g)$. With $g = 1/2$ and $K = 7$ octaves the bound is $1.98B$: adding octaves can never make mountains taller than twice the first octave's. This is why the continents in the figure do not move as octaves are added.

Its spectrum is a power law. Octave k puts its power, proportional to amplitude squared, g^{2k}, near frequency $\nu_k \propto 2^k$. So power falls off as $\nu^{-\beta}$ with $2^{-\beta k} = g^{2k}$, that is

$$\beta = -2 \log_2 g.$$

The gain $g = 1/2$ gives $\beta = 2$, the spectrum of Brownian motion (Ch. 21). This connects noise to fractals. The exponent $H = -\log_2 g$ (the Hurst exponent) controls how roughness scales, and for $0 < H < 1$ the graph of a one-dimensional profile has fractal dimension $D = 2 - H$. With $g = 0.6$, $H = 0.737$ and $D = 1.263$: a terrain profile with almost exactly the roughness of the Koch curve. We state these relations rather than prove them; the precise statement needs the theory of self-similar random processes.

? The noise that is not quite isotropic

Gradient noise on a square grid is not the same in every direction: look closely at a heightmap and features prefer to align with the axes and diagonals, and the power spectrum, viewed in 2-D, is not a perfect ring. Perlin's later *simplex noise* uses a triangular grid to reduce this, and it is also cheaper in high dimensions. But what exactly is the power spectrum of gradient noise, why is it not band-limited, and what aliasing does that cause when the terrain is sampled onto pixels? Those are sampling-theory questions, answered in Ch. 76.

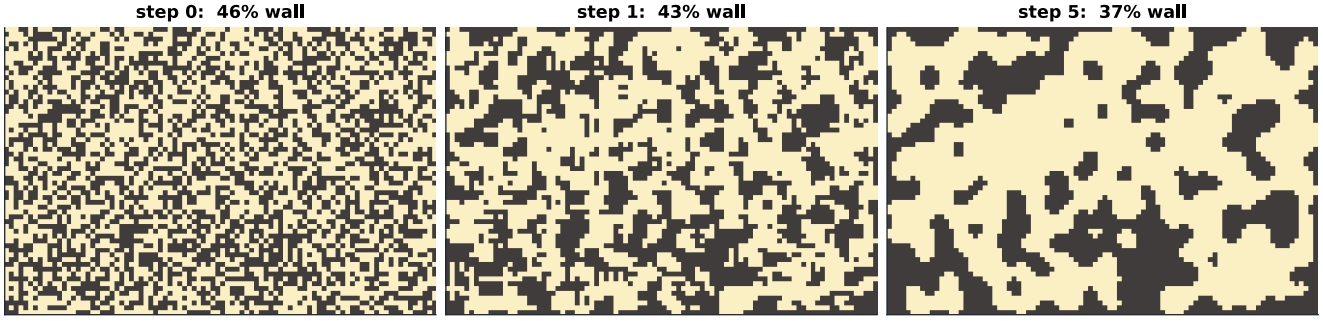
Cellular automata: caves from static

Fill a grid with walls at random, each cell independently a wall with probability p. Then apply the **4–5 rule** a few times: each cell becomes a wall if at least 5 of the 9 cells in its 3×3 block (itself included) are walls, and floor otherwise. It is a local majority vote.

After one step, before any correlations have built up, a cell is a wall with probability

$$P(\text{wall}) = \sum_{k=5}^{9} \binom{9}{k} p^k (1-p)^{9-k}.$$

For $p = 0.45$ this is 0.379: a minority shrinks under majority voting, so the floor grows. But the deeper effect is *spatial*: isolated wall cells vanish, isolated floor cells fill in, and boundaries between wall and floor straighten. After four or five steps the static has become smooth cave walls, and further steps change almost nothing.



Cave generation with the 4–5 rule on a 60×90 grid, cells outside the map counting as wall. One step already clusters the static; by step 5 the caves are smooth and almost stable.

The starting density p is the main control. Too low, and the walls dissolve into one open hall; too high, and the floor breaks into sealed pockets. The useful window is narrow because connectivity of random sets does not change gradually: it switches abruptly at a **percolation threshold**, the density at which a connected floor region spanning the whole map first appears. In practice, generators run a flood fill afterwards and either connect or delete the isolated pockets.

Grammars: L-systems

In 1968 the biologist Aristid Lindenmayer introduced string-rewriting systems to model the growth of algae. An **L-system** has an alphabet, a starting string (the axiom) and rules that replace *every* symbol at once in each generation. Lindenmayer's algae: $A \to AB$, $B \to A$, axiom A:

$$A \to AB \to ABA \to ABAAB \to ABAABABA \to \cdots$$

The lengths are $1, 2, 3, 5, 8, \ldots$: Fibonacci numbers. That is no accident, and the reason gives a general tool.

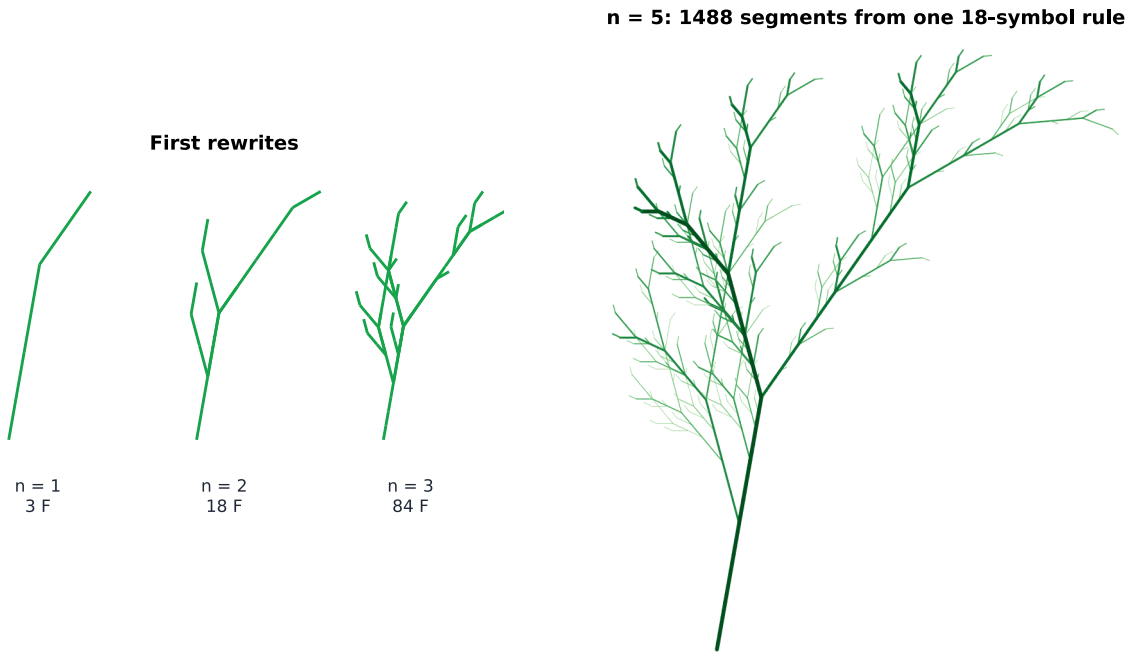
Growth of an L-system

Let c_n be the vector of symbol counts in generation n, and let $\mathbf{M}$ be the matrix whose entry M_{ab} is the number of symbols a produced by one symbol b. Then $c_{n+1} = \mathbf{M} c_n$, so $c_n = \mathbf{M}^n c_0$, and the string length grows like λ^n, where λ is the eigenvalue of $\mathbf{M}$ of largest magnitude (when c_0 has a component along its eigenvector).

Proof. Every symbol is rewritten independently, so the number of a's in generation $n+1$ is $\sum_b M_{ab}\,(c_n)_b$, which is the matrix–vector product. Iterating gives $c_n = \mathbf{M}^n c_0$. Expanding c_0 in eigenvectors of $\mathbf{M}$ (Ch. 10), the component along the largest eigenvalue dominates, exactly as in the power method. ∎

For the algae, $\mathbf{M} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ (columns: what A and B produce), with eigenvalues $\varphi = 1.618$ and -0.618: length grows like the golden ratio to the n-th power.

To draw, read the string as commands for a **turtle**: `F` draws a step forward, `+` and `-` turn by an angle, `[` saves the turtle's position and heading on a stack, `]` restores it. The brackets create branches. The plant in the figure uses $X \to F + [[X] - X] - F[-FX] + X$ and $F \to FF$ with a turn of 25°. The counts obey $f_{n+1} = 2f_n + 3x_n$, $x_{n+1} = 4x_n$, a triangular matrix with eigenvalues 2 and 4, and solving with $f_0 = 0$, $x_0 = 1$ gives $f_n = \frac{3}{2}(4^n - 2^n)$: 1488 segments at $n = 5$.



An L-system plant. One rule, applied five times, gives 1488 branch segments; line width and shade follow the depth of bracket nesting.

Spatial structures

Scatter trees by independent uniform random points and you get clumps and gaps: a Poisson process is clumpier than intuition expects. Forests, stars and village layouts look better with **blue-noise** point sets, where no two points are closer than a radius r but the points are otherwise random. **Poisson-disk sampling** produces them; Bridson's algorithm grows the set outward from a seed point, trying a few candidates in an annulus around each active point and accepting those at least r from all others, using a background grid of cell size $r/\sqrt{2}$ so that each check touches only a few neighbours. It runs in $O(N)$ time.

Given scattered points, the **Voronoi diagram** assigns every location to its nearest point: biomes around seed points, territories around capitals, cells for cracked stone. Computing it efficiently, along with its dual triangulation, is the business of Ch. 75.

74.4 The algorithm

2-D gradient noise

```
def fade(t):
    return t*t*t*(t*(6*t - 15) + 10)            # 6t^5 - 15t^4 + 10t^3

def noise2(x, y, perm, grad):                    # perm: shuffled 0..255 (twice); grad: 256 unit vectors
    i, j = int(np.floor(x)), int(np.floor(y))
    u, v = x - i, y - j                          # position inside the cell
    def corner(di, dj):
        g = grad[perm[perm[(i + di) & 255] + ((j + dj) & 255)]]   # hash the lattice point
        return g[0]*(u - di) + g[1]*(v - dj)     # dot(gradient, offset to corner)
    a, b = fade(u), fade(v)
    bottom = corner(0, 0) + a*(corner(1, 0) - corner(0, 0))
    top    = corner(0, 1) + a*(corner(1, 1) - corner(0, 1))
    return bottom + b*(top - bottom)
```

Cost. Four hashes, four dot products and three interpolations per sample in 2-D, and 2^d corners in d dimensions, which is why simplex noise ($d+1$ corners) wins in 3-D and 4-D. An fBm with K octaves costs K times as much.

Determinism. The permutation table is the seed. Shuffle it with a seeded generator once; never call an unseeded random function inside the noise. The table repeats every 256 cells, which is invisible at the scales most games use and very visible on an infinite map; hashing the full integer coordinates with a good integer hash removes the period.

Precision. At large coordinates (a million cells from the origin) single-precision floats lose the fractional part that the fade curve needs, and the terrain becomes stepped. Infinite worlds work in local coordinates, chunk by chunk.

Caves, plants and points

```
def cave(W, H, p=0.45, steps=5, seed=0):
    rng = np.random.default_rng(seed)
    G = (rng.random((H, W)) < p).astype(int)
    for _ in range(steps):
        P = np.pad(G, 1, constant_values=1)       # border is solid rock
        S = sum(P[1+dy:H+1+dy, 1+dx:W+1+dx] for dy in (-1, 0, 1) for dx in (-1, 0, 1))
        G = (S >= 5).astype(int)                  # 4-5 rule: majority of the 3x3 block
    return G                                      # then flood-fill to find connected caves

def lsystem(axiom, rules, n):
    for _ in range(n):
        axiom = "".join(rules.get(ch, ch) for ch in axiom)
    return axiom                                  # length grows like lambda^n
```

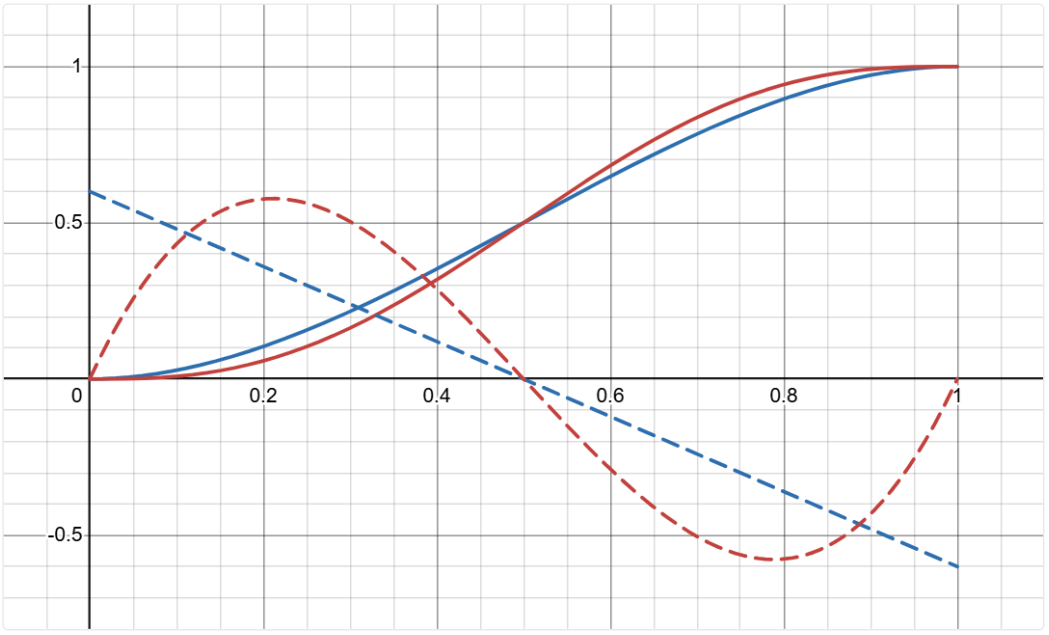
Cave generation costs $O(WH)$ per step and needs only a handful of steps. An L-system's string length grows exponentially, $O(\lambda^n)$, so memory runs out fast; production systems expand lazily, generating each branch only when the camera is close enough to see it, which is the same "compute on demand" principle as noise.

Tool	What it makes	Main knob	Typical failure
gradient noise + fBm	terrain, clouds, textures	gain g, octaves	grid artifacts, repetition, too uniform
cellular automaton	caves, islands, erosion	starting density p, steps	disconnected pockets, one giant hall
L-system	plants, rivers, cities	rules, angle, generations	exponential blow-up, self-intersection
Poisson-disk sampling	forests, stars, loot	minimum spacing r	uniform look at large scale

> **Variety is not the same as interest**
>
> Eighteen quintillion planets generated by one noise function are eighteen quintillion variations on one theme. Players quickly learn the generator's "voice". Shipped games layer rules: noise for the base, automata and erosion for local structure, hand-made pieces placed by grammars, and constraints that guarantee a playable result (a path from start to exit, a key before its lock).

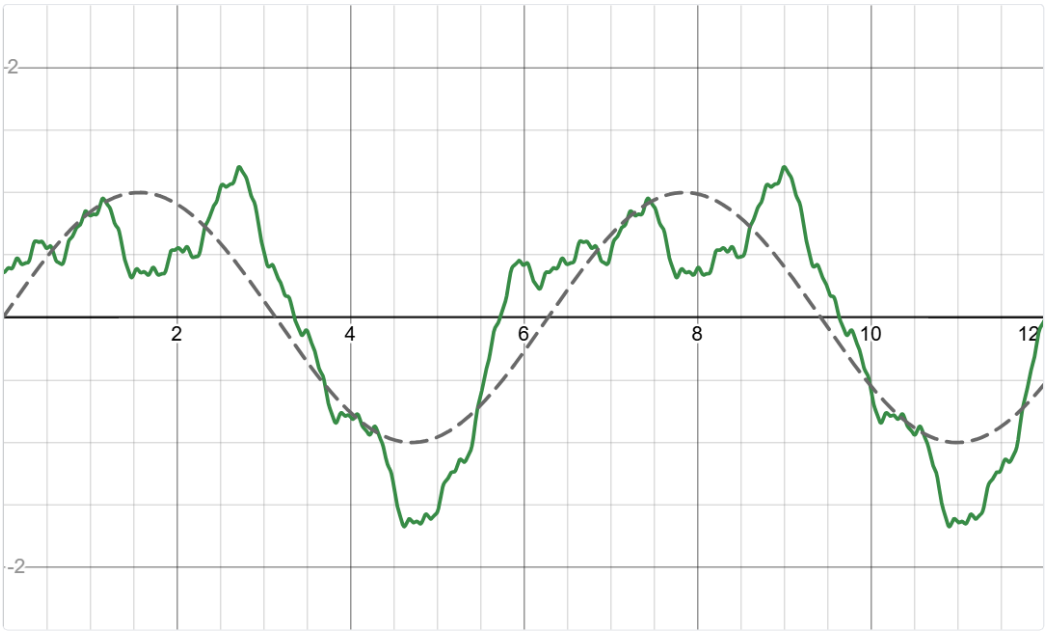
74.5 The experiment

First, see the fade curves and why the quintic is smoother. The blue curve is the cubic smoothstep, the red is the quintic, and the dashed lines are their second derivatives (scaled by $1/10$ to fit).



Cubic smoothstep (blue) and quintic fade (red) on one cell. The blue dashed second derivative is ± 0.6 at the cell edges, so it jumps between cells; the red one is zero at both ends.

Next, a sum of octaves you can edit. Desmos cannot hash, so this uses sines with fixed phases in place of noise, but the octave structure is the same: frequency 2^k, amplitude g^k with $g = 0.5$.



A profile with 7 octaves (green) over its first octave alone (grey dashed). Change the 0.5 to 0.7 for rougher terrain, or to 0.3 for gentle hills, and change the 6 to see how many octaves your eye can tell apart.

Now a real 1-D gradient-noise terrain, with knobs for the seed, the number of octaves and the gain:

```
import numpy as np
import matplotlib.pyplot as plt

seed = 74         # change it: a different world, the same every time you run
octaves = 6       # try 1, 3, 10
gain = 0.5        # amplitude ratio per octave: try 0.3 (smooth) and 0.7 (rough)

rng = np.random.default_rng(seed)
slopes = rng.uniform(-1, 1, 4096)          # one random gradient per lattice point

def fade(t):
    return t**3 * (t * (6 * t - 15) + 10)

def noise(x):
    i = np.floor(x).astype(int)
    t = x - i
    g0, g1 = slopes[i % 4096], slopes[(i + 1) % 4096]
    return (1 - fade(t)) * g0 * t + fade(t) * g1 * (t - 1)   # zero at every integer

def fbm(x):
    return sum(gain**k * noise(2.0**k * x + 17.3 * k) for k in range(octaves))

x = np.linspace(0, 20, 4000)
h = fbm(x)
print(f"range [{h.min():.3f}, {h.max():.3f}],  bound 0.5*(1-g^K)/(1-g) = {0.5 * (1 - gain**octaves) / (1 - gain):.3f}")

plt.fill_between(x, h, h.min() - 0.2, color="sienna")
plt.fill_between(x, np.minimum(h, 0), h.min() - 0.2, where=h < 0, color="steelblue")
plt.title(f"seed {seed}, {octaves} octaves, gain {gain}")
plt.show()
```

The printed bound uses the fact that 1-D gradient noise with slopes in $[-1, 1]$ never exceeds 0.5 in magnitude, so $B = 0.5$. Check it against the printed range for several seeds and gains. Then try `gain = 0.9` with `octaves = 10`: what happens to the picture, and to the gap between the range and the bound?

74.6 The challenge

1. **Intuition.** A level designer generates an island with 8 octaves of fBm, and the beach looks the same at every zoom level, which she likes. The mountains also look the same at every zoom level, which she does not: real mountains are smooth at the top and rough lower down, or the other way round. Explain, without equations, why plain fBm cannot do this, and propose a modification in which the amplitude of each octave depends on the height already accumulated.

2. **Derivation.** For 1-D gradient noise with slopes $g_0, g_1 \in [-1, 1]$ on one cell, show that $|n(x)| \le 1/2$ for all x, and find the slopes and the point t at which the bound is reached. Then find the lowest-degree fade curve whose first, second *and third* derivatives vanish at both ends.

3. **Implementation.** Implement Bridson's Poisson-disk sampling in a unit square with minimum spacing r. Compare its points with the same number of uniform random points by computing, for each set, the histogram of nearest-neighbour distances and the radially averaged power spectrum of the point pattern (place a delta at each point and take a 2-D FFT). Where does the blue-noise spectrum have *less* power than the uniform one, and why does the eye prefer that?

4. **Open investigation.** For the 4–5 cave rule on a large grid, measure, as a function of the starting density p, the probability that after 5 steps the floor contains a connected path from the left edge to the right edge. Locate the value of p at which this probability crosses $1/2$, and see how sharply it switches as the grid grows. Is it the same threshold as for plain random static (site percolation on the 8-connected grid) or is it shifted by the automaton? Nobody has a formula for the shifted threshold.

74.7 Loose threads

The hook asked how a few bytes can produce a believable, revisitable world. The answer has three parts. Make the world a pure function of position and seed, so that it is consistent without being stored. Make the randomness *correlated*: lattice noise interpolated with a fade curve whose first and second derivatives vanish at the cell edges, summed over octaves into a bounded fractal with a power-law spectrum $\beta = -2\log_2 g$. And add structure with other local rules: majority-vote automata that turn static into caves, rewriting grammars whose growth rate is the dominant eigenvalue of a count matrix, and blue-noise point sets carved into Voronoi regions.

What the chapter did not tell you:

- **Spectra and sampling.** The first mystery: what is the exact spectrum of gradient noise, and how should it be filtered before sampling on pixels? That is Ch. 76.
- **What else automata can do.** The 4–5 rule settles down. Other rules, just as simple, never do: Conway's Game of Life and the one-dimensional Rule 110 can carry out any computation. When a local rule produces stable structure, chaos or a universal computer is the subject of Ch. 86.
- **Voronoi and Delaunay.** Computing nearest-point regions and their dual triangulation in $O(N \log N)$ time is Ch. 75.
- **How random is the hash?** Every seed-to-world pipeline relies on a deterministic function behaving "randomly enough". What that means precisely is Ch. 81.

> **? The tiling that no algorithm can finish**
>
> Modern generators such as *Wave Function Collapse* build levels by placing tiles that must match their neighbours' edges, backtracking when they get stuck. It feels like a puzzle that a sufficiently clever program could always solve or reject. It is not. In 1966 Robert Berger proved that, given a finite set of square tiles with coloured edges, *no algorithm* can decide in general whether they tile the infinite plane, and some sets tile it only non-periodically. Why the answer is not merely hard but undecidable is a story about Turing machines hidden inside tiles, told in Ch. 30.

75.1 The hook

In September 1854 cholera killed more than five hundred people in a few streets of Soho, London, in ten days. The physician John Snow marked every death on a street map, and then drew one extra line on it. The line enclosed every house that was closer, by walking distance, to the water pump on Broad Street than to any other pump. The deaths clustered inside that line. The handle of the pump was removed, and the map became one of the founding documents of epidemiology.

Snow's line is a piece of a **Voronoi diagram**: give every pump the region of the plane that is nearer to it than to any other pump. He drew it by hand for a dozen pumps. Today the same question is asked millions of times a second.

- A phone network asks which tower should serve each handset.
- A game asks which of 20,000 units is nearest to the click of the mouse, sixty times a second.
- A finite-element solver needs the plane cut into well-shaped triangles whose corners are a cloud of measured points.
- A robot wants the route through a crowd of obstacles that stays as far from all of them as possible.

The naive answer to "who is nearest?" is to check every site: n distance computations per query, and n^2 to build the whole diagram. With a million sites that is 10^{12} operations, about a quarter of an hour on a fast core, and it would have to be repeated whenever a site moves.

There is a second, nastier problem. Even the tiniest geometric question ("is this point to the left of that line?") is answered by a computer with rounded arithmetic. Ask it three slightly different ways and you can get three answers that cannot all be true. Geometry programs that are correct on paper crash, loop forever or produce polygons that cross themselves.

So this chapter has two goals:

> **How do you build shapes from points (hulls, triangulations, nearest-site regions) in $O(n \log n)$ time, and how do you make every decision rest on one test you can trust?**

The answer is a small toolkit: one determinant, one circle, one paraboloid and one tree. By the end you will know why Snow's map and a mesh of triangles are the same object drawn twice.

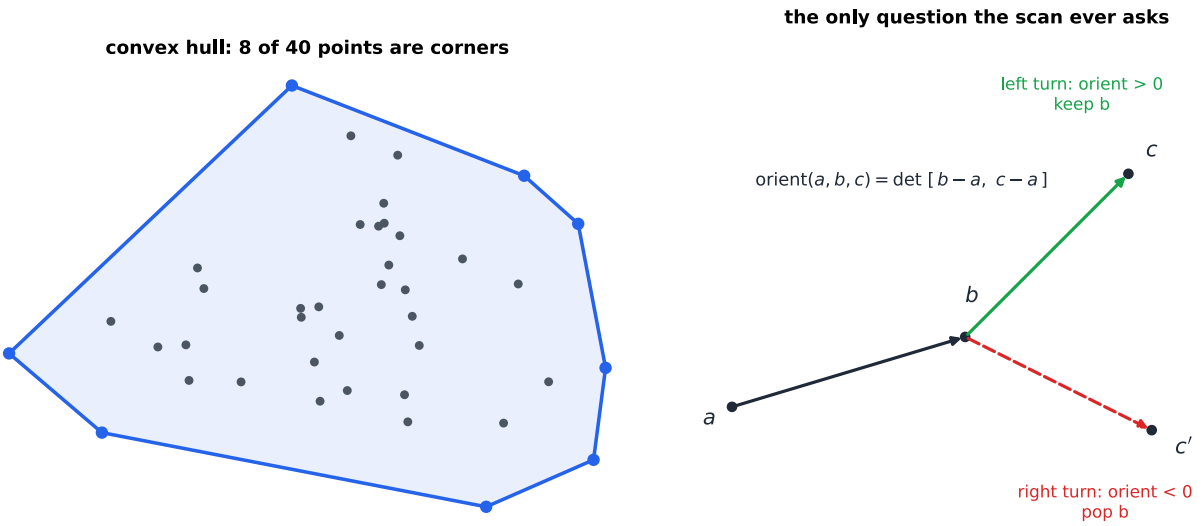
75.2 The big idea

Geometry algorithms are built from tiny yes/no questions. Almost nothing in this chapter computes a length or an angle. Every algorithm asks, over and over, a question with a one-bit answer.

- *Orientation:* do points a, b, c make a left turn, a right turn, or lie on a line?
- *In-circle:* is point d inside the circle through a, b, c?
- *Containment:* does a query box overlap this cell of space?

Each of these is the **sign of a determinant**. The whole art is to arrange the questions cleverly so that you ask as few as possible, and to compute each sign so reliably that the answers never contradict one another.

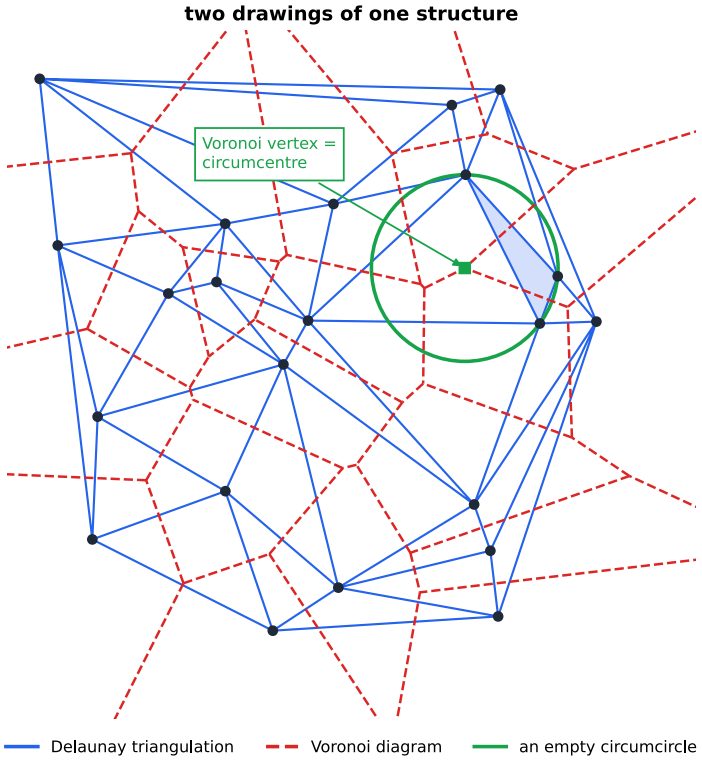
The convex hull is a rubber band. Hammer nails into a board at your points and snap a rubber band around them. The shape it settles into is the **convex hull**: the smallest convex set containing every point (Ch. 47 is the chapter about why convexity matters). Its corners are a subset of your points. To find them you walk around the cloud and keep only the points where the band turns left.



Left: the hull of 40 random points has only 8 corners. Right: the scan's only question is whether the path $a \to b \to c$ turns left (keep b) or right (discard b), and that is the sign of a 2×2 determinant.

Triangulations are the plane cut into pieces you can compute with. Given points, join them with non-crossing segments until no more can be added. You get a triangulation. There are astronomically many. The **Delaunay triangulation** is the one that avoids skinny triangles as far as possible. Its defining rule is a beautifully local one: no point lies inside the circle through the three corners of any triangle.

Voronoi and Delaunay are one structure drawn twice. Draw the Voronoi diagram of the points (Snow's regions). Now join two points whenever their regions share an edge. The result is exactly the Delaunay triangulation. Each Voronoi corner sits at the centre of an empty circle through three sites, which is the circumcircle of a Delaunay triangle.



Delaunay edges (blue) cross the Voronoi edges (red) at right angles. The green circle passes through the three corners of the shaded triangle, contains no other point, and is centred on a Voronoi vertex.

Spatial indexes are filing cabinets for space. To answer "what is near here?" without checking everything, put the points in a tree whose nodes are regions. A **quadtree** cuts a square into four quadrants, and keeps cutting any quadrant that holds too many points. Empty space costs almost nothing, and crowded regions get fine cells. A query descends only into cells that touch the region it cares about.

The analogy to keep in mind is a library. Nobody finds a book by reading every spine. The building is divided into floors, rooms, shelves. Each division answers one yes/no question ("is it in this room?") and discards most of the collection at once. That is where $\log n$ comes from, in sorting (Ch. 26) and in geometry.

75.3 The mathematics

The orientation predicate

Points live in $\mathbb{R}^2$ with coordinates $a = (a_x, a_y)$ and so on.

Orientation

$$\operatorname{orient}(a, b, c) = \det \begin{bmatrix} b_x - a_x & c_x - a_x \\ b_y - a_y & c_y - a_y \end{bmatrix} = (b_x - a_x)(c_y - a_y) - (b_y - a_y)(c_x - a_x).$$

The path $a \to b \to c$ is a **left turn** (counter-clockwise) if orient > 0, a **right turn** if orient < 0, and the three points are **collinear** if it is zero.

Why the sign means what it says: the determinant is twice the signed area of triangle abc (§8.3 interprets a determinant as signed area). It is the z-component of the cross product $(b - a) \times (c - a)$, which is positive exactly when $c - a$ lies counter-clockwise of $b - a$ by an angle between 0 and π. Example: $a = (0, 0)$, $b = (2, 0)$, $c = (1, 1)$ gives $2 \cdot 1 - 0 \cdot 1 = 2 > 0$, a left turn, and the triangle has area 1.

With this one predicate you can already decide whether two segments cross (each segment's endpoints lie on opposite sides of the other's line: four orientation tests) and whether a point is inside a convex polygon (it is left of every edge).

Convex hull by Graham's scan

Sort the points by x (ties by y). Walk left to right building the **lower hull** on a stack. Before pushing a new point p, look at the top two stack points q_1, q_2 (with q_2 on top). While $\operatorname{orient}(q_1, q_2, p) \le 0$, pop q_2. Then push p. Repeat right to left for the **upper hull**, and join the two. (This left-to-right form is Andrew's monotone chain, a variant of Graham's 1972 scan that sorts by angle.)

Graham's scan is correct and runs in $O(n \log n)$

For n points in general position the scan returns the corners of the convex hull in counter-clockwise order. After sorting, it performs at most $2n$ pushes and $2n$ pops, so its total running time is $O(n \log n)$, dominated by the sort.

Proof of correctness (lower hull). Write $p_1, \dots, p_k$ for the first k points in sorted order. We claim that after processing p_k the stack holds the lower hull of $\{p_1, \dots, p_k\}$ from p_1 to p_k. For $k = 2$ the stack is p_1, p_2 and the lower hull of two points is the segment between them. Assume the claim for $k - 1$. The new point p_k has the largest x so far, so it is certainly a corner of the new lower hull. A previous corner q stays on the lower hull exactly when it is not above the segment from its predecessor on the hull to p_k. The pops remove the top point q_2 precisely when $q_1 \to q_2 \to p_k$ fails to turn left, that is, when q_2 lies on or above segment $q_1 p_k$. Once a left turn is found at the top, every point deeper in the stack already makes left turns with its neighbours (induction hypothesis), and since p_k lies to the right of all of them those turns stay left. So the remaining stack plus p_k is a chain that turns left at every corner and has every point on or above it: the lower hull. ■

Proof of the running time. Each point is pushed once per pass and popped at most once per pass, because a popped point never returns. Each orientation test either pops something or ends the while-loop for that p. So the tests number at most (pops) + (pushes) $\le 4n$ over both passes. This is an amortised argument (§26.3): one step can pop many points, but the total over the whole run is linear. ■

Can one do better than $n \log n$? Not in the comparison-style models: if you could compute hulls faster, you could sort faster. Put the numbers $x_1, \dots, x_n$ on the parabola as points (x_i, x_i^2). All of them are hull corners, and reading the hull in order lists the x_i sorted. So the sorting lower bound of §26.3 transfers to hulls.

A hull that pays for its own size

The lower bound used a cruel input where *every* point is a corner. The figure's random cloud has 40 points but only 8 corners. Our simulations of 10^5 uniform points in a square give about 31 corners on average. Is there an algorithm whose cost depends on the *answer* size h, faster than $n \log n$ when h is small? Gift wrapping costs $O(nh)$, which is worse when h is large. Chan's 1996 algorithm achieves $O(n \log h)$ by guessing h and squaring the guess, and a matching lower bound says nobody can beat it. That kind of output-sensitive lower bound is algebraic decision-tree reasoning, the next layer of Ch. 30.

Counting a triangulation

How big is a triangulation? Suppose n points, no three collinear, h of them on the hull. Any triangulation of them, Delaunay or not, has the same size.

Size of a planar triangulation

Every triangulation of n points with h hull corners has exactly $t = 2n - 2 - h$ triangles and $e = 3n - 3 - h$ edges.

Proof. A triangulation is a connected planar graph with $V = n$ vertices. Its faces are the t triangles plus one outer face, so $F = t + 1$. Count edge–face incidences. Each triangle has 3 edges, and the outer face is bounded by the h hull edges. Each edge borders exactly two faces. So

$$3t + h = 2e.$$

Euler's formula $V - E + F = 2$ (Ch. 27) gives $n - e + (t + 1) = 2$, that is $e = n + t - 1$. Substitute into the incidence count: $3t + h = 2n + 2t - 2$, so $t = 2n - 2 - h$ and then $e = 3n - 3 - h$. ■

The 22 points in the Delaunay figure have 7 hull corners, so the formula predicts $2 \cdot 22 - 2 - 7 = 35$ triangles and $3 \cdot 22 - 3 - 7 = 56$ edges. A direct count with `scipy.spatial.Delaunay` agrees. The practical meaning is that a triangulation is **linear in size**: about $2n$ triangles, $3n$ edges, and an average vertex degree just under 6. So does the Voronoi diagram: its vertices are the $2n - 2 - h$ circumcentres.

The empty-circle test, and the paraboloid behind it

The Delaunay triangulation is defined by: *the circumcircle of every triangle contains no other point*. To use that rule we need a test for "is d inside the circle through a, b, c?" The beautiful way to find it is to lift the plane onto a paraboloid.

The lifting map

Send each point $p = (x, y)$ to $\hat{p} = (x,\ y,\ x^2 + y^2)$ on the paraboloid $z = x^2 + y^2$.

Circles become planes

Let C be a circle with centre (c_x, c_y) and radius r. The lifted points of C lie on one non-vertical plane Π. A point d lies strictly inside C if and only if $\hat{d}$ lies strictly below Π.

Proof. Expand the circle's equation:

$$(x - c_x)^2 + (y - c_y)^2 = r^2 \iff x^2 + y^2 = 2c_x x + 2c_y y + \left(r^2 - c_x^2 - c_y^2\right).$$

On the paraboloid $x^2 + y^2 = z$, so the lifted circle satisfies $z = 2c_x x + 2c_y y + (r^2 - c_x^2 - c_y^2)$. That is the plane Π. Now take any point $d = (x, y)$. Its lift has height $x^2 + y^2$, while Π above it has height $2c_x x + 2c_y y + r^2 - c_x^2 - c_y^2$. The difference is

$$(x^2 + y^2) - \left(2c_x x + 2c_y y + r^2 - c_x^2 - c_y^2\right) = (x - c_x)^2 + (y - c_y)^2 - r^2,$$

which is negative exactly when d is inside the circle. ∎

"Is $\hat{d}$ below the plane through $\hat{a}, \hat{b}, \hat{c}$?" is a 3-D orientation question, so the in-circle test is again the sign of a determinant:

$$\operatorname{incircle}(a, b, c, d) = \det \begin{bmatrix} a_x - d_x & a_y - d_y & (a_x - d_x)^2 + (a_y - d_y)^2 \\ b_x - d_x & b_y - d_y & (b_x - d_x)^2 + (b_y - d_y)^2 \\ c_x - d_x & c_y - d_y & (c_x - d_x)^2 + (c_y - d_y)^2 \end{bmatrix},$$

which is positive exactly when d is inside the circle through a, b, c taken counter-clockwise. Check it on $a = (0, 0)$, $b = (4, 0)$, $c = (1, 3)$: their circle has centre $(2, 1)$ and $r^2 = 5$. The point $d = (3.5, 2.5)$ is at squared distance $4.5 < 5$, inside, and the determinant comes out $+6$. Move d to $(4, 3)$, at squared distance 8, and it becomes -36.

The lifting theorem has a stunning corollary. A triangle abc is Delaunay when no lifted point lies below the plane through $\hat{a}, \hat{b}, \hat{c}$. That says the lifted triangle is a face of the **lower convex hull** of the lifted points in 3-D. So:

$$\text{Delaunay triangulation in 2-D} = \text{lower convex hull of the lifted points in 3-D, projected back down.}$$

Hulls and triangulations are the same problem one dimension apart, and any 3-D hull algorithm is a Delaunay algorithm.

Why Delaunay triangles are fat. Take a convex quadrilateral and its two possible diagonals. Exactly one choice makes both circumcircles empty (unless the four points are concyclic), and that choice maximises the smallest of the six angles. Flipping illegal diagonals one at a time therefore never decreases the sorted list of angles, and the process ends at the Delaunay triangulation. So among all triangulations of a point set, Delaunay **maximises the minimum angle**. That is exactly what finite-element and interpolation codes want, because skinny triangles make badly conditioned equations (§8.10).

Voronoi from Delaunay

Voronoi cell

For sites $s_1, \dots, s_n$, the Voronoi cell of s_i is $V_i = \{x : \|x - s_i\| \le \|x - s_j\| \text{ for all } j\}$.

Each condition $\|x - s_i\| \le \|x - s_j\|$ expands to the linear inequality $2(s_j - s_i) \cdot x \le \|s_j\|^2 - \|s_i\|^2$: a half-plane bounded by the perpendicular bisector of $s_i s_j$. So each cell is an intersection of half-planes, and therefore convex. A point x is a Voronoi vertex when it is equidistant from three sites and no site is closer: it is the centre of an empty circle through three sites. That is precisely the circumcentre of a Delaunay triangle, which proves the duality you saw in the figure. Two cells share an edge exactly when there is an empty circle through just those two sites, which is the condition for a Delaunay edge.

Quadtrees: how deep, how fast

A point quadtree with leaf capacity 1 on a square of side s keeps splitting any cell that contains two or more points.

Depth of a quadtree

If the closest pair of points is at distance δ, the quadtree has depth at most $\log_2(s/\delta) + \frac{3}{2}$.

Proof. A cell at depth k has side $s/2^k$ and diagonal $\sqrt{2}\, s/2^k$. A cell is split only when it holds two points, which are at least δ apart, so its diagonal is at least δ: $\sqrt{2}\, s/2^k \ge \delta$, that is $k \le \log_2(s/\delta) + \frac{1}{2}$. The children of the deepest split cell are one level further down. ∎

The depth depends on the **spread** s/δ, not on n. A thousand evenly spaced points give a shallow tree. Two points a nanometre apart in a kilometre-wide map force about 40 levels. The tree adapts to the data, which you can see in the quadtree figure of §75.4: cells subdivide only inside the two clusters, and the number of cells at each depth stays far below the 4^d of a full tree.

75.4 The algorithm

Convex hull in twenty lines

```
def orient(a, b, c):
    return (b[0]-a[0])*(c[1]-a[1]) - (b[1]-a[1])*(c[0]-a[0])

def convex_hull(points):
    pts = sorted(set(map(tuple, points)))      # sort by x, then y
    if len(pts) <= 2:
        return pts
    def chain(seq):
        h = []
        for p in seq:
            while len(h) >= 2 and orient(h[-2], h[-1], p) <= 0:
                h.pop()                        # right turn or straight: drop
            h.append(p)
        return h
    lower, upper = chain(pts), chain(reversed(pts))
    return lower[:-1] + upper[:-1]             # counter-clockwise, no repeats
```

The `<= 0` drops collinear points from the hull. Change it to `< 0` and they are kept, but then exactly collinear duplicates can loop. That edge case is the first taste of the robustness problem below.

Delaunay by incremental insertion (Bowyer–Watson)

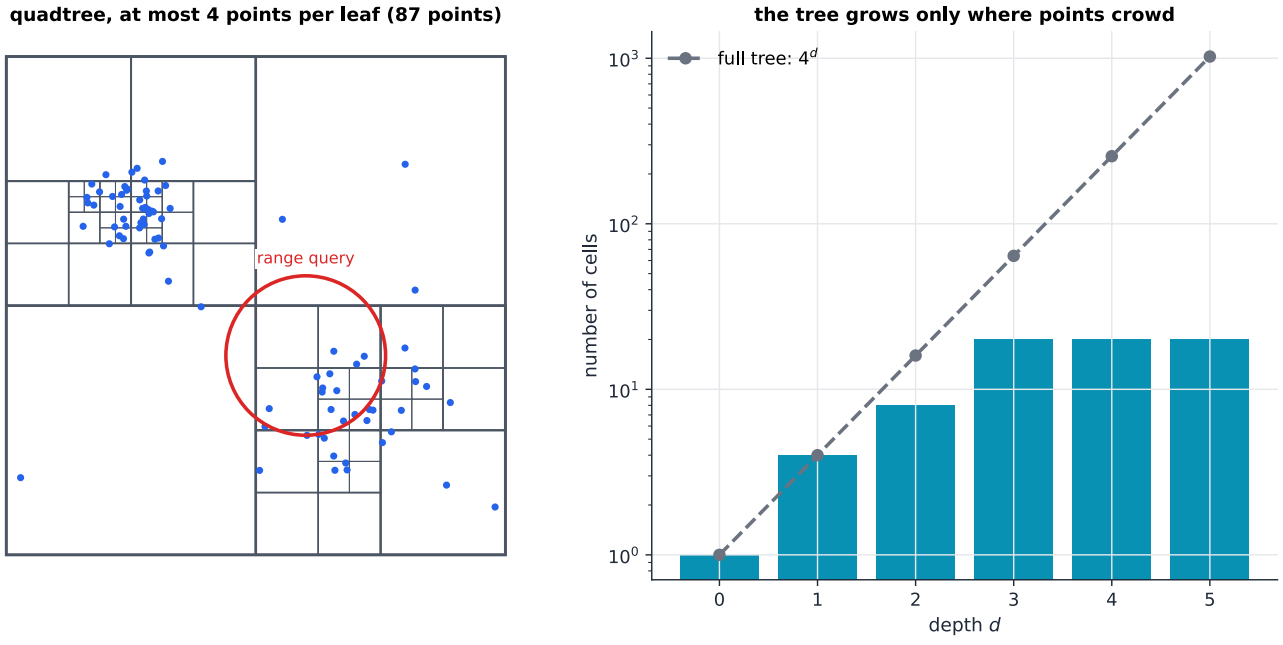
```
start with one huge triangle containing all points
for each point p, in random order:
    find all triangles whose circumcircle contains p     # in-circle test
    delete them: they form a star-shaped hole around p
    join p to every edge of the hole's boundary
remove triangles that touch the huge starting triangle
```

Inserting points in **random order** is the trick. A single insertion can destroy many triangles, but averaged over the random order each insertion creates $O(1)$ new triangles in expectation, and the expected total time is $O(n \log n)$ if a point-location structure finds the first bad triangle quickly. In the worst order (points sorted along a curve, say) the same code takes $O(n^2)$. Fortune's sweep-line algorithm reaches $O(n \log n)$ deterministically, by sweeping a line across the plane and maintaining a "beach line" of parabolic arcs.

Quadtree build and range query

```
insert(cell, p):
    if cell is a leaf with fewer than CAP points: store p; return
    if cell is a leaf: split it into 4 children, push its points down
    insert(child containing p, p)

query(cell, region):
    if cell does not overlap region: return nothing     # prune: one box test
    if cell is a leaf: return its points that lie in region
    return union of query(child, region) over the 4 children
```



Left: cells subdivide only where points crowd. A range query (red) visits only the cells it overlaps. Right: the tree has 20 cells at each of depths 3, 4 and 5, against 64, 256 and 1024 in a full tree.

For well-spread points, a range query costs $O(\log n + k)$ where k is the number of points reported. **kd-trees** do the same job by splitting on alternate coordinates at the median, which guarantees balance (depth $\lceil \log_2 n \rceil$) whatever the spread. **Bounding-volume hierarchies** group objects rather than space, and are how ray tracers (Ch. 71) and physics engines (Ch. 72) avoid testing every ray or pair against everything.

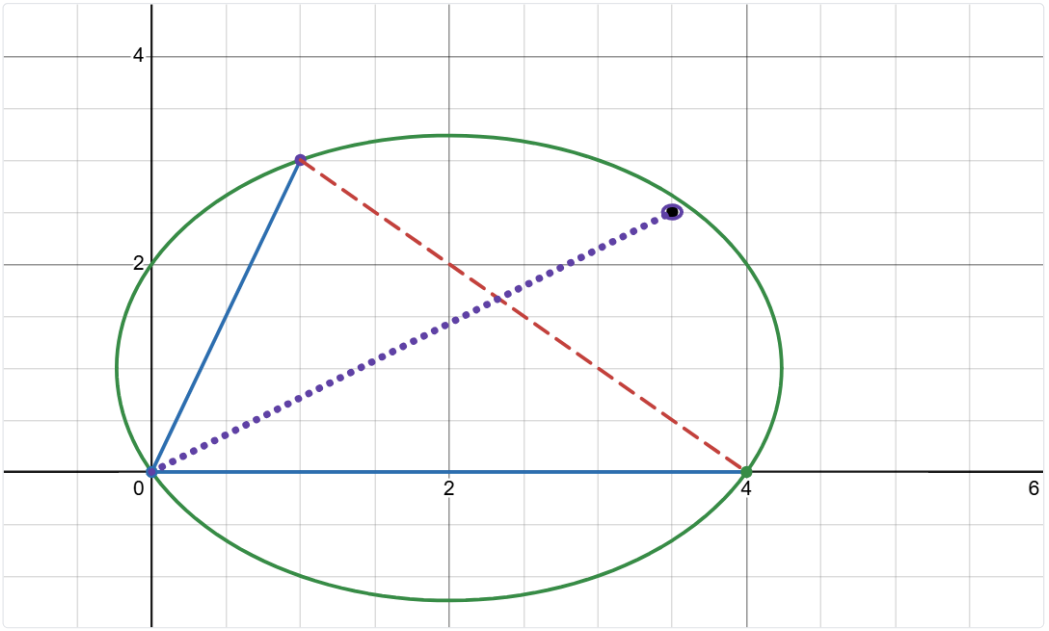
When geometry code fails

- **Degeneracies.** Three collinear points, four concyclic points, duplicate points. Every algorithm above silently assumes "general position". Real data (grids, CAD models, integer pixel coordinates) are full of exact degeneracies.
- **Rounding.** The orientation test subtracts nearly equal numbers. For nearly collinear points the computed sign can be wrong, and two tests that should agree can disagree. A hull algorithm can then pop a point that one test says is outside and another says is inside. In 2004 Kettner and co-authors published small inputs on which textbook hull and Delaunay codes in double precision return non-convex "hulls" or loop forever.
- **The fix is exactness, not tolerance.** Adding an ε ("treat $|\text{orient}| < 10^{-12}$ as zero") makes the problem worse, because "approximately equal" is not transitive. Robust libraries compute the sign exactly: in floating point when the result is clearly far from zero, and with extra-precision arithmetic only in the rare close calls.

> **? The sign you cannot trust**
>
> On a grid of points near $(0.5, 0.5)$ spaced by 2^{-53}, the double-precision orientation test against a fixed line produces a ragged staircase of wrong signs instead of a clean straight boundary. Why does subtracting two nearly equal products lose all the information, and how large can the error be? That is the floating-point error analysis of §22.1. How Shewchuk's *adaptive predicates* return the exact sign while staying almost as fast as the naive formula is a story about error-free transformations of floating-point sums that this chapter does not tell.

75.5 The experiment

Drag the fourth point. The graph shows the triangle $a = (0, 0)$, $b = (4, 0)$, $c = (1, 3)$ and its circumcircle $(x - 2)^2 + (y - 1)^2 = 5$. A fourth point $d = (3.5, 2.5)$ makes the quadrilateral $abdc$, which can be split along the diagonal bc (dashed) or ad (dotted). Because d is inside the circle, triangle abc breaks the empty-circle rule, so Delaunay chooses ad. Change every `3.5` and `2.5` in the last three lines to move d: try $(4, 3)$ (outside, so bc wins), $(3, 2.8)$ (inside) and $(2.5, 3.179)$, which is almost exactly on the circle. That last one is the degenerate case where both diagonals are legal and a tiny rounding error decides.



The green circle passes through a, b, c. When d sits inside it, triangle abc is illegal and the Delaunay triangulation uses the diagonal ad (dotted) instead of bc (dashed).

How many corners does a random hull have? The script draws n random points from three different shapes, computes the hull with the twenty-line scan of §75.4, and prints the average number of corners as n grows. Run it as is first.

```
import numpy as np
import matplotlib.pyplot as plt

SHAPE = "square"          # knob: "square", "disc" or "gauss"
NS = [10, 100, 1000, 10000, 100000]
TRIALS = 20
rng = np.random.default_rng(1)

def orient(a, b, c):
    return (b[0]-a[0])*(c[1]-a[1]) - (b[1]-a[1])*(c[0]-a[0])

def hull(P):
    pts = sorted(map(tuple, P))
    def chain(seq):
        h = []
        for p in seq:
            while len(h) >= 2 and orient(h[-2], h[-1], p) <= 0:
                h.pop()
            h.append(p)
        return h
    return chain(pts)[:-1] + chain(pts[::-1])[:-1]

def sample(n):
    if SHAPE == "square":
        return rng.uniform(-1, 1, (n, 2))
    if SHAPE == "disc":
        r, t = np.sqrt(rng.uniform(0, 1, n)), rng.uniform(0, 2*np.pi, n)
        return np.c_[r*np.cos(t), r*np.sin(t)]
    return rng.normal(size=(n, 2))

means = [np.mean([len(hull(sample(n))) for _ in range(TRIALS)]) for n in NS]
for n, m in zip(NS, means):
    print(f"n = {n:>6}:  average hull size {m:6.1f}")
plt.semilogx(NS, means, "o-"); plt.xlabel("n"); plt.ylabel("hull corners")
plt.title(SHAPE); plt.show()
```

For the square you should see roughly 6, 12, 18, 24 and 31 corners: the hull grows like $\frac{8}{3}\ln n$, so a hundred thousand points have only about thirty corners. Now set `SHAPE = "disc"`. The counts jump to about 15, 33, 74 and 158 for the larger n: growth like $n^{1/3}$. For `"gauss"` they crawl, about 9, 11, 13 and 16. Same algorithm, same n, wildly different answer sizes. Three more things to try:

- Replace the `sample` function with points on a circle, `np.c_[np.cos(t), np.sin(t)]`. Every point is now a corner, which is the worst case of the lower-bound argument.
- Put all the points on an integer grid, `rng.integers(0, 20, (n, 2))`. Now there are many exact collinearities and duplicates. Does the `<= 0` still produce a clean hull? What happens with `< 0`?
- Time the hull for $n = 10^5$ and compare with the time of `sorted` alone. How much of the work is the scan?

75.6 The challenge

1. **Intuition.** Without computing anything, sketch the Voronoi diagram of four points at the corners of a square, and then of the same square with one corner nudged slightly outward. Explain why the Delaunay triangulation of the exact square is not unique, and which of the two diagonals the nudge selects.
2. **Derivation.** Prove the "Delaunay is the lower hull of the lift" corollary carefully: show that if $\hat{a}, \hat{b}, \hat{c}$ span a face of the lower convex hull of the lifted points, then the circumcircle of abc is empty, and conversely. Then use the theorem of §75.3 on triangulation size to show that the Voronoi diagram of n sites has at most $2n - 5$ vertices and $3n - 6$ edges for $n \geq 3$.
3. **Implementation.** Write a Bowyer–Watson Delaunay triangulator from the pseudocode in §75.4, using the in-circle determinant as the only geometric test besides orientation. Check on 500 random points that every triangle's circumcircle is empty and that the triangle count equals $2n - 2 - h$. Then insert the same points sorted by x instead of in random order and measure how the running time scales.
4. **Open investigation.** Build a quadtree and a kd-tree on n points drawn from distributions with very different spreads (uniform; two tight clusters far apart; points on a spiral; a fractal dust from Ch. 73). For each, measure the average number of cells visited by a nearest-neighbour query. Is there a single statistic of the point set (its spread, its fractal dimension, something else) that predicts the query cost for both trees?

75.7 Loose threads

This chapter worked in the flat, clean plane with points in general position. Each of those three words hides a door.

> **? Three dimensions break the count**
>
> In the plane a triangulation of n points always has about $2n$ triangles. In 3-D the analogue fails dramatically: the Delaunay tetrahedralization of n points can have $\Theta(n^2)$ tetrahedra, and even on nice inputs it contains *slivers*, flat tetrahedra whose four corners are nearly coplanar yet whose circumsphere is empty. Slivers wreck finite-element solutions. Why is Euler's formula no longer enough to bound the size, and how do mesh generators get rid of slivers? That is the meshing side of the finite-element method in Ch. 89.

? The curse of the nearest neighbour

A kd-tree answers nearest-neighbour queries in about $\log n$ steps in the plane. In 100 dimensions (image descriptors, word embeddings) the same tree visits almost every leaf, and a linear scan is just as fast. Random points in high dimension are all nearly the same distance apart, so the pruning test almost never prunes. Is there any data structure with polynomial size that answers *exact* nearest-neighbour queries in sub-linear time in high dimension? Conditional lower bounds suggest not, linking the question to the strong exponential time hypothesis of Ch. 30. It is an open problem, and practice has settled for approximate answers.

The robustness mystery of §75.4 is the third thread: geometric algorithms are only as correct as the sign of a determinant, and the exact computation of that sign belongs to the floating-point analysis of Ch. 22. Two quieter threads lead elsewhere in this track. Voronoi cells of randomly placed seeds are a standard way to generate terrain regions, cracked mud and stone textures (Ch. 74). And a triangle mesh is a sampled version of a continuous surface: whether the sampling is fine enough to reconstruct the shape is a cousin of the sampling theorem in Ch. 76.

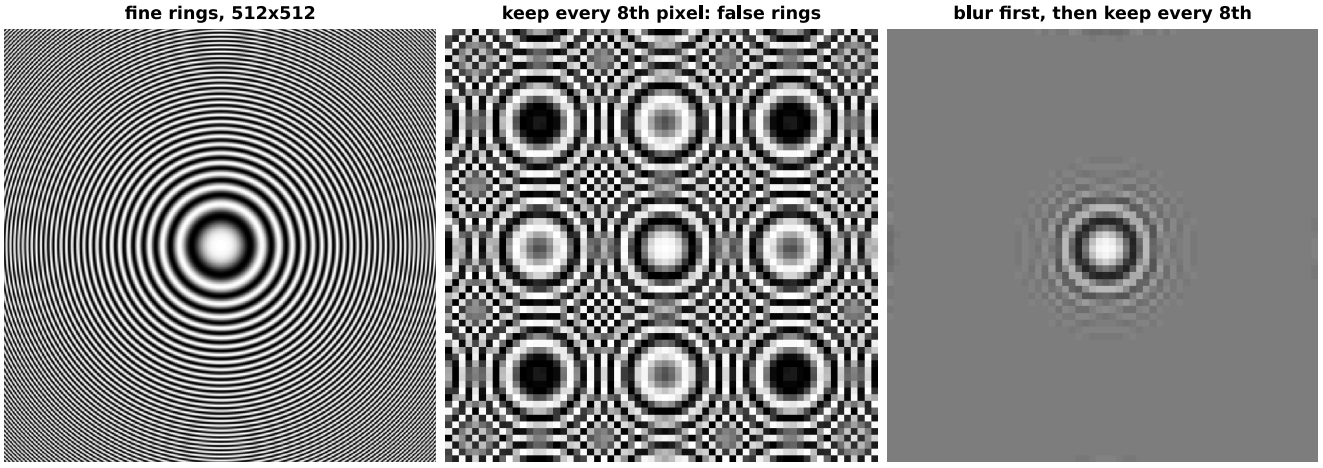
76.1 The hook

Television presenters are told never to wear a finely striped shirt or a herringbone jacket. On camera the stripes come alive. Huge, slow, swirling bands of light and dark ripple across the fabric, sometimes with false rainbows, and they crawl whenever the presenter breathes. Nothing like that is on the shirt. The pattern is manufactured by the camera.

The same ghost haunts every screen. In an old video game, a distant chain-link fence or a tiled floor shimmers and boils as the camera moves. In a western, the wagon wheels spin slowly backwards while the wagon races forward. Shrink a photograph of a brick wall in a cheap image editor and the bricks rearrange themselves into giant curved waves. Record a whistle that slides up past the limit of a sound card, and on playback the pitch slides *down*.

Here is a ring pattern that shows the effect at its most dramatic. On the left, fine concentric rings, the rings closer and closer together towards the edge. In the middle, the same picture after keeping only every eighth pixel in each direction, exactly what a careless thumbnail generator does. Whole new sets of rings appear, centred on points where the original has nothing special at all.



Left: rings whose spacing shrinks towards the edge. Centre: keep every 8th pixel and false ring centres appear on a lattice. Right: blur first, then keep every 8th pixel; the false rings are gone and the too-fine detail fades to grey.

The right-hand picture is the cure: blur first, then shrink. It throws information away on purpose and looks *more* faithful. This chapter is about why that works and about the toolkit it opens:

> **Why does sampling invent patterns that were never there, where exactly do the ghosts appear, and how do blurring, sharpening, edge detection, spectrograms and JPEG all follow from one idea about frequencies?**

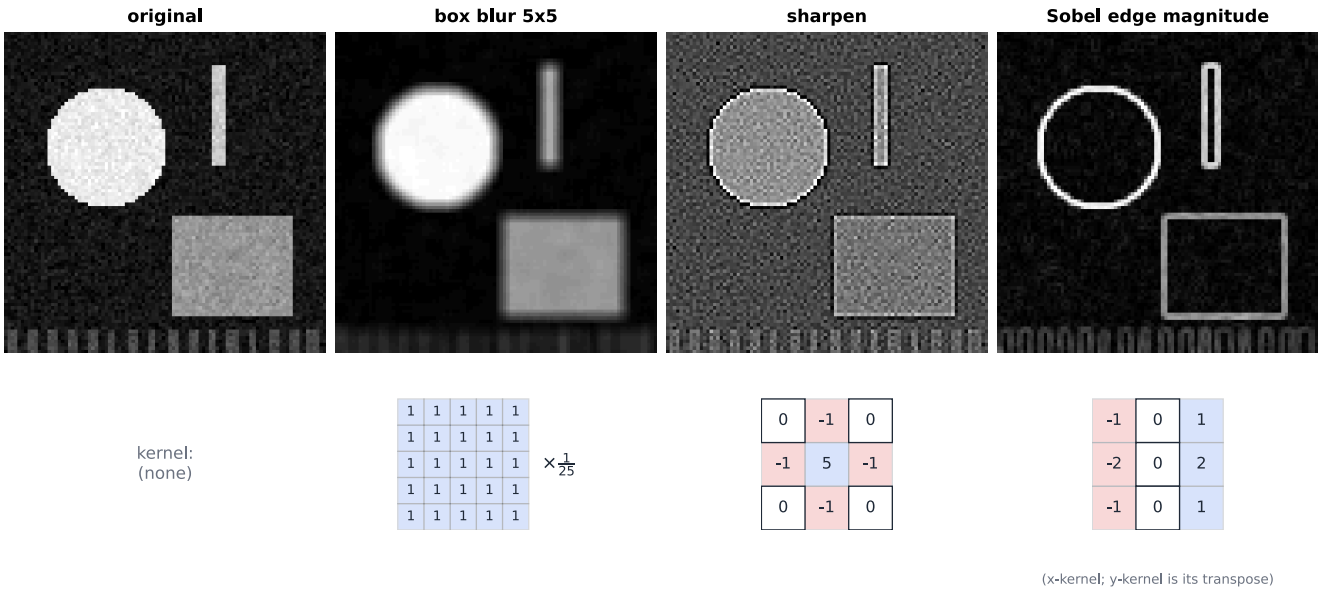
By the end you will be able to predict, from a single formula, where the false ring centres in the middle picture sit, to the pixel.

76.2 The big idea

A picture is a signal in two variables. A sound is a sequence of numbers $x[n]$, one per sample, typically 44,100 or 48,000 per second. A grey-scale image is an array $x[m, n]$ of brightness values. Everything the core chapters proved about one-dimensional signals carries over to images, with one more index.

Frequency in an image means stripes. A sinusoid in time is a pure tone. A sinusoid in an image, $\cos(2\pi(um + vn))$, is a field of parallel stripes. The pair (u, v) is its spatial frequency, in cycles per pixel: its direction is perpendicular to the stripes and its size says how close together they are. Large smooth regions of a photograph are low frequencies. Edges, textures and noise are high frequencies. The Fourier transform (Ch. 16) writes any image as a sum of such stripe fields.

Filtering is a sliding weighted average. Replace each pixel by a weighted sum of its neighbours, using the same small table of weights (a **kernel**) everywhere. Equal positive weights blur. A big positive centre with negative neighbours sharpens. Weights that are negative on one side and positive on the other respond to edges. Each of these is a 2-D convolution, and by the convolution theorem (§16.5) each one simply **multiplies every stripe frequency by a gain**. Blur turns down the high frequencies; sharpen turns them up; an edge detector keeps only a band of them.



One image, three kernels. The box blur softens every edge and wipes out the fine stripes at the bottom. Sharpening amplifies edges and noise alike. The Sobel operator keeps only the outlines. Blue cells are positive weights, red negative.

Sampling folds frequencies. A grid of pixels can only represent stripes up to half a cycle per pixel, the Nyquist limit (§16.8). Any finer stripe does not vanish when sampled. It is **folded back** and impersonates a coarser one. That is the shirt, the wheel and the ring lattice. Blurring before sampling removes the too-fine stripes while they can still be told apart from the coarse ones.

Sound needs a spectrum that changes in time. A single Fourier transform of a whole song tells you which notes occur, but not when. Cut the sound into short overlapping windows and transform each one: you get a **spectrogram**, a picture with time across and frequency up. Musicians, speech recognisers and bat biologists all read these pictures. Their resolution is limited by a trade-off that no cleverness removes.

The analogy to keep in mind is a graphic equaliser on a stereo. Each slider is the gain at one frequency band. Every linear, shift-invariant operation on a sound or an image, however it is described in pixels, is just a setting of those sliders.

76.3 The mathematics

Two-dimensional convolution and its spectrum

The discrete convolution sum of §17.1 gains a second index.

2-D convolution and the 2-D DFT

For an image $x[m,n]$ and a kernel $h[k,l]$,

$$y[m,n] = (h * x)[m,n] = \sum_{k} \sum_{l} h[k,l]\, x[m-k,\, n-l].$$

For an $M \times N$ array, the 2-D DFT is

$$X[p,q] = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} x[m,n]\, e^{-j2\pi(pm/M + qn/N)}.$$

The 2-D DFT is just the 1-D DFT of §15.7 applied to every row and then every column. The central fact is that it turns convolution into multiplication. Here is the proof for **circular** convolution, where indices wrap around modulo M and N (which is what the FFT computes).

The 2-D convolution theorem

If $y[m,n] = \sum_{k,l} h[k,l]\, x[(m-k) \bmod M,\ (n-l) \bmod N]$, then $Y[p,q] = H[p,q]\, X[p,q]$ for every p, q.

Proof. Substitute the definition of y into the DFT and swap the order of summation:

$$Y[p,q] = \sum_{k,l} h[k,l] \sum_{m,n} x[(m-k) \bmod M, (n-l) \bmod N]\, e^{-j2\pi(pm/M + qn/N)}.$$

In the inner sum put $m' = (m-k) \bmod M$ and $n' = (n-l) \bmod N$. As m runs over $0, \dots, M-1$ so does m', and because $e^{-j2\pi p \cdot M/M} = 1$ the exponential is unchanged by the wrap-around: $e^{-j2\pi pm/M} = e^{-j2\pi pm'/M}\, e^{-j2\pi pk/M}$. The inner sum therefore equals $e^{-j2\pi(pk/M + ql/N)} X[p,q]$, and

$$Y[p,q] = X[p,q] \sum_{k,l} h[k,l]\, e^{-j2\pi(pk/M + ql/N)} = H[p,q]\, X[p,q]. \qquad \blacksquare$$

So the **frequency response** of a kernel, its DFT H, is the table of equaliser gains. It also tells you how to compute big blurs fast: transform, multiply, transform back, at $O(MN \log(MN))$ cost whatever the kernel size. For small kernels, direct summation is cheaper. Real images do not wrap around, so practical code pads the borders (by zeros, by copying the edge, or by mirroring) to stop the left edge bleeding into the right.

Reading the three kernels

It is easiest to use the continuous-frequency form $H(\omega_x, \omega_y) = \sum_{k,l} h[k,l] e^{-j(\omega_x k + \omega_y l)}$, with ω in radians per pixel and $\pm\pi$ the Nyquist limit.

Box blur. The $L \times L$ box has weights $1/L^2$, and it is **separable**: it is a 1-D box of length L along the rows followed by the same along the columns. So $H(\omega_x, \omega_y) = B(\omega_x) B(\omega_y)$, with B a geometric series. For odd $L = 2r + 1$, centred,

$$B(\omega) = \frac{1}{L} \sum_{k=-r}^{r} e^{-j\omega k} = \frac{1}{L} \frac{\sin(L\omega/2)}{\sin(\omega/2)}.$$

At $\omega = 0$ the gain is 1: flat regions are untouched. The gain falls to zero at $\omega = 2\pi/L$, so for $L = 5$ stripes with a period of exactly 5 pixels are wiped out completely, and the period-6 stripes at the bottom of the figure, just beyond that zero, keep only a fifth of their contrast. But the gain does not stay small: it comes back negative, and at the Nyquist limit it is $B(\pi) = 1/5$ for $L = 5$ (and $-1/3$ for $L = 3$, a flipped-sign ripple). A box is a crude low-pass filter, and those side lobes are why box-filtered thumbnails still show some moiré. Separability also matters for speed: a 5×5 box costs 25 multiplications per pixel directly, but only $5 + 5 = 10$ as two 1-D passes.

Sharpen. The kernel in the figure is the identity minus the discrete Laplacian ∇^2 (the five-point stencil of §22.10): centre 5, the four neighbours -1. Its response is

$$H(\omega_x, \omega_y) = 5 - 2\cos\omega_x - 2\cos\omega_y.$$

The gain is 1 at $(0, 0)$, rises to 5 for the finest horizontal or vertical stripes, and reaches 9 for the checkerboard at (π, π). Sharpening is a high-frequency boost, and noise lives at high frequency, which is why the sharpened panel looks grainy.

Sobel. The horizontal Sobel kernel is the outer product of a smoothing column $[1, 2, 1]^{\mathsf{T}}$ and a difference row $[-1, 0, 1]$. Its magnitude response is

$$|H(\omega_x, \omega_y)| = 2|\sin\omega_x| \, (2 + 2\cos\omega_y).$$

The $\sin\omega_x$ factor is a derivative: it is zero for flat regions, and for slow variations it grows like ω_x, exactly as d/dx multiplies a frequency by $j\omega$ (§16.3). The $(2 + 2\cos\omega_y)$ factor smooths along the edge and kills the pixel-scale noise at $\omega_y = \pi$. Combining the horizontal and vertical responses into $\sqrt{g_x^2 + g_y^2}$ gives the edge-magnitude image.

Aliasing in two dimensions, and where the ghosts sit

Sampling theory is in §16.8: sampling at rate f_s makes the spectrum periodic with period f_s, so a frequency f is indistinguishable from $f - k f_s$ for every integer k. In audio this is immediate. A 30 kHz tone (inaudible) sampled at 44.1 kHz shows up at $44.1 - 30 = 14.1$ kHz, squarely in the audible band, which is why every sound card has an analogue low-pass filter before its converter. In images the same rule applies to each coordinate separately: a stripe pattern (u, v) sampled on a grid of spacing D pixels aliases to $(u - k/D,\ v - l/D)$ for integers k, l.

Now the ring pattern. The left image is

$$x(s, t) = \tfrac{1}{2} + \tfrac{1}{2} \cos\!\big(2\pi a \, (s^2 + t^2)\big), \qquad a = 110,$$

with s, t measured in image widths from the centre, so $-\tfrac{1}{2} \le s, t \le \tfrac{1}{2}$. Along the s-axis the phase is $2\pi a s^2$. Its local frequency is the derivative of the phase divided by 2π: $2as = 220s$ cycles per image width. The rings get finer linearly with distance from the centre. That is a **chirp** in space.

The middle image keeps every 8th of 512 pixels, so it has 64 samples per image width and its Nyquist limit is 32 cycles per width.

> **False ring centres**
>
> Sampling $\cos(2\pi a s^2)$ at points spaced $1/F$ apart produces exact copies of the central ring pattern centred at $s_0 = kF/(2a)$ for every integer k (and the same in t), up to a constant phase.

Proof. Compare the phase at a sample point $s = n/F$ with the phase of a ring pattern centred at s_0:

$$a\,(s - s_0)^2 = a s^2 - 2a s_0 s + a s_0^2.$$

At the sample points, $2a s_0 s = 2a s_0 \, n/F$. If $s_0 = kF/(2a)$ this equals kn, an integer, which shifts the cosine's phase by a whole number of turns and so changes nothing. The remaining term $a s_0^2$ is the same constant for every sample. So on the sampling grid, the pattern centred at 0 and the pattern centred at s_0 agree, apart from that fixed phase. ■

For our picture $F = 64$ and $a = 110$, so the ghosts sit at $s_0 = 64/220 \approx 0.291$ image widths from the centre, which is about 149 of the original 512 pixels, in each direction: a 3×3 lattice of false centres, exactly as in the middle panel. The constant phase $a s_0^2 \approx 9.31$ turns is not a whole number, so the ghost centres are not as bright as the true one. On the axes the sampled centre value is about 0.33 on the 0-to-1 scale; along the diagonals the phase doubles to about 18.62 turns and the centres are darker still, about 0.12. Aliasing starts where the local frequency crosses Nyquist: $220s = 32$ gives $s \approx 0.145$ widths, about 74 pixels from the centre. Inside that radius the sampled rings are faithful.

The cure in the right panel is a Gaussian blur of standard deviation 4.8 pixels before decimation. A Gaussian's spectrum is again a Gaussian (§16.1), and with that width its gain $e^{-\sigma^2\omega^2/2}$ is about 0.17 at the new Nyquist limit $\omega = \pi/8$ and below 0.001 at twice that frequency. What remains is a faithful picture of the part of the image the coarse grid *can* represent. Ray tracers (Ch. 71) and texture samplers face the same choice with pixels and texels; mipmaps are pre-blurred copies of a texture at each power-of-two size, precisely so that a distant floor is sampled from a version with no stripes finer than the screen can show.

The short-time Fourier transform

STFT and spectrogram

Choose a window $w[n]$ of length L (for example a Hann window) and a hop R. The short-time Fourier transform of $x[n]$ is

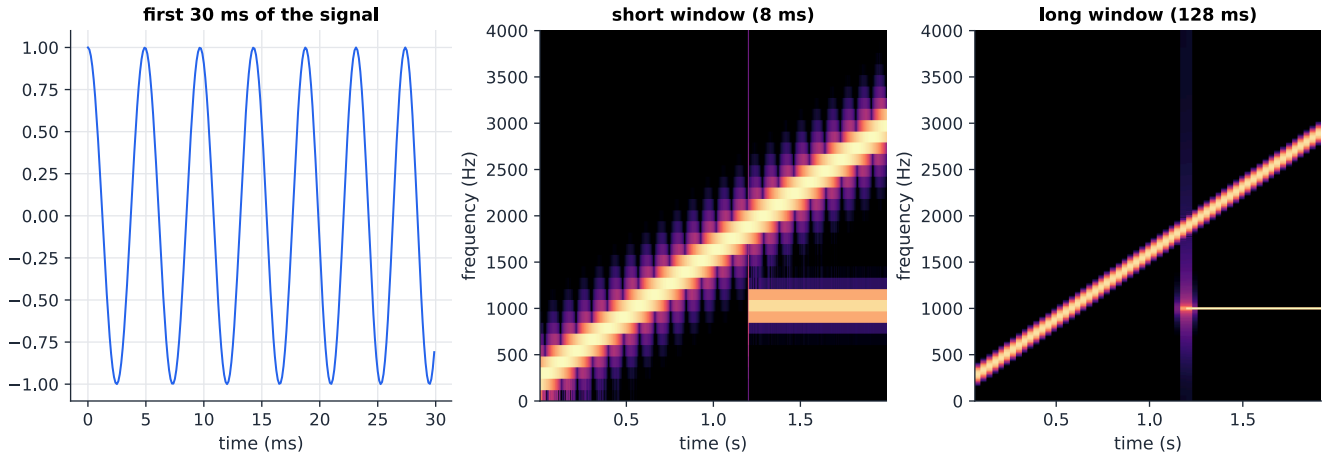
$$X[r,k] = \sum_{n=0}^{L-1} w[n]\, x[rR+n]\, e^{-j2\pi kn/L},$$

the DFT of the r-th windowed frame. The **spectrogram** is $|X[r,k]|^2$, usually drawn in decibels with time rR/f_s across and frequency kf_s/L up.

The window is a short-time version of the leakage story in §16.6: each frame's spectrum is the true local spectrum convolved with the window's spectrum. That leads to the fundamental trade-off. A window of L samples lasts $T = L/f_s$ seconds and has frequency bins spaced $\Delta f = f_s/L$ apart. Their product is

$$T\,\Delta f = 1,$$

whatever the sample rate. Short windows locate events precisely in time and smear them in frequency. Long windows do the opposite.



A chirp sweeping from 200 Hz to 3 kHz in 2 s at $f_s = 8$ kHz, with a 1 kHz tone switched on at 1.2 s. The short window (centre) pins down the onset but blurs every frequency over about 125 Hz. The long window (right) resolves the steady tone to within 8 Hz but smears the onset and thickens the sweeping chirp.

How long should the window be for a chirp? Suppose the frequency rises at κ Hz per second (here $\kappa = 1400$). During a window of length T the chirp sweeps κT hertz, while the bin width is $1/T$. Total frequency blur is roughly $\kappa T + 1/T$, which is smallest when $\kappa T = 1/T$:

$$T_{\text{best}} = \frac{1}{\sqrt{\kappa}} = \frac{1}{\sqrt{1400}}\ \text{s} \approx 26.7\ \text{ms}.$$

The 8 ms window has $1/T = 125$ Hz of bin blur and only about 11 Hz of sweep; the 128 ms window has under 8 Hz of bin blur but sweeps about 179 Hz. Each is far from balanced, and each is bad in the opposite direction.

? A window sharp in both directions?

$T\,\Delta f = 1$ was a statement about DFT bins. Is there some cleverer window, perhaps not a frame at all, that is sharply concentrated in time *and* in frequency? There is a hard limit: the product of the root-mean-square durations in time and frequency can never fall below $1/(4\pi)$, and only the Gaussian attains it. The proof is the same Cauchy–Schwarz argument that gives Heisenberg's uncertainty principle in quantum mechanics, and it is told in Ch. 92. Wavelets, which use long windows for low notes and short windows for high ones, are one way to cheat the trade-off locally; their theory lives in the function spaces of Ch. 61.

The idea behind JPEG

A photograph has strong correlation between neighbouring pixels: most 8×8 blocks are smooth, with a little texture. JPEG exploits this with the **discrete cosine transform** (DCT). For a block of 8 values,

$$c_k = \alpha_k \sum_{n=0}^{7} x[n] \cos\!\left(\frac{\pi(2n+1)k}{16}\right), \qquad \alpha_0 = \sqrt{1/8},\ \alpha_k = \sqrt{2/8}\ (k \ge 1).$$

These eight cosines are orthonormal (§9.7), so the transform is a rotation: no information is lost and energy is preserved. The 2-D version applies it to rows and then columns, giving 64 coefficients per block. Then comes the lossy step. Each coefficient is divided by a step size from a table, larger steps for higher frequencies, and rounded. Most high-frequency coefficients round to zero, and long runs of zeros cost almost nothing to store. A quality setting simply scales the table.

Why cosines rather than the DFT? The DFT treats a block as one period of a periodic signal, so a smooth ramp from dark to light becomes a sawtooth with a jump at the block edge. Jumps make Fourier coefficients decay slowly, like $1/k$ (§15.7). The DCT implicitly extends the block by its mirror image, which is continuous, so coefficients decay like $1/k^2$. On the ramp $x = (0, 1, \dots, 7)$, the first two DCT coefficients carry 99.6% of the energy (all even-index coefficients beyond c_0 are exactly zero). The DFT needs three coefficients (the mean and the ± 1 frequencies) to capture only 89.5%. Audio codecs such as MP3 and AAC use a close relative, the modified DCT on overlapping windows: a spectrogram, quantised according to what the ear cannot hear.

? Why the cosine is nearly optimal

For any family of images you can compute the *best possible* orthogonal transform for compaction: the Karhunen–Loève transform, whose basis vectors are the eigenvectors of the pixel covariance matrix (Ch. 10, Ch. 21). It depends on the data and is expensive. The fixed, data-independent DCT turns out to be almost exactly as good for natural photographs. Why should one universal set of cosines nearly match the eigenvectors of every photograph's statistics? And how many bits per pixel are truly necessary for a given distortion? Both questions are answered by transform coding and rate–distortion theory in Ch. 80.

76.4 The algorithm

Filtering an image

```
input: image x (M x N), kernel h (K x K), border rule
if K is small (say K <= 9):
    if h is separable (h = column * row): filter rows with row, then columns with column
    else: direct sum, K^2 multiply-adds per pixel
else:
    pad x by K pixels on every side using the border rule
    Y = FFT2(x_padded) * FFT2(h, same size)      # convolution theorem
    y = IFFT2(Y), cropped back to M x N
```

Direct filtering costs $O(MNK^2)$, separable filtering $O(MNK)$, and FFT filtering $O(MN \log MN)$ regardless of K. A 1920×1080 frame has about two million pixels; a direct 31×31 blur costs about two billion multiply-adds, while two separable passes cost about 130 million. A Gaussian is separable, which is one reason it is everyone's favourite blur.

Failure cases are mostly about edges and numbers. With no padding, FFT filtering wraps the top of the image into the bottom. With zero padding, blur darkens the borders. Sharpening can push values below 0 or above 255, and integer pipelines must clip. Filters with many large positive and negative weights lose precision in 8-bit arithmetic.

Downsampling without ghosts

```
to shrink an image by an integer factor D:
    blur with a low-pass kernel whose gain is small beyond 1/(2D) cycles per pixel
    keep every D-th pixel in each direction
```

Real resizers fold the two steps into one kernel (bilinear, bicubic, Lanczos), evaluated only at the output pixels. A box of width D is the cheapest acceptable prefilter; as §76.3 showed, its side lobes let some aliasing through. Mipmapping pre-computes the blurred versions at every power-of-two size, and a GPU picks the level whose texel size matches the pixel's footprint on screen.

A spectrogram in ten lines

```
import numpy as np

def spectrogram(x, fs, L=256, hop=64):
    w = np.hanning(L)
    starts = range(0, len(x) - L + 1, hop)
    frames = np.array([w * x[s:s + L] for s in starts])
    S = np.abs(np.fft.rfft(frames, axis=1))**2           # power per frame
    times = (np.array(list(starts)) + L / 2) / fs
    freqs = np.fft.rfftfreq(L, 1 / fs)
    return times, freqs, 10 * np.log10(S.T + 1e-12)      # dB, frequency on rows
```

The cost is one FFT of length L per hop, $O((N/R)\, L \log L)$ for N samples. Choosing the hop $R = L/4$ with a Hann window means the overlapping windows add up to a constant, so the frames can be put back together exactly: you can edit a spectrogram (remove a cough, a hum line, a squeak) and resynthesise sound. Its failure case is the trade-off itself: no setting of L is right for a sound containing both drum hits and sustained bass notes.

The JPEG pipeline

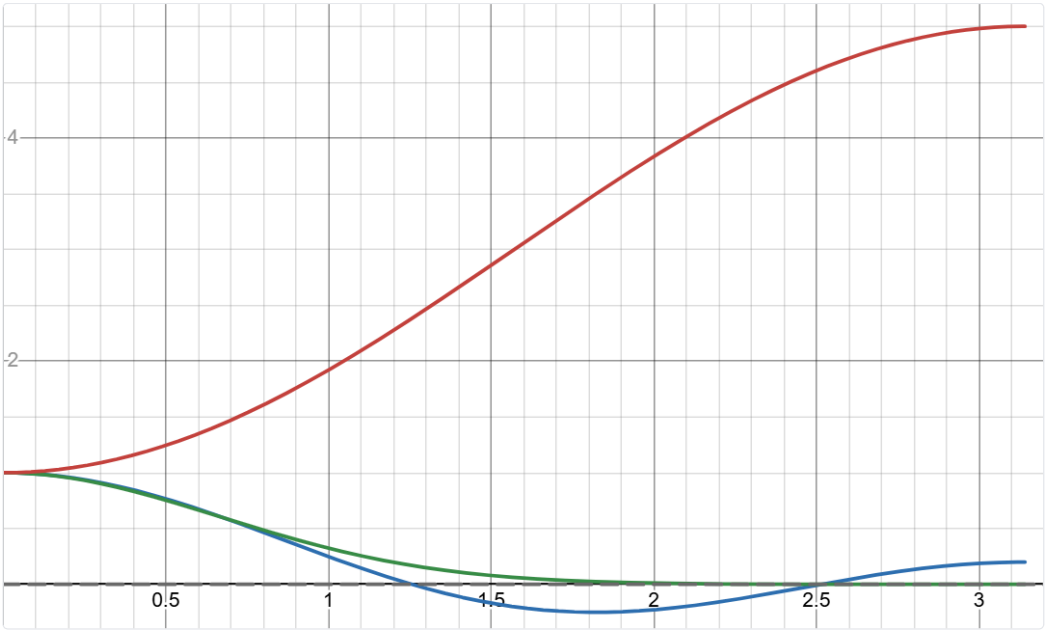
```
convert RGB to luminance + two colour channels; halve the colour resolution
for each 8x8 block of each channel:
    subtract 128; apply the 2-D DCT
    divide each coefficient by its quantisation step, round to an integer
    read coefficients in zig-zag order (low to high frequency)
    run-length encode the zeros, then Huffman-code the result
decoding reverses every step except the rounding
```

Only the rounding loses information. Halving the colour resolution works because the eye is far less sensitive to fine detail in colour than in brightness. The failure case is famous: at high compression the block boundaries become visible ("blocking"), and sharp edges ring with faint ripples, Gibbs-like overshoot (§15.6) from the discarded high frequencies.

76.5 The experiment

Turn the equaliser knobs. The three curves are 1-D frequency responses from $\omega = 0$ to the Nyquist limit $\omega = \pi$: the box blur of length 5 (blue), a Gaussian blur with $\sigma = 1.5$ pixels (green) and the 1-D sharpen kernel $[-1, 3, -1]$ (red). Change the `5`s in the first line to `3` or `9` and watch the zeros of the box move and its negative side lobes appear. Change `1.125` (which is $\sigma^2/2$) to `0.125` or `2` to make the Gaussian narrower or wider. The Gaussian never goes negative, which is

why it never flips the contrast of fine detail the way the box does.



Gain against frequency (radians per pixel). Blurs pass low frequencies and attenuate high ones; sharpening does the opposite, with gain 5 for the finest stripes.

Summon the ghosts, then banish them. The script builds the ring pattern of the hook, samples it naively and with a Gaussian prefilter applied by the convolution theorem, and also sharpens it through the FFT. It prints where the false ring centres should be (149 pixels apart on the original grid) and the sharpen kernel's gains at the two ends of the spectrum (1 and 9).

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
A = 110          # ring chirp rate: local frequency is 2*A*r cycles per width
D = 8            # keep every D-th pixel
SIGMA = 0.6 * D  # Gaussian prefilter width in pixels (try 0, 0.3*D, 1.0*D)
KERNEL = np.array([[0, -1, 0], [-1, 5, -1], [0, -1, 0]], float)  # sharpen

M = 512
y, x = (np.mgrid[0:M, 0:M] - M / 2) / M
img = 0.5 + 0.5 * np.cos(2 * np.pi * A * (x**2 + y**2))

def filt(im, H):                       # multiply spectra: convolution theorem
    return np.real(np.fft.ifft2(np.fft.fft2(im) * H))

f = np.fft.fftfreq(M)                  # cycles per pixel
FX, FY = np.meshgrid(f, f)
gauss = np.exp(-2 * (np.pi * SIGMA)**2 * (FX**2 + FY**2))
K = np.zeros((M, M)); K[:3, :3] = KERNEL
K = np.roll(K, (-1, -1), axis=(0, 1))  # centre the kernel on pixel (0, 0)
sharp = np.fft.fft2(K)

naive = img[::D, ::D]
clean = filt(img, gauss)[::D, ::D]
print("false ring centres expected every", round(M * (M / D) / (2 * A)), "pixels")
print("sharpen gain at DC and at (pi, pi):", sharp[0, 0].real, sharp[M//2, M//2].real)

fig, ax = plt.subplots(1, 4, figsize=(13, 3.6))
for a, im, t in zip(ax, [img, naive, clean, filt(img, sharp)],
                    ["original", f"every {D}th pixel", f"blur sigma={SIGMA:.1f}, then sample",
                     "sharpened"]):
    a.imshow(im, cmap="gray", vmin=0, vmax=1); a.set_title(t); a.axis("off")
plt.tight_layout(); plt.show()
```

Things to try:

- Set `D = 4` and predict before running: the ghosts should move twice as far out, to $s_0 = 128/220 \approx 0.58$ widths, which is outside the image. Do any remain?
- Set `SIGMA = 0.3 * D`. The prefilter is now too narrow: how much of the false lattice survives? Then `1.0 * D`: the ghosts are gone, but how much real detail near the centre have you thrown away?
- Replace the Gaussian by a box prefilter of width `D` (build its 2-D transfer function from the formula for $B(\omega)$ in §76.3) and compare. The side lobes should let faint ghosts through.
- Replace `KERNEL` with the Sobel x-kernel `[[-1,0,1],[-2,0,2],[-1,0,1]]` and display `np.abs(...)`. Which ring segments vanish, and why does the formula for $|H|$ predict it?

76.6 The challenge

1. **Intuition.** A camera films a wheel with 12 spokes turning at 2.2 revolutions per second, at 24 frames per second. Without a calculator, decide whether the wheel appears to turn forwards or backwards, and roughly how fast. Then explain in one sentence why a fast-moving fan photographed under a flickering 100 Hz light can appear frozen.
2. **Derivation.** Derive the frequency response of the 3×3 Gaussian-like kernel $\frac{1}{16}[1,2,1]^{\mathsf{T}}[1,2,1]$ and show it is non-negative everywhere, with a zero exactly at the Nyquist limit in each direction. Then prove that the discrete Laplacian kernel (centre -4, neighbours 1) has response $2\cos\omega_x + 2\cos\omega_y - 4$, and use it to explain why "unsharp masking", $x + \lambda(x - \mathrm{blur}(x))$, sharpens.
3. **Implementation.** Implement an 8x8 block DCT codec for a grey-scale image (any photograph you own, or a synthetic one): DCT, a single quantisation step q for all coefficients, rounding, inverse DCT. Plot the fraction of non-zero coefficients and the root-mean-square error against q. Then replace the uniform q with one that grows with frequency and compare the two curves at equal numbers of non-zero coefficients.
4. **Open investigation.** For the chirp of §76.3, the balanced window length was $1/\sqrt{\kappa}$. Real sounds contain several chirps with different rates at once (a bird call, a siren, a speech formant). Design an experiment to measure how readable a spectrogram is (for example, how accurately you can recover the instantaneous frequency of each component) as a function of the window length and the window shape. Is there a single window that is close to the best for most natural sounds, or does each sound need its own?

76.7 Loose threads

The chapter treated sampling as a regular grid, filters as fixed and linear, and images as arbitrary arrays. Each of those assumptions is a door that this chapter leaves closed.

> **? Beating Nyquist**
>
> Sampling theory says you need twice the highest frequency, or ghosts appear. Yet a modern MRI scanner reconstructs a sharp image from a small fraction of the Fourier samples the theorem demands, by sampling them at *random* and assuming the image is sparse in some basis (a few large wavelet coefficients). Random sampling turns structured ghosts into faint noise-like error, and a convex optimization (Ch. 47) then removes it. How few samples are enough, and why does randomness help where a regular grid fails? That is compressed sensing, one of the central stories of Ch. 91.

The two mysteries of §76.3 are the other threads. The time–frequency uncertainty limit and its Gaussian optimum are proved in Ch. 92, and wavelets that sidestep it live in Ch. 61. Why one universal cosine basis nearly matches the eigenvectors of every photograph's statistics, and how many bits a picture truly needs, are questions of transform coding and rate–distortion theory in Ch. 80, built on the entropy of Ch. 33.

Two quieter connections stay inside this track. Noise textures in procedural generation (Ch. 74) are designed by shaping their power spectrum, the 2-D version of the power spectral density in §21.4. And the irregular sample patterns a ray tracer uses for anti-aliasing (Ch. 71) are chosen, like Poisson-disk points, to push aliasing energy into high frequencies where the eye forgives it. Why the eye forgives it, nobody can yet write down as a theorem.

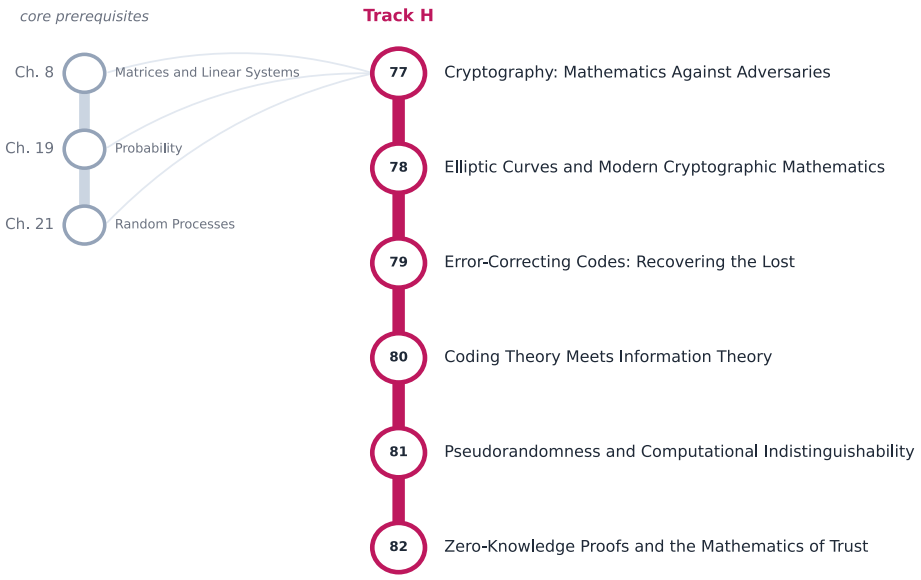
Track H — Cryptography, Coding, and Digital Security

> **Level 2 — Specializations.** Mathematics against adversaries and noise. Correct mathematics alone does not guarantee a secure implementation.



Suggested reading order for Track H. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 8 — Matrices and Linear Systems
- Ch. 19 — Probability
- Ch. 21 — Random Processes

Chapters

Ch.	Chapter	What it explores
77	Cryptography: Mathematics Against Adversaries	Security definitions, symmetric encryption, public-key cryptography.
78	Elliptic Curves and Modern Cryptographic Mathematics	Finite fields, elliptic-curve groups, discrete logarithms.
79	Error-Correcting Codes: Recovering the Lost	Hamming distance, linear codes, cyclic codes, Reed–Solomon codes.
80	Coding Theory Meets Information Theory	Channel capacity, entropy, coding bounds, compression.
81	Pseudorandomness and Computational Indistinguishability	Randomness tests, pseudorandom generators, computational security.
82	Zero-Knowledge Proofs and the Mathematics of Trust	Interactive proofs, commitment schemes, proof systems.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 77 — Cryptography: Mathematics Against Adversaries

> **Level 2 · Track H — Cryptography, Coding, and Digital Security Builds on:** Ch. 19, Ch. 57, Ch. 30, Ch. 33 · **Leads to:** Ch. 78, Ch. 81, Ch. 82 · **Related:** Ch. 46, Ch. 32, Ch. 56 **Reading time:** ~25 min

77.1 The hook

In the winter of 1942, with German armies outside Moscow, the Soviet office that printed one-time pads ran short of time. A one-time pad is a booklet of random numbers. Sender and receiver hold identical copies; each page is added to one message and then destroyed. Used correctly it is the only cipher in history that has been *proved* unbreakable. Under wartime pressure, some pages were printed twice and issued to different users.

The American codebreakers of the Venona project, working from 1943 on, noticed. Over the next four decades they read parts of nearly three thousand Soviet messages, among them traffic that exposed spies inside the Manhattan Project. The unbreakable cipher broke. Nobody beat its mathematics; someone *used it twice*.

The lesson keeps returning. Ciphers in Wi-Fi routers, payment cards and game consoles are rarely defeated by mathematics; they fall to a reused number, a predictable seed or a timing leak. And yet mathematics is what makes modern security possible at all. Your browser has never met your bank and shares no secret with it, yet over wires anyone may tap, the two agree within milliseconds on a key the eavesdropper cannot compute.

So there are three questions, and this chapter is about all of them:

- What does it even *mean* for a cipher to be secure, stated precisely enough to prove?
- How can a short key protect a long message, when the one provably perfect cipher needs a key as long as the message?
- How can two strangers agree on a secret in public?

77.2 The big idea

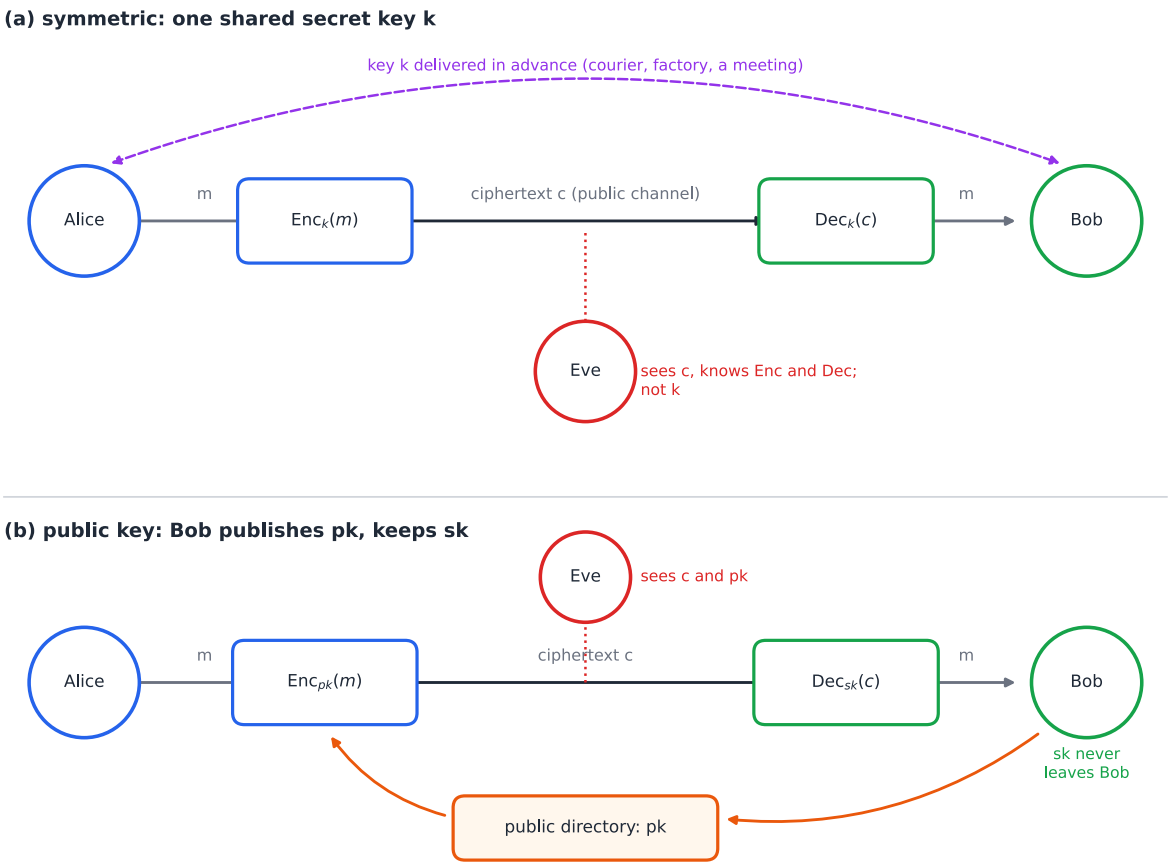
Cryptography is **mathematics with an opponent**. In most of this book the world is indifferent: noise is random, a circuit does not try to fool you. Here the noise is a clever person, Eve, who reads everything you send, knows exactly which algorithm you use, and will exploit any pattern you leave. A security claim is therefore a statement about *every possible strategy* Eve could follow, which is why it has to be framed as a game.

The game has three rules that took cryptographers a century to agree on.

1. **Eve knows the system.** Only the key is secret. This is **Kerckhoffs' principle** (1883), the cryptographer's version of publishing your mixed strategy in Ch. 46. A cipher whose security rests on a secret design is broken the day the design leaks.
2. **Say exactly what Eve can do.** Only listen? Get messages of her choice encrypted? Submit forged ciphertexts and watch your reaction? Each is a different attack model.
3. **Say exactly what "winning" means.** If Eve learns *one bit* about the message, say "buy" versus "sell", she has won.

With the game fixed, there are three levels of security, and they form the spine of this chapter.

- **Perfect secrecy.** The ciphertext carries no information at all about the message, even for an Eve with infinite computing power. Achievable, but the key must be as long as everything you will ever send.
- **Computational security.** Eve could in principle learn something, but only by a computation so large it will not finish before the Sun burns out. This is how short keys protect long messages.
- **Public-key security.** Some functions are easy to compute but hard to invert unless you hold a hidden "trapdoor". Bob publishes the lock and keeps the key; anyone can snap the padlock shut, only Bob can open it.



The two architectures. In symmetric cryptography the hard problem is getting k to Bob in the first place. Public-key cryptography removes that problem by splitting the key in two, at the price of much slower arithmetic; real systems use public keys only to agree on a symmetric key.

The analogy to keep in mind: a symmetric cipher is a **safe with two identical keys**, one for Alice and one for Bob. A public-key cipher is a **mailbox with a slot**: anyone can drop a letter in, but only the owner has the key to the back door.

Never roll your own crypto

This chapter separates two things that are easy to confuse. The *mathematics* of a cryptosystem can be correct, proved and beautiful while an *implementation* of it is trivially broken: by a reused nonce, a weak random-number generator, a non-constant-time comparison, a padding error message, or a key left in memory. Every code sample in this chapter uses toy parameters and textbook constructions chosen for clarity, and every one of them is insecure. For real systems use a vetted, maintained library (libsodium, your platform's TLS stack, a FIPS-validated module) through its highest-level interface, and follow current guidance from bodies such as NIST. Designing ciphers, protocols or even "small tweaks" is a job for specialists, and their work is trusted only after years of public attack.

77.3 The mathematics

Encryption schemes

Symmetric encryption scheme

A scheme is three algorithms. Gen outputs a key k from a key space $\mathcal{K}$. $\mathrm{Enc}_k(m)$ turns a message $m \in \mathcal{M}$ into a ciphertext c; it may use fresh randomness. $\mathrm{Dec}_k(c)$ returns a message. **Correctness** demands $\mathrm{Dec}_k(\mathrm{Enc}_k(m)) = m$ for every k and m.

Treat the message as a random variable M (Eve has some prior belief about what Alice might say) and the key as an independent random variable K, chosen by Gen. Then the ciphertext $C = \mathrm{Enc}_K(M)$ is random too, and we can ask what seeing it does to Eve's beliefs. That is a conditional-probability question, and Ch. 19 has the tools.

Perfect secrecy (Shannon, 1949)

A scheme is **perfectly secret** if for every prior distribution of M, every message m and every ciphertext c with $P(C = c) > 0$,

$$P(M = m \mid C = c) = P(M = m).$$

Seeing the ciphertext does not change Eve's beliefs at all. Equivalently, M and C are independent, so their mutual information (Ch. 33) is zero.

Result 1: the one-time pad is perfectly secret

Let messages, keys and ciphertexts all be n-bit strings, let Gen choose K uniformly from all 2^n strings, and encrypt by bitwise XOR (addition mod 2, written $\oplus$):

$$\mathrm{Enc}_k(m) = m \oplus k, \qquad \mathrm{Dec}_k(c) = c \oplus k.$$

Correctness is one line: $(m \oplus k) \oplus k = m \oplus (k \oplus k) = m \oplus 0 = m$.

The one-time pad is perfectly secret

For any distribution of M independent of the uniform key K, $P(M = m \mid C = c) = P(M = m)$.

Proof. Fix m and c. Given $M = m$, the ciphertext equals c exactly when $K = m \oplus c$, a single key. Because K is uniform and independent of M,

$$P(C = c \mid M = m) = P(K = m \oplus c) = 2^{-n},$$

the same number for every m. By the law of total probability, $P(C = c) = \sum_{m'} P(C = c \mid M = m')P(M = m') = 2^{-n}$. Bayes' theorem then gives

$$P(M = m \mid C = c) = \frac{P(C = c \mid M = m)\,P(M = m)}{P(C = c)} = \frac{2^{-n}\,P(M = m)}{2^{-n}} = P(M = m). \qquad \blacksquare$$

Read the proof again and see where it used its assumptions. It needed K **uniform** (otherwise $P(K = m \oplus c)$ depends on m), **independent of** M, and **used once**. Break the last condition and the pad cancels: if $c_1 = m_1 \oplus k$ and $c_2 = m_2 \oplus k$, then

$$c_1 \oplus c_2 = m_1 \oplus m_2,$$

which no longer involves the key at all. The XOR of two English texts is full of structure, and guessing a common word in one reveals the other at the same position. That is all Venona needed, and it is the experiment in §77.5.

Result 2: perfect secrecy needs a key as long as the message

Could a cleverer scheme achieve perfect secrecy with a shorter key? Shannon proved that it cannot.

Shannon's key-length bound

If a scheme is perfectly secret, then $|\mathcal{K}| \geq |\mathcal{M}|$.

Proof. Take M uniform on $\mathcal{M}$ and pick any ciphertext c that can occur. Let $D(c) = \{\mathrm{Dec}_k(c) : k \in \mathcal{K}\}$ be the set of messages that c could decrypt to under some key. It has at most $|\mathcal{K}|$ elements. Suppose $|\mathcal{K}| < |\mathcal{M}|$. Then some message m^* lies outside $D(c)$, and by correctness c can never be an encryption of m^*, so $P(M = m^* \mid C = c) = 0$. But $P(M = m^*) = 1/|\mathcal{M}| > 0$. This contradicts perfect secrecy. $\blacksquare$

The counting argument covers every cipher anyone will ever invent: a 128-bit key cannot perfectly protect a 129-bit message. That is why the one-time pad lived on only in diplomatic bags and hotlines, and why the rest of cryptography had to change the rules of the game.

Computational security: limiting Eve's budget

The way out is to stop defending against an Eve with unlimited computing power. Instead we ask that every Eve who runs for at most t steps succeeds with probability at most ε above blind guessing. The scheme is then called (t, ε)**-secure**. Asymptotically, with a security parameter λ (roughly the key length), we demand that every adversary running in time polynomial in λ has an advantage that is **negligible**: smaller than $1/\lambda^c$ for every constant c once λ is large enough, as $2^{-\lambda}$ is.

How large is large enough? A 128-bit key has $2^{128} \approx 3.4 \times 10^{38}$ values. A machine testing 10^{18} keys per second, far beyond any that exists, would need about 1.1×10^{13} years to try them all, some 800 times the age of the universe. In 1998 a purpose-built machine searched the 56-bit key space of the old DES standard in 56 hours. Key length is not a detail; each extra bit doubles Eve's work.

Two caveats make computational security a different kind of mathematics from Results 1 and 2.

- **It rests on assumptions.** We cannot prove that any practical cipher needs 2^{128} steps to break, only that "if Eve breaks this scheme, she also solves problem X", where X has resisted the world for decades. This is a **reduction**, the tool Ch. 30 uses to spread undecidability, now spreading hardness.
- **It needs average-case hardness.** NP-hardness (Ch. 30) says that *some* instances are hard. A cipher needs *random* instances, those made by a random key, to be hard almost always. The minimal object that delivers this is a **one-way function**: a function f that is easy to compute, but such that for a random x every efficient algorithm, given $f(x)$, finds some preimage only with negligible probability. If one-way functions exist then $\mathrm{P} \neq \mathrm{NP}$, because inverting f is an NP search problem; the converse is not known. This is the precise sense in which modern cryptography is a bet against $\mathrm{P} = \mathrm{NP}$, and a stronger bet than that.

The engine of symmetric cryptography is the **pseudorandom generator** (PRG): a deterministic function G that stretches a short random seed k into a long string $G(k)$ that no efficient test can tell apart from truly random bits. Replace the one-time pad by $G(k)$ and you have a **stream cipher**: $c = m \oplus G(k)$. Its security proof is a reduction. If some Eve could learn anything about m from c, then running her on $m \oplus s$ for a challenge string s would tell you whether s came from G or from fair coins, because against truly random s we already proved she learns nothing. So a break of the cipher *is* a break of the generator.

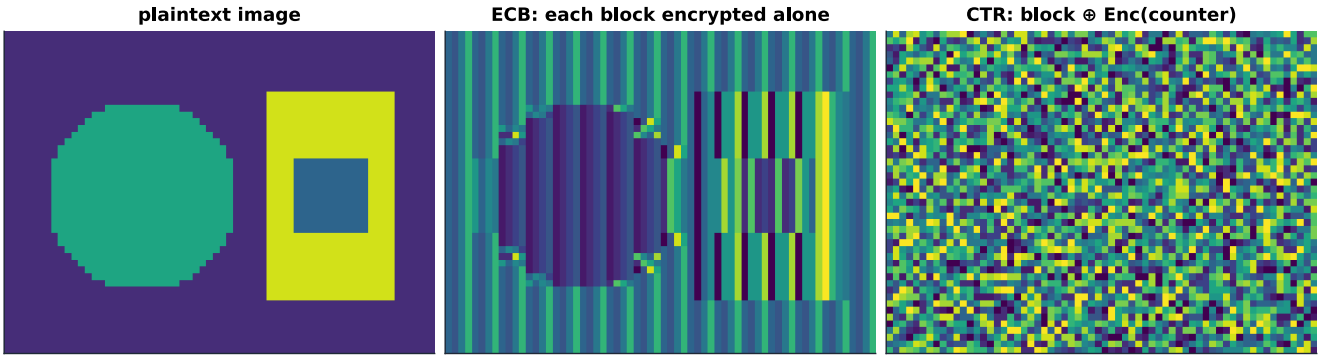
? Do one-way functions exist?

Every computational guarantee in this chapter is conditional. Remarkably, a single assumption would suffice for almost all of symmetric cryptography: Håstad, Impagliazzo, Levin and Luby proved in 1999 that a pseudorandom generator can be built from *any* one-way function. But nobody can prove that a single one-way function exists, and doing so would settle $\mathrm{P} \neq \mathrm{NP}$ along the way. What "indistinguishable from random" means exactly, and how the construction squeezes randomness out of mere one-wayness, is Ch. 81.

Block ciphers, and why encryption must be randomised

Most data is encrypted with a **block cipher**, a keyed permutation E_k of fixed-size blocks. AES, standardised in 2001, permutes 128-bit blocks under a 128-, 192- or 256-bit key. The security goal is that E_k, for a random hidden k, is indistinguishable from a permutation chosen uniformly at random from all $(2^{128})!$ of them, a **pseudorandom permutation**.

A block cipher alone is not an encryption scheme for long messages; you need a **mode of operation**. The obvious one, encrypting each block separately (electronic codebook, ECB), is a famous mistake. Equal plaintext blocks give equal ciphertext blocks, so every repetition in the data survives encryption.



A toy 16-bit "block cipher" (a random permutation of 2^{16} values) applied to an image four pixels at a time. In ECB mode every block of uniform colour maps to the same ciphertext block, so the shapes survive. In counter (CTR) mode each block is XORed with $E_k(\text{counter})$, a fresh pseudorandom pad, and the structure disappears.

The image shows a general fact, and the right definition of security exposes it. In the game of **indistinguishability under chosen-plaintext attack** (IND-CPA), Eve may ask for encryptions of any messages she likes. Then she submits two messages m_0, m_1 of equal length, receives $c^* = \mathrm{Enc}_k(m_b)$ for a secret fair coin b, may ask for more encryptions, and finally guesses b. The scheme is IND-CPA secure if no efficient Eve guesses correctly with probability non-negligibly above $\frac{1}{2}$.

> **Deterministic encryption is never IND-CPA secure**
>
> If Enc_k is a deterministic function of m, there is an Eve who wins the IND-CPA game with probability 1.

Proof. Eve picks any two distinct messages $m_0 \neq m_1$ and asks the encryption oracle for $c_0 = \mathrm{Enc}_k(m_0)$. She submits (m_0, m_1) and receives c^*. Since encryption is deterministic, $c^* = c_0$ if $b = 0$. If $b = 1$, then $c^* = \mathrm{Enc}_k(m_1) \neq c_0$, because by correctness two messages with the same ciphertext under one key would decrypt to the same thing. So Eve outputs 0 if $c^* = c_0$ and 1 otherwise, and is always right. ■

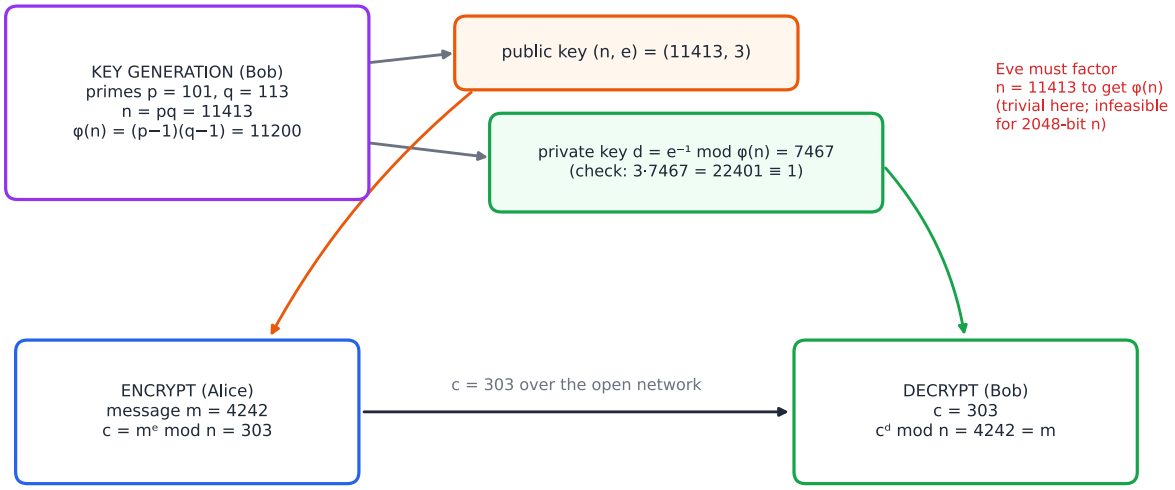
This three-line proof condemns ECB, and it equally condemns the textbook RSA of Ch. 57, where $c = m^e \bmod n$ depends on nothing but m. Secure encryption must use fresh randomness or a never-repeating **nonce** every time. That is why counter mode feeds a counter into the cipher, why real RSA encryption pads the message with random bytes (OAEP), and why, as Venona showed, *reusing* the fresh value destroys everything.

Confidentiality is also not enough. CTR mode is **malleable**: flipping ciphertext bit i flips plaintext bit i, so Eve can turn "pay 100" into "pay 900" blind. Real systems use **authenticated encryption** (AES-GCM, ChaCha20-Poly1305), which adds a tag no forger can compute and rejects tampered ciphertexts.

Public-key cryptography

The key-distribution problem in the figure is solved by functions with a trapdoor. You have met the two classical ones in Ch. 57, which proves why they work; here we look at them as security engineers.

- **Diffie–Hellman** (1976). In a cyclic group with generator g, Alice sends g^a, Bob sends g^b, both compute g^{ab}. Getting g^{ab} from g, g^a, g^b is the **computational Diffie–Hellman** problem; the stronger **decisional** assumption says g^{ab} even *looks* random to Eve. Unauthenticated, the exchange falls to a "man in the middle" who runs one exchange with each party; signatures fix that.
- **RSA** (1977). Bob publishes $n = pq$ and e, keeps $d = e^{-1} \bmod \varphi(n)$. Inverting $m \mapsto m^e \bmod n$ without d is the **RSA problem**; it is no harder than factoring n, and is believed to be no easier. RSA also gives **signatures**: Bob signs a hash h of a document as $s = h^d \bmod n$, and anyone checks $s^e \equiv h$.



Toy RSA from key generation to decryption. Everything Eve needs is public except $\varphi(n)$, and computing $\varphi(n)$ is as hard as factoring n. With 4-digit n that takes microseconds; with a 617-digit n the best known classical algorithm, the number field sieve, would take longer than any realistic budget.

Public-key arithmetic is thousands of times slower than AES, so practice is always **hybrid**: a public-key step agrees on a fresh symmetric key, and authenticated symmetric encryption carries the data. That is what happens in the handshake when your browser opens a bank's page.

Result 3: what a quantum computer would change

Every public-key system above rests on factoring or on discrete logarithms. Both reduce to a single task: finding the **period** of a function. Here is the reduction for factoring, which is completely classical.

> **Factoring reduces to order finding**
>
> Let n be odd and composite, and let a be coprime to n with multiplicative order r (the least $r \geq 1$ with $a^r \equiv 1 \pmod{n}$). If r is even and $a^{r/2} \not\equiv -1 \pmod{n}$, then $\gcd(a^{r/2} - 1,\ n)$ is a non-trivial factor of n.

Proof. Let $x = a^{r/2} \bmod n$. Then $x^2 \equiv 1$, so n divides $x^2 - 1 = (x-1)(x+1)$. Now n does not divide $x - 1$, because $x \equiv 1$ would mean $a^{r/2} \equiv 1$ with $r/2 < r$, contradicting the minimality of r. And n does not divide $x + 1$ by hypothesis. So n divides the product without dividing either factor, which is only possible if n shares a proper factor with each. Hence $1 < \gcd(x-1, n) < n$. ■

For $n = 15$ and $a = 7$: the powers of 7 mod 15 are $7, 4, 13, 1$, so $r = 4$; then $x = 7^2 \bmod 15 = 4$, and $\gcd(3, 15) = 3$, $\gcd(5, 15) = 5$. One can show that when n has at least two distinct odd prime factors, a random a satisfies the hypotheses with probability at least $\frac{1}{2}$; for the toy modulus $n = 11413$ the fraction is about 91 %. So factoring is no harder than order finding.

Classically, order finding is as hard as factoring. But $k \mapsto a^k \bmod n$ is a *periodic sequence*, and finding a period is what Fourier transforms do (Ch. 16). Shor's 1994 algorithm prepares a quantum superposition over all k, computes $a^k \bmod n$ in superposition, and applies a quantum Fourier transform, whose output peaks near multiples of $1/r$; continued fractions then recover r. A large, error-corrected quantum computer would thus break RSA, Diffie–Hellman and the elliptic-curve systems of Ch. 78 in polynomial time. None exists yet, but traffic recorded today can be decrypted later, so the migration has begun: in 2024 NIST standardised **post-quantum** algorithms built on finding short vectors in high-dimensional lattices ("learning with errors"), for which no efficient quantum attack is known. ML-KEM (FIPS 203) replaces Diffie–Hellman key agreement and ML-DSA (FIPS 204) replaces RSA and elliptic-curve signatures; SLH-DSA (FIPS 205) is a conservative backup whose signatures rest only on the security of a hash function. The price is size: post-quantum keys and signatures run to kilobytes instead of tens of bytes. Symmetric ciphers survive with longer keys, since Grover's quantum search only square-roots brute force.

77.4 The algorithm

The code below is a teaching model. It implements textbook RSA and the classical half of Shor's algorithm with numbers small enough to check by hand. Python's built-in three-argument `pow` does modular exponentiation by square-and-multiply (Ch. 57 §57.4), and `pow(e, -1, phi)` computes a modular inverse by the extended Euclidean algorithm.

```
from math import gcd
import random

# --- toy RSA: illustration only, NEVER for real data ---
def keygen(p, q, e=3):
    n, phi = p * q, (p - 1) * (q - 1)
    assert gcd(e, phi) == 1
    return (n, e), pow(e, -1, phi)          # public key, private exponent

def enc(pk, m):  n, e = pk; return pow(m, e, n)
def dec(pk, d, c): n, _ = pk; return pow(c, d, n)

pk, d = keygen(101, 113)
c = enc(pk, 4242)
print(pk, d, c, dec(pk, d, c))              # (11413, 3) 7467 303 4242

# --- factoring from order finding (the classical half of Shor's algorithm) ---
def order(a, n):                            # brute force: the step a quantum computer replaces
    r, x = 1, a % n
    while x != 1:
        x, r = x * a % n, r + 1
    return r

def factor_via_order(n, tries=20):
    for _ in range(tries):
        a = random.randrange(2, n - 1)
        g = gcd(a, n)
        if g > 1:
            return g                        # lucky guess
        r = order(a, n)
        if r % 2 == 0 and pow(a, r // 2, n) != n - 1:
            return gcd(pow(a, r // 2, n) - 1, n)
    return None

print(factor_via_order(15), factor_via_order(11413))   # e.g. 3 101
```

Complexity. Encryption and decryption cost $O(\log d)$ multiplications of λ-bit numbers, roughly $O(\lambda^3)$ bit operations: fast for $\lambda = 2048$. The function `order` may loop r times, and r can be close to $\varphi(n)/2$, around 2^{2047} for a 2048-bit modulus. That one loop is the gap between "encrypt in a millisecond" and "break never". Shor's algorithm replaces exactly that loop, and nothing else changes.

Failure cases, mathematical. `keygen` fails when $\gcd(e, \varphi(n)) > 1$; with $p = 7$, $q = 13$ and $e = 3$, $\varphi(n) = 72$ is divisible by 3 and d does not exist. Decryption fails if $m \geq n$, since only $m \bmod n$ survives. `factor_via_order` fails for prime powers $n = p^k$ (try $n = 9$), which need a separate test.

Failure cases, engineering. These are the ones that break real systems, and the code above has all of them.

- *Determinism.* `enc` is deterministic, so by the theorem of §77.3 it is not IND-CPA secure. With $e = 3$ and a message $m < n^{1/3}$, m^3 never wraps around n, and an ordinary integer cube root recovers m.
- *Malleability.* $\mathrm{Enc}(m_1)\,\mathrm{Enc}(m_2) = \mathrm{Enc}(m_1 m_2) \bmod n$, so Eve can transform ciphertexts meaningfully without the key.
- *Side channels.* `pow` takes time, and draws current, that depends on the bits of d; such measurements have recovered keys from smart cards and remote servers. Production code is constant-time and blinded.
- *Bad randomness.* Devices with poor entropy at boot have produced moduli that share a prime; one $\gcd(n_1, n_2)$ then factors both.
- *Wrong error messages.* A server that reports "bad padding" differently from other errors lets Eve decrypt any ciphertext by adaptive queries (Bleichenbacher, 1998).

None of these is a mistake in the number theory. Each is a gap between a mathematical object and a running program, which is why the warning in §77.2 is not a formality.

> **? Why are elliptic-curve keys so short?**
>
> To get security comparable to a 128-bit symmetric key, current guidance asks for an RSA modulus of about 3072 bits, but an elliptic-curve key of only 256 bits. Both rest on "easy forward, hard backward" arithmetic in a finite group. Why does one group need twelve times fewer bits than the other, and what exactly is the group made of? The answer is a curve, a chord, and the absence of a shortcut, in Ch. 78.

77.5 The experiment

The script below plays Eve against a **two-time pad**. Two messages are encrypted with the same random pad, exactly the Venona mistake. Eve XORs the ciphertexts, which cancels the pad, and then **drags a crib**: she guesses that a common word appears in one message, slides it along $c_1 \oplus c_2$, and at each position XORs it in. Wherever the guess is right, a fragment of the *other* message appears in plain text.

```
import numpy as np
import matplotlib.pyplot as plt

M1 = b"meet the courier at the north gate at dawn"   # KNOB: first secret message
M2 = b"the shipment leaves the harbour on tuesday"   # KNOB: second secret message
CRIB = b" the "                                      # KNOB: a word Eve guesses is in one message
REUSE = True                                         # KNOB: False gives each message a fresh pad

rng = np.random.default_rng(2024)
L = min(len(M1), len(M2))
m1 = np.frombuffer(M1[:L], dtype=np.uint8)
m2 = np.frombuffer(M2[:L], dtype=np.uint8)
k1 = rng.integers(0, 256, L, dtype=np.uint8)
k2 = k1 if REUSE else rng.integers(0, 256, L, dtype=np.uint8)
c1, c2 = m1 ^ k1, m2 ^ k2               # what Eve intercepts
x = c1 ^ c2                             # the pad cancels if it was reused

crib = np.frombuffer(CRIB, dtype=np.uint8)
score = []
for pos in range(L - len(crib) + 1):    # crib dragging: slide the guess along
    frag = x[pos:pos + len(crib)] ^ crib
    ok = np.mean([(32 <= b < 127) and (chr(b).isalpha() or b == 32) for b in frag])
    score.append(ok)
    if ok == 1.0:
        print(f"pos {pos:2d}: other message reads {bytes(frag)!r}")

plt.bar(range(len(score)), score)
plt.xlabel("crib position"); plt.ylabel("fraction of letters/spaces")
plt.title("crib dragging on c1 XOR c2"); plt.show()
```

With the defaults, six positions produce readable-looking fragments. One of them, at position 4, reads `'shipm'`: a genuine piece of the second message, exposed because the first message has " the " there. Another, at position 19, reads `' the '` because *both* messages happen to contain " the " at the same place. The rest are look-alikes such as `'mridr'` that a human rejects at a glance. Things to try:

- **Extend a hit.** Guess that `shipm` continues as `shipment`, set `CRIB = b"shipment"` and look at position 4 again: you now read eight characters of the first message. Real codebreakers bootstrapped whole messages this way, one guessed word at a time.
- **Set `REUSE = False`.** Every position now gives noise, and no fragment passes the filter. Result 1 is at work: with independent pads, $c_1 \oplus c_2$ is itself a uniformly random string, and no guess can be confirmed.
- **Change the language model.** The filter accepts any lowercase letters, which is crude. Score by English letter frequencies instead (English carries only about 1 to 1.5 bits per letter out of a possible $\log_2 26 \approx 4.7$, Ch. 33). How short a crib still finds the true position?

77.6 The challenge

No answers are given.

1. **Intuition.** A friend proposes "double encryption": encrypt with a one-time pad k_1 and then again with an independent pad k_2, for twice the security. Explain in words why this gains nothing. Then explain why encrypting twice with a *block cipher* under two keys (as in "double DES") also gains far less than doubling the key length suggests. (Think of meeting in the middle.)
2. **Derivation.** Prove the converse half of Shannon's theory: if $|\mathcal{K}| = |\mathcal{M}| = |\mathcal{C}|$ and the scheme is perfectly secret, then every key is used with probability $1/|\mathcal{K}|$, and for every pair (m, c) there is exactly one key with $\mathrm{Enc}_k(m) = c$. Then show that the definition of perfect secrecy is equivalent to: for all m_0, m_1, c, $P(C = c \mid M = m_0) = P(C = c \mid M = m_1)$.
3. **Implementation.** Extend the toy RSA code with the Chinese-remainder speed-up for decryption (compute c^d mod p and mod q separately and combine). Measure the speed-up for 512-bit primes generated with a Miller–Rabin test. Then implement a toy version of the common-factor attack: generate 1000 moduli where, through a deliberately weak random generator, a few share a prime, and find them all with pairwise gcds. Keep everything in a sandbox: this is to understand the failure, not to build anything.
4. **Open investigation.** In the experiment, replace the letter filter by a statistical score and automate crib dragging over a dictionary of the 200 most common English words. For two messages of length L, how does the fraction of plaintext you can recover automatically grow with L? Is there a threshold length below which the two-time pad is "practically safe", and how does it depend on the language (try a language with a different letter distribution, or compressed text)?

77.7 Loose threads

The hook asked three questions. **Security** means winning a precisely defined game against every allowed adversary; perfect secrecy and IND-CPA are two such games, and the second showed in three lines that deterministic ciphers fail. **Short keys** protect long messages only against a bounded Eve, through pseudorandom generators and block ciphers resting on unproved assumptions; Shannon's counting shows nothing else is possible. **Strangers agree on a secret** through trapdoor arithmetic whose hardness rests on factoring and discrete logarithms, which a quantum computer would turn into period finding.

The Venona lesson runs under all of it: mathematics proves a scheme secure *under stated conditions*, and practice fails by quietly violating one.

What we did not tell you:

- **Where good randomness comes from**, and what "looks random" must mean so that a stream cipher inherits the one-time pad's security. The first mystery points to Ch. 81.
- **What the elliptic-curve group is.** The second mystery points to Ch. 78, and the finite fields underneath are introduced in Ch. 57.
- **Hash functions.** Signatures, passwords and blockchains all depend on functions where finding two inputs with the same output is infeasible. The birthday bound of Ch. 32 is why a 256-bit hash gives only 128 bits of collision resistance.

- **Why lattice problems resist quantum computers.** Nobody knows. Ajtai (1996) and Regev (2005) showed that random lattice instances are as hard as the worst ones, a guarantee factoring never had, but a quantum algorithm for short lattice vectors has not been ruled out.

? Proving you know a secret without revealing it

A signature convinces Bob that Alice holds a private key, but the signature itself is a lasting piece of evidence that Bob can show to anyone. Is it possible to convince Bob that you know the factorisation of n, or the password, or the solution to a puzzle, so that he learns *nothing* except that the claim is true, not even enough to convince a third party? It is, and the definition of "learns nothing" is one of the strangest ideas in computer science: anything Bob could see, he could have simulated alone. See Ch. 82.

Chapter 78 — Elliptic Curves and Modern Cryptographic Mathematics

Level 2 · Track H — Cryptography, Coding, and Digital Security Builds on: Ch. 57, Ch. 56, Ch. 77, Ch. 1 · **Leads to:** Ch. 79, Ch. 82, Ch. 94 · **Related:** Ch. 32, Ch. 26, Ch. 81 **Reading time:** ~25 min

78.1 The hook

The PlayStation 3 was, for four years, the console nobody could crack. Every program it ran had to carry a digital signature from Sony, made with Sony's private key using the Elliptic Curve Digital Signature Algorithm (ECDSA). The mathematics behind it is the same that protects most of today's secure web connections, and nobody has ever broken it. Without the private key, no unofficial software would run.

In December 2010, a group of hackers calling themselves failoverflow stood on stage at a computer congress in Berlin and showed that they had the key. They had not solved a hard problem. They had noticed that two different signed programs shared one number in their signatures. ECDSA requires a fresh secret random number for every signature, and Sony had used the same one every time. From two signatures and a few lines of algebra, high-school algebra modulo a prime, the private key fell out. Anyone could now sign software as Sony.

Three years later the same mistake emptied Bitcoin wallets: a flaw in a random-number generator on Android phones made some wallets repeat their signing numbers, and thieves who watched the public blockchain for repeats took the coins.

The cryptosystem was not wrong. The mathematics was flawless, the implementation was not. To understand both the strength and the fragility, we need to know what these signatures are made of. The answer is surprising: a *curve*, a rule for "adding" points on it that is built from straight lines, and arithmetic in a finite field where the curve stops looking like a curve at all.

78.2 The big idea

Public-key cryptography needs a group where going forward is easy and going back is hard. In Ch. 57 the group was $\mathbb{Z}_p^\times$: computing g^a is fast, recovering a from g^a (the **discrete logarithm**) is believed slow. Elliptic curves supply a different group with the same shape and, as far as anyone knows, no shortcuts.

The construction is geometric. Draw the cubic curve $y^2 = x^3 + ax + b$. Pick two points on it, draw the straight line through them, and the line hits the curve in exactly **one more point**. Reflect that point in the x-axis: that is the "sum" of the two. To add a point to itself, use the tangent line. Astonishingly, this rule obeys the laws of a group, so you can add a point G to itself again and again, $G,\ 2G,\ 3G, \ldots$, and the multiples behave like the powers $g, g^2, g^3, \ldots$ of a number.

Now do the same arithmetic modulo a prime p. The curve dissolves into a scattered cloud of points on a $p \times p$ grid, but the formulas still work, and the multiples kG hop around the cloud with no visible pattern. Computing kG from k is fast, by doubling and adding. Recovering k from kG is the **elliptic-curve discrete logarithm problem**, and the best known general attack is no better than a sophisticated form of guessing.

An analogy: imagine a billiard table with strange, perfectly deterministic walls. You shoot a ball from a known spot, and it bounces k times and stops. Anyone can simulate k bounces quickly if they know k. But seeing only where the ball stopped, finding k means re-simulating bounce after bounce, because the table remembers nothing about how many bounces got it there.

78.3 The mathematics

The fields underneath

We need a field: a number system where we can add, subtract, multiply and divide by anything nonzero. Over the real numbers we can draw pictures. For cryptography we use the finite field $\mathbb{F}_p = \mathbb{Z}_p$ of integers mod a prime p, where division means multiplying by a modular inverse from the extended Euclidean algorithm. Ch. 57 builds these fields, and the prime-power fields $\mathbb{F}_{2^m}$, and we use them without re-deriving anything. One caution: the formulas below divide by 2 and by 3, so we assume the field's characteristic is not 2 or 3. (Binary curves exist but use a different equation.)

Elliptic curve

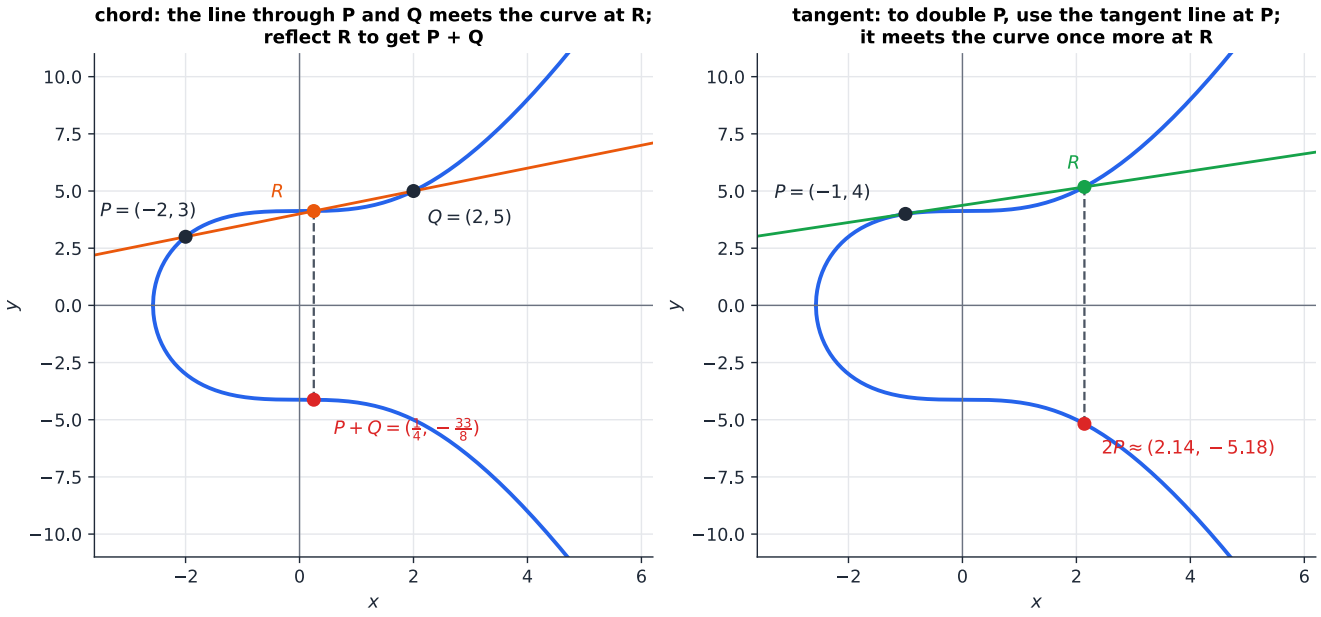
Let K be a field with $1+1 \neq 0$ and $1+1+1 \neq 0$, and let $a, b \in K$ satisfy $4a^3 + 27b^2 \neq 0$. The **elliptic curve** E is the set

$$E(K) = \{(x, y) \in K^2 : \ y^2 = x^3 + ax + b\} \ \cup \ \{\mathcal{O}\},$$

where $\mathcal{O}$ is an extra **point at infinity**.

The condition $4a^3 + 27b^2 \neq 0$ says the cubic $x^3 + ax + b$ has no repeated root, which keeps the curve smooth: no cusps, no self-crossings, and a well-defined tangent everywhere. The point $\mathcal{O}$ is best pictured as sitting infinitely far up (and down) every vertical line; every vertical line meets the curve there.

Result 1: the chord-and-tangent law



Addition and doubling on $y^2 = x^3 + 17$. All four named points have rational coordinates: rational points add to rational points, because the formulas use only field operations.

The addition formulas

Let $P = (x_1, y_1)$ and $Q = (x_2, y_2)$ lie on E with $Q \neq -P$, where $-P = (x_1, -y_1)$. Put

$$\lambda = \begin{cases} \dfrac{y_2 - y_1}{x_2 - x_1}, & P \neq Q, \\ \dfrac{3x_1^2 + a}{2y_1}, & P = Q. \end{cases}$$

Then the line of slope λ through P meets E in a third point $R = (x_3, -y_3)$, and $P + Q := (x_3, y_3)$ is given by

$$x_3 = \lambda^2 - x_1 - x_2, \qquad y_3 = \lambda(x_1 - x_3) - y_1.$$

Proof. The line through P with slope λ is $y = \lambda(x - x_1) + y_1$. In the case $P \neq Q$ it passes through Q by the choice of λ. Substitute it into the curve:

$$\big(\lambda(x - x_1) + y_1\big)^2 = x^3 + ax + b \quad \Longleftrightarrow \quad x^3 - \lambda^2 x^2 + (\cdots)x + (\cdots) = 0.$$

This is a monic cubic in x, and its roots are the x-coordinates where line and curve meet. Two roots are known: x_1 and x_2. A cubic over a field with two roots in the field has a third, because dividing out $(x - x_1)(x - x_2)$ leaves a linear factor. By Vieta's formula the three roots sum to minus the coefficient of x^2:

$$x_1 + x_2 + x_3 = \lambda^2 \quad \Longrightarrow \quad x_3 = \lambda^2 - x_1 - x_2.$$

The third intersection point lies on the line, so its y-coordinate is $\lambda(x_3 - x_1) + y_1$; reflecting changes its sign, giving $y_3 = \lambda(x_1 - x_3) - y_1$. For $P = Q$, implicit differentiation of $y^2 = x^3 + ax + b$ gives $2y\,y' = 3x^2 + a$, so the tangent slope is $(3x_1^2 + a)/(2y_1)$; the tangent touches the curve at P with multiplicity two, so x_1 counts as a double root and the same Vieta argument applies with $x_2 = x_1$. ■

Check it on the figure. For $P = (-2, 3)$, $Q = (2, 5)$ on $y^2 = x^3 + 17$: $\lambda = \frac{2}{4} = \frac{1}{2}$, $x_3 = \frac{1}{4} + 2 - 2 = \frac{1}{4}$, $y_3 = \frac{1}{2}(-2 - \frac{1}{4}) - 3 = -\frac{33}{8}$. And indeed $(\frac{1}{4})^3 + 17 = \frac{1089}{64} = (\frac{33}{8})^2$. Doubling $P = (-1, 4)$: $\lambda = \frac{3}{8}$, and $2P = (\frac{137}{64}, -\frac{2651}{512})$. The denominators grow quickly, which is one reason cryptographers prefer finite fields.

Nothing in the proof used real numbers. It used only $+, -, \times, \div$ and the fact that a cubic with two roots in the field has a third. So **the same formulas define addition on $E(\mathbb{F}_p)$.**

The group

$E(K)$ is an abelian group

With the chord-and-tangent rule, $P + \mathcal{O} = P$, and $P + (-P) = \mathcal{O}$, the set $E(K)$ is an abelian group with identity $\mathcal{O}$.

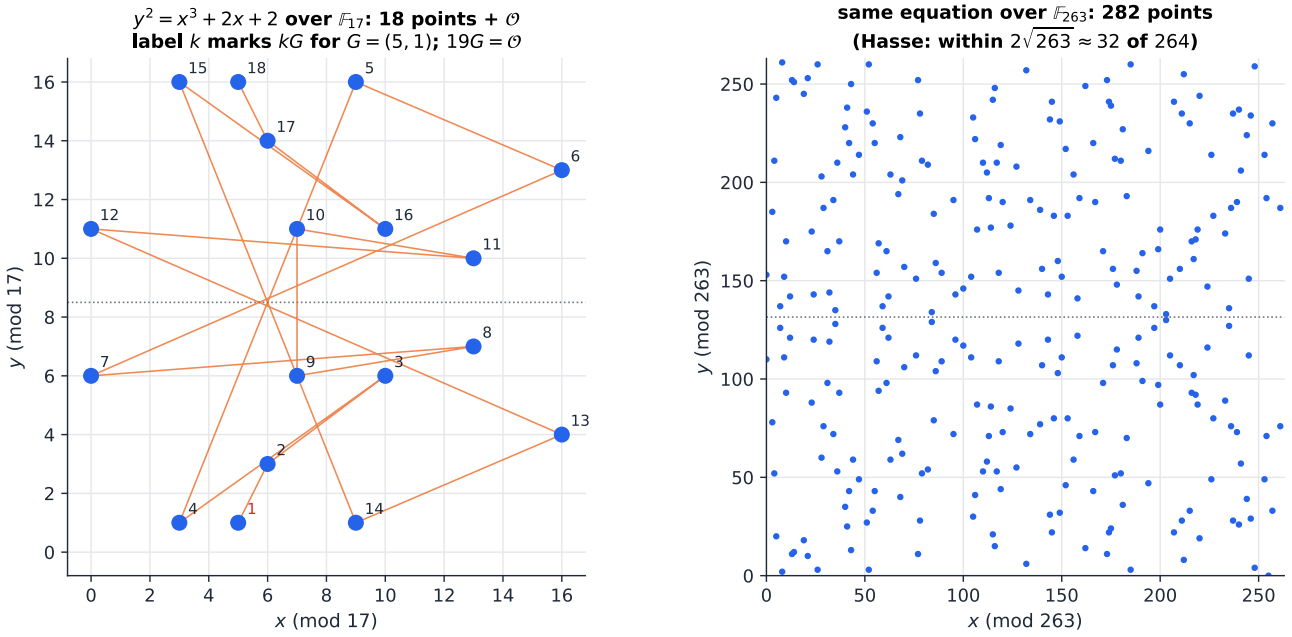
Most axioms are immediate. The identity: the vertical line through P meets the curve at P, $-P$ and $\mathcal{O}$, so "the third point" of P and $\mathcal{O}$ is $-P$, reflected back to P. Inverses: the line through P and $-P$ is vertical, its third point is $\mathcal{O}$. Commutativity: the line through P and Q is the line through Q and P.

Associativity is the miracle. Why should $(P + Q) + R = P + (Q + R)$ for a rule made of lines? One can grind it out from the formulas (a computer algebra system does it in seconds, a human in many pages). A cleaner argument uses a classical fact about cubics: *if two cubic curves meet in exactly nine points, then any cubic passing through eight of them also passes through the ninth* (the Cayley–Bacharach theorem). Multiply the equations of three lines, the line through P and Q, the line through $P + Q$ and R, and the vertical line through $Q + R$, to get a cubic C_1. Likewise the line through Q and R, the line through P and $Q + R$,

and the vertical line through $P+Q$ give a cubic C_2. Each meets E in nine points, and eight are shared: $P, Q, R, \mathcal{O}, \pm(P+Q), \pm(Q+R)$. The ninth intersection of C_1 with E is $-\big((P+Q)+R\big)$, and Cayley–Bacharach forces C_2 through it, which means it equals $-\big(P+(Q+R)\big)$. (The special cases where some of the points coincide need a limiting argument.)

> **? Why lines make a group**
>
> The nine-point argument shows associativity is *true*, but not *why* a cubic curve, of all things, should carry a group law. Conics do not; curves of degree four do not in this simple way. The deep reason is that an elliptic curve is secretly a doughnut: over $\mathbb{C}$ it is the plane modulo a lattice, $\mathbb{C}/\Lambda$, where addition is just addition of complex numbers, and the coordinates x, y are doubly periodic functions of the kind Ch. 18 hints at. Over any field, the group is a shadow of a more general object, the group of "divisors" on a curve of genus one. That story is Ch. 94.

Curves over finite fields



Over a finite field the curve becomes a cloud. The group law still works: the orange path visits all 18 affine points as $G, 2G, \dots, 18G$ and returns to $\mathcal{O}$ at $19G$. Each x gives either no points or a mirror pair $(x, \pm y)$, the only trace left of the real picture.

How many points does $E(\mathbb{F}_p)$ have? Each $x \in \mathbb{F}_p$ gives two points if $x^3 + ax + b$ is a nonzero square mod p, one if it is zero, and none otherwise. Roughly half of the nonzero residues are squares, so we expect about p affine points plus $\mathcal{O}$.

> **Hasse's theorem (1933)**
>
> The number of points satisfies $\big|\,\#E(\mathbb{F}_p) - (p+1)\,\big| \le 2\sqrt{p}$.

On $y^2 = x^3 + 2x + 2$ the count is 19 over $\mathbb{F}_{17}$, within 1 of $p+1 = 18$, and 282 over $\mathbb{F}_{263}$, within 18 of 264; the bound allows 8.2 and 32.4. We will not prove Hasse's theorem here; it is the first case of a vast generalisation (the Weil conjectures) that took most of the twentieth century to prove.

Since 19 is prime, Lagrange's theorem (Ch. 56) leaves every point except $\mathcal{O}$ only one possible order, 19: each one generates the whole group, and $E(\mathbb{F}_{17}) \cong \mathbb{Z}_{19}$. Cryptographic curves are chosen the same way, with a group of prime order n (or a small multiple of it) near 2^{256}.

The discrete logarithm, and how fast it can be attacked

> **Elliptic-curve discrete logarithm problem (ECDLP)**
>
> Given a point G of order n and a point Q in the group it generates, find $d \in \{0, \dots, n-1\}$ with $Q = dG$.

The forward direction is fast. **Double-and-add** reads the bits of d from the top: double the running total at each bit and add G when the bit is 1. That computes dG in at most $2\log_2 d$ group operations, about 510 for a 256-bit d. Brute force in reverse tries $G, 2G, 3G, \dots$ and needs up to n steps. Can we do better than brute force without any special structure? Yes, but only to the square root.

> **Baby-step giant-step (Shanks)**
>
> The ECDLP in a group of order n can be solved with $O(\sqrt{n})$ group operations and $O(\sqrt{n})$ memory.

Proof. Let $m = \lceil \sqrt{n} \rceil$. Every d with $0 \le d < n \le m^2$ can be written uniquely as $d = im + j$ with $0 \le i, j < m$ (division with remainder). Then

$$Q = dG = imG + jG \quad \Longleftrightarrow \quad Q - i(mG) = jG.$$

Baby steps: compute jG for $j = 0, \dots, m-1$ and store them in a hash table (m additions). **Giant steps:** compute $Q,\ Q - mG,\ Q - 2mG, \dots$ and look each one up ($\le m$ additions). Some $i < m$ must produce a hit, because the true d has such a decomposition; the hit gives $d = im + j$. Total work is at most $2m = O(\sqrt{n})$. ■

For a group of order near 2^{256}, $\sqrt{n} \approx 2^{128} \approx 3.4 \times 10^{38}$ operations: the same scale as brute-forcing a 128-bit AES key in Ch. 77. The memory problem is removed by **Pollard's rho** method, which takes a pseudorandom walk through the group and waits for it to collide with itself. By the birthday bound of Ch. 32, a collision arrives after about $\sqrt{\pi n/2}$ steps, using almost no memory.

Two further facts shape how curves are chosen.

- **Pohlig–Hellman.** If the group order n factors into small primes, the ECDLP splits by the Chinese remainder theorem into small problems, one per prime power, so its cost is governed by the *largest prime factor* of n, not n itself. Hence the insistence on prime (or nearly prime) group order.
- **Generic lower bound.** Shoup proved in 1997 that any algorithm that treats the group as a black box, only adding and comparing points, needs $\Omega(\sqrt{n})$ operations. Baby-step giant-step and rho are optimal among such algorithms.

The state of play. For $\mathbb{Z}_p^\times$ there are faster, non-generic attacks: **index calculus** factors many powers g^k over a base of small primes and solves linear equations for their logarithms, giving sub-exponential running time. That is why finite-field Diffie–Hellman and RSA need 3072-bit numbers for 128-bit security. Points on an elliptic curve have no known notion of "small" that a factor base could exploit. So, as far as anyone knows, the best attack on a well-chosen curve is generic, and 256-bit curves give roughly 128-bit security. That is the whole reason elliptic-curve keys are twelve times shorter.

"Well-chosen" carries weight. Some curves *do* have shortcuts: on **supersingular** curves a pairing maps the ECDLP into a finite field where index calculus applies (the MOV attack, 1993), and on **anomalous** curves with exactly p points the ECDLP can be solved in polynomial time (Smart; Satoh–Araki; Semaev, 1998–99). Standard curves are checked against every known weakness, and whether some cleverer index calculus exists for general curves is an open question.

Pairings: a weakness that became a tool

A **pairing** is a map $e : \langle P \rangle \times \langle Q \rangle \to \mathbb{F}_{p^k}^\times$ from pairs of points of prime order n into the multiplicative group of an extension field, which is **bilinear**, $e(aP, bQ) = e(P, Q)^{ab}$, and **non-degenerate**, $e(P, Q) \neq 1$. The Weil and Tate pairings, built from rational functions on the curve, have these properties for every elliptic curve, and Miller's algorithm (1986) evaluates them with $O(\log n)$ operations, in a sense the double-and-add of pairings. The catch is the field they land in. The values are n-th roots of unity, which live in $\mathbb{F}_{p^k}$ only once n divides $p^k - 1$; the least such k is the **embedding degree**. For a random curve k is about as large as n itself, so the target field has some $2^{2^{256}}$ elements and the pairing cannot even be written down. Only special curves have small k: supersingular curves have $k \le 6$, and families such as BN and BLS12 are constructed on purpose to have $k = 12$.

Small k cuts both ways. It is exactly the MOV attack: $e(P, dP) = e(P, P)^d$ moves the discrete logarithm into $\mathbb{F}_{p^k}^\times$, where index calculus works, so pairing-friendly curves must be made larger to stay safe. But it also gives a capability no ordinary group has: anyone can test a *multiplicative* relation between hidden exponents. Given aG, bG and cG, the check $e(aG, bG) = e(G, cG)$ holds exactly when $ab \equiv c \pmod n$, yet reveals none of the three. **BLS signatures** use this directly: the signature on m is $\sigma = d\,H(m)$ for a hash-to-curve point $H(m)$, and it verifies when $e(\sigma, G) = e(H(m), dG)$. Signatures from many signers on many messages can be added into one point, which is why blockchains with thousands of validators use them.

Using the group: key exchange and signatures

ECDH is Diffie–Hellman with points: public G; Alice sends aG, Bob sends bG, and both compute abG. **ECDSA** signs a message hash h (an integer mod n) with private key d and public key $Q = dG$:

1. pick a secret, fresh, uniformly random **nonce** $k \in \{1, \dots, n-1\}$;
2. compute $r = x(kG) \bmod n$ (the x-coordinate of kG, reduced mod n);
3. compute $s = k^{-1}(h + rd) \bmod n$. The signature is (r, s).

To verify, compute $w = s^{-1}$, $u_1 = hw$, $u_2 = rw$ and check that $x(u_1 G + u_2 Q) \bmod n = r$. This works because $u_1 G + u_2 Q = (h + rd)wG = kG$.

Result 3: one repeated nonce reveals the key

Nonce reuse breaks ECDSA

If two signatures (r, s_1) on h_1 and (r, s_2) on $h_2 \neq h_1$ were made with the same nonce k, then anyone can compute

$$k = \frac{h_1 - h_2}{s_1 - s_2} \bmod n, \qquad d = \frac{s_1 k - h_1}{r} \bmod n.$$

Proof. The same k gives the same kG, hence the same r; that is how the repeat is spotted. From $s_i k \equiv h_i + rd \pmod n$ for $i = 1, 2$, subtract: $(s_1 - s_2)k \equiv h_1 - h_2$. Since $h_1 \neq h_2$ and k is invertible, $s_1 \neq s_2$, so divide to get k. Then solve $s_1 k = h_1 + rd$ for d ($r \neq 0$ is required by the standard). Everything happens in the field $\mathbb{Z}_n$, since n is prime. ■

That is the PlayStation 3 key and the Android wallets. The theorem needs no hard problem to be solved; it is two linear equations in two unknowns. Worse, it is not only exact repetition that kills: if the nonces are merely *biased*, say their top few bits are often zero, lattice methods recover the key from a few hundred signatures. This is why modern implementations derive k deterministically from the key and the message (RFC 6979) or use schemes like Ed25519 that do so by design.

? From one multiplication to a whole computation

A pairing checks a single product of hidden exponents, $ab = c$. Yet pairing-based SNARKs convince a verifier, with three curve points, that a computation of a billion steps was carried out correctly, while revealing nothing about its inputs. How does one hidden multiplication grow into a check of an entire program, and what does it mean for a verifier to "learn nothing"? See Ch. 82.

78.4 The algorithm

Here is the whole pipeline, from point addition to the PlayStation-style key recovery, on the 19-point curve of the figure. Every value is small enough to check by hand against the labelled multiples in the left panel.

```
# Toy ECDSA on y^2 = x^3 + 2x + 2 over F_17 (group order 19). NEVER use for real data.
p, a, b = 17, 2, 2
G, n = (5, 1), 19

def add(P, Q):
    if P is None: return Q
    if Q is None: return P
    (x1, y1), (x2, y2) = P, Q
    if x1 == x2 and (y1 + y2) % p == 0: return None            # P + (-P) = O
    if P == Q: lam = (3 * x1 * x1 + a) * pow(2 * y1, -1, p) % p
    else:      lam = (y2 - y1) * pow(x2 - x1, -1, p) % p
    x3 = (lam * lam - x1 - x2) % p
    return (x3, (lam * (x1 - x3) - y1) % p)

def mul(k, P):                                  # double-and-add, NOT constant time
    R = None
    for bit in bin(k)[2:]:
        R = add(R, R)
        if bit == "1": R = add(R, P)
    return R

def sign(d, h, k):                              # k MUST be fresh and secret for every signature
    r = mul(k, G)[0] % n
    s = pow(k, -1, n) * (h + r * d) % n
    return r, s

def verify(Q, h, r, s):
    w = pow(s, -1, n)
    X = add(mul(h * w % n, G), mul(r * w % n, Q))
    return X is not None and X[0] % n == r

d = 11; Q = mul(d, G)                           # private key, public key
r1, s1 = sign(d, 5, k=10)                       # two messages, SAME nonce
r2, s2 = sign(d, 12, k=10)
print(Q, (r1, s1), (r2, s2), verify(Q, 5, r1, s1), verify(Q, 12, r2, s2))

# Eve sees only public data: r1 == r2 betrays the repeated nonce
k = (5 - 12) * pow(s1 - s2, -1, n) % n
d_found = (s1 * k - 5) * pow(r1, -1, n) % n
print("recovered k =", k, " recovered d =", d_found)
```

The output is `(13, 10) (7, 12) (7, 7) True True`, then `recovered k = 10 recovered d = 11`. Both signatures verify, both share $r = 7$, and Result 3 hands Eve the private key.

Complexity. One addition costs one modular inversion and a few multiplications. Real implementations avoid the inversion by working in **projective coordinates** $(X : Y : Z)$, with $x = X/Z$, $y = Y/Z$, which turn each addition into about a dozen multiplications and postpone the single division to the end. Scalar multiplication is $O(\log n)$ additions, so $O(\lambda^3)$ bit operations for a λ-bit curve, on par with RSA at a far smaller λ.

Failure cases, mathematical. If $4a^3 + 27b^2 = 0$, the curve is singular, the group law degenerates, and its "discrete logarithm" collapses into one in the additive or multiplicative group of the field, which is easy or much easier. If n is not prime, Pohlig–Hellman splits the problem into pieces. If a received point is not checked to lie on the curve, an attacker can send a point on a *different* curve with a weak group (the formulas never use b!) and harvest the private key bit by bit. This **invalid-curve attack** has broken real TLS implementations.

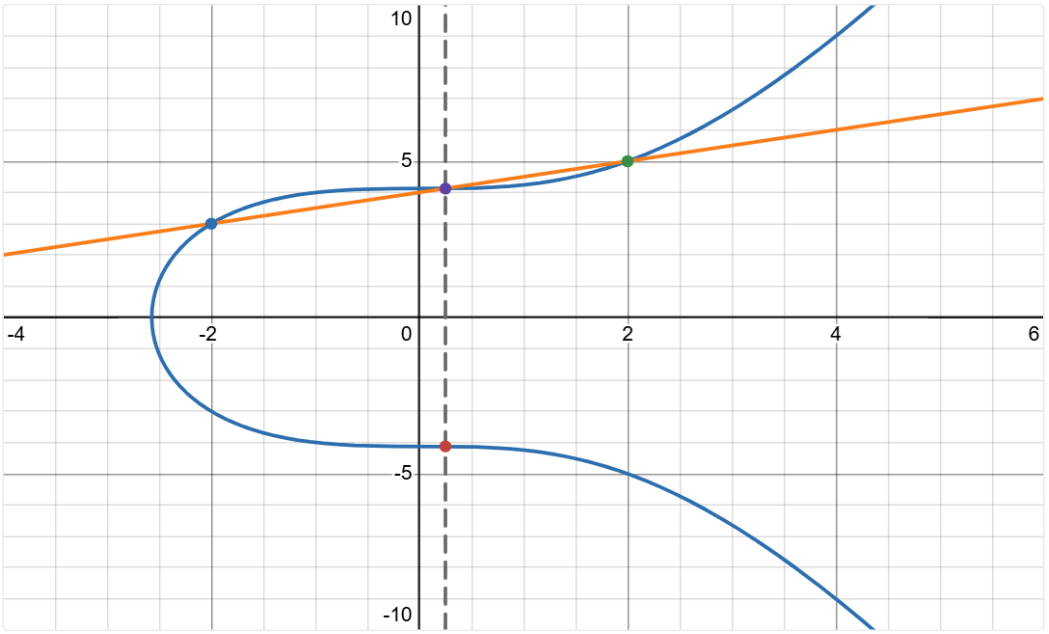
Failure cases, engineering. `mul` branches on the bits of the secret scalar, so its running time and power draw leak them. Production code uses constant-time ladders (the Montgomery ladder does one addition and one doubling for every bit, whatever its value), complete addition formulas without special cases, and libraries such as libsodium or a platform's TLS stack. Nonces must come from a cryptographically secure generator, or be derived deterministically as in RFC 6979 or Ed25519.

> **Never roll your own crypto**
>
> The 30 lines above are correct mathematics and a catastrophically insecure implementation: a 19-element group, a branching scalar multiplication, no point validation, a caller-supplied nonce and no hashing of the message. Production elliptic-curve code is written by specialists, verified, fuzzed, audited and attacked for years. Use a vetted library's high-level API (for example X25519 for key exchange and Ed25519 for signatures), standard curves, and current guidance; never invent curves, nonce schemes or "simplified" protocols.

> **? The generator with a hidden key**
>
> Where do the "random" numbers of cryptography come from? In 2006 a standards body published Dual_EC_DRBG, a random-number generator built from two elliptic-curve points P and Q: each output is roughly the x-coordinate of a multiple of Q, and the internal state advances via P. Researchers soon pointed out that whoever knew a secret e with $P = eQ$ could predict every future output from one sample. The points' origin was never explained, and documents leaked in 2013 suggested that the generator had been deliberately backdoored. How can a generator look perfectly random to everyone but one person, and what definition of "random" would have ruled this out? See Ch. 81.

78.5 The experiment

First, drag the geometry. The block draws $y^2 = x^3 + 17$ with the chord through $P = (-2, 3)$ and $Q = (2, 5)$ and its reflection.



The chord through P and Q on $y^2 = x^3 + 17$ meets the curve at $R = (\frac{1}{4}, \frac{33}{8})$; its mirror image is $P + Q$.

- Replace the orange line by the tangent at $(-1, 4)$, `y=0.375x+4.375`, and find where it meets the curve again (near $x = 2.14$).
- Change the curve to `y^2=x^3-3x+2`. Here $4a^3 + 27b^2 = -108 + 108 = 0$: the curve crosses itself at $(1, 0)$, where no tangent is defined. Then try `y^2=x^3-3x+3` and `y^2=x^3-3x+1`; the second splits into two pieces, an oval and an infinite branch, and the group law still works across both.

Then go finite. The script counts the points of a curve mod p, checks Hasse's bound, and attacks a discrete logarithm with baby-step giant-step.

```
import numpy as np
import matplotlib.pyplot as plt

P_MOD, A, B = 1009, 2, 3      # KNOBS: a prime p > 3 and the curve y^2 = x^3 + A x + B
SECRET = 777                  # KNOB: Alice's private scalar d

sq = {}                                       # y^2 mod p -> list of y
for y in range(P_MOD): sq.setdefault(y * y % P_MOD, []).append(y)
pts = [(x, y) for x in range(P_MOD) for y in sq.get((x**3 + A*x + B) % P_MOD, [])]
N = len(pts) + 1                              # + point at infinity (None)
print(f"N = {N}, p + 1 = {P_MOD + 1}, Hasse bound 2*sqrt(p) = {2*np.sqrt(P_MOD):.1f}")

def add(P, Q):
    if P is None: return Q
    if Q is None: return P
    (x1, y1), (x2, y2) = P, Q
    if x1 == x2 and (y1 + y2) % P_MOD == 0: return None
    lam = ((3*x1*x1 + A) * pow(2*y1, -1, P_MOD) if P == Q else (y2 - y1) * pow(x2 - x1, -1, P_MOD)) % P_MOD
    x3 = (lam * lam - x1 - x2) % P_MOD
    return (x3, (lam * (x1 - x3) - y1) % P_MOD)

def mul(k, P):                                # double-and-add
    R = None
    for bit in bin(k)[2:]:
        R = add(R, R)
        if bit == "1": R = add(R, P)
    return R

G = pts[1]
n = next(k for k in range(1, N + 1) if N % k == 0 and mul(k, G) is None)   # order of G
Q = mul(SECRET % n, G)                        # Alice's public key
m = int(np.ceil(np.sqrt(n)))                  # baby-step giant-step
baby = {}; R = None
for j in range(m): baby.setdefault(R, j); R = add(R, G)
step, R = mul(n - m, G), Q                    # step = -mG
for i in range(m):
    if R in baby: print(f"order of G = {n}; recovered d = {i*m + baby[R]} after {m + i} group ops"); break
    R = add(R, step)
plt.scatter(*np.array(pts).T, s=2); plt.title(f"{N} points mod {P_MOD}"); plt.show()
```

With the defaults the curve has $N = 1068$ points, within 58 of $p + 1 = 1010$ and inside the Hasse bound of 63.5. The chosen G has order only 267, so the script "recovers" $d = 243$: the secret 777 only matters modulo the order, and $777 - 2 \cdot 267 = 243$. Things to try:

- **Factor N.** $1068 = 2^2 \cdot 3 \cdot 89$. A real attacker would not run baby-step giant-step on the full group but on the pieces of size 4, 3 and 89, as Pohlig–Hellman suggests. Can you find A, B for $p = 1009$ that make N prime?
- **Scale p.** Try $p = 10007$ and $p = 100003$, keeping a prime-order or near-prime-order curve. The number of group operations grows like $\sqrt{N}$: it is about 320 for $p = 100003$. Extrapolate to $N \approx 2^{256}$.
- **Break the curve.** Set $A = 0$, $B = 0$, which makes $4A^3 + 27B^2 = 0$. The count comes out as exactly $p + 1$, and the script then crashes while looking for the order of G. Which point is to blame, and what group do the remaining points form?

78.6 The challenge

No answers are given.

1. **Intuition.** On the real curve, a line through two points of an elliptic curve meets it in a third. Why must a line through two points of a *conic* (a circle, say) fail to give a useful "third point", and what replaces the group law there? Then explain, using only the pictures, why the points of order 2 on $y^2 = x^3 + ax + b$ are exactly those with $y = 0$, and why there are at most three of them.
2. **Derivation.** Show that a point $P = (x, y)$ has order 3 exactly when it is an inflection point of the curve. Derive the polynomial whose roots are the x-coordinates of the points of order 3, and check that it has degree 4. Then prove that the map $x \mapsto x^3 + ax + b$ cannot be a square for *every* $x \in \mathbb{F}_p$, so that $\#E(\mathbb{F}_p) < 2p + 1$.
3. **Implementation.** Implement Pollard's rho for the ECDLP (partition the group into three sets by x mod 3 and walk by $R \mapsto R + G$, $2R$, or $R + Q$; detect a cycle with Floyd's tortoise and hare). Measure the number of steps for prime group orders n between 10^3 and 10^7, and compare the average with $\sqrt{\pi n / 2}$.
4. **Open investigation.** For $p = 1009$, compute $N - (p + 1)$ for every pair (a, b) with $4a^3 + 27b^2 \neq 0$, and normalise by $2\sqrt{p}$. Plot the histogram. Does it look like a semicircle? Repeat for other primes and for a fixed curve over many primes. (The Sato–Tate conjecture, proved for most curves only in 2011, predicts a distribution here; find out which one by experiment.)

78.7 Loose threads

The hook asked how one repeated number broke an unbroken system. The **group** is real and strong: the chord-and-tangent law makes the points of a cubic into an abelian group, the same formulas work over $\mathbb{F}_p$, and the best known attack on the discrete logarithm in a well-chosen curve is generic, needing $\sqrt{n}$ steps, which is why 256-bit curves rival 3072-bit RSA. The **signature** is fragile: ECDSA hides the private key behind a fresh secret nonce, and repeating that nonce turns the hard problem into two linear equations. Sony's mathematics was perfect and its implementation reused k.

What we did not tell you:

- **Why the group law exists at all.** The first mystery points to Ch. 94, where curves of genus one, complex tori and divisors live.
- **How to count points on a 256-bit curve.** Brute force is hopeless at that size, yet curve designers need the exact group order. Schoof's algorithm (1985) computes it in polynomial time by computing N modulo many small primes, using the points of small order, then gluing the answers with the Chinese remainder theorem.
- **Whether randomness can be trusted.** The second mystery points to Ch. 81.
- **What pairings make possible.** The third mystery points to Ch. 82.
- **What quantum computers do here.** Shor's period-finding algorithm (Ch. 77) solves the ECDLP too, and with fewer qubits than factoring a comparable RSA modulus. Elliptic curves are not a refuge from quantum computers; lattices may be.
- **Fermat's last theorem.** The proof by Wiles in 1994 runs through elliptic curves over $\mathbb{Q}$ and the modularity of their point counts: the same numbers $N - (p + 1)$ that you histogrammed in the challenge, arranged into a single object.

79.1 The hook

Look at a QR code on a restaurant menu or a concert poster. Many have a logo pasted right over the middle: a coffee cup, a band's face, a company emblem. Those pixels are simply gone, replaced by something that is not data at all. Point your phone at it anyway. It scans on the first try.

Scratch a music CD with a key and it will usually still play. The disc can lose about 4,000 consecutive bits, some 2.5 mm of track, and reproduce the sound *exactly*, not approximately. In 1989 Voyager 2 sent pictures of Neptune from 4.4 billion kilometres away, with a transmitter of about 20 watts, roughly a refrigerator light bulb. By the time the signal reached Earth it was far weaker than the noise in the receiving antennas, and yet the images arrived essentially without a wrong pixel.

None of these systems has a way to ask for the data again. The QR code cannot re-print itself; Neptune is not taking requests. The missing information is *recovered*, computed from what remains. That sounds impossible: how can you reconstruct what was destroyed?

The answer is that nothing useful was destroyed. Before sending, the data was dressed in carefully designed redundancy, so that any small enough damage leaves a pattern that points back, unambiguously, to the original. This chapter is about how to design that redundancy: what makes it efficient, how the receiver finds and fixes errors it cannot see, and where the limits lie.

79.2 The big idea

The naive way to protect a bit is to repeat it: send `000` for 0 and `111` for 1, and decode by majority vote. One flipped bit is corrected. But you have tripled the cost, and if you want to survive two flips you must send five copies. There must be a better way.

The key idea is **distance**. Think of every possible received word as a point in a space, and the words you actually send, the **codewords**, as a few special points. Noise moves a codeword a short distance. If the codewords are spread so far apart that the little "clouds" of damaged versions around them never overlap, then any received word lies in exactly one cloud, and the receiver simply snaps it back to the centre. Error correction is **nearest-neighbour decoding**, and code design is the art of packing as many non-overlapping clouds as possible into the space.

An analogy: the NATO spelling alphabet. Over a crackling radio, "B" and "D" and "E" sound alike, but "Bravo", "Delta" and "Echo" do not. The longer words carry redundancy, but it is *arranged* so that the words are far apart in sound. A burst of static that blurs one syllable still leaves a word closer to the right one than to any other.

Three questions organise the chapter.

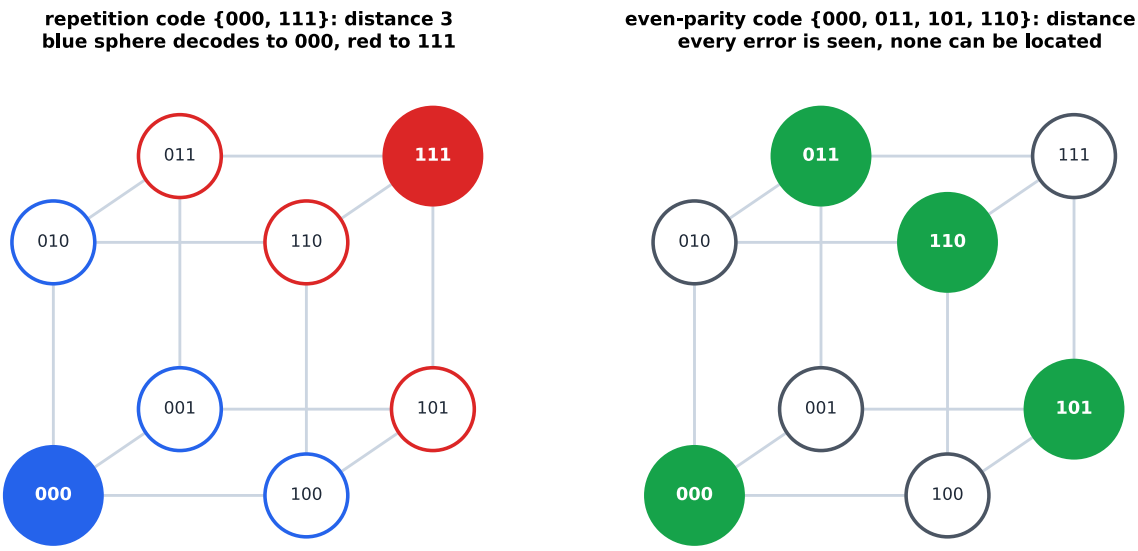
1. **Geometry.** How far apart must codewords be to correct t errors, and how many codewords can fit?
2. **Algebra.** Searching for the nearest of 2^k codewords is hopeless when $k = 200$. Codes built from linear algebra, and then from polynomials, let the receiver compute the error instead of searching for it.
3. **Erasures versus errors.** A logo on a QR code is damage *at a known place*. A scratch the reader cannot detect is damage at an unknown place. Knowing where damage is turns out to be worth exactly a factor of two.

79.3 The mathematics

Hamming distance

> **Codes and distance**
>
> A **block code** of length n over an alphabet A is a set $C \subseteq A^n$ of codewords. The **Hamming distance** $d(x, y)$ between two words is the number of positions where they differ. The **minimum distance** of C is $d = \min\{d(x, y) : x, y \in C,\ x \neq y\}$. A code with $|C| = q^k$ codewords over a q-letter alphabet has **rate** k/n.

Hamming distance is a genuine metric (Ch. 60 lists it among its examples): it is symmetric, zero only for equal words, and satisfies the **triangle inequality** $d(x, z) \leq d(x, y) + d(y, z)$, because any position where x and z differ must be one where x differs from y or y differs from z. The **Hamming ball** of radius t around c is the set of all words within distance t of c: the "cloud" of the big idea.



Codes as points on the cube $\{0,1\}^3$, where neighbours differ in one bit. Left: distance 3; the radius-1 balls around the two codewords tile the cube, so every single error is corrected. Right: distance 2; a single error always lands on a non-codeword (detected), but that word is equally close to three codewords, so it cannot be corrected.

Result 1: distance decides everything

Detection and correction

A code with minimum distance d can **detect** any pattern of up to $d-1$ errors, and **correct** any pattern of up to $t=\lfloor (d-1)/2 \rfloor$ errors by nearest-codeword decoding.

Proof. Detection. If c is sent and between 1 and $d-1$ positions change, the received word r satisfies $0 < d(c,r) \le d-1$. Since distinct codewords are at least d apart, r is not a codeword, so the receiver sees that something is wrong.

Correction. Suppose c is sent and r is received with $d(c,r) \le t$. Let $c' \neq c$ be any other codeword. By the triangle inequality,

$$d \le d(c,c') \le d(c,r) + d(r,c') \quad\Longrightarrow\quad d(r,c') \ge d - t \ge 2t+1-t = t+1 > t \ge d(c,r).$$

So c is strictly the closest codeword to r, and nearest-codeword decoding returns it. ■

Both bounds are sharp. With d errors, c can be turned into another codeword, and nobody can tell. With $t+1$ errors, r can land at distance $t+1$ from c and $d-t-1 \le t+1$ from some c', and the decoder may be fooled. The parity code on the right of the figure has $d=2$, so it detects one error and corrects none; the repetition code on the left has $d=3$ and corrects one.

Result 2: the sphere-packing bound

Large distance costs codewords. How many can a binary code of length n correcting t errors have?

Hamming bound

A binary code of length n that corrects t errors has

$$|C| \sum_{i=0}^{t} \binom{n}{i} \;\le\; 2^n.$$

Proof. A ball of radius t around a word contains the word itself, the $\binom{n}{1}$ words differing in one position, the $\binom{n}{2}$ differing in two, and so on: $V = \sum_{i \le t} \binom{n}{i}$ words. The proof of Result 1 shows that if the code corrects t errors then balls of radius t around distinct codewords are disjoint (a word in two balls would be decoded two ways). So $|C|$ disjoint balls of V words each fit inside the 2^n words of the whole space. ■

A code meeting the bound with equality is **perfect**: its balls tile the space with nothing left over. The repetition code of length 3 is perfect: $2 \cdot (1+3) = 8 = 2^3$. So is the code of the next section, with $16 \cdot (1+7) = 128 = 2^7$, and so is the remarkable binary **Golay code** of length 23 with 2^{12} codewords correcting 3 errors: $2^{12}\left(1+23+253+1771\right) = 2^{12} \cdot 2^{11} = 2^{23}$. Apart from repetition codes and these families, there are no other perfect binary codes; that was a hard theorem of the 1970s.

Linear codes: let the algebra search for you

Use the alphabet $\mathbb{F}_2 = \{0,1\}$ with addition mod 2 (XOR), so that words of length n form the vector space $\mathbb{F}_2^n$ of Ch. 9.

Linear code

A **linear** $[n,k,d]$ **code** is a k-dimensional subspace $C \subseteq \mathbb{F}_2^n$ with minimum distance d. It has a $k \times n$ **generator matrix** $\mathbf{G}$ whose rows form a basis, so the codewords are $\mathbf{mG}$ for messages $\mathbf{m} \in \mathbb{F}_2^k$, and an $(n-k) \times n$ **parity-check matrix** $\mathbf{H}$ whose null space is C: $\mathbf{c} \in C \iff \mathbf{Hc}^{\mathsf{T}} = \mathbf{0}$.

Linearity buys two things at once. First, the **minimum distance equals the minimum weight** (number of 1s) of a nonzero codeword: $d(\mathbf{x},\mathbf{y}) = \mathrm{wt}(\mathbf{x}-\mathbf{y})$, and $\mathbf{x}-\mathbf{y}$ is again a codeword. Second, the **syndrome** of a received word $\mathbf{r} = \mathbf{c} + \mathbf{e}$ depends only on the error:

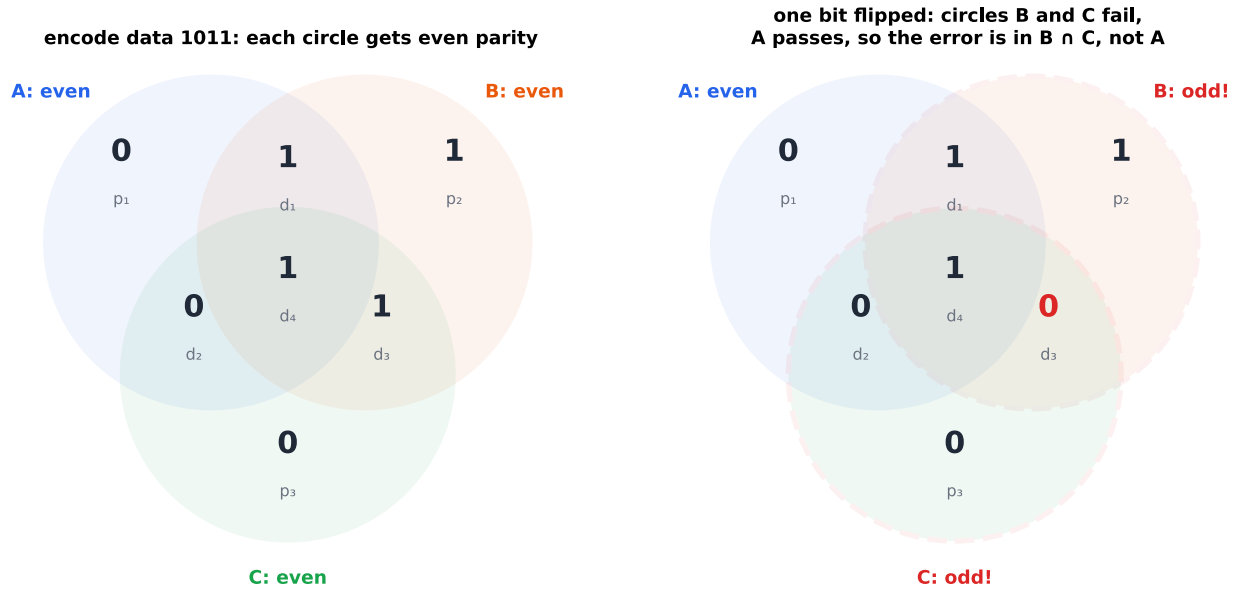
$$\mathbf{s} = \mathbf{H}\mathbf{r}^{\mathsf{T}} = \mathbf{H}\mathbf{c}^{\mathsf{T}} + \mathbf{H}\mathbf{e}^{\mathsf{T}} = \mathbf{H}\mathbf{e}^{\mathsf{T}}.$$

The receiver never needs to know what was sent. If $\mathbf{e}$ has a single 1, in position j, then $\mathbf{s}$ is column j of $\mathbf{H}$. So: if all columns of $\mathbf{H}$ are distinct and nonzero, any single error can be located by reading the syndrome, and $d \geq 3$. (The null-space picture of Ch. 9 §9.6 is exactly what is happening.)

Richard Hamming turned this into the most economical possible design in 1950. Take as the columns of $\mathbf{H}$ *all* the nonzero binary vectors of length 3, in counting order:

$$\mathbf{H} = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}.$$

Column j is the number j in binary (least significant bit on top). This is the **Hamming** $[7,4,3]$ **code**: 7 bits carry 4 data bits, at rate $4/7$ instead of the repetition code's $1/3$, and the syndrome of a single error *is the binary address of the wrong bit*. Positions 1, 2 and 4 (one 1 in their column) hold parity bits p_1, p_2, p_3; positions 3, 5, 6, 7 hold data $d_1, \ldots, d_4$. Each row of $\mathbf{H}$ is one parity rule, and the three rules are three overlapping circles.



The Hamming code as three parity circles. Each circle must contain an even number of 1s. A single flipped bit upsets exactly the circles that contain it, and each of the seven regions lies inside a different combination of circles, so the pattern of failures names the culprit. Here B and C fail and A passes: the error is d_3, at position $6 = 110_2$.

Cyclic codes and CRCs: codes as polynomials

Write a word $(c_0, \ldots, c_{n-1})$ as a polynomial $c(x) = c_0 + c_1 x + \cdots + c_{n-1}x^{n-1}$ over $\mathbb{F}_2$. A **cyclic shift** of the word is multiplication by x, followed by reducing x^n to 1, that is, working in the ring $\mathbb{F}_2[x]/(x^n - 1)$ of Ch. 56. A linear code is **cyclic** if every cyclic shift of a codeword is a codeword. Algebraically, cyclic codes are exactly the ideals of that ring, and every one has the form

$$C = \{\, m(x)\, g(x) \;:\; \deg m < n - \deg g \,\},$$

for a **generator polynomial** $g(x)$ that divides $x^n - 1$. Over $\mathbb{F}_2$, $x^7 + 1 = (x+1)(x^3 + x + 1)(x^3 + x^2 + 1)$, and $g(x) = x^3 + x + 1$ generates a $[7,4,3]$ cyclic code equivalent to Hamming's. Encoding is now polynomial multiplication, which hardware does with a shift register and a few XOR gates.

The same division trick gives the **cyclic redundancy check** (CRC) on every Ethernet frame, USB packet and ZIP file. To protect a message $m(x)$, append the remainder $r(x) = x^r m(x) \bmod g(x)$, where $r = \deg g$; the transmitted word $x^r m(x) + r(x)$ is then divisible by $g(x)$. With $g = x^3 + x + 1$ (bits `1011`) and message `1101`, the remainder of `1101000` is `001`, and `1101001` is sent. The receiver divides by g and accepts only remainder zero. If g has a nonzero constant term, every **burst** of errors confined to r consecutive positions is detected: such an error is $x^i b(x)$ with $\deg b < r$ and $b \neq 0$, and g can divide neither x^i (it is not a power of x) nor b (whose degree is too small). CRC-32 detects every burst up to 32 bits long. It *detects*; it does not correct. For that we need bigger fields.

Reed–Solomon codes: data as a polynomial

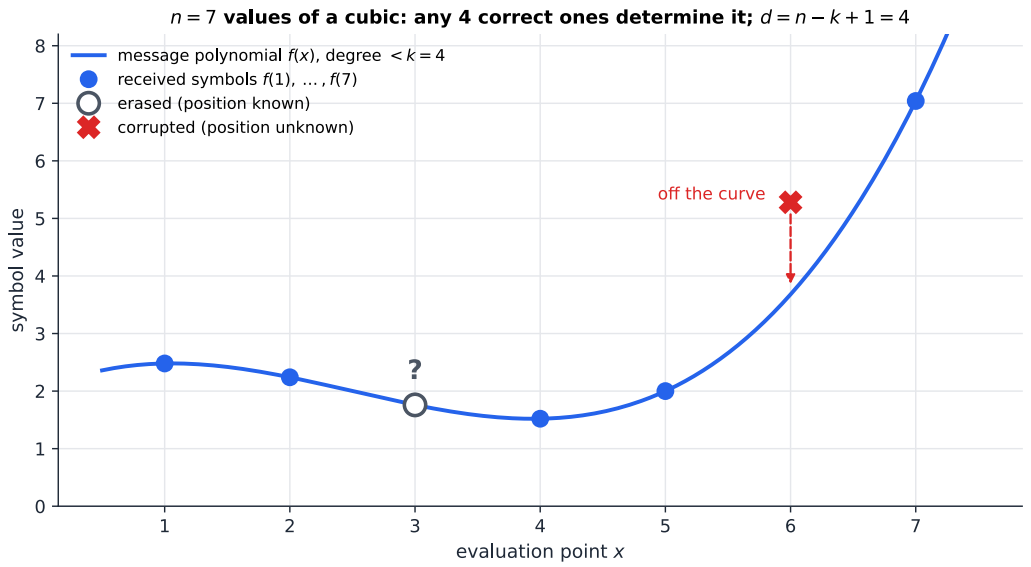
Bits flip one at a time, but scratches, dust and logos destroy whole **symbols**: bytes, or blocks of pixels. Reed and Solomon (1960) chose a large alphabet, a finite field $\mathbb{F}_q$ such as $\mathbb{F}_{2^8}$ whose elements are bytes (Ch. 57), and a beautifully simple idea.

Reed–Solomon code

Fix distinct points $\alpha_1, \ldots, \alpha_n \in \mathbb{F}_q$ (so $n \leq q$) and $k \leq n$. A message $(m_0, \ldots, m_{k-1}) \in \mathbb{F}_q^k$ becomes the polynomial $f(x) = m_0 + m_1 x + \cdots + m_{k-1}x^{k-1}$, and its codeword is the list of values

$$\big(f(\alpha_1),\, f(\alpha_2),\, \ldots,\, f(\alpha_n)\big) \in \mathbb{F}_q^n.$$

Send n samples of a curve that is determined by k of them. The extra $n - k$ samples are the redundancy.



Reed–Solomon, drawn over the real numbers for intuition (real codes use a finite field). The message is a cubic ($k = 4$) and seven values are sent. Any four correct values pin the cubic down, so up to three erasures can be filled in; an undetected wrong value, like the red cross, costs twice as much to fix.

Result 3: Reed–Solomon codes are as good as possible

How large can the minimum distance of *any* code be? There is a simple ceiling.

Singleton bound, and Reed–Solomon meets it

(a) Any code of length n with q^k codewords over a q-letter alphabet has $d \le n - k + 1$. (b) The Reed–Solomon code has $d = n - k + 1$ exactly.

Proof. (a) Delete the last $d - 1$ positions of every codeword. Two distinct codewords differ in at least d places, so they still differ after deleting $d - 1$ of them: the shortened words, of length $n - d + 1$, are all distinct. There are q^k of them and only q^{n-d+1} possible words of that length, so $k \le n - d + 1$.

(b) The code is linear (adding messages adds polynomials and their values), so d is the minimum weight of a nonzero codeword. A nonzero polynomial f of degree at most $k - 1$ has at most $k - 1$ roots in a field, so at most $k - 1$ of the values $f(\alpha_i)$ are zero, and at least $n - k + 1$ are nonzero. Hence every nonzero codeword has weight $\ge n - k + 1$, and with (a), $d = n - k + 1$. ■

Codes meeting the Singleton bound are called **maximum distance separable** (MDS). Combined with Result 1 and a small extension of it to erasures, Result 3 says what a Reed–Solomon decoder can do: with s erasures (positions known) and e errors (positions unknown), it recovers the message whenever

$$2e + s \le n - k.$$

An erasure costs one redundant symbol, an error costs two: knowing *where* damage is halves its price. With only erasures, any k surviving values determine f by Lagrange interpolation, which is the uniqueness of the interpolating polynomial in Ch. 22 §22.5 carried over to a finite field.

That answers the hook. A QR code splits its data into blocks, each a Reed–Solomon codeword over $\mathbb{F}_{2^8}$. At the highest error-correction level, H, the smallest code has 26 bytes of which 17 are redundant, enough to fix 8 wrong bytes, about 30 % of the block. A designer pasting a logo over the centre is spending part of that budget on purpose. The CD uses two Reed–Solomon codes over bytes with the data shuffled between them, so that a long scratch becomes many short, correctable damages spread across many codewords. Deep-space links use a $(255, 223)$ Reed–Solomon code, correcting 16 byte errors in every 255, wrapped around a convolutional code.

? How good can a code be?

The repetition code drives errors to zero only by driving the rate to zero. Hamming's code has rate $4/7$ but corrects only one error in seven. Is there a trade-off you cannot beat? Shannon proved in 1948 that for a channel flipping bits with probability p, every rate below $1 - H_b(p)$ (the binary entropy of Ch. 33) is achievable with error probability *as small as you like*, and no rate above it is. His proof used random codes and was not constructive at all. What that capacity is, why random codes reach it, and how LDPC and polar codes finally got there in practice, is Ch. 80.

79.4 The algorithm

Two decoders, one per idea. The Hamming decoder computes a syndrome and flips one bit. The Reed–Solomon decoder works over the prime field $\mathbb{F}_{929}$ (the field used by the PDF417 barcode on many boarding passes and driving licences) and recovers the message by interpolation.

```
import numpy as np
from itertools import combinations

# --- Hamming(7,4): column j of H is j in binary, positions p1 p2 d1 p3 d2 d3 d4 ---
H = np.array([[(j >> i) & 1 for j in range(1, 8)] for i in range(3)])
DATA_POS = [2, 4, 5, 6]                       # 0-based positions of d1..d4

def ham_encode(d):
    c = np.zeros(7, dtype=int); c[DATA_POS] = d
    for i, pos in enumerate([0, 1, 3]):       # parity bit i fixes row i of H
        c[pos] = H[i] @ c % 2
    return c

def ham_decode(r):
    s = H @ r % 2
    j = s[0] + 2 * s[1] + 4 * s[2]            # syndrome = position of the error
    r = r.copy()
    if j: r[j - 1] ^= 1
    return r[DATA_POS]

c = ham_encode([1, 0, 1, 1]); r = c.copy(); r[5] ^= 1
print(c, r, ham_decode(r))                    # [0 1 1 0 0 1 1] [0 1 1 0 0 0 1] [1 0 1 1]

# --- Reed-Solomon over the prime field GF(929): evaluate, then interpolate ---
P = 929
def rs_encode(msg, n):                        # msg = k coefficients, codeword = f(1..n)
    return [sum(m * pow(x, i, P) for i, m in enumerate(msg)) % P for x in range(1, n + 1)]

def interpolate(pts, x0):                     # Lagrange: value at x0 of the poly through pts
    total = 0
    for xi, yi in pts:
        num = den = 1
        for xj, _ in pts:
            if xj != xi: num, den = num * (x0 - xj) % P, den * (xi - xj) % P
        total += yi * num * pow(den, -1, P)
    return total % P

def rs_decode_bruteforce(word, k):            # try k-subsets; exponential, for illustration only
    n = len(word)
    known = [(x, y) for x, y in zip(range(1, n + 1), word) if y is not None]
    t = (len(known) - k) // 2                 # errors we can afford: 2e + erasures <= n - k
    for sub in combinations(known, k):
        cand = [interpolate(sub, x) for x in range(1, n + 1)]
        if sum(c != y for c, y in zip(cand, word) if y is not None) <= t:
            return cand
    return None

cw = rs_encode([3, 1, 4, 1], n=7)             # k = 4, n = 7, d = 4
print(cw)                                     # [9, 29, 69, 135, 233, 369, 549]
bad = cw.copy(); bad[2] = None; bad[5] = (bad[5] + 100) % P   # one erasure, one error
print(rs_decode_bruteforce(bad, 4) == cw)     # True: 2*1 + 1 <= 7 - 4
```

The Hamming part reproduces the Venn figure: data `1011` becomes `0110011`, the flipped sixth bit gives syndrome 6, and the data comes back. The Reed–Solomon part erases one symbol and corrupts another, a damage pattern with $2e + s = 3 = n - k$, right at the limit, and still recovers the codeword exactly.

Complexity. Hamming decoding is a matrix–vector product: $O(n \log n)$ bit operations for a length-n Hamming code. The Reed–Solomon decoder above is deliberately naive. It tries up to $\binom{n}{k}$ subsets, which is fine for $n = 7$ and absurd for the $(255, 223)$ deep-space code, where $\binom{255}{223} \approx 5 \times 10^{40}$. Real decoders find the errors algebraically. The **Berlekamp–Welch** idea fits in three lines. Let $E(x)$ be the unknown **error-locator** polynomial, monic of degree e, vanishing exactly at the error positions. Then at *every* evaluation point,

$$y_i \, E(\alpha_i) = f(\alpha_i) \, E(\alpha_i) = Q(\alpha_i), \qquad Q := fE, \ \deg Q < k + e,$$

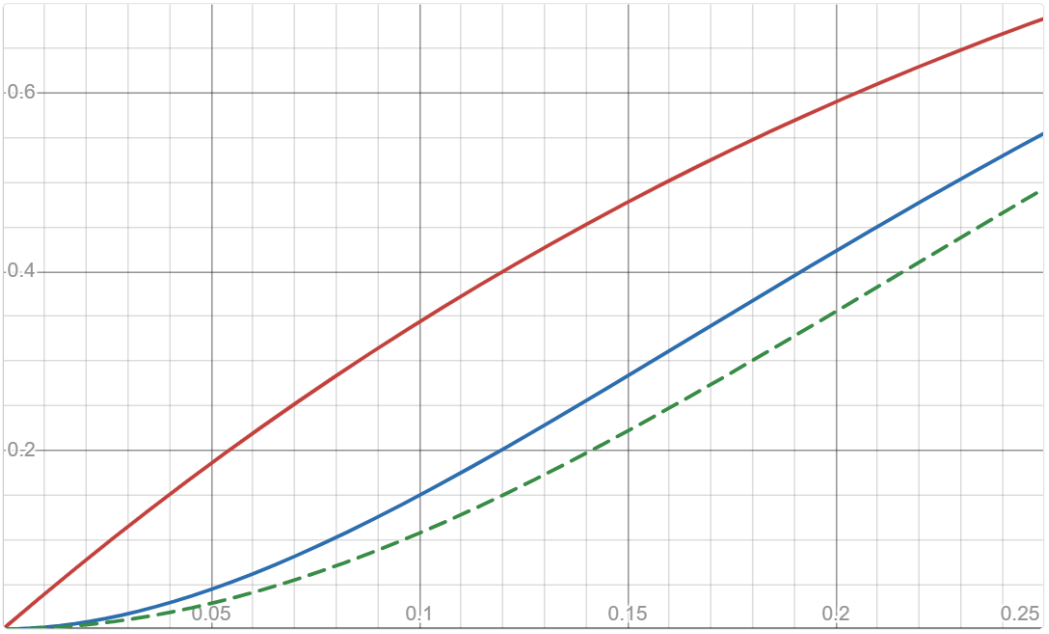
because where y_i is wrong, $E(\alpha_i) = 0$ kills both sides. These are n *linear* equations in the $k + 2e \le n$ unknown coefficients of E and Q. Solve them by Gaussian elimination (Ch. 8 §8.7) in $O(n^3)$, then divide: $f = Q/E$. The nonlinear problem "where are the errors?" has become linear algebra. Production decoders (Berlekamp–Massey with Chien search and Forney's formula) do the same job in $O(n^2)$ or better.

Failure cases. Every decoder has a breaking point, and its behaviour past that point matters.

- *Too many errors.* With $t + 1$ errors, a nearest-codeword decoder may confidently return the *wrong* codeword. For the Hamming code, two errors always produce a nonzero syndrome pointing at a third, innocent bit; the "correction" makes three errors. A system that must know when it failed adds an overall parity bit (the extended $[8, 4, 4]$ code corrects one error *and* detects two).
- *Burst errors.* A scratch destroys many neighbouring bits. Bit-level codes are helpless against it; symbol-level codes plus **interleaving** (spreading each codeword across the medium) turn one long burst into many small, correctable damages.
- *The wrong noise model.* Codes designed for independent flips can do badly on channels where noise comes in bursts or fades. The design starts from the channel, not from the code.
- *Detection is not security.* A CRC catches accidents, but anyone can recompute it after tampering. Protection against an adversary needs the keyed authentication tags of Ch. 77, not a checksum.

79.5 The experiment

First, the formulas. A 4-bit message sent unprotected over a channel that flips each bit with probability x survives only if all four bits survive. Sent as a Hamming codeword, it survives if at most one of the seven bits flips (using the binomial distribution of Ch. 19 §19.6).



Message error probability against bit-flip probability x: uncoded (red), Hamming(7,4) (blue), triple repetition of each bit (green, dashed). At $x = 0.01$ the Hamming code cuts the failure rate from 3.9 % to 0.2 %.

Change the exponents to explore. Replace the blue curve by $1-(1-x)^{15}-15x(1-x)^{14}$, the $[15, 11, 3]$ Hamming code, which carries 11 bits instead of 4; compare it with $1-(1-x)^{11}$. The longer code is cheaper (rate $11/15$ instead of $4/7$), but its curve rises much faster: one correction per 15 bits is spread thinner than one per 7. Where on the x-axis does that difference start to matter?

Then simulate. The script sends many random 4-bit messages through a binary symmetric channel, decodes them three ways, and plots the measured error rates.

```
import numpy as np
import matplotlib.pyplot as plt

FLIP_PROBS = np.linspace(0.001, 0.2, 25)   # KNOB: channel bit-flip probabilities to test
BLOCKS = 20000                             # KNOB: 4-bit messages sent per probability
SEED = 79

rng = np.random.default_rng(SEED)
H = np.array([[(j >> i) & 1 for j in range(1, 8)] for i in range(3)])   # Hamming(7,4)
DATA = [2, 4, 5, 6]
G = np.zeros((4, 7), dtype=int)            # generator: encode each unit data vector
for row, pos in enumerate(DATA):
    c = np.zeros(7, dtype=int); c[pos] = 1
    c[[0, 1, 3]] = H @ c % 2               # parity bits are the syndrome of the data part
    G[row] = c

def run(p):
    d = rng.integers(0, 2, (BLOCKS, 4))
    raw = (rng.random(d.shape) < p).any(axis=1).mean()                    # uncoded: any flip
    rep = d.repeat(3, axis=1) ^ (rng.random((BLOCKS, 12)) < p)            # repetition x3
    rep_dec = rep.reshape(BLOCKS, 4, 3).sum(axis=2) >= 2
    rep_err = (rep_dec != d).any(axis=1).mean()
    r = (d @ G % 2) ^ (rng.random((BLOCKS, 7)) < p)                       # Hamming(7,4)
    j = (H @ r.T % 2).T @ np.array([1, 2, 4])                            # syndrome -> position
    r[np.arange(BLOCKS)[j > 0], j[j > 0] - 1] ^= 1
    ham_err = (r[:, DATA] != d).any(axis=1).mean()
    return raw, rep_err, ham_err

res = np.array([run(p) for p in FLIP_PROBS])
for lab, col in zip(["uncoded (rate 1)", "repetition x3 (rate 1/3)", "Hamming(7,4) (rate 4/7)"], res.T):
    plt.semilogy(FLIP_PROBS, np.maximum(col, 1e-5), "o-", label=lab)
plt.xlabel("bit-flip probability p"); plt.ylabel("message error rate")
plt.legend(); plt.grid(True, which="both"); plt.show()
print("at p = %.3f:" % FLIP_PROBS[5], res[5])
```

At $p \approx 0.042$ the run prints roughly `0.155 0.022 0.031`: uncoded messages fail 15.5 % of the time, Hamming-coded ones 3.1 %, and triple repetition 2.2 %. Repetition wins on reliability, but it sends 12 bits per message where Hamming sends 7. Things to try:

- **Equalise the cost.** Compare codes at the same *rate*, not the same message. Add a $[15, 11]$ Hamming code (column j of $\mathbf{H}$ is j in 4-bit binary) and send 11-bit messages. Which wins per transmitted bit?

- **Add a burst.** Instead of independent flips, flip three *consecutive* bits of each block with probability `p`. Watch the Hamming code fall apart, then interleave: send bit 1 of ten codewords, then bit 2 of each, and so on.
- **Find the wall.** Push `FLIP_PROBS` up to 0.5. All three curves converge on the same failure rate as $p \to \frac{1}{2}$. Why can no code, however clever, help at $p = \frac{1}{2}$, and what happens if you push past it to $p = 0.9$?

79.6 The challenge

No answers are given.

1. **Intuition.** A QR code at level H can survive about 30 % damage, yet a logo covering only 20 % of the symbol can still make it unreadable if placed badly. Using erasures, errors and the structure of the code (data split into several Reed–Solomon blocks, plus fixed finder patterns in three corners), explain why *where* the damage falls matters as much as how much there is.
2. **Derivation.** Prove the **Gilbert–Varshamov bound**: there exists a binary code of length n and minimum distance d with at least $2^n / \sum_{i=0}^{d-1} \binom{n}{i}$ codewords. (Hint: build the code greedily; when you can add no more words, the balls of radius $d-1$ around the codewords must cover the whole space.) Compare with the Hamming bound for $n = 15$, $d = 3$.
3. **Implementation.** Implement Berlekamp–Welch over $\mathbb{F}_{929}$: set up the $n \times (k + 2e)$ linear system, solve it by Gaussian elimination mod 929, and divide polynomials to get f. Test it on the $(7, 4)$ example above, then on $n = 100$, $k = 50$ with 25 random errors, and compare its running time with the brute-force decoder.
4. **Open investigation.** For n up to about 12, search exhaustively (or with a clever backtracking search) for the largest binary code with minimum distance 3, and compare with the Hamming bound and the Gilbert–Varshamov bound. How fast does the exhaustive search blow up? Can a random-restart greedy search match the known optimum for $n = 10$ and $n = 11$ (72 and 144 codewords)?

79.7 Loose threads

The hook asked how a QR code with a logo, a scratched CD or a faint signal from Neptune can recover data that is literally gone. The answer is geometry and algebra. Codewords are placed far apart in Hamming distance, so that damaged words still point home (Result 1), at a cost bounded by sphere packing (Result 2). Linear codes compute the error from a syndrome instead of searching for it. Reed–Solomon codes turn a block of data into a polynomial and send extra samples of it; because a low-degree polynomial has few roots, any k intact samples determine it, and the code meets the Singleton bound exactly (Result 3). Erasures, like a logo at a known place, cost half as much as errors.

What we did not tell you:

- **The limit.** The first mystery points to Ch. 80: Shannon's capacity, and the codes that approach it.
- **Convolutional codes and Viterbi decoding.** Instead of blocks, a convolutional encoder passes an endless bit stream through a shift register. Its decoder finds the most likely path through a trellis of states, a shortest-path dynamic program (Ch. 52).
- **Decoding beyond half the distance.** Result 1 seems to forbid correcting more than $(d-1)/2$ errors. But if the decoder may output a short *list* of candidates, Guruswami and Sudan (1999) showed that Reed–Solomon codes can be decoded far beyond that radius, using curves through the received points.

? Are random codes the best possible?

The Gilbert–Varshamov bound of the challenge says that, as $n \to \infty$ with $d/n = \delta$ fixed, there exist binary codes of rate at least $1 - H_b(\delta)$, and a random linear code achieves it. Seventy years later, nobody has found an explicit family of binary codes that beats it, and nobody has proved that none exists. Upper bounds from linear programming leave a wide gap. Over larger alphabets, codes built from algebraic curves *do* beat the corresponding bound, a stunning result from 1982. For binary codes, the true best rate is an open problem.

? Checking a million symbols by reading twenty

A Reed–Solomon codeword has a rigid structure: its values come from a low-degree polynomial. Suppose a prover sends you a list of a million field values and claims it is (close to) such a codeword. Could you check that claim by reading only a few dozen randomly chosen positions? Surprisingly, yes, and this "proximity test" is the engine of modern succinct proofs, which let a blockchain verify a long computation in milliseconds. How a few random queries can certify a huge object, and how this connects to proving things without revealing them, is Ch. 82.

80.1 The hook

A wire flips 11 % of the bits you send through it, at random. You want to send a file so that it arrives intact.

The obvious remedy is repetition. Send every bit three times and let the receiver take a majority vote. A bit is now lost only if two of its three copies flip, which happens with probability $3(0.11)^2(0.89) + (0.11)^3 \approx 0.034$. That is three times better, and it costs you two thirds of your throughput. Want one error in a million? Repetition needs each bit sent about 21 times (error 3.5×10^{-6}) and drops the rate to under 5 %. One error in a billion needs 39 copies. Error-free means infinitely many copies and a rate of zero. Every engineer in the 1940s took that trade-off for granted: reliability is paid for with speed, and perfect reliability costs everything.

In 1948 Claude Shannon said this is wrong. For this wire, he claimed, there are codes that send **0.49 bits of information per bit transmitted** with an error probability *as small as you like*: one in a billion, one in 10^{100}, whatever you name. The rate does not have to fall as the reliability rises. There is a single number, the channel's **capacity**, here $C = 1 - H_b(0.11) \approx 0.500$. Below it, reliability is free in the limit of long blocks. Above it, failure is certain.

Ch. 33 stated that claim and then refused to explain it. Its mystery asked two things: why a code chosen *at random* should work, and why it took until the 1990s to build codes that come close. This chapter answers the first question with a complete proof, and goes as far into the second as a single chapter can. On the way you will see where the most famous formula in communications, $C = B\log_2(1 + S/N)$, comes from, and why no radio link anywhere can work with less than -1.59 dB of energy per bit.

80.2 The big idea

Noise is random for one bit and almost deterministic for a million. If you send one bit, it either flips or it doesn't, and you cannot tell which. Send a block of $n = 10\,000$ bits, and the law of large numbers (Ch. 19) guarantees that very nearly 1100 of them flip: the standard deviation is only 31. You still don't know *which* bits flipped, but you know *how many*, to within a few percent. Figure 80.2 (right) shows the fraction of flipped bits concentrating around 0.11 as the block grows.

So the noise draws a ball around each codeword. Picture all 2^n binary words of length n as points in a huge space. Send codeword $\mathbf{x}$, and the received word $\mathbf{y}$ lands, almost surely, at Hamming distance about $0.11n$ from $\mathbf{x}$ (Ch. 79 defined Hamming distance). The set of such words is a "noise ball" around $\mathbf{x}$ containing roughly $2^{nH_b(0.11)}$ words. If the balls around different codewords do not overlap, the receiver just asks which ball $\mathbf{y}$ fell into.

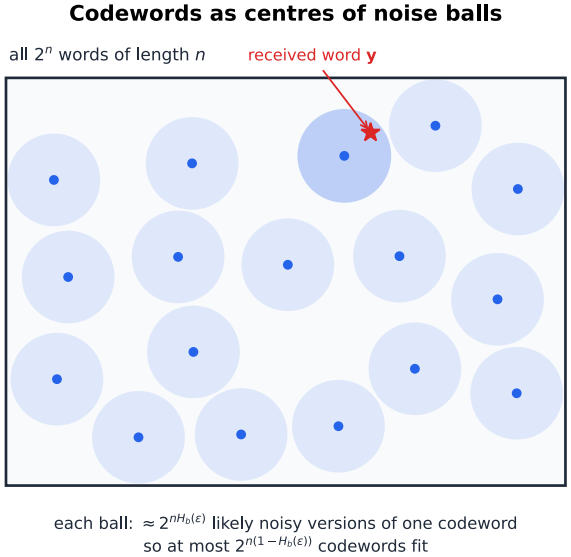
Capacity is a packing count. The space holds 2^n words. Each ball holds about $2^{nH_b(\varepsilon)}$. So at most

$$\frac{2^n}{2^{nH_b(\varepsilon)}} = 2^{n(1-H_b(\varepsilon))}$$

codewords fit, and with 2^{nR} codewords you send nR bits in n channel uses. The rate cannot exceed $1 - H_b(\varepsilon)$. That is the converse, by counting.

And random placement nearly achieves the packing. In a space of a million dimensions, balls scattered at random almost never overlap, as long as there are fewer of them than the count above. You don't need to design a clever arrangement. You need to throw darts. That is why Shannon's proof picks a code at random, and why that proof gives no help at all in building one.

The analogy. A cocktail party where everyone speaks at once is hopeless for one word at a time, but a long sentence from your friend has a statistical fingerprint, the voice, the topic and the rhythm, that no other speaker's sentence will match by accident. Long messages are distinguishable even when every single sound is ambiguous.



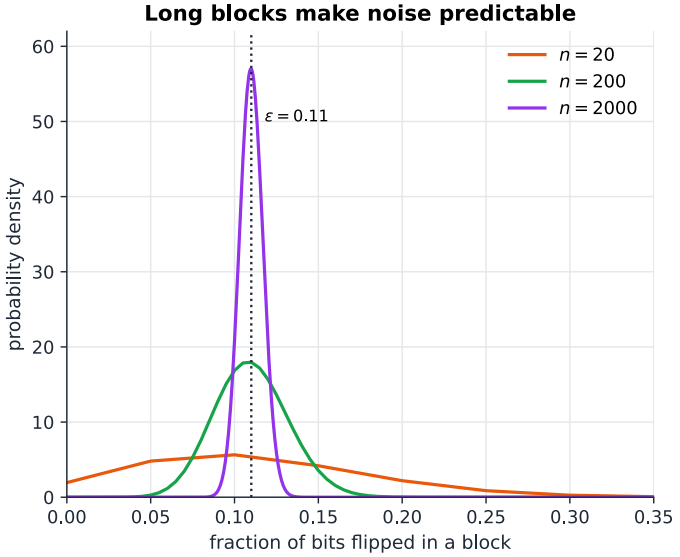


Figure 80.2 — Left: codewords (dots) as centres of noise balls in the space of all 2^n words. A received word falls, with high probability, inside the ball of the codeword that was sent. Right: the fraction of bits flipped in a block of n bits on a channel with $\varepsilon = 0.11$. For long blocks it is pinned to ε, which is what gives the balls a definite size.

80.3 The mathematics

Logarithms are base 2. $H_b(p) = -p\log p - (1-p)\log(1-p)$ is the binary entropy of Ch. 33 §33.3, where entropy, mutual information $I(X;Y)$ and KL divergence are defined. We do not repeat them.

Channels and capacity

Discrete memoryless channel and capacity

A **discrete memoryless channel** (DMC) takes an input symbol x and outputs y with probability $W(y \mid x)$, independently on each use. Its **information capacity** is

$$C = \max_{p_X} I(X;Y),$$

the largest mutual information between input and output over all input distributions.

Three channels carry most of the intuition.

- **Binary symmetric channel** BSC(ε): each bit flips with probability ε. With a uniform input, $I = H(Y) - H(Y \mid X) = 1 - H_b(\varepsilon)$, and no input does better since $H(Y) \le 1$. So $C = 1 - H_b(\varepsilon)$: 0.919 at $\varepsilon = 0.01$, 0.500 at $\varepsilon = 0.11$, zero at $\varepsilon = \tfrac12$.
- **Binary erasure channel** BEC(α): each bit is either delivered or replaced by "?" with probability α. Here $C = 1 - \alpha$, which is exactly the fraction of bits that get through. It is as if the sender knew in advance which bits would be erased. The receiver knows, and remarkably that is enough.
- **Gaussian channel**: $Y = X + Z$ with $Z \sim \mathcal{N}(0, \sigma^2)$ and a power limit $E[X^2] \le P$, treated below.

The definition of C is a maximisation. The theorem that gives it meaning is about *codes*.

Codes, rates and errors

An (n, M) **code** maps each message $w \in \{1, \dots, M\}$ to a codeword $\mathbf{x}(w)$ of n channel symbols. A decoder maps each received word to a guess $\hat{w}$. The **rate** is $R = \frac{\log M}{n}$ bits per channel use. A rate R is **achievable** if there are codes with $M \ge 2^{nR}$ and error probability tending to zero as $n \to \infty$.

Noisy-channel coding theorem (Shannon, 1948)

Every rate $R < C$ is achievable. No rate $R > C$ is achievable: for such rates the error probability stays bounded away from zero, and in fact tends to one.

We prove the achievability half for the BSC, where every step can be done by hand. The same plan works for every DMC, with "typical sets" in place of Hamming balls.

Result 1: the size of a Hamming ball

Let $V(n, r) = \sum_{k=0}^{r} \binom{n}{k}$ be the number of binary words within Hamming distance r of a fixed word.

Volume bound

For $0 < \lambda \le \tfrac12$,

$$V(n, \lambda n) \le 2^{n H_b(\lambda)}.$$

Proof. By the binomial theorem, $1 = (\lambda + (1-\lambda))^n \ge \sum_{k \le \lambda n} \binom{n}{k} \lambda^k (1-\lambda)^{n-k}$. Write each term as $\binom{n}{k}(1-\lambda)^n \left(\frac{\lambda}{1-\lambda}\right)^k$. Because $\lambda \le \tfrac12$, the ratio $\frac{\lambda}{1-\lambda}$ is at most 1, so its k-th power only shrinks as k grows, and for $k \le \lambda n$ it is at least $\left(\frac{\lambda}{1-\lambda}\right)^{\lambda n}$. Hence

$$1 \;\ge\; V(n,\lambda n)\,(1-\lambda)^n \left(\frac{\lambda}{1-\lambda}\right)^{\lambda n} = V(n,\lambda n)\,\lambda^{\lambda n}(1-\lambda)^{(1-\lambda)n} = V(n,\lambda n)\,2^{-n H_b(\lambda)}. \qquad \square$$

The bound is tight in the exponent. For $n = 1000$ and $\lambda = 0.11$, $\log_2 V = 495.5$ while $n H_b(\lambda) = 499.9$: the ball really does hold about 2^{nH_b} words, give or take a factor polynomial in n.

Result 2: random codes achieve every rate below capacity

Random coding on the BSC

Fix $\varepsilon < \tfrac12$, a margin $\delta > 0$ with $\rho = \varepsilon + \delta < \tfrac12$, and a rate $R < 1 - H_b(\rho)$. Then for every n there is a code with $M = 2^{nR}$ codewords whose error probability, averaged over the messages, is at most

$$\frac{\varepsilon(1-\varepsilon)}{n\delta^2} + 2^{-n(1 - H_b(\rho) - R)} \;\xrightarrow[n\to\infty]{}\; 0.$$

Proof. Choose every bit of every codeword independently and uniformly at random. (We have no idea what the code looks like, and we don't need to.) The decoder is simple: given $\mathbf{y}$, output the unique w with $d(\mathbf{x}(w), \mathbf{y}) \le \rho n$. If there is none, or more than one, declare an error.

Suppose message w is sent. The decoder can fail in only two ways.

(a) Too much noise. The number of flips is Binomial(n, ε), with mean $n\varepsilon$ and variance $n\varepsilon(1-\varepsilon)$. Chebyshev's inequality gives

$$P\big(d(\mathbf{x}(w), \mathbf{y}) > \rho n\big) \le P\big(|\text{flips} - n\varepsilon| \ge n\delta\big) \le \frac{\varepsilon(1-\varepsilon)}{n\delta^2}.$$

(b) An impostor. Some other codeword $\mathbf{x}(w')$ lies within ρn of $\mathbf{y}$. Here is the key: $\mathbf{x}(w')$ was drawn independently of $\mathbf{x}(w)$ and of the noise, hence independently of $\mathbf{y}$, and it is uniform on all 2^n words. So the chance that it lands in the ball of radius ρn around $\mathbf{y}$ is the ball's share of the space. By Result 1,

$$P\big(d(\mathbf{x}(w'), \mathbf{y}) \le \rho n\big) = \frac{V(n, \rho n)}{2^n} \le 2^{-n(1-H_b(\rho))}.$$

There are fewer than 2^{nR} impostors, so by the union bound, (b) has probability at most $2^{nR} \cdot 2^{-n(1-H_b(\rho))}$.

Adding (a) and (b) bounds the error probability for each message, *averaged over the random choice of code*. An average over codes is a weighted mean of the averages of individual codes, so at least one code does at least as well as the mean. $\square$

Since δ can be as small as we like, every rate below $1 - H_b(\varepsilon)$ is achievable. Two remarks finish the job. First, "average over messages" can be upgraded to "worst message": throw away the worse half of the codewords. The survivors all have error at most twice the average, and the rate drops by only $1/n$. Second, the proof is an instance of the **probabilistic method** of Ch. 32: it shows that a good code exists by showing that a random one is good on average, and it never exhibits one.

The converse in one line. Fano's inequality says that if the decoder errs with probability P_e, the remaining uncertainty about the message is at most $H(W \mid \mathbf{Y}) \le 1 + P_e\, nR$. And n channel uses can carry at most nC bits of mutual information: $I(W;\mathbf{Y}) \le nC$. A uniform message has $nR = H(W) = I(W;\mathbf{Y}) + H(W \mid \mathbf{Y}) \le nC + 1 + P_e nR$, so

$$P_e \;\ge\; 1 - \frac{C}{R} - \frac{1}{nR}.$$

Above capacity the error probability cannot vanish. This is the counting argument of §80.2, made rigorous. A sharper argument, the **strong converse**, shows that the error probability tends to *one*.

> **? The codes that finally got there**
>
> Result 2 proves that good codes exist, and the experiment in §80.5 will show that finding them by brute force is hopeless: decoding a random code means comparing against 2^{nR} codewords. The codes that reach capacity in practice impose structure. LDPC codes (Gallager, 1960, forgotten until 1996) and turbo codes (1993) come within a fraction of a dB, decoded by passing beliefs along a sparse graph. Polar codes (Arıkan, 2009, now in 5G) are the first *provably* capacity-achieving codes with an $O(n \log n)$ decoder. They work because combining two copies of a channel splits it into one better and one worse channel, and repeating this pushes almost every channel to be perfect or useless. Why must that split polarize, rather than settle somewhere in between? The proof is a martingale convergence argument: see Ch. 97.

Result 3: the Gaussian channel and the Shannon limit

For the channel $Y = X + Z$ with Gaussian noise of variance σ^2 and input power at most P, the entropies are *differential* entropies $h(\cdot)$, the continuous analogue flagged at the end of Ch. 33. Two facts do all the work. Noise independent of the input gives $h(Y \mid X) = h(Z) = \tfrac{1}{2}\log(2\pi e\sigma^2)$. And among all variables with a given variance, the Gaussian has the largest differential entropy, so $h(Y) \le \tfrac{1}{2}\log\big(2\pi e(P+\sigma^2)\big)$, since $\mathrm{Var}(Y) \le P + \sigma^2$. Subtracting,

$$C = \max I(X;Y) = \frac{1}{2}\log_2\!\left(1 + \frac{P}{\sigma^2}\right) \text{ bits per real sample,}$$

with equality for a Gaussian input. A channel of bandwidth B carries $2B$ independent real samples per second (the sampling theorem of Ch. 16), and white noise of spectral density $N_0/2$ (Ch. 21 §21.6) gives noise power $N = N_0 B$. This is the **Shannon–Hartley theorem**:

$$C = B\log_2\!\left(1 + \frac{S}{N}\right) \text{ bits per second.}$$

A 3 kHz telephone line at 30 dB SNR ($S/N = 1000$) has $C = 3000\log_2(1001) \approx 29.9$ kbit/s. The last generation of analogue modems, at 33.6 kbit/s over slightly better lines, ran within a whisker of it. Splitting power among several parallel channels of different quality is the "water-filling" problem solved with Lagrange multipliers in Ch. 6 §6.11.

> **The Shannon limit**
>
> On an AWGN channel, reliable communication at any rate requires
>
> $$\frac{E_b}{N_0} > \ln 2 \approx 0.693 \quad (-1.59 \text{ dB}),$$
>
> where E_b is the energy spent per information bit.

Proof. At rate R bits per real sample, each sample carries energy $E_s = RE_b$, and the noise variance per sample is $\sigma^2 = N_0/2$. So $P/\sigma^2 = 2RE_b/N_0$, and $R < C$ requires

$$R < \frac{1}{2}\log_2\!\left(1 + \frac{2RE_b}{N_0}\right) \quad\Longleftrightarrow\quad \frac{E_b}{N_0} > \frac{2^{2R}-1}{2R}.$$

The right side increases with R. As $R \to 0$, $2^{2R} = e^{2R\ln 2} = 1 + 2R\ln 2 + O(R^2)$, so the bound decreases to $\ln 2$. $\square$

You can buy speed with energy, or save energy by going slowly, but below -1.59 dB no amount of slowness, bandwidth or cleverness helps. Figure 80.1 (right) shows the whole trade-off. Uncoded binary signalling needs 9.6 dB to reach a bit error rate of 10^{-5} at one bit per sample. The Shannon bound at that rate is 1.76 dB. The 7.8 dB between them is the room in which coding theory has worked for seventy years: a factor of six in transmitter power, or in battery life, or in the

distance to a space probe.

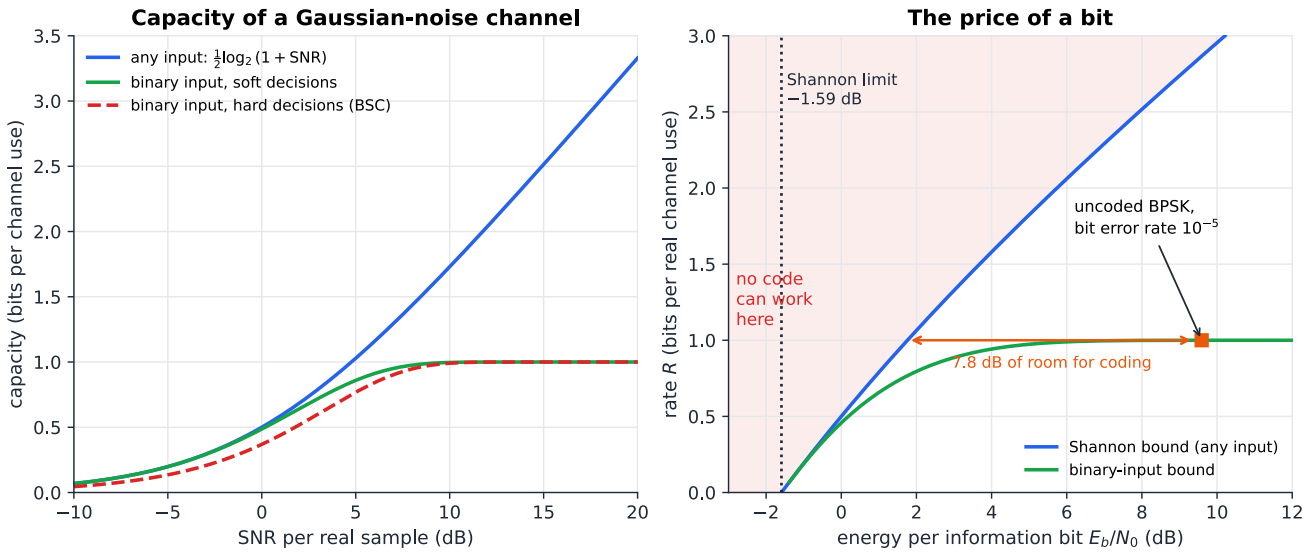

Figure 80.1 — Left: capacity versus SNR. Restricting the input to ± 1 (green) caps the rate at one bit; throwing away the analogue value and keeping only the sign (red, dashed) costs a further fixed loss, about 2 dB at low SNR. Right: the minimum energy per bit at each rate. The shaded region is forbidden by Result 3. The vertical line is the Shannon limit, which no rate escapes.

> **Engineering note: soft decisions**
>
> At low SNR, hard decisions (rounding each received sample to a bit before decoding) multiply the required power by $\pi/2$, a loss of 1.96 dB. That is why modern receivers pass *probabilities*, not bits, to the decoder.

Coding bounds: how far apart can codewords be?

Capacity concerns *random* noise and *average* error. Ch. 79 asked a worst-case question: a code with minimum distance d corrects every pattern of fewer than $d/2$ errors. For long codes write $\delta = d/n$ for the relative distance. What rates are compatible with a given δ? Counting gives an upper and a lower bound.

- **Hamming (sphere-packing) bound.** Balls of radius $\delta n/2$ around codewords are disjoint, so $2^{nR} V(n, \delta n/2) \le 2^n$, which gives asymptotically $R \le 1 - H_b(\delta/2)$.
- **Gilbert–Varshamov bound.** Pick codewords greedily, each at distance at least δn from those chosen so far. You can only get stuck when the balls of radius δn cover the whole space, so you get at least $2^n / V(n, \delta n)$ codewords: $R \ge 1 - H_b(\delta)$ is achievable.
- **Singleton bound.** Delete $d-1$ coordinates and the codewords stay distinct, so $R \le 1 - \delta$. Reed–Solomon codes meet it exactly, but only over large alphabets.

At $\delta = 0.11$, Gilbert–Varshamov guarantees rate 0.50 and the Hamming bound forbids rates above 0.69. The true answer lies somewhere between, and nobody knows where.

> **? Is the greedy code the best code?**
>
> The Gilbert–Varshamov bound comes from the dumbest possible construction, yet for binary codes no one has ever found a family that beats it, and the best upper bound (the "linear programming bound" of McEliece, Rodemich, Rumsey and Welch, 1977) still sits well above it. Over alphabets of size $q \ge 49$, codes built from algebraic curves *do* beat Gilbert–Varshamov, a shock when it was found in 1982. For binary codes, whether $1 - H_b(\delta)$ is the true answer is one of the oldest **open problems** in coding theory.

Compression: the same picture, run backwards

Source coding (Ch. 33 §33.3) and channel coding are mirror images. A source of entropy H produces, in n symbols, about 2^{nH} "typical" sequences that carry nearly all the probability. A compressor indexes them with nH bits and so *removes* redundancy. A channel code *adds* structured redundancy so that noise balls do not overlap. Both rest on the same law of large numbers.

If you will tolerate some error, you can compress below the entropy. The **rate–distortion function** $R(D)$ is the fewest bits per symbol that let you reconstruct with average distortion at most D. For fair random bits with Hamming distortion, $R(D) = 1 - H_b(D)$: allowing 11 % of bits to be wrong halves the file. For a Gaussian source of variance σ^2 with squared error, $R(D) = \frac{1}{2}\log(\sigma^2/D)$, so each extra bit buys 6 dB of quality. This is the theory behind JPEG and MP3 (Ch. 76). Shannon's **separation theorem** says that compressing optimally and then channel-coding optimally loses nothing compared with any joint scheme, as long as the blocks are long. That theorem is why your phone has separate codecs and modems at all.

Correct mathematics is not a secure system

Everything above assumes *random* noise that knows nothing about your code. An adversary is not random. An error-correcting code, or a checksum such as CRC-32, detects accidents but gives no integrity against an attacker. Because CRC is linear, anyone can flip chosen bits of a message *and* fix up the checksum without knowing any key. The original Wi-Fi encryption standard, WEP, relied on a CRC for integrity and was broken in exactly this way in 2001. Integrity against an adversary needs a cryptographic message authentication code (Ch. 77), and resistance to a jammer who knows your code needs secret randomness that the jammer cannot predict (Ch. 81). A capacity theorem is a statement about a probability model. Whether your real channel fits that model is an engineering question that the theorem cannot answer.

80.4 The algorithm

Capacity is defined as a maximum over input distributions. For the BSC symmetry gives the answer, but for a lopsided channel you must compute it. The **Blahut–Arimoto algorithm** (1972) does this by alternating maximisation. It repeatedly reweights each input symbol x by 2^{D_x}, where $D_x = D\big(W(\cdot \mid x) \,\|\, p_Y\big)$ measures how distinctive the outputs of x are compared with the average output.

```
import numpy as np

def blahut_arimoto(W, tol=1e-12, max_iter=10_000):
    """Capacity (bits) of a discrete memoryless channel with transition matrix W[x, y]."""
    q = np.full(W.shape[0], 1.0 / W.shape[0])          # start from the uniform input
    for _ in range(max_iter):
        py = q @ W                                      # output distribution
        with np.errstate(divide="ignore", invalid="ignore"):
            D = np.where(W > 0, W * np.log2(W / py), 0.0).sum(axis=1)   # D(W(.|x) || p_Y)
        lower, upper = q @ D, D.max()                   # I(q) <= C <= max_x D_x
        if upper - lower < tol:
            break
        q = q * np.exp2(D); q /= q.sum()                # reweight inputs by 2^D
    return lower, q

bsc = np.array([[0.89, 0.11], [0.11, 0.89]])
z   = np.array([[1.0, 0.0], [0.5, 0.5]])               # Z-channel: a sent 1 arrives as 0 half the time
print(blahut_arimoto(bsc))   # (0.5000..., [0.5, 0.5])
print(blahut_arimoto(z))     # (0.3219..., [0.6, 0.4])
```

The stopping rule is a certificate, not a guess. For any input q, $I(q) = \sum_x q(x) D_x$ is achievable, and a standard duality argument shows that $C \le \max_x D_x$. When the two meet, you have the capacity to within `tol`. For the Z-channel the optimum sends 1s only 40 % of the time, because 1s are the fragile symbol, and the capacity is $\log_2(1.25) = 0.322$ bits.

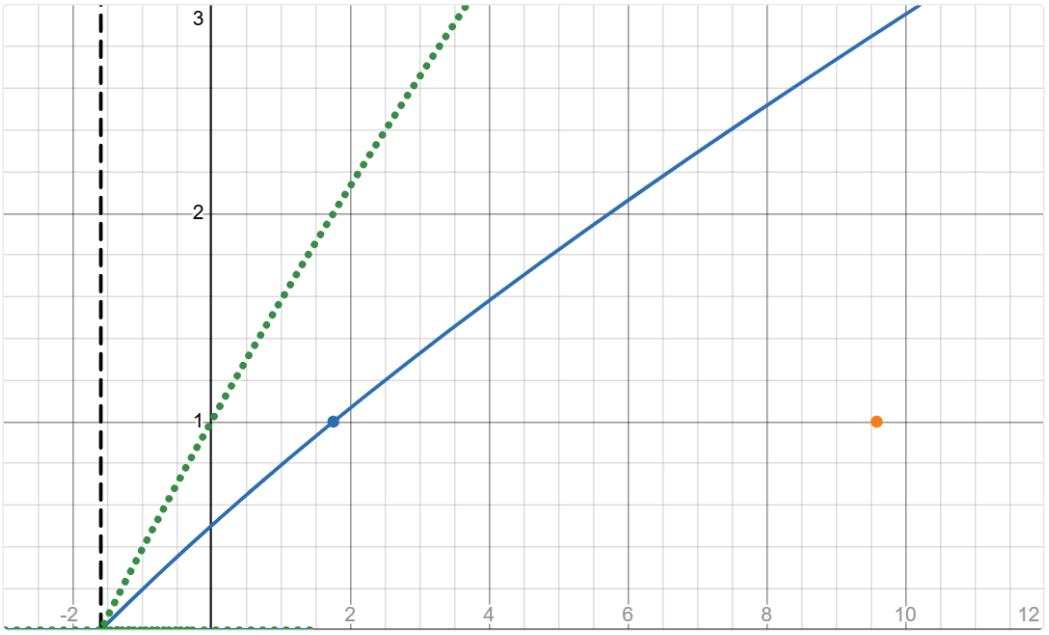
Complexity. Each iteration costs $O(|\mathcal{X}||\mathcal{Y}|)$. Convergence is monotone, and the gap shrinks like $O(1/k)$ in general, much faster when the optimum is unique and in the interior.

Failure cases.

1. *Capacity is not a code.* Blahut–Arimoto tells you the target, not how to hit it. Decoding a random code by brute force costs $n\,2^{nR}$ operations per block. At $n = 1000$ and $R = \frac{1}{2}$ that is 2^{500} comparisons.
2. *Structure helps encoding, not decoding.* Linear codes (Ch. 79) encode in $O(n^2)$ time, and random linear codes still achieve capacity on the BSC. But decoding a general linear code is NP-hard (Berlekamp, McEliece and van Tilborg, 1978). Cryptographers turned that hardness into a weapon: the McEliece cryptosystem hides a decodable code inside a random-looking one.
3. *Finite blocklength.* Capacity is a limit. At $n = 1000$ the best possible rate for a given error probability is noticeably below C, by roughly $\sqrt{V/n}\,Q^{-1}(P_e)$, where V is the "channel dispersion". Short packets, such as control messages in 5G, pay this penalty.

80.5 The experiment

First, drag the Shannon bound around. The curve gives the least E_b/N_0 (in dB, horizontal) needed at each rate R (vertical).



Blue: real channel, $E_b/N_0 > (2^{2R}-1)/(2R)$. Green: the same bound per complex sample (two real dimensions), $(2^R-1)/R$. Both reach -1.59 dB as $R \to 0$. Move the orange point to your own modem's operating point (for example $(4.4, 0.5)$, the classic rate-$\frac{1}{2}$ convolutional code of deep-space links at a bit error rate of 10^{-5}) and read off how much is left to gain. Then add the point $(-1, 0.1)$: any system claiming that operating point is claiming the impossible.

Next, build random codes and watch Result 2 happen, slowly.

```
import numpy as np
rng = np.random.default_rng(1)

EPS = 0.05     # bit-flip probability of the channel (capacity 1 - H(EPS) = 0.714)
R = 0.25       # code rate in bits per channel use: try 0.5, 0.7, 0.8
TRIALS = 1000  # messages sent per block length
MAXBITS = 12   # keeps 2^(nR) codewords manageable

H = lambda p: -p * np.log2(p) - (1 - p) * np.log2(1 - p)
print(f"capacity C = {1 - H(EPS):.3f} bits/use, rate R = {R}")

for n in range(4, int(MAXBITS / R) + 1, max(1, int(2 / R))):
    k = round(n * R)                                # message bits
    M = 2 ** k                                      # codewords
    code = rng.integers(0, 2, (M, n), dtype=np.int8)   # a random codebook
    sent = rng.integers(0, M, TRIALS)
    noise = (rng.random((TRIALS, n)) < EPS).astype(np.int8)
    y = code[sent] ^ noise                          # received words
    dist = (y[:, None, :] ^ code[None, :, :]).sum(axis=2)
    guess = dist.argmin(axis=1)                     # minimum-distance decoding
    err = np.mean(guess != sent)
    print(f"n = {n:3d}  k = {k:2d}  codewords = {M:5d}  block error = {err:.3f}")
```

At $R = 0.25$, a third of capacity, the block error falls from about 4% at $n = 4$ to zero in a thousand trials by $n = 36$. At $R = 0.5$ it hovers around 6–10% up to $n = 24$: the theorem promises it will fall, but only for blocks far longer than your memory allows. At $R = 0.8$, above capacity, it *rises* with n, which is the strong converse in action. Raise `MAXBITS` to 14 or 15 and see how quickly time and memory run out. That wall is the whole reason the codes in the first mystery took fifty years.

80.6 The challenge

1. **Intuition.** On the erasure channel BEC(α) the receiver knows which bits were erased, but the sender does not. Explain in words why capacity is still $1 - \alpha$, as if the sender had known, and why this argument fails on the BSC, where nobody knows which bits flipped.
2. **Derivation.** Prove the lower bound $V(n, \lambda n) \geq \frac{1}{n+1} 2^{n H_b(\lambda)}$ for λn an integer, so that Result 1 is tight up to a polynomial factor. Then use it to prove the sphere-packing converse $R \leq 1 - H_b(\varepsilon)$ for codes that correct *every* pattern of up to εn errors.
3. **Implementation.** Modify the experiment so that the codebook is a random *linear* code: a random $k \times n$ generator matrix over $\mathbb{F}_2$, with codewords $\mathbf{u}\mathbf{G}$. Compare block error rates with the fully random code at the same n and k. Then extend Blahut–Arimoto to a channel with input *cost* (for example, sending a 1 costs energy) and plot capacity against the cost budget.
4. **Open investigation.** For the BSC with $\varepsilon = 0.05$, estimate by simulation the smallest block error achievable at $n = 24$ and $R = 0.5$ by searching over many random codes and keeping the best. How close can you get to the normal approximation $C - \sqrt{V/n}\, Q^{-1}(P_e)$? Exact optimal codes at moderate n are unknown for almost every parameter choice, and your search will not settle it. Where does the improvement curve flatten, and why?

80.7 Loose threads

The question Ch. 33 left open now has its answer. A random code works because, in high dimensions, the noise around each codeword fills a ball of predictable size, and randomly placed balls almost never collide while there are fewer than $2^{n(1-H_b(\varepsilon))}$ of them. The proof is three lines of counting and a law of large numbers. What it does not give is a code you can decode. Bridging that gap took from 1948 to 2009, and the codes that did it are still being refined.

What we did not tell you:

- **How fast the error falls.** Result 2 says the error tends to zero. In fact the best codes drive it down exponentially, $P_e \approx 2^{-nE(R)}$, and the **reliability function** $E(R)$ is known exactly only for rates near capacity. At low rates the best upper and lower bounds disagree, and closing that gap is an open problem tied to the Gilbert–Varshamov mystery above.
- **Feedback.** If the receiver can talk back, capacity does not increase for a memoryless channel (another theorem of Shannon's), but the error exponent improves dramatically and simple schemes become possible.
- **Networks.** With many senders and receivers, the capacity region of even a three-node relay channel is unknown.
- **Secrecy.** Shannon wrote a second great paper in 1949, on secrecy systems. In it he proved that a cipher is *perfectly* secret, revealing nothing about the message to an eavesdropper with unlimited computing power, only if the key carries at least as much entropy as the message. The one-time pad meets this bound, and nothing shorter can.

> **? A short key for a long secret**
>
> By Shannon's 1949 theorem, a 256-bit key can perfectly hide only 256 bits. Yet every web browser encrypts gigabytes with a 256-bit key, and nobody can read the traffic. Both statements are true. The escape is to give up on *perfect* secrecy against *unlimited* adversaries, and to demand only that no *efficient* adversary can tell the ciphertext from random noise. What exactly does "cannot tell" mean, and how can 256 random bits be stretched into a gigabyte of bits that look just as random? See Ch. 81.

Chapter 81 — Pseudorandomness and Computational Indistinguishability

> **Level 2 · Track H — Cryptography, Coding, and Digital Security Builds on:** Ch. 19, Ch. 21, Ch. 77, Ch. 80 · **Leads to:** Ch. 82 · **Related:** Ch. 30, Ch. 38, Ch. 57, Ch. 24 **Reading time:** ~30 min

81.1 The hook

1968. George Marsaglia publishes a paper with a blunt title: "Random numbers fall mainly in the planes." The generator he is talking about, IBM's RANDU, had been the standard random number source on mainframes for years. It computes $x_{k+1} = 65539\,x_k \bmod 2^{31}$. Plot its outputs as points (x_k, x_{k+1}, x_{k+2}) in a cube, rotate the cube to the right angle, and the "random" cloud collapses onto just **15 parallel planes**, with nothing at all in between. Physics simulations had been run on those planes for years.

1995. Two Berkeley graduate students, Ian Goldberg and David Wagner, look at how the Netscape browser picks the secret keys that protect credit-card numbers. The keys came from a generator seeded with the time of day and two process IDs. An attacker who could estimate those three numbers was left with a search small enough to finish in minutes on 1995 hardware, so the "128-bit" keys were worth only a few dozen bits.

2008. A Debian developer had removed two lines from the OpenSSL random generator two years earlier, to silence a warning from a code-checking tool. After the change, the only unpredictable input left was the process ID, at most 32,768 values. Every SSH and TLS key generated on Debian and Ubuntu systems in those two years came from a list short enough to print out.

In each case the output *looked* random. RANDU passes the simple frequency tests. The Netscape and Debian keys would pass any statistical test you could name, because each key, on its own, is just a string of bits. What failed was not the look of the numbers but their *unpredictability* to someone who knew how they were made.

So what does it mean for a deterministic program to produce randomness? If an algorithm, a seed and a little arithmetic produce every bit, then each bit is fully determined. In what sense can it be "random" at all? And Ch. 80 left a sharper version of the question. Shannon proved that perfect secrecy needs a key as long as the message, yet a 256-bit key protects gigabytes of web traffic every day. This chapter resolves the contradiction. The answer changes the meaning of "random" itself.

81.2 The big idea

Randomness is in the eye of the observer. A sequence is not random or non-random in itself. It is random *to someone*, if that someone cannot tell it apart from coin flips. A shuffled deck is random to the players and not to the dealer who stacked it. The digits of π are random enough for a dice game and useless as a password, because anyone can compute them.

Make the observer a program with a time limit. Modern cryptography fixes the observer: any algorithm that runs in a reasonable time. It plays a game (Figure 81.2). A challenger secretly flips a coin and hands the algorithm either a truly random string or the output of our generator on a random short seed. The algorithm, the *distinguisher*, must guess which one it got. If no efficient distinguisher guesses right noticeably more often than half the time, the generator is **pseudorandom**. Its output is, for every practical purpose, as good as random, *even though it is not random at all*.

Statistical tests are just distinguishers. A frequency count, a chi-square test or a spectral test is a particular distinguisher. Passing a hundred of them is evidence, not proof: the hundred-and-first may be the one that finds the planes. Cryptographic pseudorandomness asks for something far stronger, namely that *every* efficient test fails.

The analogy. An art forger does not need a painting that *is* a Vermeer. She needs one that no expert can tell from a Vermeer within the time the auction allows. Give the expert unlimited time and an electron microscope and the forgery falls. Bound the expert, and the forgery is, operationally, a Vermeer.

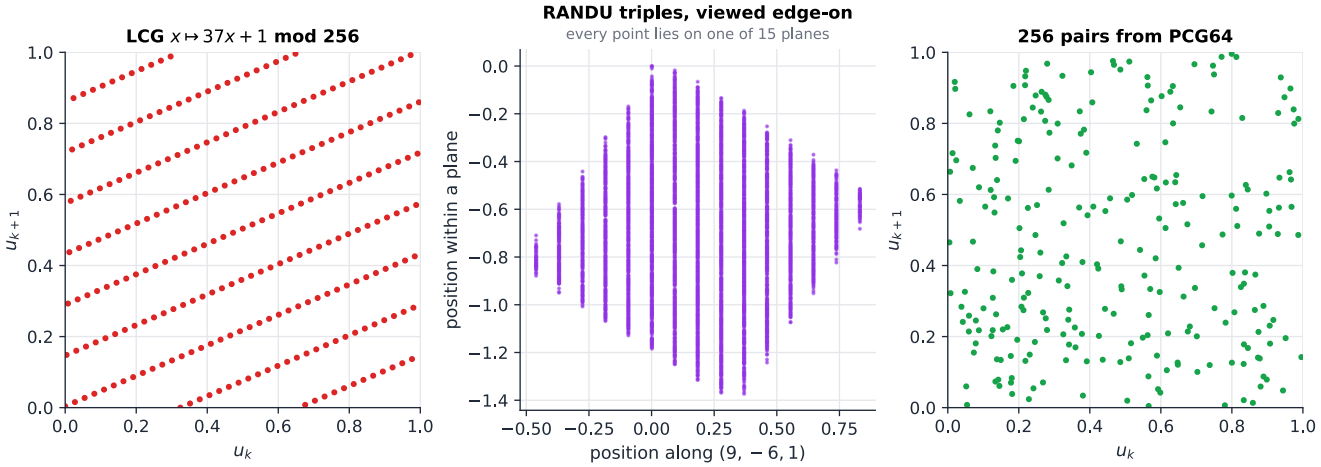

Figure 81.1 — Left: all 256 consecutive pairs of a full-period linear congruential generator lie on a handful of parallel lines. Centre: 6000 RANDU triples projected along the direction $(9, -6, 1)$; every one of them lies on one of 15 planes. Right: pairs from a modern generator (PCG64) show no visible structure. That does not make PCG64 safe for cryptography.

81.3 The mathematics

Throughout, U_ℓ denotes a uniformly random string of ℓ bits, and a "generator" is a deterministic function $G : \{0,1\}^s \to \{0,1\}^\ell$ with $\ell > s$. Its output distribution is $G(U_s)$: the result of feeding it a uniformly random seed.

Result 1: no generator fools an unbounded observer

How different are two distributions P and Q on the same finite set? The natural measure is the **statistical distance**

$$\Delta(P,Q) = \max_A \bigl|P(A) - Q(A)\bigr| = \frac{1}{2}\sum_y \bigl|P(y) - Q(y)\bigr|,$$

the largest difference in probability any event can show. If Δ is tiny, no test whatever, however slow, can tell P from Q with more than tiny advantage.

Generators are statistically far from uniform

For every $G : \{0,1\}^s \to \{0,1\}^\ell$ with $\ell > s$,

$$\Delta\bigl(G(U_s), U_\ell\bigr) \;\geq\; 1 - 2^{s-\ell} \;\geq\; \tfrac{1}{2}.$$

Proof. Let $A = G(\{0,1\}^s)$ be the set of strings the generator can output. There are at most 2^s of them. The generator's output always lies in A, so $P(A) = 1$ for $P = G(U_s)$. A uniform string lands in A with probability $|A|/2^\ell \leq 2^{s-\ell}$. The event A alone therefore shows a difference of at least $1 - 2^{s-\ell}$. □

The distinguisher in this proof is easy to describe ("is y one of the possible outputs?") but it takes 2^s steps to run: try every seed. That is the whole loophole. Statistically, a generator is always a fake. Computationally, checking whether it is a fake may be infeasible.

This is also where Shannon's 1949 theorem from Ch. 80 bites. Perfect secrecy is a statement about statistical distance: the ciphertext's distribution must not depend on the message *at all*. Result 1 says no short key can achieve that. Weaken "not at all" to "not detectably by any efficient algorithm", and the door opens.

Computational indistinguishability

Distinguisher, advantage, pseudorandom generator

A **distinguisher** is an algorithm D that reads a string and outputs 0 or 1. Its **advantage** against G is

$$\mathrm{Adv}(D) = \Bigl|P\bigl(D(G(U_s)) = 1\bigr) - P\bigl(D(U_\ell) = 1\bigr)\Bigr|.$$

G is a (t,ϵ)**-secure pseudorandom generator** if every distinguisher running in time at most t has advantage at most ϵ.

Concrete numbers make the definition real. A generator with a 128-bit seed is considered secure if no attack with t operations has advantage much above $t/2^{128}$. That is the advantage of the trivial attack that guesses seeds at random and checks each guess. Asymptotic cryptography says the same thing with a security parameter κ: G is pseudorandom if every distinguisher running in time polynomial in κ has advantage smaller than every inverse polynomial (a *negligible* function, such as $2^{-\kappa}$).

Two properties make the notion workable.

- **Closure under efficient processing.** If $G(U_s)$ is indistinguishable from U_ℓ, so is $f(G(U_s))$ from $f(U_\ell)$, for any efficient f. Otherwise, composing f with the distinguisher would break G. This is the computational version of the data-processing inequality.
- **Hybrid arguments.** Indistinguishability is "almost transitive": if $X \approx Y$ with advantage ϵ_1 and $Y \approx Z$ with ϵ_2, then $X \approx Z$ with advantage at most $\epsilon_1 + \epsilon_2$, by the triangle inequality. Long chains of small steps are the workhorse of every security proof.

With these, the contradiction of Ch. 80 disappears. Encrypt a long message m as $c = m \oplus G(k)$, where k is a short random key. If G is pseudorandom, c is indistinguishable from $m \oplus U_\ell$, which is a one-time pad and so perfectly random. An efficient eavesdropper learns nothing she could detect. This is the skeleton of every **stream cipher**, from ChaCha20 in your browser to the counter mode of AES (Ch. 77).

Result 2: why RANDU falls on 15 planes

The generator $x_{k+1} = a x_k \bmod m$ with $a = 65539 = 2^{16} + 3$ and $m = 2^{31}$ was chosen because multiplying by $2^{16} + 3$ is fast on binary hardware. That choice is also its downfall.

RANDU's planes

Every RANDU triple satisfies $x_{k+2} \equiv 6x_{k+1} - 9x_k \pmod{2^{31}}$. Consequently the normalised triples $u_k = x_k/2^{31}$ all lie on the 15 planes $9u - 6v + w = j$, $j = -5, \dots, 9$.

Proof. Square the multiplier: $a^2 = 2^{32} + 6 \cdot 2^{16} + 9$. Modulo 2^{31} the first term vanishes, and $6 \cdot 2^{16} = 6(a-3)$, so

$$a^2 \equiv 6(a-3) + 9 = 6a - 9 \pmod{2^{31}}.$$

Since $x_{k+2} \equiv a^2 x_k$ and $x_{k+1} \equiv a x_k$, we get $x_{k+2} \equiv 6x_{k+1} - 9x_k$. Hence $9x_k - 6x_{k+1} + x_{k+2}$ is a multiple of 2^{31}, and dividing by 2^{31} shows that $9u_k - 6u_{k+1} + u_{k+2}$ is an integer. With each u in $[0,1)$, that integer lies strictly between -6 and 10, so it is one of the 15 values $-5, \dots, 9$. □

Every linear congruential generator has some version of this flaw. Marsaglia's theorem says that d-tuples from any LCG with modulus m lie on at most about $(d!\,m)^{1/d}$ hyperplanes. The **spectral test** measures the gap between them, and it is the standard way to grade an LCG multiplier. The Hull–Dobell conditions for a full period (Ch. 57) say nothing about these planes. A generator can visit every value and still be badly structured.

The flaw is a distinguisher in disguise. Compute $9u_k - 6u_{k+1} + u_{k+2}$ for a few consecutive outputs. For RANDU it is always an integer; for true random numbers, essentially never. The advantage is almost exactly 1, and the test costs three multiplications.

Result 3: unpredictability is the same as indistinguishability

A cryptographer's first instinct is a different definition: a good generator is one whose next bit you cannot predict. Given $y_1, \dots, y_{i-1}$, no efficient algorithm should guess y_i with probability noticeably above $\tfrac{1}{2}$. Andrew Yao proved in 1982 that this **next-bit test** is not merely necessary. It is sufficient.

> **Yao's next-bit theorem**
>
> If some distinguisher D running in time t has advantage ϵ against $G : \{0,1\}^s \to \{0,1\}^\ell$, then for some position i there is a predictor A, running in time about t, that guesses y_i from $y_1 \dots y_{i-1}$ with probability at least $\tfrac{1}{2} + \epsilon/\ell$.

Proof. Let $y = G(U_s)$ and define $\ell + 1$ **hybrid** distributions. In H_i the first i bits come from y and the remaining $\ell - i$ bits are fresh coin flips. So $H_0 = U_\ell$ and $H_\ell = G(U_s)$. Let $p_i = P(D(H_i) = 1)$. Replacing D by $1 - D$ if necessary, we may assume $p_\ell - p_0 = \epsilon$. The telescoping sum

$$\epsilon = p_\ell - p_0 = \sum_{i=1}^{\ell} (p_i - p_{i-1})$$

has ℓ terms, so for some i, $p_i - p_{i-1} \geq \epsilon/\ell$. The neighbours H_{i-1} and H_i differ only in bit i: real in H_i, random in H_{i-1}.

The predictor, given $y_1 \dots y_{i-1}$, flips a coin b and fresh coins $r_{i+1}, \dots, r_\ell$, and runs D on $(y_1, \dots, y_{i-1}, b, r_{i+1}, \dots, r_\ell)$. If D says 1 ("looks real"), it predicts $y_i = b$; otherwise it predicts $y_i = 1 - b$.

To analyse it, let q be the probability that D outputs 1 when bit i is set to the *wrong* value $1 - y_i$. Half the time $b = y_i$, and the input to D is distributed exactly as H_i. Half the time $b \neq y_i$. So $p_{i-1} = \tfrac{1}{2}p_i + \tfrac{1}{2}q$, which gives $q = 2p_{i-1} - p_i$. The predictor is right when $b = y_i$ and D says 1, or when $b \neq y_i$ and D says 0:

$$P(\text{correct}) = \tfrac{1}{2}p_i + \tfrac{1}{2}(1 - q) = \tfrac{1}{2} + p_i - p_{i-1} \;\geq\; \tfrac{1}{2} + \frac{\epsilon}{\ell}. \qquad \square$$

Read in reverse, the theorem says that a generator whose bits cannot be predicted passes *every* efficient statistical test, including all the tests nobody has invented yet. That is the strongest guarantee anyone could ask of a sequence, and it follows from a single, natural property.

Where pseudorandom generators come from

A generator needs a source of hardness. The classical recipe has three steps.

1. Start from a **one-way function** f: easy to compute, hard to invert on random inputs. Candidates are multiplying two primes (Ch. 57) and exponentiation in a group (Ch. 78).
2. Find a **hard-core bit**: one bit of x that is as hard to guess from $f(x)$ as x is to find. Goldreich and Levin (1989) showed that every one-way function has one: the parity of a random subset of the bits of x.
3. **Iterate**: output the hard-core bit, apply f, repeat. Yao's theorem, read backwards, proves the output unpredictable.

The **Blum–Blum–Shub** generator is the textbook instance. Pick primes $p \equiv q \equiv 3 \pmod 4$, set $N = pq$, square repeatedly ($x \mapsto x^2 \bmod N$) and output the lowest bit each time. Predicting its bits is provably as hard as factoring N. It is also very slow, which is why practical generators (ChaCha20, AES in counter mode, the DRBGs of NIST SP 800-90A) are built from ciphers whose security is assumed, not proved.

> **? Does pseudorandomness exist at all?**
>
> Everything above is conditional. Håstad, Impagliazzo, Levin and Luby proved in 1999 that pseudorandom generators exist *if and only if* one-way functions exist. But nobody has proved that any one-way function exists, and doing so would prove P $\neq$ NP along the way (Ch. 30). Every stream cipher you have ever used rests on an **open problem**: is there any function that is easy to compute and hard to invert?

81.4 The algorithm

Two short programs show both sides. The first *breaks* a linear congruential generator from three outputs. With a prime modulus and unknown multiplier a and increment c, two consecutive differences satisfy $x_2 - x_1 \equiv a(x_1 - x_0)$, so a is one modular division away. The division uses the inverse from the extended Euclidean algorithm (Ch. 57).

```
def crack_lcg(x0, x1, x2, m):
    """Recover (a, c) of x -> (a*x + c) mod m from three outputs; m prime."""
    a = (x2 - x1) * pow(x1 - x0, -1, m) % m     # modular inverse of (x1 - x0)
    c = (x1 - a * x0) % m
    return a, c

m, a, c = 2**31 - 1, 48271, 12345               # toy secret parameters
xs = [987654]
for _ in range(4):
    xs.append((a * xs[-1] + c) % m)
A, C = crack_lcg(*xs[:3], m)
print(A, C, (A * xs[3] + C) % m == xs[4])       # 48271 12345 True: every future output known
```

That is a next-bit predictor with advantage $\tfrac{1}{2}$: it predicts every bit. By Yao's theorem in its easy direction, it is also a perfect distinguisher. When the modulus is unknown or the outputs are truncated, lattice reduction still recovers the state. The Mersenne Twister, NumPy's legacy default, falls to linear algebra over $\mathbb{F}_2$ after 624 consecutive 32-bit outputs.

The second program is a **toy** Blum–Blum–Shub generator.

```
def bbs_bits(seed, nbits, p=499, q=547):
    """Blum-Blum-Shub with TOY primes p, q = 3 mod 4. Real use needs primes of 1500+ bits."""
    N = p * q
    x = seed * seed % N                          # seed must be coprime to N
    bits = []
    for _ in range(nbits):
        x = x * x % N
        bits.append(x & 1)
    return bits

print("".join(map(str, bbs_bits(2024, 64))))
```

Complexity. An LCG costs one multiply per output. BBS costs one modular squaring of a κ-bit number per output *bit*, about $O(\kappa^2)$ bit operations, so it is thousands of times slower than a cipher-based generator. That is why it lives in textbooks.

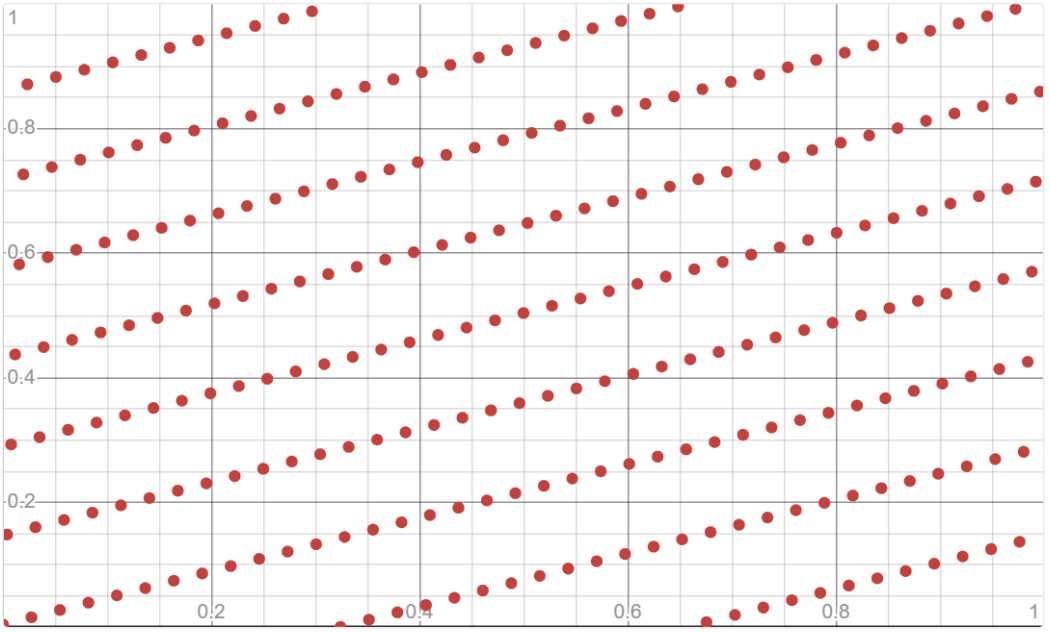
Failure cases.

1. *Toy parameters are toys.* With $p = 499$ and $q = 547$, the seed 2024 enters a cycle of only 492 states, and anyone can factor $N = 272\,953$ instantly. The theorem "as hard as factoring" is worthless when factoring is easy.
2. *The seed is the secret.* A perfect generator on a guessable seed is a guessable generator. Netscape and Debian had sound generators and broken seeds.
3. *Statistical quality is not security.* PCG64 and the Mersenne Twister are excellent for Monte Carlo (Ch. 38) and trivial to predict. Conversely, a CSPRNG (cryptographically secure generator) is fine for simulation, only slower.

> **Correct mathematics is not a secure implementation**
>
> A proof that "G is pseudorandom if factoring is hard" says nothing about where your seed came from, whether two virtual machines cloned from one snapshot now share the same generator state, whether the state leaks through a crash dump or a timing side channel, or whether the standard you followed was designed honestly. (The NIST generator Dual_EC_DRBG was withdrawn in 2014 after evidence that its constants could hide a back door.) In code, use the operating system's generator: `secrets` or `os.urandom` in Python, never `random` or `numpy.random`, for keys, tokens, nonces and passwords. Every generator in this chapter's code is a teaching toy.

81.5 The experiment

First, see the lines. Every point below is a pair (u_k, u_{k+1}) from a full-period LCG with modulus 256.



Change the multiplier 37 *to* 5, 69, 101, 137 *or* 197 *(each keeps the full period, since it is* 1 mod 4*) and count the lines. Which multiplier spreads the points most evenly? That question, asked in higher dimensions, is the spectral test. Then try an even multiplier such as* 38 *and watch the period collapse.*

Now play the distinguishing game of Figure 81.2. Each test below is a distinguisher; the script estimates its advantage against two broken generators.

```
import numpy as np
rng = np.random.default_rng()
N, GAMES = 1200, 400            # numbers per challenge string, rounds of the game

def lcg(a, c, m, seed, n):      # a linear congruential generator, scaled to [0, 1)
    x, out = seed, np.empty(n)
    for i in range(n):
        x = (a * x + c) % m; out[i] = x / m
    return out

GENERATORS = {                  # toy, broken generators: never use these for anything real
    "RANDU":       lambda s: lcg(65539, 0, 2**31, s | 1, N),
    "LCG mod 2^32": lambda s: lcg(1664525, 1013904223, 2**32, s, N),
}
TESTS = {                       # each test is a distinguisher: 1 means "I think this is fake"
    "plane test":  lambda u: np.mean(np.abs(np.round(9*u[:-2] - 6*u[1:-1] + u[2:])
                                    - (9*u[:-2] - 6*u[1:-1] + u[2:])) < 1e-6) > 0.5,
    "low bits":    lambda u: np.all(((u * 2**31).astype(np.int64) & 3)[8:]
                                == ((u * 2**31).astype(np.int64) & 3)[:-8]),
    "pair chi^2":  lambda u: np.sum((np.histogram2d(u[:-1], u[1:], 8)[0] - (N-1)/64)**2
                                / ((N-1)/64)) > 100,
}

for gname, G in GENERATORS.items():
    for tname, D in TESTS.items():
        said_fake, played = [0, 0], [0, 0]
        for _ in range(GAMES):
            b = rng.integers(2)                    # the challenger's secret coin
            u = G(int(rng.integers(2**31))) if b else rng.random(N)
            said_fake[b] += D(u); played[b] += 1
        adv = abs(said_fake[1] / played[1] - said_fake[0] / played[0])
        print(f"{gname:13s} vs {tname:11s} advantage ~ {adv:.2f}")
```

The plane test destroys RANDU (advantage about 1.00) and sees nothing in the other LCG. The low-bits test, which checks whether the two lowest bits repeat with period 8, destroys *both*, because the low bits of any LCG with a power-of-two modulus have tiny periods. The chi-square test on pairs, the kind of check a textbook recommends, has advantage near zero against both. A generator can pass the test you ran and fail the one you didn't. Write your own distinguisher and add it to `TESTS`. Then replace a broken generator by `lambda s: np.random.default_rng(s).random(N)` and try to find *any* test with a visible advantage.

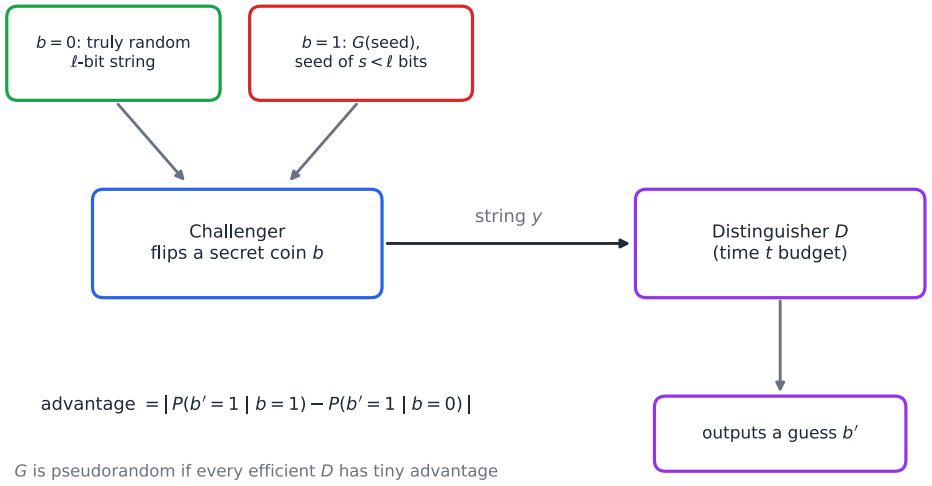


Figure 81.2 — The game that defines pseudorandomness. The challenger hands the distinguisher either true randomness or generator output; the distinguisher's advantage is how much more often it says "1" in one case than in the other. Security means every efficient distinguisher has negligible advantage.

81.6 The challenge

1. **Intuition.** The digits of π are believed to pass every standard statistical test of randomness. Explain why they are nonetheless a terrible pseudorandom generator in the sense of this chapter, and describe a distinguisher with advantage close to 1. What resource does your distinguisher need that a chi-square test does not?
2. **Derivation.** Suppose $G : \{0,1\}^s \to \{0,1\}^{s+1}$ is a (t, ϵ)-secure generator that stretches by just one bit. Define G' by applying G to the seed, outputting the last bit, feeding the first s bits back in, and repeating ℓ times. Use a hybrid argument to show that G' is $(t', \ell\epsilon)$-secure for t' slightly less than t. Identify exactly where the proof uses that each hybrid can be sampled efficiently.
3. **Implementation.** Implement the NIST "runs" test and the "approximate entropy" test, and apply them to the bits of the toy BBS generator, to the lowest bit of an LCG with modulus 2^{32}, and to `os.urandom`. Then write a program that recovers the parameters of an LCG with an *unknown* modulus from eight consecutive outputs. (Hint: the numbers $t_k = x_{k+1} - x_k$ satisfy $t_{k+2}t_k - t_{k+1}^2 \equiv 0 \pmod{m}$.)

4. **Open investigation.** Design the best distinguisher you can against `numpy.random.default_rng` (PCG64) given 10^9 outputs and an hour of laptop time. PCG64 is not a cryptographic generator, and its output function is known, so a distinguisher must exist. How large an advantage can you actually measure? Finding a practical distinguisher, or arguing convincingly that none exists at this budget, is an open experimental question.

81.7 Loose threads

The hook asked how a deterministic program can produce randomness. The answer is that "random" was never a property of the bits alone. It is a relation between a distribution and an observer with limited time. Result 1 shows that no generator fools an unbounded observer. Yao's theorem shows that fooling bounded predictors is the same as fooling bounded tests. And a short key, stretched by a pseudorandom generator, is how a 256-bit secret protects a gigabyte, the answer to the mystery of Ch. 80.

What we did not tell you:

- **Pseudorandom functions.** A generator produces one long string. Many protocols need a random-looking *function*: give it any input and it returns an output that looks fresh. Goldreich, Goldwasser and Micali (1986) built one from any generator, using a binary tree of generator calls. Block ciphers such as AES are modelled as pseudorandom permutations.
- **Extracting randomness.** Seeds come from physical noise (clock jitter, thermal noise in a diode, the timing of keystrokes), which is unpredictable but not uniform. *Randomness extractors* turn such weak sources into nearly uniform bits. Their analysis uses the min-entropy, a cousin of the entropy of Ch. 33.
- **Does randomness help computation?** Ch. 30 and Ch. 38 both asked whether every randomised algorithm can be made deterministic. Pseudorandomness gives a striking conditional answer. Impagliazzo and Wigderson (1997) proved that if some problem solvable in exponential time requires exponential-size circuits, then there are generators strong enough to fool every polynomial-time algorithm, and then $\mathsf{BPP} = \mathsf{P}$. Try all seeds of a logarithmic-length generator and take a majority vote. *Hardness can be traded for randomness*, in both directions.

> **? Is the hardness really there?**
>
> The Impagliazzo–Wigderson theorem turns a lower bound into derandomisation. But no one can prove the lower bound: the best known circuit lower bound for an explicit problem is barely larger than linear. Conversely, Kabanets and Impagliazzo (2003) showed that derandomising even one specific problem (testing whether a polynomial is identically zero) would itself imply new circuit lower bounds. So $\mathsf{BPP} = \mathsf{P}$ and circuit lower bounds rise or fall together. Most researchers believe $\mathsf{BPP} = \mathsf{P}$; proving it is an **open problem** at the heart of complexity theory.

There is one more use for computational indistinguishability, perhaps the most surprising. We used it to say that a ciphertext reveals nothing. It can also say that a *conversation* reveals nothing: that everything you saw while someone convinced you of a fact, you could have produced yourself.

> **? A proof that teaches you nothing**
>
> Suppose a prover convinces you that she knows the password to an account, and the transcript of your conversation is indistinguishable from one you could have generated on your own, without her, without the password. Then you learned nothing except that the claim is true. Can a proof really be both convincing and empty? How do you prove such a property, and why does the proof rely on a simulator that rewinds time? See Ch. 82.

Chapter 82 — Zero-Knowledge Proofs and the Mathematics of Trust

> **Level 2 · Track H — Cryptography, Coding, and Digital Security Builds on:** Ch. 19, Ch. 57, Ch. 77, Ch. 78, Ch. 81 · **Leads to:** Ch. 67, Ch. 94 · **Related:** Ch. 30, Ch. 46, Ch. 63 **Reading time:** ~30 min

82.1 The hook

Every time you log in to a website, you prove who you are by handing over your password. That is a strange way to prove you know a secret: you give it away. If the server is fake, or hacked, or simply logs too much, your secret now belongs to someone else. Could you instead convince the server that you know the password *without revealing anything about it*? Not a hint, not a hash it could attack offline, nothing except the single fact "this person knows it".

That sounds like a contradiction. A proof is supposed to *transfer* understanding. Read a proof that $\sqrt{2}$ is irrational and you can repeat it to someone else. How could a proof convince you and leave you with nothing you could pass on?

Here is a small version. Your friend is red–green colour-blind, and you hold two balls, one red and one green, identical in every other way. You want to convince him that they really are different colours, without telling him which is which. He takes the balls, hides them behind his back, and either swaps them or not, at random. Then he shows them to you and asks: "Did I swap?" You can always answer correctly, because you can see the colours. If the balls were really the same colour, you would be guessing, and you would be right only half the time. After 20 rounds without a mistake, the chance that you were lucky is below one in a million. He is convinced that the colours differ. Yet he has learned nothing about *which* ball is red: every answer you gave was one he already knew, since he did the swapping.

In 1985, Shafi Goldwasser, Silvio Micali and Charles Rackoff turned this idea into mathematics and called it **zero knowledge**. Their theory now protects blockchains worth billions and digital identity documents. This chapter asks the question in the title of their field: how can you prove a statement while revealing nothing beyond its truth? And what, precisely, does "revealing nothing" mean?

82.2 The big idea

A proof can be a conversation. A classical proof is a static text. An *interactive* proof is a dialogue between a **prover** (call her Peggy) and a **verifier** (Victor). Victor asks random questions; Peggy answers. A prover who knows the truth can always answer. A prover who is bluffing will, with high probability, be caught by some question she could not anticipate. Randomness is the verifier's weapon: Peggy cannot prepare for a question that has not been chosen yet.

The cave. A ring-shaped cave has one entrance and a magic door deep inside that blocks the ring (Figure 82.1). Peggy claims to know the word that opens the door. Victor waits outside while she walks in, by path A or path B, and he cannot see which. Then he steps in and shouts a random path: "come out by A!" If Peggy knows the word, she can always comply, passing through the door if necessary. If she does not, she can comply only when Victor happens to name the path she took: probability $\frac{1}{2}$. Thirty rounds drive the bluffing probability to $2^{-30} \approx 10^{-9}$.

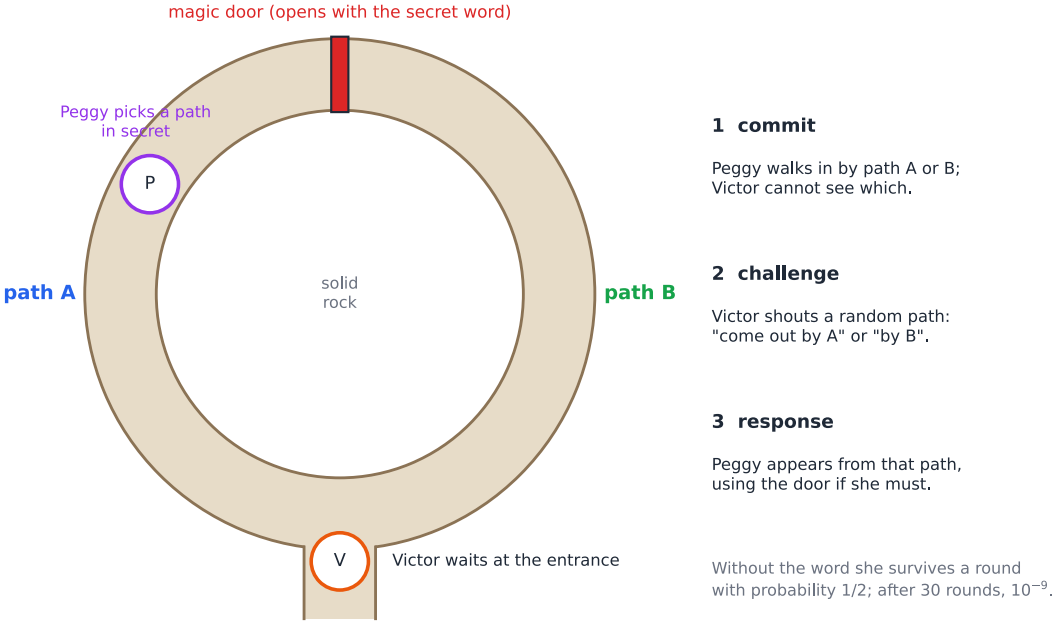

Figure 82.1 — The zero-knowledge cave of Quisquater and colleagues (1989). Commit, challenge, respond: Peggy picks a side in secret, Victor names a side at random, and Peggy must appear from it. Every protocol in this chapter has the same three moves.

Knowledge is what you could not have produced yourself. Victor films the whole session and shows it to a friend. The friend is unimpressed: Peggy and Victor could have agreed in advance which paths would be called, or simply cut out the rounds she failed. A video of a *successful* session can be faked without knowing the word. That observation is the definition. Victor gained nothing from the interaction, because everything he saw, he could have **simulated** alone. What convinced *him* was not the content of the transcript but the fact that he chose the challenges himself, live, after Peggy had committed.

The analogy. A magician performs a card trick at your table. You are sure she has a real method, because you chose the card yourself. But a recording of the trick proves nothing to anyone else, and you leave no closer to knowing how it was done.

82.3 The mathematics

We work in a cyclic group of prime order q, generated by g: for concreteness, the order-q subgroup of $\mathbb{Z}_p^*$ for a prime $p = 2q + 1$, or an elliptic-curve group (Ch. 78). The **discrete logarithm assumption** says that given $y = g^x$ for random x, no efficient algorithm finds x with non-negligible probability (Ch. 57, Ch. 77). Exponents live in $\mathbb{Z}_q$, so they can be added, multiplied and divided modulo q.

Interactive proofs and zero knowledge

Interactive proof

An interactive proof for a claim is a protocol between a prover P and an efficient, randomised verifier V with two properties.

- **Completeness:** if the claim is true and P follows the protocol, V accepts (with probability 1, or close to it).
- **Soundness:** if the claim is false, then *whatever* any cheating prover P^* does, V accepts with probability at most σ, the **soundness error**.

A **proof of knowledge** strengthens soundness: any prover who convinces V with probability noticeably above σ "knows" a witness, in the sense that an efficient **extractor** could compute it by interacting with her.

Repetition shrinks the error: k independent rounds give σ^k.

Zero knowledge

A protocol is **zero-knowledge** if for every efficient verifier V^* there is an efficient **simulator** S that, given only the claim (and no witness), outputs transcripts whose distribution is indistinguishable from that of real conversations between P and V^*. It is *perfect*, *statistical* or *computational* zero-knowledge according to whether the two distributions are identical, statistically close or computationally indistinguishable in the sense of Ch. 81. If this is required only for the honest V, the protocol is **honest-verifier zero-knowledge** (HVZK).

The logic is that of the video. Anything V^* could compute from a real conversation, it could compute from a simulated one, and the simulator needs no secret. So the conversation gave V^* no ability it did not already have.

Commitments: sealed envelopes made of mathematics

Peggy's first move in the cave, entering a path Victor cannot see, is a **commitment**: she fixes a choice now and reveals it later. In digital protocols this is done with a commitment scheme, a mathematical sealed envelope.

Commitment scheme

To commit to a value m, compute $\mathrm{Com}(m; r)$ with fresh randomness r and publish it. To open, reveal (m, r). The scheme is **hiding** if the commitment reveals nothing about m, and **binding** if no one can open it to two different values.

No scheme can be both *perfectly* hiding and *perfectly* binding. If every commitment is consistent with every message (perfect hiding), an unbounded cheater can always find a second opening. One of the two properties must rest on computational hardness.

Pedersen commitment

Let h be a second generator whose discrete logarithm $\log_g h$ nobody knows. Commit to $m \in \mathbb{Z}_q$ as $C = g^m h^r$ with r uniform in $\mathbb{Z}_q$. Then the scheme is perfectly hiding, and any algorithm that breaks binding computes $\log_g h$.

Proof. Hiding. For any fixed m, the map $r \mapsto g^m h^r$ is a bijection from $\mathbb{Z}_q$ onto the group, because h has order q. So with r uniform, C is uniform on the group whatever m is. Its distribution does not depend on m at all.

Binding. Suppose someone produces two openings, $g^m h^r = g^{m'} h^{r'}$ with $m \neq m'$. Then $g^{m-m'} = h^{r'-r}$. Since $m \neq m'$ the left side is not 1, so $r' \neq r$ and $r' - r$ is invertible modulo q. Raising both sides to the power $(r' - r)^{-1}$,

$$h = g^{(m-m')(r'-r)^{-1}}, \qquad \text{so} \qquad \log_g h = (m - m')(r' - r)^{-1} \bmod q.$$

Breaking binding is therefore as hard as computing a discrete logarithm. □

The Schnorr protocol

Peggy's public key is $y = g^x$, and she wants to prove that she knows x. Claus Schnorr's protocol (1989) has the three moves of the cave (Figure 82.2).

1. **Commit.** Peggy picks a random $r \in \mathbb{Z}_q$ and sends $t = g^r$.
2. **Challenge.** Victor picks a random $c \in \{0, \dots, q - 1\}$ and sends it.
3. **Respond.** Peggy sends $s = r + cx \bmod q$. Victor accepts if $g^s = t\, y^c$.

Completeness is one line: $g^s = g^{r+cx} = g^r (g^x)^c = t\, y^c$.

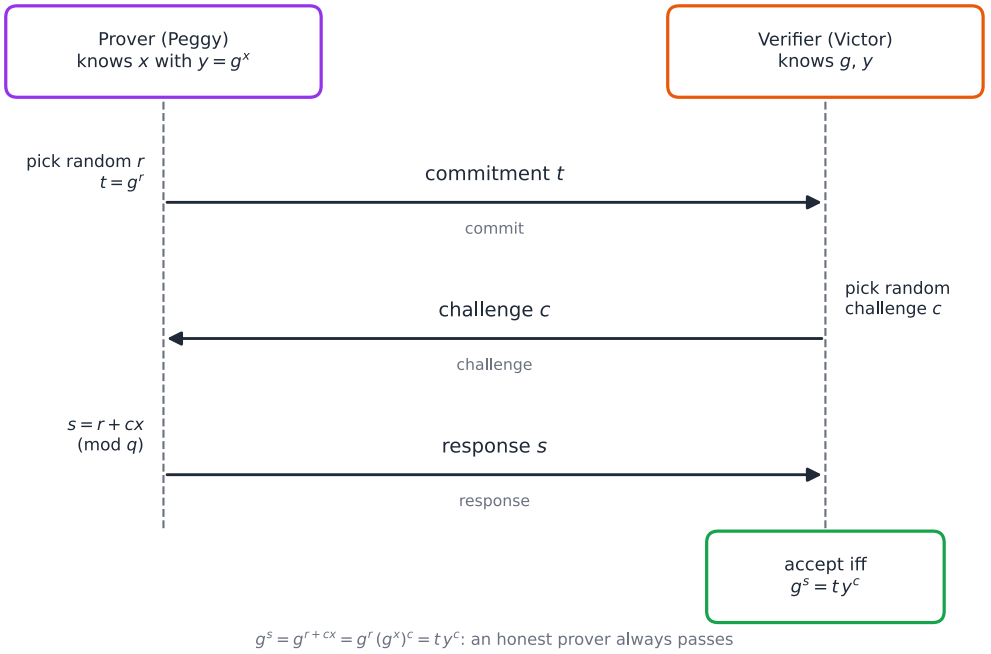

Figure 82.2 — Schnorr's identification protocol. The random r masks the secret x inside s the way a one-time pad masks a message. The challenge c arrives only after t has fixed r.

Special soundness

From two accepting transcripts (t, c, s) and (t, c', s') with the same commitment and $c \neq c'$, the secret is

$$x = (s - s')(c - c')^{-1} \bmod q.$$

Consequently a prover who does not know x can answer at most one challenge per commitment, and convinces Victor with probability at most $1/q$.

Proof. Both transcripts pass the check: $g^s = t y^c$ and $g^{s'} = t y^{c'}$. Dividing eliminates the unknown t: $g^{s-s'} = y^{c-c'} = g^{x(c-c')}$. Since g has prime order q, exponents agree modulo q, so $s - s' \equiv x(c - c')$, and $c - c'$ is invertible. For the second claim, fix any strategy and any commitment t that the strategy sends. If it could answer two different challenges for this t, the formula would produce x, contradicting the assumption that the prover cannot compute it. So for each t at most one of the q equally likely challenges is answerable. □

The rigorous version of the second claim, for a prover who succeeds only sometimes, uses an extractor that **rewinds** her: run her to get t, send a challenge, then rewind to the moment after t and send a different challenge. A forking argument shows that if she succeeds with probability noticeably above $1/q$, two accepting answers for the same t turn up after a few tries. Rewinding is legitimate in a proof, because the extractor is a thought experiment that controls the prover as a program. In the real world nobody can rewind Peggy.

Honest-verifier zero knowledge

The following simulator, which never sees x, outputs transcripts with exactly the same distribution as honest conversations: pick c and s uniformly from $\mathbb{Z}_q$, and set $t = g^s y^{-c}$.

Proof. In a real conversation r and c are independent and uniform. Then $s = r + cx$ is uniform and independent of c, because for each fixed c the map $r \mapsto r + cx$ is a bijection of $\mathbb{Z}_q$. So (c, s) is a uniform pair, and t is the unique value that makes the check pass, $t = g^s y^{-c}$. The simulator produces a uniform pair (c, s) and the same function $t = g^s y^{-c}$ of it. The two distributions are identical. □

The simulator does what Peggy in the cave cannot. It picks the challenge *first* and then builds a commitment to match, exactly like the staged video. Its transcripts are perfectly valid. They only lack the time order that made the real ones convincing.

What about a *dishonest* verifier, whose challenge depends on t? With challenges restricted to $\{0, 1\}$ the simulator can guess c, build t to match, and rewind whenever the verifier asks the other bit. That takes two tries on average, and the protocol is fully zero-knowledge with soundness error $\frac{1}{2}$ per round. With challenges from all of $\mathbb{Z}_q$, the guess succeeds with probability only $1/q$, and no efficient simulator for Schnorr's protocol is known. Large challenges give soundness in one round; small challenges give zero knowledge for every verifier. Getting both at once needs an extra idea, such as having the verifier commit to his challenge in advance.

From conversations to signatures: Fiat–Shamir

Interaction is inconvenient: Victor has to be online. Amos Fiat and Adi Shamir (1986) removed him by replacing his random challenge with a hash of everything said so far, $c = H(g, y, t, \text{message})$. Peggy can now produce (t, s) alone, and anyone can check it. That pair is a **Schnorr signature** on the message. EdDSA (Ed25519, used in SSH and Signal) and Bitcoin's Taproot signatures are Schnorr signatures of this kind.

The security argument models H as a *random oracle*, a truly random function that the prover cannot predict. Then a cheating signer faces the same unpredictable challenge as in the interactive protocol, and the special-soundness extractor works by "rewinding" the oracle.

? The leap of faith in Fiat–Shamir

Real hash functions such as SHA-256 are fixed public programs, not random oracles. Goldwasser and Kalai (2003) built a protocol that is secure as an interactive proof but becomes *insecure* under Fiat–Shamir with **every** concrete hash function. So the transformation is not sound in general. For Schnorr signatures, decades of attacks have found nothing. Which protocols survive the transformation with which hash functions? Recent work using lattice assumptions has proved soundness for some protocols. The general question is an **open problem**.

Zero knowledge for every NP statement

Discrete logarithms are one claim. Goldreich, Micali and Wigderson (1986) showed that *every* claim with a short, checkable certificate (every NP statement, Ch. 30) has a zero-knowledge proof. Since graph 3-colouring is NP-complete, a protocol for it is enough. Peggy knows a proper 3-colouring of a graph with $|E|$ edges.

1. She permutes the three colours at random and commits to the colour of every vertex.
2. Victor picks a random edge.
3. Peggy opens the two commitments at its endpoints. Victor checks that the two colours differ.

A cheater with no valid colouring has at least one bad edge, so she is caught with probability at least $1/|E|$ per round. Soundness error $(1 - 1/|E|)^k$ after k rounds needs about $|E| \ln(1/\sigma)$ rounds: for 20 edges and $\sigma = 10^{-9}$, about 400. Zero knowledge holds because each opening shows two *different random colours*, which the simulator can fake by guessing the edge in advance and rewinding. This is where Ch. 81 enters: the commitments need only computational hiding, and Naor (1991) built them from any pseudorandom generator.

Proof systems beyond NP

Interaction and randomness are astonishingly powerful. Shamir proved in 1990 that IP $=$ PSPACE: interactive proofs can certify any claim checkable with polynomial *memory*, including "the first player has a winning strategy" in any game that lasts polynomially many moves, far beyond NP as far as anyone knows. The proof turns logic into polynomials over a finite field and checks them at random points. The **PCP theorem** (1992) says that any NP proof can be rewritten so that a verifier, reading only a *constant number* of randomly chosen bits, rejects any false claim with probability at least $\frac{1}{2}$.

? A proof shorter than the computation

Modern **SNARKs** (succinct non-interactive arguments of knowledge) prove that a computation of a billion steps was done correctly with a proof of a few hundred bytes, checked in milliseconds, and in zero knowledge. The best-known construction, Groth16, uses three elliptic-curve points. The recipe combines PCP-style polynomial checking with **pairings**, bilinear maps on elliptic curves that let a verifier test a polynomial identity "in the exponent" without seeing the polynomial. What is a pairing, and why do only special curves have efficient ones? See Ch. 78.

Correct mathematics is not a secure implementation

The special-soundness proof *is* an attack. If Peggy ever uses the same random r twice, two signatures share one commitment, and anyone can compute $x = (s - s')(c - c')^{-1}$ by the formula above. In 2010, hackers recovered the master signing key of Sony's PlayStation 3 in exactly this way: its ECDSA signatures used a constant nonce. Even slightly *biased* nonces leak the key through lattice attacks. In 2022, several open-source zero-knowledge libraries were found to compute Fiat–Shamir challenges without hashing all the public inputs ("Frozen Heart"), which allowed forged proofs. A protocol proved secure on paper is secure only when its randomness is fresh, its hash covers everything, and its arithmetic does not leak through timing. The group in this chapter's code has order 1019: a discrete logarithm in it takes microseconds. Real deployments use groups of order about 2^{256} and audited libraries.

82.4 The algorithm

The complete Schnorr protocol, the simulator and the extractor fit in a few lines, using toy parameters. With $p = 2039 = 2 \cdot 1019 + 1$ and $g = 4$, g generates the subgroup of prime order $q = 1019$.

```
import secrets
p, q, g = 2039, 1019, 4          # TOY group, insecure: real q has ~256 bits

def keygen():
    x = secrets.randbelow(q - 1) + 1
    return x, pow(g, x, p)                          # secret x, public y = g^x

def prove_commit():
    r = secrets.randbelow(q)                        # FRESH randomness, every time
    return r, pow(g, r, p)

def prove_respond(x, r, c):
    return (r + c * x) % q

def verify(y, t, c, s):
    return pow(g, s, p) == t * pow(y, c, p) % p

def extract(c1, s1, c2, s2):                        # special soundness
    return (s1 - s2) * pow(c1 - c2, -1, q) % q

x, y = keygen()
r, t = prove_commit(); c = secrets.randbelow(q); s = prove_respond(x, r, c)
print(verify(y, t, c, s))                           # True
```

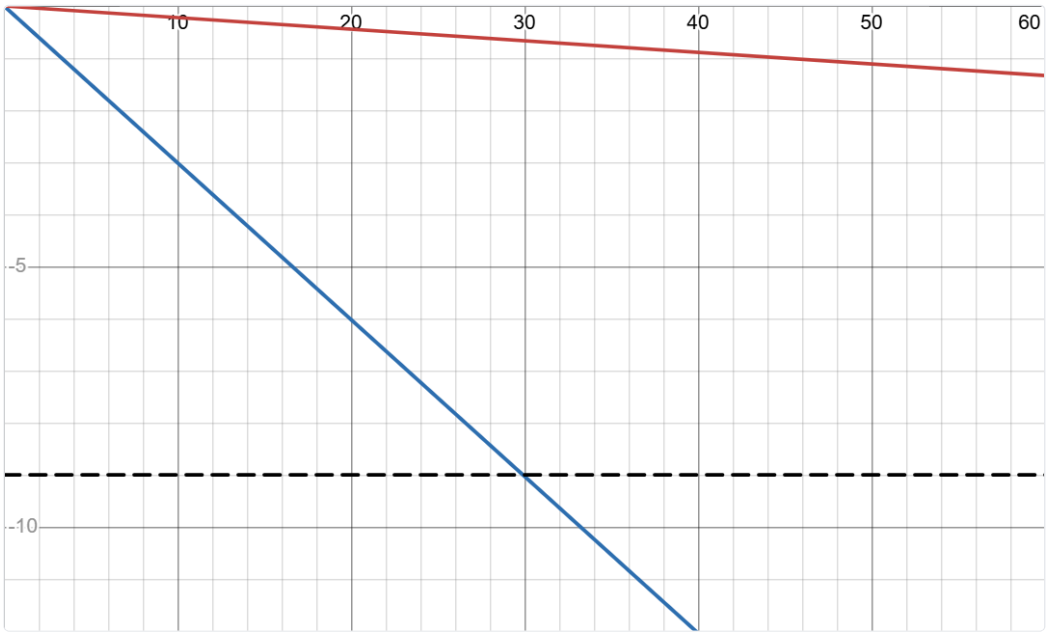
Complexity. The prover does one exponentiation, the verifier two, each $O(\log q)$ group multiplications. With $q \approx 2^{256}$ that is a few hundred multiplications of 256-bit numbers, well under a millisecond. The graph-colouring protocol costs $O(|V|)$ commitments per round and $O(|E|)$ rounds, which is why general-purpose zero knowledge was a theoretical curiosity until SNARKs made proofs short.

Failure cases.

1. *Predictable or repeated r.* As above: the key falls out. The random module of Python, or any generator of Ch. 81 that is not cryptographic, is enough to break it. Deterministic nonces, $r = H(x, \text{message})$, as in EdDSA, remove the dependence on a good runtime generator.
2. *Wrong group.* If g does not have prime order, exponents are not a field, $c - c'$ may not be invertible, and small-subgroup attacks leak bits of x. Every received group element must be checked to lie in the right subgroup.
3. *Challenges not bound to context.* If the Fiat–Shamir hash omits the public key or the statement, a cheater can choose them *after* seeing the challenge. That is the Frozen Heart bug.

82.5 The experiment

How many rounds does trust cost? The curves show $\log_{10}$ of the soundness error after x rounds.



Blue: the cave, or Schnorr with one-bit challenges: error 2^{-x}, below 10^{-9} (the dashed line) after 30 rounds. Red: graph 3-colouring with 20 edges: error $(1 - \frac{1}{20})^x$. Change 20 to 200 and set `right=4000` to see how large graphs blow up the round count.

Now run the protocol, the simulator, a cheater, and the nonce-reuse attack.

```
import random
p, q, g = 2039, 1019, 4          # TOY group: g has prime order q mod p. Real systems use ~256-bit q.
x = random.randrange(1, q)       # Peggy's secret
y = pow(g, x, p)                 # her public key
C = 1019                         # size of the challenge space: try 2

def accept(t, c, s):             # Victor's check: g^s == t * y^c
    return pow(g, s, p) == t * pow(y, c, p) % p

def honest():                    # a real run of the protocol (uses x)
    r = random.randrange(q); t = pow(g, r, p)
    c = random.randrange(C)
    return t, c, (r + c * x) % q

def simulate():                  # a fake transcript made WITHOUT x
    c, s = random.randrange(C), random.randrange(q)
    return pow(g, s, p) * pow(y, -c, p) % p, c, s

def cheat():                     # a prover without x: bet on the challenge in advance
    t, c_bet, s = simulate()
    c = random.randrange(C)      # Victor's real challenge
    return accept(t, c, s) if c == c_bet else accept(t, c, random.randrange(q))

N = 20000
print("honest accepted   ", sum(accept(*honest()) for _ in range(N)) / N)
print("simulated accepted", sum(accept(*simulate()) for _ in range(N)) / N)
print("cheater accepted  ", sum(cheat() for _ in range(N)) / N, " vs 1/C =", 1 / C)
print("three honest:", [honest() for _ in range(3)])
print("three fake:  ", [simulate() for _ in range(3)])

r = random.randrange(q); t = pow(g, r, p)          # the fatal mistake: reuse r
s1, s2 = (r + 5 * x) % q, (r + 9 * x) % q          # two challenges, same commitment
print("secret x =", x, " extracted =", (s1 - s2) * pow(5 - 9, -1, q) % q)
```

Honest and simulated transcripts are both accepted every time. Look at the three of each and try to tell them apart: you cannot, because they have the same distribution. The cheater, who has to bet on the challenge before committing, succeeds about 0.2% of the time: $1/C$, plus a $1/q$ chance that a random guess at s happens to pass. Set `C = 2` and the cheater wins half the time. The last line recovers the secret from two answers to one commitment. (This script uses Python's `random` module only because it is a toy. Real code would use `secrets`.)

82.6 The challenge

1. **Intuition.** In the cave, suppose Victor, instead of choosing at random, always shouts "A". Explain why a Peggy who does not know the word can now fool him every time, and why Victor's recording of a session in which he chose at random is still not evidence for a third party. What exactly is the difference between what convinced Victor and what the recording contains?
2. **Derivation.** Prove that the Pedersen commitment is *additively homomorphic*: $\mathrm{Com}(m_1; r_1) \cdot \mathrm{Com}(m_2; r_2) = \mathrm{Com}(m_1 + m_2; r_1 + r_2)$. Then design a three-move protocol, in the style of Schnorr's, by which Peggy proves she knows an opening (m, r) of a commitment $C = g^m h^r$, and prove that it has special soundness and is honest-verifier zero-knowledge.
3. **Implementation.** Turn the toy Schnorr protocol into a Fiat–Shamir signature: $c = H(y \,\|\, t \,\|\, \text{message}) \bmod q$ with SHA-256, and write `sign` and `verify`. Then deliberately introduce the Frozen Heart bug by leaving y out of the hash, and write a forger that produces a valid-looking signature for a public key of its own choosing without knowing any secret.
4. **Open investigation.** Implement the graph 3-colouring protocol with hash-based commitments, $\mathrm{Com}(m; r) = \text{SHA-256}(r \,\|\, m)$, on random graphs. Measure the total proof size needed for soundness error 2^{-40} as the number of edges grows. How do real systems avoid this cost? Investigate the trade-offs between proof size, prover time and trust assumptions among SNARKs and STARKs. Which assumptions are actually needed for short zero-knowledge proofs is a question still under active research.

82.7 Loose threads

The hook asked how a proof can convince and reveal nothing. The answer has three parts. Randomness in the verifier's challenges makes bluffing detectable. A commitment fixes the prover's choices before she sees those challenges. And "reveals nothing" means "could be simulated": everything the verifier sees, he could have produced alone, so it can carry no knowledge that he lacked. Schnorr's protocol shows all three in four lines of algebra, and the GMW theorem extends them to every statement in NP.

What we did not tell you:

- **Proofs about secrets you share.** Zero knowledge is one tool of *secure multiparty computation*, in which several parties compute a function of their private inputs (an auction, an average salary, a vote count) while learning nothing but the output. The theory again rests on simulators and commitments.
- **Witness indistinguishability.** A weaker property than zero knowledge, but one that survives running many sessions in parallel, which zero knowledge in general does not.
- **Who checks the checker?** A SNARK verifier is a program, and bugs in it have caused real losses. Formally verifying such code, proving the program correct with a proof assistant, is the subject of Ch. 67.
- **Polynomials everywhere.** Modern proof systems reduce every statement to identities between polynomials, which are tested at random points (the Schwartz–Zippel lemma: two different polynomials of degree d agree on at most a fraction d/q of a field of size q). The geometry of polynomial equations is the subject of Ch. 94.

? When the verifier is quantum

Shor's algorithm would compute discrete logarithms on a large quantum computer, breaking Schnorr's assumption outright. There is a subtler problem too. Every zero-knowledge and soundness proof in this chapter **rewinds** a party and runs it twice. A quantum verifier cannot be copied (the no-cloning theorem), and measuring its answer can disturb its state, so rewinding is no longer free. Which zero-knowledge proofs survive against quantum adversaries, and what replaces discrete logarithms? Watrous found the first quantum rewinding technique in 2006, and lattice-based and hash-based proofs are the leading candidates. Post-quantum cryptography is taken up in Ch. 77, and the quantum mechanics behind no-cloning in Ch. 92.

This is the end of Track H. Its six chapters started from codes that defeat noise and ended with proofs that defeat suspicion, and the same tools ran through all of them: probability, finite fields, and the gap between what is true and what can be efficiently checked.

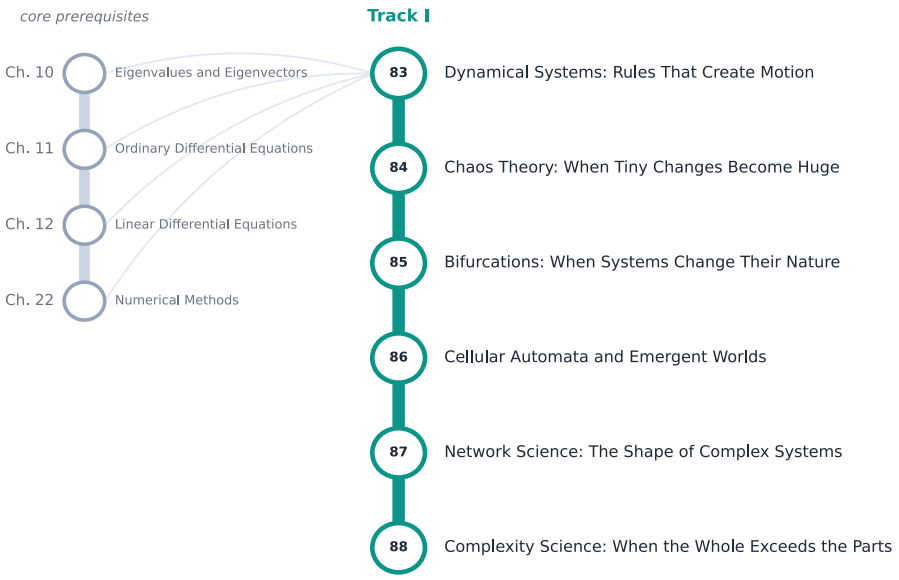
Track I — Dynamical Systems, Chaos, and Complexity

> **Level 2 — Specializations.** Tools for epidemics, ecosystems, power grids, neural networks, traffic, and emergent behavior in games.



Suggested reading order for Track I. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 10 — Eigenvalues and Eigenvectors
- Ch. 11 — Ordinary Differential Equations
- Ch. 12 — Linear Differential Equations
- Ch. 22 — Numerical Methods

Chapters

Ch.	Chapter	What it explores
83	Dynamical Systems: Rules That Create Motion	State spaces, fixed points, stability, phase portraits.
84	Chaos Theory: When Tiny Changes Become Huge	Sensitivity, Lyapunov exponents, strange attractors.
85	Bifurcations: When Systems Change Their Nature	Stability transitions, bifurcation diagrams, nonlinear behavior.
86	Cellular Automata and Emergent Worlds	Local rules, global patterns, computational universality.
87	Network Science: The Shape of Complex Systems	Random networks, scale-free networks, contagion, synchronization.
88	Complexity Science: When the Whole Exceeds the Parts	Emergence, self-organization, feedback, adaptive systems.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 83 — Dynamical Systems: Rules That Create Motion

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 11 (§11.7 existence and uniqueness, §11.9 phase plane and linearisation), Ch. 10 (eigenvalues), Ch. 22 (§22.3 fixed-point iteration, §22.9 Runge–Kutta) · **Leads to:** Ch. 84, Ch. 85, Ch. 87 · **Related:** Ch. 45, Ch. 51, Ch. 72, Ch. 25 **Reading time:** ~30 min

83.1 The hook

For almost a century the Hudson's Bay Company kept careful books on the furs its trappers brought in from the Canadian north. When the ecologist Charles Elton went through the ledgers in the 1920s and 1930s he found something nobody had designed and nobody could explain. The number of snowshoe hare pelts rose and fell with a period of roughly ten years. The number of lynx pelts did the same, with the same period, peaking a year or two after the hares.

No calendar sets that ten-year beat. The cycle is made *inside* the system, by two facts: lynx eat hares, and lynx starve without them. Plentiful hares feed more lynx; the lynx eat the hares down, then starve; the hares, relieved, recover. Round and round.

The first serious model of this, written in the 1920s by Alfred Lotka and Vito Volterra independently, is two lines:

$$\dot{x} = \alpha x - \beta x y, \qquad \dot{y} = \delta x y - \gamma y,$$

where x is prey, y is predators, and $\alpha, \beta, \gamma, \delta > 0$. It has an equilibrium where both species coexist, and if you do what Ch. 11, §11.9 taught you, linearise there and compute eigenvalues, you get a pure imaginary pair, $\pm j\sqrt{\alpha\gamma}$. A centre. Oscillation forever, neither growing nor shrinking.

And then §11.9 hands you a warning: a linear centre is exactly the case where linearisation tells you *nothing*. Hartman–Grobman needs every eigenvalue off the imaginary axis. The nonlinear terms you threw away get the deciding vote. They could make the oscillation spiral slowly inward to a quiet balance, or outward until one day the hares crash so low that the lynx die out. A small push either way, accumulated over centuries, decides between eternal cycles, calm and extinction.

So here is the question this chapter will answer: **does the Lotka–Volterra model really cycle forever, and how would you know without solving it?** It has no closed-form solution in elementary functions. You will answer it anyway, in about six lines, by asking not "what is $x(t)$?" but "what *shape* do the solutions have?". That change of question is the founding move of dynamical systems.

83.2 The big idea

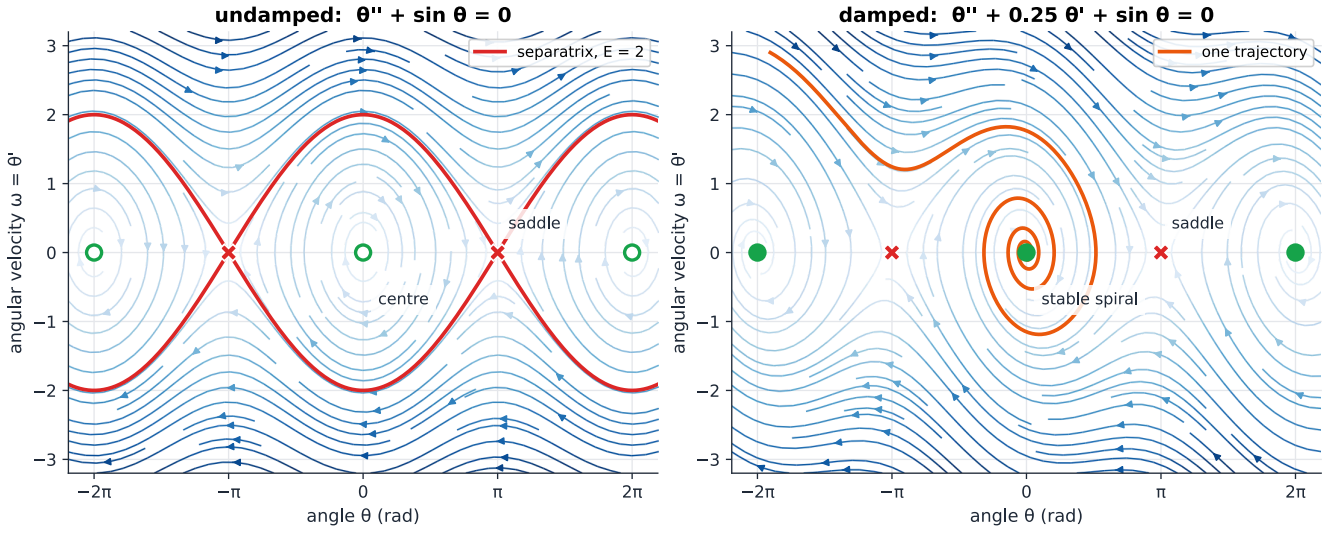
A rule, and the motion it creates

A **dynamical system** is a state and a rule. The state is everything you need to know right now to determine the future: for a pendulum, angle and angular velocity; for the forest, the two populations; for a circuit, capacitor voltages and inductor currents (Ch. 25, §25.2). The rule says how the state changes, either continuously ($\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$, a **flow**) or in jumps ($\mathbf{x}_{n+1} = \mathbf{f}(\mathbf{x}_n)$, a **map**).

The rule is local and dumb: at each point it only says "from here, move that way, this fast". Yet the motion it creates can cycle, settle, switch, and in the next chapter, turn chaotic.

Think in pictures: a river of arrows

Draw the state space as a sheet of paper and, at every point, the arrow $\mathbf{F}(\mathbf{x})$: a picture of a river's surface. A leaf dropped anywhere drifts along a curve tangent to the arrows, a **trajectory** (or **orbit**). Currents plus representative trajectories make the **phase portrait**. Three features matter most: **still water**, points where $\mathbf{F}(\mathbf{x}) = \mathbf{0}$ (**fixed points**); whether nearby leaves drift into still water (**stable**), away from it (**unstable**) or circle it; and **closed loops** of current that attract nearby leaves (**limit cycles**), self-sustained oscillations of a definite size.



Left: the frictionless pendulum. Hanging-down states (green circles) are centres surrounded by closed orbits; the inverted states (red crosses) are saddles. The red separatrix, at energy $E = 2$, divides swinging back and forth from whirling over the top. Right: add friction and the centres become stable spirals; the orange trajectory whirls over the top once, loses energy, and is captured.

In one glance you see every possible motion of the pendulum from every starting state. Henri Poincaré, who invented this way of thinking in the 1880s for planetary orbits, called it the **qualitative theory**: you give up exact numbers and get the shape of all futures.

Why the nonlinear part is the interesting part

Ch. 10 and Ch. 12 solved linear systems completely: every solution is a combination of modes $e^{\lambda t}\mathbf{v}$. A linear system has at most one isolated fixed point, and its oscillations have amplitudes set purely by the initial condition. It cannot choose an amplitude of its own, have two resting states, or switch between them. A flip-flop, an oscillator that grows from noise to one definite amplitude, a pendulum that can hang or whirl: all of these are nonlinear, and the phase portrait is the tool built to see them.

83.3 The mathematics

Flows and the no-crossing rule

Autonomous system, flow, orbit

An **autonomous system** is $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$ with $\mathbf{x} \in \mathbb{R}^n$ (the **state space**) and $\mathbf{F}$ continuously differentiable. Its **flow** $\varphi_t(\mathbf{x}_0)$ is the state at time t of the solution that starts at $\mathbf{x}_0$. The **orbit** of $\mathbf{x}_0$ is the set of all states $\varphi_t(\mathbf{x}_0)$ it passes through.

"Autonomous" means $\mathbf{F}$ does not depend on t: the river's currents do not change with time. A forced system $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x}, t)$ can always be made autonomous by adding time as an extra state, $\dot{\tau} = 1$, at the cost of one dimension.

The flow property

For all s, t (for which the solutions exist), $\varphi_{t+s} = \varphi_t \circ \varphi_s$. Consequently two distinct orbits never cross, and an orbit that returns to a state it has visited before is periodic.

Proof. Fix s and $\mathbf{x}_0$, and compare two functions of t: $\mathbf{u}(t) = \varphi_{t+s}(\mathbf{x}_0)$ and $\mathbf{w}(t) = \varphi_t(\varphi_s(\mathbf{x}_0))$. Both satisfy $\dot{\mathbf{u}} = \mathbf{F}(\mathbf{u})$: the first because shifting time does not change an autonomous equation, the second by definition of the flow. Both equal $\varphi_s(\mathbf{x}_0)$ at $t = 0$. Because $\mathbf{F}$ is C^1, it is locally Lipschitz, and the uniqueness theorem of Ch. 11, §11.7 says the two must coincide. If two orbits shared a point $\mathbf{p}$, both would be "the solution through $\mathbf{p}$", so by uniqueness they would be the same orbit. Finally, if $\varphi_T(\mathbf{x}_0) = \mathbf{x}_0$ for some $T > 0$, then $\varphi_{t+T}(\mathbf{x}_0) = \varphi_t(\varphi_T(\mathbf{x}_0)) = \varphi_t(\mathbf{x}_0)$ for every t. ■

In the plane the no-crossing rule is enormously restrictive, and it is the reason two-dimensional flows are tame.

Fixed points of maps

For a map $x_{n+1} = f(x_n)$, a fixed point is x^* with $f(x^*) = x^*$. You have met the numerical side of this in Ch. 22, §22.3, where fixed-point iteration converges when $|g'| < 1$. Read as dynamics, the same statement is a stability theorem:

Stability of a fixed point of a map

Let f be C^1 with $f(x^*) = x^*$. If $|f'(x^*)| < 1$, nearby orbits converge to x^* geometrically. If $|f'(x^*)| > 1$, nearby orbits are pushed away.

Proof. Take $|f'(x^*)| < k < 1$. By continuity, $|f'| \le k$ on some interval $I = [x^* - r, x^* + r]$. For $x_n \in I$ the mean value theorem gives $x_{n+1} - x^* = f(x_n) - f(x^*) = f'(\xi)(x_n - x^*)$ with ξ between them, so $|x_{n+1} - x^*| \le k|x_n - x^*|$. Hence $x_{n+1} \in I$ too, and by induction $|x_n - x^*| \le k^n |x_0 - x^*| \to 0$. The unstable case is the same argument with the inequality reversed. ■

The sign of $f'(x^*)$ matters too: positive means orbits approach from one side, negative means they hop from side to side. That alternation is the seed of the period-doubling cascade of Ch. 85.

What "stable" means

Stability of an equilibrium

An equilibrium $\mathbf{x}^*$ of $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$ is **(Lyapunov) stable** if for every $\varepsilon > 0$ there is a $\delta > 0$ such that $\|\mathbf{x}(0) - \mathbf{x}^*\| < \delta$ implies $\|\mathbf{x}(t) - \mathbf{x}^*\| < \varepsilon$ for all $t \ge 0$. It is **asymptotically stable** if, in addition, $\mathbf{x}(t) \to \mathbf{x}^*$ for all starts close enough.

A centre is stable but not asymptotically stable; a pendulum with friction is both. For a hyperbolic equilibrium the Jacobian decides everything (§11.9). This chapter is about the cases where it does not, and the tool that works anyway.

Lyapunov's direct method: stability without solving

In 1892 Aleksandr Lyapunov proposed generalising the most physical idea in mechanics: if energy never increases, a system at the bottom of a bowl cannot climb out.

Lyapunov's stability theorem

Let $\mathbf{x}^* = \mathbf{0}$ be an equilibrium of $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$, and let V be a C^1 function on a neighbourhood U of $\mathbf{0}$ with $V(\mathbf{0}) = 0$ and $V(\mathbf{x}) > 0$ for $\mathbf{x} \neq \mathbf{0}$. Its derivative along trajectories is

$$\dot{V}(\mathbf{x}) = \nabla V(\mathbf{x}) \cdot \mathbf{F}(\mathbf{x}).$$

If $\dot{V} \leq 0$ on U, the equilibrium is stable. If $\dot{V} < 0$ on $U \setminus \{\mathbf{0}\}$, it is asymptotically stable.

Proof (stability). Given $\varepsilon > 0$ (small enough that the closed ball $\bar{B}_\varepsilon \subset U$), let m be the minimum of V on the sphere $\|\mathbf{x}\| = \varepsilon$; it is positive because $V > 0$ away from the origin and the sphere is compact. By continuity of V and $V(\mathbf{0}) = 0$, choose $\delta < \varepsilon$ with $V < m$ on B_δ. Start at $\mathbf{x}(0) \in B_\delta$. Along the trajectory $\frac{d}{dt} V(\mathbf{x}(t)) = \dot{V} \leq 0$, so $V(\mathbf{x}(t)) \leq V(\mathbf{x}(0)) < m$ for all $t \geq 0$. To leave B_ε the trajectory would have to cross the sphere, where $V \geq m$. It cannot, so $\|\mathbf{x}(t)\| < \varepsilon$ forever.

(Asymptotic stability.) $V(\mathbf{x}(t))$ is decreasing and bounded below by 0, so it tends to a limit $c \geq 0$. If $c > 0$, the trajectory stays in the compact shell $\{\mathbf{x} \in \bar{B}_\varepsilon : V(\mathbf{x}) \geq c\}$, which excludes a neighbourhood of the origin. On that shell $\dot{V}$ is continuous and negative, so $\dot{V} \leq -a$ for some $a > 0$, and $V(\mathbf{x}(t)) \leq V(\mathbf{x}(0)) - at$, which becomes negative: a contradiction. So $c = 0$, and since V is positive away from $\mathbf{0}$, $\mathbf{x}(t) \to \mathbf{0}$. ∎

The theorem needs no solution and no eigenvalues. It works at a centre, where the Jacobian is silent, and it can certify whole regions, not just infinitesimal neighbourhoods.

The damped pendulum, by energy

Take $\dot{\theta} = \omega$, $\dot{\omega} = -\sin\theta - b\omega$ with $b \geq 0$ (time scaled so that $g/L = 1$). Try the mechanical energy $V = \tfrac{1}{2}\omega^2 + (1 - \cos\theta)$, which is zero at $(0, 0)$ and positive nearby. Then

$$\dot{V} = \omega\dot{\omega} + \sin\theta\,\dot{\theta} = \omega(-\sin\theta - b\omega) + \omega\sin\theta = -b\,\omega^2 \leq 0.$$

So the hanging pendulum is stable. But $\dot{V} = 0$ on the whole line $\omega = 0$, so the theorem does not give asymptotic stability, though every simulation shows the damped pendulum coming to rest. The fix, **LaSalle's invariance principle**, notes that a trajectory cannot *stay* on $\omega = 0$ unless $\sin\theta = 0$, so the only motion compatible with $\dot{V} = 0$ forever is the equilibrium itself.

With $b = 0$, energy is **conserved** and the left panel of the pendulum figure is just a contour map of $E = \tfrac{1}{2}\omega^2 + 1 - \cos\theta$; the separatrix is the level $E = 2$ of the inverted pendulum. Its period betrays the nonlinearity: relative to the small-swing period 2π, the swing is 1.066 times longer at amplitude 1 rad, 1.329 times at 2 rad, 2.571 times at 3 rad, and infinitely long as the amplitude approaches π, where the orbit creeps past a saddle.

The answer to the hook: a hidden conserved quantity

Back to the forest. The trick is to look not at $x(t)$ and $y(t)$ but at the orbit, the curve y versus x. Divide the two equations:

$$\frac{dy}{dx} = \frac{y(\delta x - \gamma)}{x(\alpha - \beta y)}.$$

This is separable (Ch. 11, §11.2). Collect the y's on the left and the x's on the right:

$$\frac{\alpha - \beta y}{y}\,dy = \frac{\delta x - \gamma}{x}\,dx \quad\Longrightarrow\quad \alpha \ln y - \beta y = \delta x - \gamma \ln x - C.$$

The Lotka–Volterra invariant

For $x, y > 0$ the function

$$H(x, y) = \delta x - \gamma \ln x + \beta y - \alpha \ln y$$

is constant along every solution. Every orbit in the open quadrant other than the equilibrium $(\gamma/\delta,\ \alpha/\beta)$ is a closed curve, so every solution is periodic.

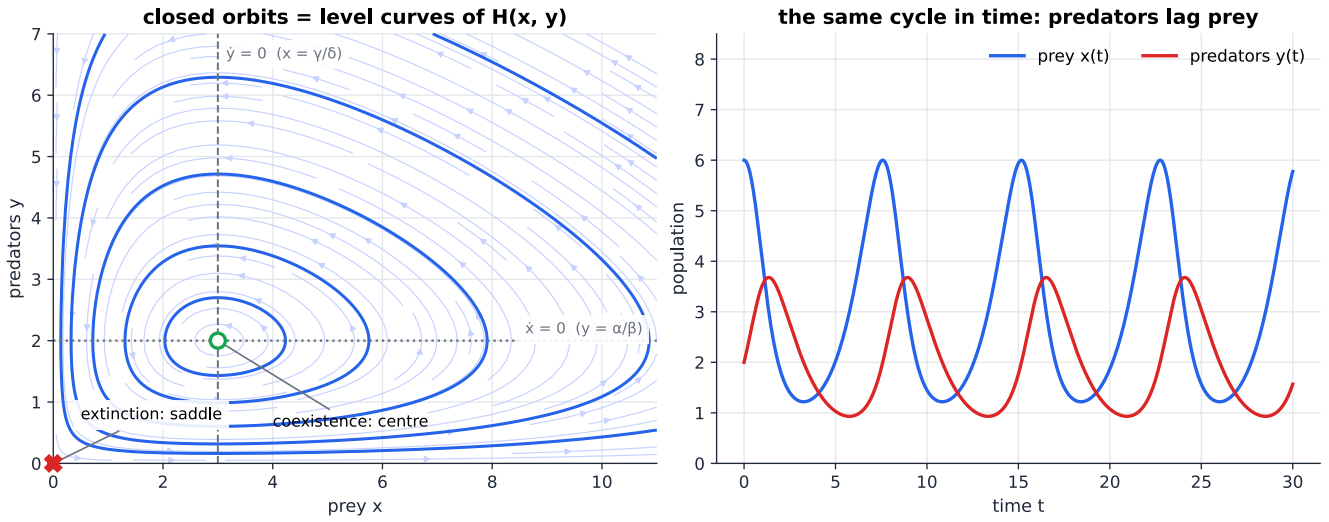
Proof. Constancy is a direct check:

$$\begin{aligned} \dot{H} &= \Big(\delta - \frac{\gamma}{x}\Big)\dot{x} + \Big(\beta - \frac{\alpha}{y}\Big)\dot{y} \\ &= \Big(\delta - \frac{\gamma}{x}\Big)x(\alpha - \beta y) + \Big(\beta - \frac{\alpha}{y}\Big)y(\delta x - \gamma) \\ &= (\delta x - \gamma)(\alpha - \beta y) + (\beta y - \alpha)(\delta x - \gamma) = 0. \end{aligned}$$

Now the shape. The x-part of H, $\delta x - \gamma \ln x$, has second derivative $\gamma/x^2 > 0$: it is strictly convex with a unique minimum at $x = \gamma/\delta$, and tends to $+\infty$ as $x \to 0^+$ and as $x \to \infty$. The y-part is the same with minimum at $y = \alpha/\beta$. So H is a bowl with its lowest point at the coexistence equilibrium and walls rising to infinity at the edges of the quadrant, and every level set $\{H = c\}$ above the minimum is a single closed curve around the equilibrium.

A solution starting on such a curve stays on it, and moves along it with speed $\|\mathbf{F}\|$ bounded below by a positive constant (the curve is compact and contains no zero of $\mathbf{F}$). So it goes all the way round in finite time and returns to its start; by the flow property, it is periodic. ∎

The populations cycle forever, and the size of the cycle is fixed for all time by the initial value of H. You have the complete phase portrait without solving anything.



Left: orbits of the Lotka–Volterra model with $\alpha = 1$, $\beta = 0.5$, $\gamma = 0.75$, $\delta = 0.25$ are the level curves of H, nested around the coexistence centre at $(3, 2)$. The nullclines (dashed and dotted) cross there. Right: the orbit starting at $(6, 2)$ in time. Prey swing between 1.22 and 6, predators between 0.93 and 3.68, with period 7.58, longer than the small-oscillation period $2\pi/\sqrt{\alpha\gamma} = 7.26$. The predator peak lags the prey peak.

The predators' lag, visible in the fur ledgers too, is in the phase plane simply the fact that orbits go round anticlockwise.

A centre is a knife edge

The eternal cycles depend on H being exactly conserved. Give the prey a carrying capacity, $\dot{x} = x(\alpha - \beta y - \varepsilon x)$ with small $\varepsilon > 0$, and the trace of the Jacobian at coexistence becomes $-\varepsilon x^* < 0$: the centre turns into a stable spiral and the cycles die out. A model whose qualitative behaviour changes under arbitrarily small perturbations is **structurally unstable**, and good modellers distrust it. Real lynx–hare cycles persist for reasons the two-line model does not capture.

The invariant reaches beyond ecology. Josef Hofbauer showed in 1981 that the replicator equation of Ch. 45 with $n + 1$ strategies becomes, under the change of variables $y_i = x_i / x_{n+1}$ and a rescaling of time, a Lotka–Volterra system with n species, so the theory of the forest transfers to populations of strategies.

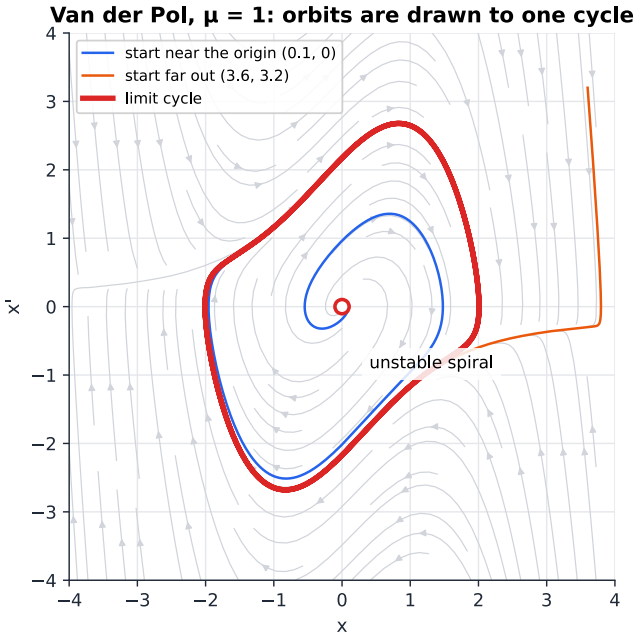
Limit cycles: oscillation with a size of its own

The predator–prey cycles have no preferred amplitude. A clock, a heartbeat or an oscillator circuit should instead settle to *one* amplitude however it was started. That is a limit cycle, and no linear system can have one.

Balthasar van der Pol found the classic example in 1920 while studying triode oscillators:

$$\ddot{x} - \mu(1 - x^2)\dot{x} + x = 0, \qquad \mu > 0.$$

The middle term is a nonlinear damping. For small $|x|$ it is *negative* damping, pumping energy in; for $|x| > 1$ it is positive damping, draining energy out. Small oscillations grow, large ones shrink, and in between there is one closed orbit where the energy pumped in over a cycle exactly balances the energy drained.



The Van der Pol oscillator with $\mu = 1$. A trajectory starting near the unstable spiral at the origin (blue) grows outward; one starting far out (orange) falls inward; both are captured by the same limit cycle (red), with amplitude about 2.01 and period 6.66.

The fact that this picture is typical, not special, is a theorem about the plane:

Poincaré–Bendixson (stated)

Let $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$ be a C^1 system in the **plane**. If a trajectory stays in a closed bounded region that contains no fixed point, it approaches a periodic orbit.

The proof leans on the no-crossing rule and the Jordan curve theorem. For Van der Pol you can build an annulus around the origin whose boundary currents all point inward; it contains no fixed point, so a periodic orbit lives inside. The consequence is strong: in the plane a bounded trajectory approaches a fixed point, a cycle, or a chain of fixed points joined by orbits. There is no fourth option, no wandering forever without repeating.

? Where do limit cycles come from?

Turn the Van der Pol knob μ down through zero and the limit cycle vanishes: for $\mu < 0$ the origin is a stable spiral and every oscillation dies. So at $\mu = 0$ a cycle is *born*. Is it born small, or at full size? Can you predict its amplitude, and does every oscillator start up the same way? That is the Hopf bifurcation of Ch. 85. How many limit cycles a polynomial system in the plane can have is the second half of Hilbert's 16th problem, posed in 1900 and still open even for quadratics.

83.4 The algorithm

A reasonable pipeline for drawing the phase portrait of a planar system $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$:

1. **Find the fixed points.** Run Newton's method for $\mathbf{F}(\mathbf{x}) = \mathbf{0}$ (Ch. 22, §22.4) from a grid of seeds; keep the distinct limits.
2. **Classify each one.** Estimate the Jacobian by central differences, compute its eigenvalues, and read off the type with the §11.9 table. Flag any eigenvalue with real part near zero as *undecided*: that is a case for a Lyapunov function, not for the computer.
3. **Integrate representative trajectories** with RK4 (Ch. 22, §22.9), forward from seeds near unstable points and *backward* in time (integrate $-\mathbf{F}$) to trace stable manifolds of saddles, which are the separatrices that divide basins.
4. **Draw the background current** with a streamline plot.

```
import numpy as np

def F(u):                                   # damped pendulum
    th, w = u
    return np.array([w, -np.sin(th) - 0.25 * w])

def jacobian(F, u, h=1e-6):
    n = len(u); J = np.zeros((n, n))
    for k in range(n):
        e = np.zeros(n); e[k] = h
        J[:, k] = (F(u + e) - F(u - e)) / (2 * h)
    return J

def newton(F, u, iters=50):
    for _ in range(iters):
        u = u - np.linalg.solve(jacobian(F, u), F(u))
    return u

def classify(J, tol=1e-8):
    lam = np.linalg.eigvals(J)
    if np.any(np.abs(lam.real) < tol):  return "non-hyperbolic: undecided", lam
    if lam.real.min() < 0 < lam.real.max(): return "saddle", lam
    kind = "spiral" if np.any(np.abs(lam.imag) > tol) else "node"
    return ("stable " if lam.real.max() < 0 else "unstable ") + kind, lam

seeds = [np.array([a, b]) for a in np.linspace(-4, 4, 9) for b in (-1.0, 0.0, 1.0)]
found = {tuple(np.round(newton(F, s), 6)) for s in seeds}
for p in sorted(found):
    print(p, *classify(jacobian(F, np.array(p))))
```

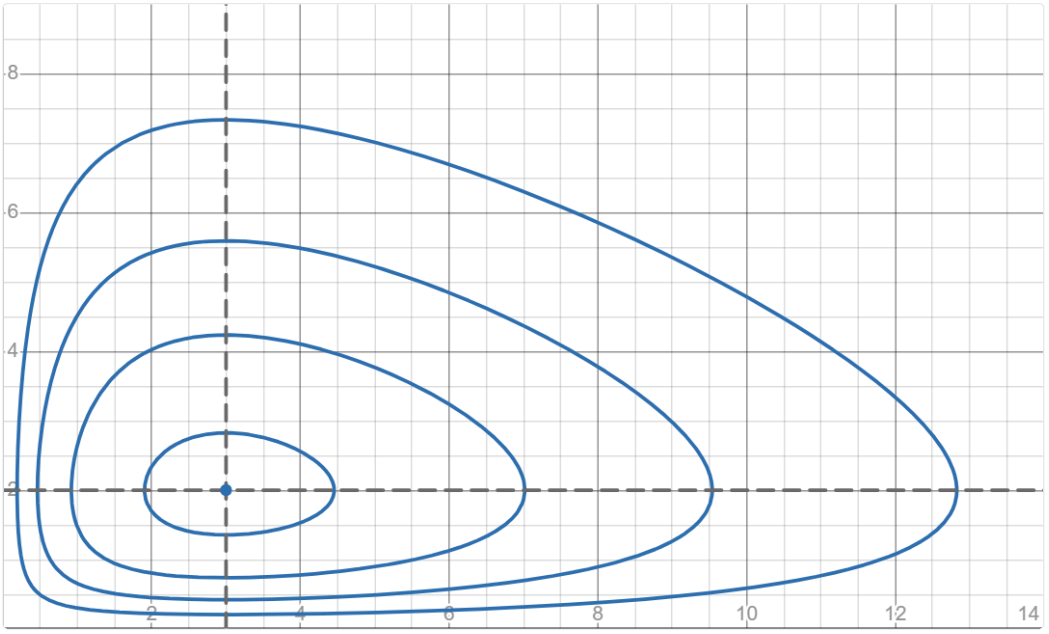
It reports a stable spiral at $(0, 0)$ with eigenvalues $-0.125 \pm 0.992j$ and saddles at $(\pm\pi, 0)$ with eigenvalues 0.883 and -1.133. (Widen the seed grid and it also finds the copies at $\pm 2\pi$, $\pm 3\pi$, and so on.)

Cost and failure modes. Fixed-point finding is cheap; integrating trajectories costs $O(N)$ steps each. The dangerous failures are qualitative:

- **Newton from a grid can miss fixed points** with small Newton basins. There is no general guarantee of finding them all; for polynomial $\mathbf{F}$, algebraic methods do better (Ch. 94).
- **The integrator can change the phase portrait.** Forward Euler turns a centre into an outward spiral: for $\dot{x} = y,\ \dot{y} = -x$ each step multiplies the squared amplitude by exactly $1 + h^2$, so with $h = 0.1$ the amplitude has grown 145-fold by $t = 100$. RK4 is far better but not exact; methods that preserve the conserved quantity by construction (symplectic integrators, Ch. 72) are the principled fix.
- **Non-hyperbolic points** are where step 2 cannot decide, and also where systems change character as parameters move. Treat an "undecided" flag as a signpost to Ch. 85.

83.5 The experiment

First, the forest without solving anything. The curves below are level sets of $H(x, y) = 0.25x - 0.75 \ln x + 0.5y - \ln y$, the invariant for $\alpha = 1$, $\beta = 0.5$, $\gamma = 0.75$, $\delta = 0.25$; its minimum value, at $(3, 2)$, is about 0.233.



Orbits of the predator–prey model as level curves of H. Change the level values (0.3 to 1.6) to see larger and smaller cycles. Then change the coefficient 0.25 of x (that is δ) and move the dashed line to the new $x^* = 0.75/\delta$: how do the cycles shift?

Now draw portraits yourself. The script below integrates a planar system from a ring of starting points with RK4 and overlays streamlines.

```
import numpy as np
import matplotlib.pyplot as plt

b = 0.25          # pendulum damping: try 0, 0.25, 1.0, and negative values
mu = 1.0          # Van der Pol strength: try 0.1, 1, 4
system = "pendulum"   # or "vanderpol"

def F(x, y):
    if system == "pendulum":
        return y, -np.sin(x) - b * y
    return y, mu * (1 - x**2) * y - x

def rk4(x, y, h, n):
    path = [(x, y)]
    for _ in range(n):
        k1 = np.array(F(x, y)); k2 = np.array(F(x + h/2*k1[0], y + h/2*k1[1]))
        k3 = np.array(F(x + h/2*k2[0], y + h/2*k2[1])); k4 = np.array(F(x + h*k3[0], y + h*k3[1]))
        x, y = np.array([x, y]) + h/6 * (k1 + 2*k2 + 2*k3 + k4)
        path.append((x, y))
    return np.array(path)

X, Y = np.meshgrid(np.linspace(-7, 7, 200), np.linspace(-4, 4, 200))
U, V = F(X, Y)
plt.streamplot(X, Y, U, V, color="lightgrey", density=1.2)
for a in np.linspace(0, 2 * np.pi, 12, endpoint=False):
    p = rk4(3 * np.cos(a), 2.5 * np.sin(a), 0.02, 2000)
    plt.plot(p[:, 0], p[:, 1], lw=1)
plt.xlim(-7, 7); plt.ylim(-4, 4); plt.xlabel("x"); plt.ylabel("x'")
plt.title(f"{system}: b={b}, mu={mu}"); plt.show()
```

Things to try:

- Pendulum with `b = 0`, `0.25`, `2.5`. Somewhere in between, the spirals at $\theta = 0$ become nodes and the pendulum stops overshooting. Predict the value ($b = 2$) from the §11.9 table and confirm it.
- Pendulum with `b = -0.1`, a pumped swing. Where do trajectories end up now?
- Van der Pol with `mu = 0.1` and `mu = 4`. The cycle changes from a near-circle to a sharp-cornered **relaxation oscillation**, yet its amplitude stays near 2. Why should it be nearly independent of μ?

83.6 The challenge

1. **Intuition.** A friend claims that $\dot{x} = f(x)$, with x a scalar, can oscillate if f is wiggly enough. Use the no-crossing rule to explain why every bounded solution is monotone and converges to a fixed point. Why does the argument fail for a scalar *map* $x_{n+1} = f(x_n)$?

2. **Derivation.** For the competing-species model $\dot{x} = x(3 - x - 2y)$, $\dot{y} = y(2 - x - y)$, find all four fixed points and classify them with the Jacobian. Then sketch the phase portrait and identify the stable manifold of the saddle: show that it divides the quadrant into two basins, so that one species always wins and which one depends only on the starting point.

3. **Implementation.** Extend the algorithm of §83.4: for each saddle, start two trajectories 10^{-4} either side of it along its stable eigenvector and integrate them *backward* in time. Plot the result for the damped pendulum and for Problem 2's model. You have drawn the separatrices that bound the basins of attraction.

4. **Open investigation.** Lyapunov's theorem needs a function V, and nobody tells you how to find one, or how much of the basin of attraction it can certify. Run the Van der Pol oscillator backward in time: $\dot{x} = -y$, $\dot{y} = x + (x^2 - 1)y$. The origin is now asymptotically stable, and its true basin is the inside of the (now repelling) limit cycle. Show that $V = x^2 + y^2$ certifies the disc $\{V < 1\}$ (with LaSalle's principle). Then search over quadratic forms $V = ax^2 + 2bxy + cy^2$ for the largest certified region $\{V < k\}$, and compare it with the true basin from simulation. How close can quadratics get? What do quartic V buy you? There is no known formula for the best certificate of a given degree.

83.7 Loose threads

The hook asked whether the Lotka–Volterra forest cycles forever, and how you could know without a formula. It does: $H = \delta x - \gamma \ln x + \beta y - \alpha \ln y$ is conserved, its level curves are closed loops, and every orbit is one of them. The same move, finding a function that does something simple along trajectories, gave Lyapunov's theorem. The no-crossing rule, through Poincaré–Bendixson, limits every bounded planar motion to a point, a cycle or a chain of saddles. And the knife-edge warning stands: the forest's cycles die under any perturbation that breaks the conservation law, while self-sustained cycles like Van der Pol's are robust.

What the chapter left open:

- **The birth of cycles.** The first mystery, above, is answered in Ch. 85.
- **Fractal basin boundaries.** In some systems the boundary between two basins is a fractal, and which attractor you reach becomes unpredictable in practice (Ch. 73, Ch. 84).
- **Many interacting units.** Couple thousands of oscillators through a network and they can lock into step, the synchronisation story of Ch. 87.
- **Controlling the flow.** If you may choose part of the rule to steer the state, you are doing optimal control (Ch. 51), where Lyapunov functions reappear as cost-to-go.

? Why the plane cannot be chaotic, and what a third dimension unlocks

Poincaré–Bendixson leaves bounded planar orbits three fates, all eventually regular. Add one state variable and the theorem fails completely: there are three-variable systems with just two quadratic terms whose orbits stay bounded forever, never settle, never repeat, and separate exponentially from their neighbours. What does such an orbit look like, and how do you measure how unpredictable it is? That is Ch. 84.

? Can a computer find the Lyapunov function for you?

Lyapunov's theorem turns stability into a search for a function, and the challenge's Problem 4 shows how unguided that search can be. For systems with polynomial right-hand sides there is a remarkable modern answer: look for V as a *sum of squares* of polynomials, and the conditions $V > 0$, $\dot{V} < 0$ become a convex optimisation problem a computer can solve. Why convexity turns an art into an algorithm is the theme of Ch. 47; how far sum-of-squares certificates can reach, and when they must fail, is an open research area.

Chapter 84 — Chaos Theory: When Tiny Changes Become Huge

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 83 (flows, fixed points, Poincaré–Bendixson), Ch. 7 (divergence), Ch. 22 (§22.1 floating point, §22.9 Runge–Kutta), Ch. 10 · **Leads to:** Ch. 85, Ch. 87, Ch. 88 · **Related:** Ch. 73, Ch. 72, Ch. 45, Ch. 97 **Reading time:** ~30 min

84.1 The hook

In the winter of 1961 the meteorologist Edward Lorenz, at MIT, wanted to look again at a stretch of weather his computer had produced. His model was a dozen equations for a toy atmosphere, run on a Royal McBee LGP-30, a vacuum-tube machine the size of a desk that printed its results line by line. To save time he did not restart from the beginning. He typed in the state from the middle of an earlier printout and went for a coffee.

When he came back, the new run had first copied the old one and then wandered away from it. After a couple of simulated months the two weather histories had nothing to do with each other.

Nothing was broken. The computer stored six digits, the printout showed three. Lorenz had typed 0.506 where the machine had held 0.506127. A difference of one part in four thousand, smaller than any thermometer could measure, had grown until it was as large as the weather itself.

The model was **deterministic**: the same input always gave the same output. Yet it could not be predicted in practice, because the input could never be known exactly. If the real atmosphere behaves like this, Lorenz concluded, long-range forecasting is impossible in principle.

That raises the question this chapter answers: **if a deterministic system amplifies errors, how far ahead can you predict it, and what does it cost to see further?** The answer is a single number per system, and it is not kind. Ten times more precise measurements do not make the forecast ten times longer; they add a fixed amount of time, the same for every digit you pay for.

84.2 The big idea

Stretch, fold, repeat

Watch a baker make puff pastry: roll the dough to twice its length (**stretch**), fold it back on itself (**fold**), repeat. Two flecks of flour a millimetre apart are two millimetres apart after one roll, four after two, and after ten would be a metre apart, except that the fold keeps bringing them back. After a dozen rounds their relative position is effectively random, though every step was deterministic.

That is the mechanism of chaos, in every chaotic system ever found:

- **Stretching** pulls nearby states apart exponentially. This is **sensitive dependence on initial conditions**.
- **Folding** keeps the motion bounded. Without the fold, stretching is just instability: a ball rolling off a hill, which is perfectly predictable.
- **Repetition** mixes. After enough rounds, a tiny region of initial states has been smeared over the whole space.

The rate of stretching is the key number. If errors grow like $\delta(t) \approx \delta_0 e^{\lambda t}$, the error reaches the size Δ of the whole attractor (where your forecast is worthless) at

$$T_{\text{predict}} \approx \frac{1}{\lambda} \ln \frac{\Delta}{\delta_0}.$$

The initial error sits inside a *logarithm*. Divide δ_0 by ten and you gain only $(\ln 10)/\lambda$ extra time units. Exponential growth of error becomes logarithmic return on precision. That is the answer to the hook in outline; the rest of the chapter makes λ precise and computes it.

Why you need room to fold

Ch. 83 proved that a flow in the plane cannot do this: by Poincaré–Bendixson every bounded planar orbit settles on a point, a cycle, or a chain of saddles. Orbits cannot cross, so in two dimensions there is no way to fold a sheet of trajectories back over itself. In three dimensions there is: trajectories can pass over and under one another, the way strands of pastry lie on top of each other after a fold. Three is the minimum for a chaotic flow.

Maps jump, so they need less room: a non-invertible map can be chaotic in one dimension (the logistic map folds an interval onto itself), an invertible one in two (the Hénon map of Ch. 73).

84.3 The mathematics

Sensitivity and the Lyapunov exponent

> **Sensitive dependence**
>
> A map f on a set X has **sensitive dependence on initial conditions** if there is a $\Delta > 0$ such that for every $x \in X$ and every neighbourhood of x, however small, some y in it has an orbit that eventually separates from the orbit of x by more than Δ: $|f^n(x) - f^n(y)| > \Delta$ for some n.

Sensitivity says errors grow; the Lyapunov exponent says how fast. Start with a one-dimensional map $x_{k+1} = f(x_k)$ and two nearby starting points, x_0 and $x_0 + \delta_0$. After n steps, to first order,

$$\delta_n \approx \left(f^n\right)'(x_0)\, \delta_0.$$

The chain rule turns the derivative of the n-fold composition into a product along the orbit:

$$\left(f^n\right)'(x_0) = f'(x_{n-1})\, f'(x_{n-2}) \cdots f'(x_0) = \prod_{k=0}^{n-1} f'(x_k).$$

So the error is multiplied at each step by the local stretching factor $|f'(x_k)|$. Writing $|\delta_n| \approx e^{n\lambda}|\delta_0|$ and solving for λ:

Lyapunov exponent of a one-dimensional map

$$\lambda(x_0) = \lim_{n\to\infty} \frac{1}{n} \ln \left|\left(f^n\right)'(x_0)\right| = \lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n-1} \ln|f'(x_k)|.$$

$\lambda < 0$: nearby orbits converge (a stable fixed point or cycle). $\lambda > 0$ on a bounded orbit: sensitive dependence, the signature of chaos.

The exponent is the **time-average of the logarithm of the stretching**. The logarithm is what makes it an average: stretching factors multiply, their logarithms add. For a stable fixed point x^* the orbit sits at x^*, every term is $\ln|f'(x^*)|$, and $\lambda = \ln|f'(x^*)| < 0$, which is the stability theorem of Ch. 83 in logarithmic dress.

For a flow $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$ the same idea applies to a small separation vector $\boldsymbol{\delta}$, which evolves by the linearised equation $\dot{\boldsymbol{\delta}} = \mathbf{J}(\mathbf{x}(t))\,\boldsymbol{\delta}$ along the orbit. The **largest Lyapunov exponent** is $\lambda_1 = \lim_{t\to\infty} \frac{1}{t} \ln\left(\|\boldsymbol{\delta}(t)\|/\|\boldsymbol{\delta}(0)\|\right)$ for a generic $\boldsymbol{\delta}(0)$. In n dimensions there are n exponents $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$, the growth rates of lengths, areas, volumes and so on, the **Lyapunov spectrum**.

The horizon of §84.2 uses λ_1, and holds while the error is small enough for linearisation.

A chaotic system you can solve exactly: the doubling map

Take $x \in [0, 1)$ and the map

$$D(x) = 2x \bmod 1.$$

Write x in binary, $x = 0.b_1b_2b_3\ldots$. Doubling shifts the binary point one place to the right, and "mod 1" throws away the digit that crosses it:

$$D(0.b_1b_2b_3b_4\ldots) = 0.b_2b_3b_4\ldots$$

Everything about the dynamics can now be read off.

The doubling map is chaotic

(a) D has Lyapunov exponent $\ln 2$ at every point. (b) It has sensitive dependence with $\Delta = 1/4$. (c) Its periodic points are dense in $[0, 1)$. (d) It has orbits that come arbitrarily close to every point.

Proof. (a) $D'(x) = 2$ wherever it is defined, so every term of the average is $\ln 2$.

(b) Take any x and any $\varepsilon > 0$. Choose n with $2^{-n} < \varepsilon$, and let y be x with its binary digit $n+1$ flipped, that is $y = x \pm 2^{-(n+1)}$ with no carry. Then $|y - x| < \varepsilon$, and after n shifts the two points differ only in their first digit, so $|D^n(y) - D^n(x)| = \frac{1}{2} > \frac{1}{4}$.

(c) A point whose binary expansion repeats with period p, such as $0.\overline{011}$, returns to itself after p shifts. Given any x and n, the repeating number made of the first n digits of x is within 2^{-n} of x. So periodic points are arbitrarily close to every point.

(d) Write down every finite binary string, in order of length, and concatenate them into one infinite expansion $z = 0.0\,1\,00\,01\,10\,11\,000\ldots$. Any target x is approximated to n digits by some block of z, and shifting z to that block lands within 2^{-n} of x. ■

Predicting the doubling map n steps ahead requires knowing the initial condition to n binary digits. Each step consumes one bit you had and exposes one you never had: the exponent $\ln 2$ is exactly one bit per step.

Properties (b), (c) and (d) are Robert Devaney's three ingredients of chaos: sensitivity, dense periodic orbits and topological transitivity (some orbit visits everywhere). Notice the paradox in (c): the chaotic set is *packed* with periodic orbits, every one of them unstable, and a typical orbit wanders among them forever, never settling on any.

The logistic map at $r = 4$ is the doubling map in disguise

The logistic map $x_{n+1} = r x_n(1 - x_n)$ on $[0, 1]$ is the textbook example of a non-invertible chaotic map: it stretches the interval and folds it in half. At $r = 4$ its exponent can be found exactly by a change of variables. Set

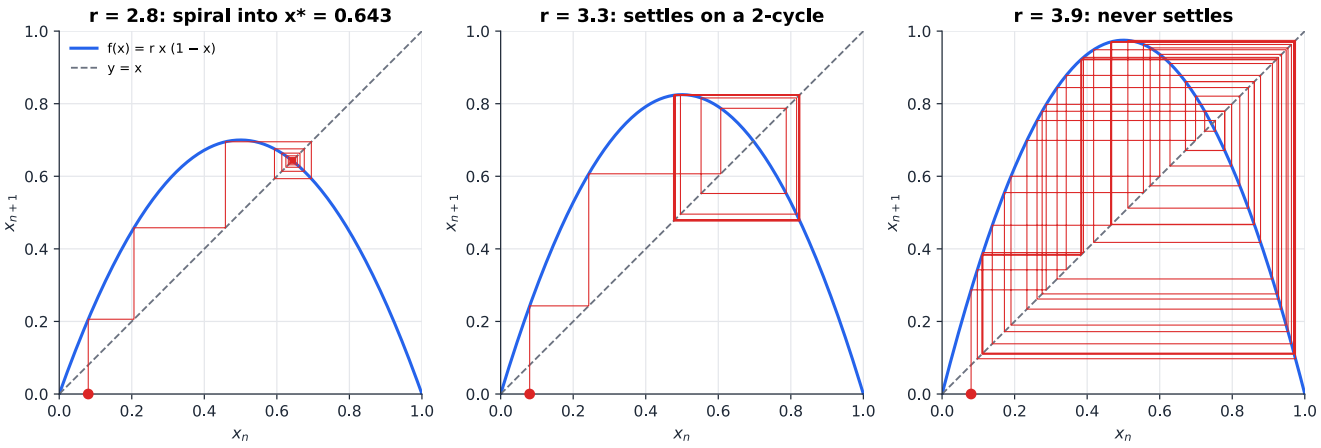
$$x = \sin^2(\pi\theta), \qquad \theta \in [0, 1).$$

Then

$$4x(1 - x) = 4\sin^2(\pi\theta)\cos^2(\pi\theta) = \left(2\sin(\pi\theta)\cos(\pi\theta)\right)^2 = \sin^2(2\pi\theta) = \sin^2\left(\pi\, D(\theta)\right),$$

the last step because $\sin^2$ has period π in its argument, so dropping the integer part of 2θ changes nothing. In words: **if x corresponds to θ, then $4x(1 - x)$ corresponds to $D(\theta)$.** The logistic map at $r = 4$ and the doubling map are the same dynamical system seen through the lens $h(\theta) = \sin^2(\pi\theta)$. Such a change of variables is called a **conjugacy**: $f \circ h = h \circ D$.

A smooth conjugacy cannot change the long-run stretching rate, because h' contributes at most a bounded factor at the start and the end of the orbit, which disappears when divided by n. (There is a fine print: h' vanishes at $\theta = 0$ and $\frac{1}{2}$, so the argument needs typical orbits to avoid lingering there, which they do.) So the logistic map at $r = 4$ has $\lambda = \ln 2 \approx 0.693$ too, and a numerical average of $\ln|4(1 - 2x_k)|$ over 2×10^5 iterates gives 0.6931.



Cobweb diagrams of the logistic map from $x_0 = 0.08$: go up to the curve, across to the diagonal, repeat. At $r = 2.8$ the orbit spirals into the fixed point $x^* = 1 - 1/r = 0.643$, where $f'(x^*) = 2 - r = -0.8$ (the alternation is the negative slope). At $r = 3.3$ it settles onto a cycle of two values. At $r = 3.9$ it never settles; its Lyapunov exponent is about 0.50.

How the logistic map gets from the tidy left panel to the chaotic right one, as r is turned up, is a story of its own.

? The road from order to chaos has a speed limit

Turn r up slowly from 2.8. At $r = 3$ the fixed point gives way to a 2-cycle; at 3.4495 the 2-cycle gives way to a 4-cycle; then 8, 16, 32, faster and faster, until at $r \approx 3.5699$ the period is infinite and chaos begins. The gaps between successive doublings shrink by a ratio that tends to $4.6692\ldots$. Mitchell Feigenbaum found the same ratio in every one-humped map he tried, and experimenters later measured it in convecting fluids and electronic circuits. Why should one number govern systems that have nothing in common? The cascade itself is mapped out in Ch. 85, and the reason for its universality is a renormalisation argument from Ch. 92.

The Lorenz equations: a strange attractor

In 1963 Lorenz boiled a model of a convecting fluid down to three equations:

$$\dot{x} = \sigma(y - x), \qquad \dot{y} = x(\rho - z) - y, \qquad \dot{z} = xy - \beta z,$$

with the classic values $\sigma = 10$, $\rho = 28$, $\beta = 8/3$. Here x measures the strength of the convective roll, y the temperature difference between rising and sinking fluid, and z the distortion of the vertical temperature profile. There are only two nonlinear terms, xz and xy.

Every equilibrium is unstable. The origin has Jacobian eigenvalues 11.83, -2.67, -22.83: a saddle. The other two equilibria are $C_\pm = \big(\pm\sqrt{\beta(\rho-1)},\ \pm\sqrt{\beta(\rho-1)},\ \rho - 1\big) = (\pm 8.49, \pm 8.49, 27)$, each with eigenvalues -13.85 and $0.094 \pm 10.19j$: a spiral that unwinds slowly outward. Orbits spiral away from C_+ until they are flung over to spiral around C_-, then back, with an unpredictable number of turns each time.

Yet orbits stay bounded, and in fact they are squeezed onto a set of zero volume. That is a theorem you can prove in two lines.

Volume contraction in the Lorenz system

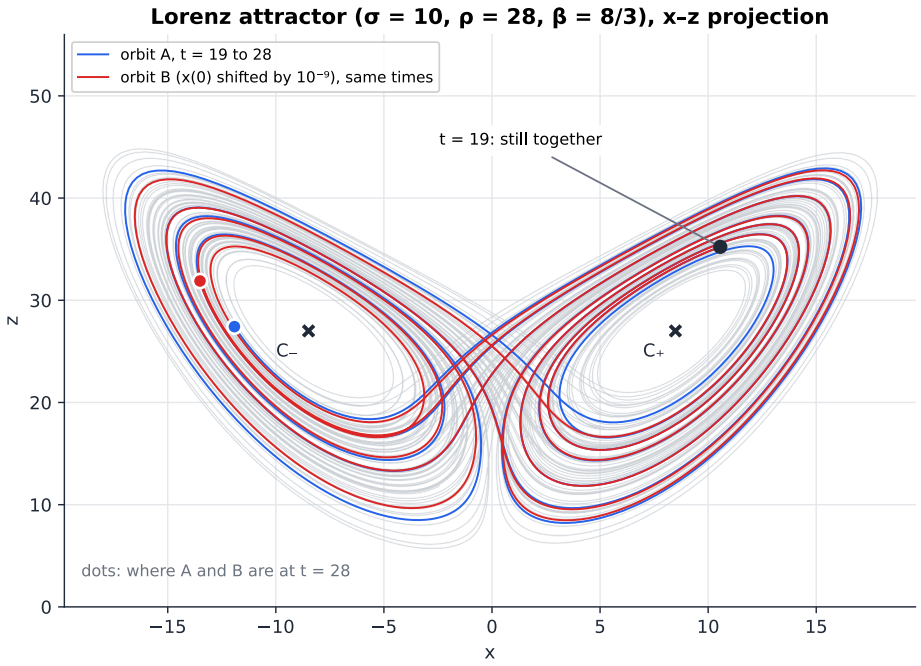
Let $V(t)$ be the volume of a region of initial states carried along by the flow. Then $\dot{V} = \int (\nabla \cdot \mathbf{F})\, dV$, and for the Lorenz equations

$$\nabla \cdot \mathbf{F} = \frac{\partial \dot{x}}{\partial x} + \frac{\partial \dot{y}}{\partial y} + \frac{\partial \dot{z}}{\partial z} = -\sigma - 1 - \beta = -\frac{41}{3} \approx -13.67,$$

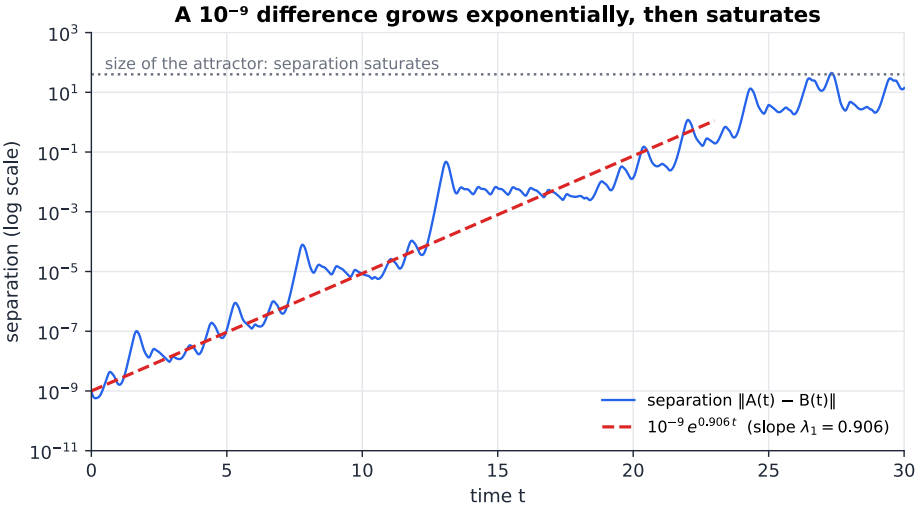
so $V(t) = V(0)\, e^{-13.67\, t}$.

Proof. The rate at which a moving region's volume changes is the flux of the velocity field through its boundary, $\dot{V} = \oint_S \mathbf{F} \cdot \hat{\mathbf{n}}\, dS$, which by the divergence theorem (Ch. 7) equals $\int (\nabla \cdot \mathbf{F})\, dV$. For Lorenz the divergence is the constant $-(\sigma + 1 + \beta)$, so $\dot{V} = -(\sigma + 1 + \beta)V$. ■

In one time unit any blob of states shrinks to $e^{-13.67} \approx 10^{-6}$ of its volume. Combined with boundedness, this means all orbits end on an **attractor** of zero volume. But it cannot be a fixed point (all are unstable), and it cannot be a cycle (nearby orbits separate). It is something new: a set that is locally like a stack of sheets, infinitely many of them, layered like folded pastry. Lorenz called it "an infinite complex of surfaces". It is now called a **strange attractor**: an attractor with sensitive dependence on initial conditions, and with fractal structure.



The Lorenz attractor in the x–z plane (grey), computed with RK4 at step $h = 0.005$. Orbits A and B started 10^{-9} apart. At $t = 19$ they are still indistinguishable on this scale; by $t = 28$ they are on different wings. The crosses are the unstable equilibria $C_{\pm}$.



The distance between orbits A and B on a logarithmic axis. Apart from wiggles (the stretching rate varies around the attractor), it follows a straight line of slope $\lambda_1 = 0.906$ until it reaches the size of the attractor at about $t = 27$, where it saturates: the fold.

This is the hook's answer made quantitative. With $\lambda_1 \approx 0.906$, each factor of ten in initial precision buys $\ln 10 / 0.906 \approx 2.5$ time units. Starting 10^{-9} apart, the forecast fails near $t \approx \ln(40/10^{-9})/0.906 \approx 27$, as plotted. Lorenz's rounding error of about 1.3×10^{-4} would buy about 14 time units in this system; data a millionfold better would add just 15 more.

The full Lyapunov spectrum of the Lorenz attractor, computed by the method of §84.4, is $(0.906,\ 0,\ -14.57)$. The zero exponent belongs to the direction along the flow: shifting a point slightly forward in time along its own orbit neither grows nor shrinks. And the sum is $0.906 + 0 - 14.57 = -13.67$, the divergence, as it must be: the exponents are the growth rates of the principal axes of a small blob, and the volume is their product.

The dimension of a strange attractor

Ch. 73 left a question for this chapter: why should chaotic attractors be fractals, and why can their dimension be predicted from the Lyapunov exponents?

A small ball of states near the attractor stretches at rate $\lambda_1 > 0$, keeps its length along the flow, and contracts at rate $|\lambda_3|$. Stretching makes the attractor at least two-dimensional, contraction makes it less than three-dimensional, and folding stacks the contracted sheets inside each other like the layers of a Cantor set. James Kaplan and James Yorke proposed in 1979 that the dimension balances the expanding directions against the contracting direction that just barely wins:

Kaplan–Yorke (Lyapunov) dimension

If $\lambda_1 + \cdots + \lambda_k \geq 0$ but $\lambda_1 + \cdots + \lambda_{k+1} < 0$, then

$$D_{KY} = k + \frac{\lambda_1 + \cdots + \lambda_k}{|\lambda_{k+1}|}.$$

For Lorenz, $k = 2$ and $D_{KY} = 2 + 0.906/14.57 = 2.06$: a set barely thicker than a surface, which is why it *looks* like two sheets. For the Hénon map of Ch. 73 the exponents are 0.42 and -1.62, so $D_{KY} = 1 + 0.42/1.62 = 1.26$, matching the box-counting dimension measured there. Kaplan and Yorke conjectured that D_{KY} equals the attractor's information dimension for typical systems; it has been proved in some classes of systems and is believed far more widely.

Can a simulation of chaos be trusted?

Every number in this chapter came from a computer, and every computed orbit is wrong. In double precision each RK4 step makes a relative error of about 10^{-16}, and chaos amplifies it by $e^{0.906t}$. By $t \approx 40$ the computed Lorenz orbit has no relation to the true orbit that starts from the same point. So why believe the pictures?

The answer is the **shadowing lemma**, proved by Dmitri Anosov and Rufus Bowen for systems that are *uniformly hyperbolic*: at every point of the invariant set, directions split cleanly into ones that stretch and ones that contract, at rates bounded away from zero.

> **Shadowing lemma (stated)**
>
> On a uniformly hyperbolic invariant set, for every $\varepsilon > 0$ there is a $\delta > 0$ such that every δ**-pseudo-orbit** (a sequence with $\|x_{k+1} - f(x_k)\| < \delta$ at every step, which is what a computer produces) stays within ε of some **true** orbit for all time.

So the computed orbit is not the orbit you asked for, but it is a faithful copy of an orbit from a slightly different start, and its statistics (time averages, exponents, the shape of the attractor) are the statistics of the real system. The doubling map is uniformly hyperbolic, so it is covered. The Lorenz and Hénon attractors are not: Lorenz's contains an equilibrium, and Hénon's has tangencies where stretching and contracting directions line up. For such systems shadowing has been proved only for long but finite stretches of time, with computer-assisted bounds. Warwick Tucker's 1999 proof that the Lorenz attractor really exists, answering Smale's 14th problem, was itself a rigorous computation of this kind.

> **Floating point can kill chaos outright**
>
> Iterate the doubling map in double precision from $x_0 = 0.1234567$ and after 55 steps the computer returns exactly 0, forever. Each doubling shifts a bit out of the 53-bit mantissa and shifts in a zero (Ch. 22, §22.1). Shadowing assumes small random-like errors, not arithmetic that discards information systematically. The logistic map at $r = 4$ survives, because rounding $4x(1-x)$ keeps generating new low-order bits.

Recognising chaos

Ch. 45 asked how you would recognise chaos in a population game; the same question arises for a circuit on a bench or a heartbeat on a monitor. Three tests, each with traps:

- **A positive largest Lyapunov exponent** on a bounded orbit (§84.4). The trap: noise also separates nearby trajectories, so on measured data the estimate must stay positive as you vary the embedding and time scale.
- **A broadband spectrum.** Periodic signals have line spectra (Ch. 15); chaos has a continuous one. The trap: so does noise. The spectrum can rule chaos out, never in.
- **Low-dimensional structure.** Plot a measured signal $s(t)$ against $s(t-\tau)$ and $s(t-2\tau)$. Floris Takens proved in 1981 that these **delay coordinates** reconstruct a faithful copy of a deterministic attractor: chaos appears as a thin folded object, while noise fills the space.

84.4 The algorithm

The definition of λ_1 cannot be used literally: two orbits started close together separate until they saturate at the size of the attractor, after which their distance says nothing. Giancarlo Benettin and colleagues (1976) fixed this by **renormalising**: let the separation grow for a short time, record how much it grew, shrink it back to its original size along the same direction, and repeat.

```
import numpy as np

def lorenz(u, s=10.0, r=28.0, b=8/3):
    x, y, z = u
    return np.array([s*(y - x), x*(r - z) - y, x*y - b*z])

def rk4(f, u, h):
    k1 = f(u); k2 = f(u + h/2*k1); k3 = f(u + h/2*k2); k4 = f(u + h*k3)
    return u + h/6*(k1 + 2*k2 + 2*k3 + k4)

def largest_lyapunov(f, u, h=0.01, d0=1e-8, steps_per_renorm=10, n_renorm=20000):
    for _ in range(2000):                      # discard the transient
        u = rk4(f, u, h)
    v = u + d0 * np.array([1.0, 0, 0])
    total = 0.0
    for _ in range(n_renorm):
        for _ in range(steps_per_renorm):
            u, v = rk4(f, u, h), rk4(f, v, h)
        d = np.linalg.norm(v - u)
        total += np.log(d / d0)                # growth since the last renormalisation
        v = u + (v - u) * (d0 / d)             # shrink back, keep the direction
    return total / (n_renorm * steps_per_renorm * h)

print(largest_lyapunov(lorenz, np.array([1.0, 1.0, 1.0])))   # about 0.91
```

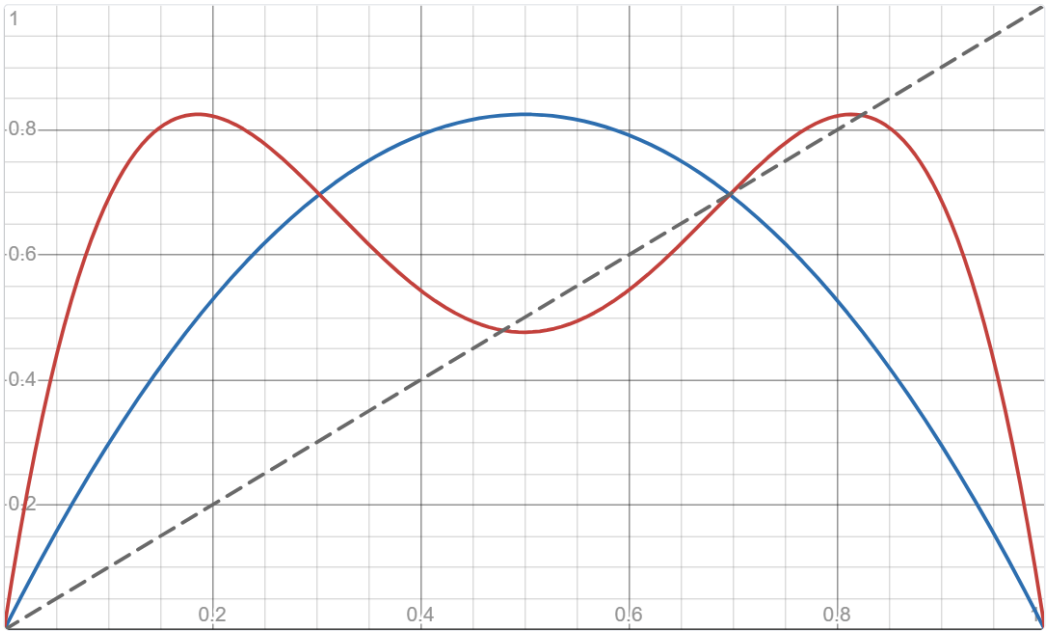
Why it works. The separation stays tiny, so it obeys the linearised dynamics, and its direction swings toward the most-stretched one. The summed logarithms are the logarithm of the product in the definition, computed without ever letting the separation saturate.

Cost and accuracy. Twice the cost of one simulation; the estimate converges roughly like $1/\sqrt{T}$ in the averaging time T. With $T = 2000$ it gives 0.909 against the accepted 0.906. For the full spectrum, evolve n separation vectors with the Jacobian and re-orthonormalise them by QR factorisation (Ch. 24, §24.3); the logarithms of the diagonal of $\mathbf{R}$ accumulate the exponents.

Failure modes. If `d0` is too large the separation leaves the linear regime and the estimate is biased low; if it is near 10^{-16} relative to the state, rounding noise dominates. Too few steps between renormalisations wastes work; too many lets the separation saturate. And a transient that is not discarded measures the approach to the attractor, not the attractor.

84.5 The experiment

First, look at the logistic map and its second iterate. A 2-cycle of f is a pair of fixed points of $f \circ f$ that are not fixed points of f.



The logistic map f (blue) and $f \circ f$ (red) at $r = 3.3$. The red curve crosses the diagonal four times: two of the crossings are the fixed points of f, the other two (near 0.479 and 0.824) are the 2-cycle in the cobweb figure. Change every 3.3 to 2.8, and to 3.9, and watch the crossings appear and the hump steepen.

Now scan the Lyapunov exponent of the logistic map across r. Where it is negative the map settles onto a stable cycle; where it is positive the orbit is chaotic.

```
import numpy as np
import matplotlib.pyplot as plt

r_min, r_max = 2.8, 4.0     # zoom in: try 3.82, 3.86 (the period-3 window)
n_r = 1500                  # number of r values
n_transient = 1000          # iterations thrown away
n_avg = 4000                # iterations averaged

r = np.linspace(r_min, r_max, n_r)
x = np.full(n_r, 0.3)
for _ in range(n_transient):
    x = r * x * (1 - x)
lam = np.zeros(n_r)
for _ in range(n_avg):
    lam += np.log(np.abs(r * (1 - 2 * x)) + 1e-300)
    x = r * x * (1 - x)
lam /= n_avg

plt.plot(r, lam, lw=0.8)
plt.axhline(0, color="k", lw=0.8)
plt.axhline(np.log(2), color="r", ls="--", lw=0.8, label="ln 2")
plt.xlabel("r"); plt.ylabel("Lyapunov exponent λ"); plt.legend()
plt.ylim(-2.5, 1); plt.title("Logistic map: λ < 0 periodic, λ > 0 chaotic"); plt.show()
for rv in (2.8, 3.5, 3.7, 3.83, 3.9, 4.0):
    print(rv, round(float(np.interp(rv, r, lam)), 3))
```

Things to notice and try:

- At $r = 2.8$ the exponent is $\ln 0.8 = -0.223$, the stable fixed point's slope. At $r = 4$ it reaches $\ln 2$.
- The plot touches zero from below at $r = 3$ and $r = 3.4495$ (where cycles double) and dives toward $-\infty$ in between, at **superstable** values where the cycle passes through $x = \tfrac{1}{2}$ and $f' = 0$.
- Above 3.5699, chaos is interrupted by **windows** of negative exponent, the widest near $r = 3.83$ (period 3, with $\lambda \approx -0.37$). Zoom in on one. How many windows can you find, and how does their width change as you go?

84.6 The challenge

1. **Intuition.** A weather service improves its observations so that initial errors fall by a factor of 1000. If the forecast horizon was 7 days and errors grow exponentially with a doubling time of 2 days, how much longer is the horizon now? Explain why a forecaster would rather halve the doubling time's effect than buy better thermometers, and what that would even mean.

2. **Derivation.** The **tent map** is $T(x) = 2x$ for $x \le \frac{1}{2}$ and $2 - 2x$ for $x > \frac{1}{2}$. Compute its Lyapunov exponent. Then show that T is conjugate to the logistic map at $r = 4$ via $x = \sin^2(\pi y/2)$, and explain why the conjugacy is consistent with both exponents being $\ln 2$.

3. **Implementation.** Extend the algorithm of §84.4 to the full Lyapunov spectrum of the Lorenz system using QR re-orthonormalisation. Check that the exponents sum to $-41/3$ and that the middle one tends to 0. Then compute D_{KY} as a function of ρ from 25 to 40.

4. **Open investigation.** Take a chaotic signal you did not generate: a dripping tap timed with a microphone, a double pendulum filmed with a phone, or a published series of sunspot numbers. Build delay coordinates and estimate the largest Lyapunov exponent. How sensitive is your estimate to the delay, the embedding dimension, and noise? Can you convince a sceptic that the signal is chaos and not noise? For short, noisy data there is no agreed method.

84.7 Loose threads

The hook asked how far ahead an error-amplifying deterministic system can be predicted. The answer is $T \approx \lambda_1^{-1} \ln(\Delta/\delta_0)$: a horizon that grows only logarithmically with precision. For Lorenz's equations each extra digit buys 2.5 time units, no more. The mechanism is stretching plus folding; the result, a strange attractor of zero volume and dimension 2.06. The doubling map showed chaos as the loss of one bit per step, and shadowing explained why computed chaos still tells the truth about statistics.

What the chapter left open:

- **The route into chaos.** The Feigenbaum mystery above is mapped out in Ch. 85.
- **Chaos and fractals.** Why D_{KY} matches a box-counting dimension is a theorem only in special cases; the measure-theoretic notions of dimension it needs are in Ch. 97.
- **Chaos with many parts.** Turbulence and weather have millions of positive exponents; how such systems can still have predictable large-scale statistics is a theme of Ch. 88.

? Why does the average exist at all?

The Lyapunov exponent is a limit of averages along a single orbit. Why should that limit exist, and why should almost every starting point give the *same* number, when the orbits themselves are wildly different? For the doubling map you can almost see it: the binary digits of a typical number behave like fair coin flips. In general, the answer is the ergodic theorem, which equates time averages with averages over the attractor, and Oseledets' theorem, which guarantees the whole spectrum. Both are theorems of measure theory, in Ch. 97.

? Two chaotic circuits in lockstep

Chaos amplifies every difference, so two chaotic systems, however alike, should drift apart. Yet Louis Pecora and Thomas Carroll showed in 1990 that two chaotic circuits, one driving the other through a single wire, can fall into perfect step and stay there, both still chaotic. How can coupling beat exponential divergence, how strong must it be, and what happens in a network of thousands of chaotic units? That is the synchronisation story of Ch. 87.

Chapter 85 — Bifurcations: When Systems Change Their Nature

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 83 (fixed points, limit cycles), Ch. 84 (logistic map, Lyapunov exponents), Ch. 6 (implicit function theorem, Taylor series), Ch. 22 (§22.4 Newton's method) · **Leads to:** Ch. 86, Ch. 88, Ch. 89, Ch. 92 · **Related:** Ch. 73, Ch. 25, Ch. 11 **Reading time:** ~30 min

85.1 The hook

A power line feeds a city. As evening comes and air conditioners switch on, the load rises, and the voltage at the city end sags a little, as it always does: current through the line's reactance drops some of the voltage before it arrives. Operators watch the voltage. At 50% of the line's maximum transfer it is at 97% of the sending voltage. At 90% it is still at 85%. Nothing alarming.

Then the load rises a few percent more, and the voltage does not sag a little more. It slides, and keeps sliding, and the protection trips. Voltage collapse of this kind has blacked out whole regions: France in December 1978 and Tokyo on a hot July afternoon in 1987 are textbook cases.

Right up to the edge, the system looked healthy: voltage acceptable, every eigenvalue in the left half-plane. Nothing in a snapshot of the state said "you are 2% from the cliff", because the cliff was not in the state. It was in the *parameter*, the load: past a critical value, the operating point simply ceased to exist.

The model is short. A source of voltage E feeds a resistive load drawing power P through a line of reactance X. The load voltage V satisfies $E^2 = V^2 + (XP/V)^2$ (the line drop XI is at right angles to V, and $I = P/V$), which rearranges to

$$V^4 - E^2V^2 + X^2P^2 = 0 \quad\Longrightarrow\quad \frac{V^2}{E^2} = \frac{1 \pm \sqrt{1 - (P/P_{\max})^2}}{2}, \qquad P_{\max} = \frac{E^2}{2X}.$$

For $P < P_{\max}$ there are two operating voltages, a high one (normal operation) and a low one. At $P = P_{\max}$ they merge at $V = E/\sqrt{2}$. Above it there are none. Plotted, this is the **nose curve** of power engineering, and it is the subject of this chapter in disguise.

The question: **can you see the cliff coming?** If the state looks fine right up to the edge, is there *any* measurable symptom of approaching it? There is, and it follows from one line of algebra about how equilibria are born and die.

85.2 The big idea

Parameters move slowly; states move fast

Every model in Chapters 83 and 84 had knobs: damping b, Van der Pol's μ, the logistic r, Lorenz's ρ. Turn a knob slowly and usually the phase portrait just deforms. Occasionally, at special values, it changes its *nature*: two fixed points collide and annihilate, a stable point throws off a cycle, a cycle doubles. These events are **bifurcations**.

Picture a ball in a valley of a landscape you are slowly tilting. Mostly the ball just shifts. But if the valley gets shallower as you tilt, its floor and rim eventually merge, the valley vanishes, and the ball rolls somewhere completely different, and tilting back a little will not undo it.

The warning sign is in the restoring force

Just before the valley vanishes it is very flat, and a nudged ball rolls back slowly. That is the symptom: **recovery from small disturbances slows down as a bifurcation approaches**, called **critical slowing down**. Measure not where the state *is*, but how quickly it comes back when kicked. The recovery rate is an eigenvalue of the linearisation, and bifurcations happen where an eigenvalue reaches zero or a pair reaches the imaginary axis: the "non-hyperbolic, inconclusive" cases that Ch. 11, §11.9 set aside.

85.3 The mathematics

Where bifurcations can happen

Consider a one-parameter family $\dot{x} = f(x, \mu)$ with f smooth, and an equilibrium x_0 at μ_0: $f(x_0, \mu_0) = 0$.

> **Hyperbolic equilibria persist**
>
> If $f_x(x_0, \mu_0) \neq 0$, then for μ near μ_0 there is exactly one equilibrium $x^*(\mu)$ near x_0, it depends smoothly on μ, and it has the same stability as x_0.

Proof. This is the implicit function theorem (Ch. 6): $f(x, \mu) = 0$ with $f_x \neq 0$ can be solved for x as a smooth function of μ near (x_0, μ_0), uniquely in a neighbourhood, with slope $dx^*/d\mu = -f_\mu / f_x$. Stability is decided by the sign of $f_x(x^*(\mu), \mu)$, which is continuous in μ and nonzero at μ_0, so it keeps its sign nearby. ■

The same holds in n dimensions with "$f_x \neq 0$" replaced by "the Jacobian has no eigenvalue on the imaginary axis". So **local bifurcations of equilibria happen only where the linearisation has an eigenvalue with zero real part.** There are two ways to get there: a real eigenvalue passing through 0, or a complex pair crossing the imaginary axis. The first gives saddle-nodes, transcritical and pitchfork bifurcations; the second gives Hopf bifurcations.

The saddle-node: creation from nothing

The simplest way for f_x to vanish is the **saddle-node** (or **fold**) bifurcation, with normal form

$$\dot{x} = \mu - x^2.$$

For $\mu < 0$ there are no equilibria; $\dot{x} < 0$ everywhere and every state drifts off to $-\infty$. For $\mu > 0$ there are two, $x^* = \pm\sqrt{\mu}$, and since $f_x = -2x^*$, the upper one is stable (eigenvalue $-2\sqrt{\mu}$) and the lower one unstable (eigenvalue $+2\sqrt{\mu}$). At $\mu = 0$ they merge into one half-stable point and annihilate.

Why should this cartoon matter? Because it is what *every* fold looks like up close. Suppose $f(x_0, \mu_0) = 0$, $f_x = 0$, but $f_{xx} \neq 0$ and $f_\mu \neq 0$ there. Taylor expanding,

$$f(x, \mu) \approx f_\mu\,(\mu - \mu_0) + \tfrac{1}{2} f_{xx}\,(x - x_0)^2,$$

and after shifting and scaling x and μ, this is $\mu - x^2$ (or $-\mu + x^2$). The nose curve has exactly this structure at $P = P_{\max}$: near the tip, V differs from $E/\sqrt{2}$ by an amount proportional to $\pm\sqrt{P_{\max} - P}$. The square root is the fingerprint of a fold.

Critical slowing down and the bottleneck

For $\dot{x} = \mu - x^2$: (a) for $\mu > 0$, perturbations of the stable equilibrium decay like $e^{-t/\tau}$ with recovery time $\tau = 1/(2\sqrt{\mu})$, which diverges as $\mu \to 0^+$; (b) for $\mu < 0$, a state takes time $\pi/\sqrt{-\mu}$ to pass from $x = +\infty$ to $x = -\infty$, almost all of it spent near $x = 0$, the "ghost" of the vanished equilibria.

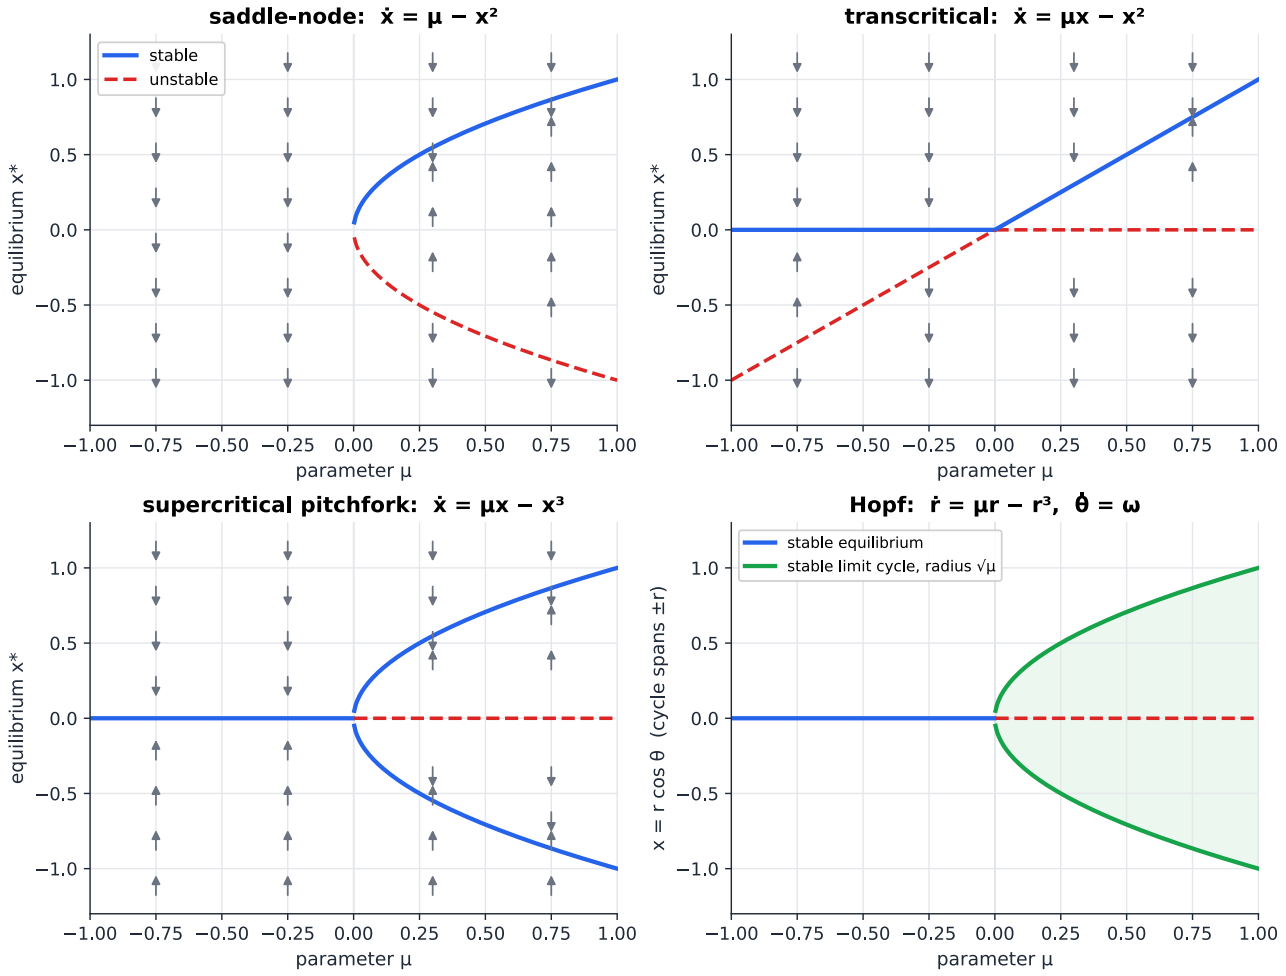
Proof. (a) The linearisation at $x^* = \sqrt{\mu}$ is $\dot{\eta} = f_x\,\eta = -2\sqrt{\mu}\,\eta$, so $\eta(t) = \eta(0)e^{-2\sqrt{\mu}\,t}$.

(b) Separate variables, writing $\mu = -a^2$:

$$T = \int_{+\infty}^{-\infty} \frac{dx}{\dot{x}} = \int_{+\infty}^{-\infty} \frac{dx}{-(a^2 + x^2)} = \int_{-\infty}^{\infty} \frac{dx}{a^2 + x^2} = \frac{1}{a}\Big[\arctan\frac{x}{a}\Big]_{-\infty}^{\infty} = \frac{\pi}{a} = \frac{\pi}{\sqrt{-\mu}}.$$

The integrand is largest near $x = 0$, where $\dot{x} = \mu$ is tiny. Half the passage time is spent in $|x| < a$, an interval that shrinks to nothing as $\mu \to 0^-$. ■

Part (a) answers the hook. At $\mu = 0.01$ the recovery time is 5; at $\mu = 0.0001$ it is 50. The equilibrium moves only from 0.1 to 0.01, easy to miss, while the sluggishness grows tenfold, easy to measure from how the system recovers from the random kicks that loads give it all the time. Voltage-stability monitors use this idea in the form of the smallest eigenvalue or singular value of the power-flow Jacobian, which tends to zero at the nose. Part (b) says that just past the cliff the system lingers in the bottleneck, one reason a collapse can take seconds to minutes to unfold: a window for emergency action.



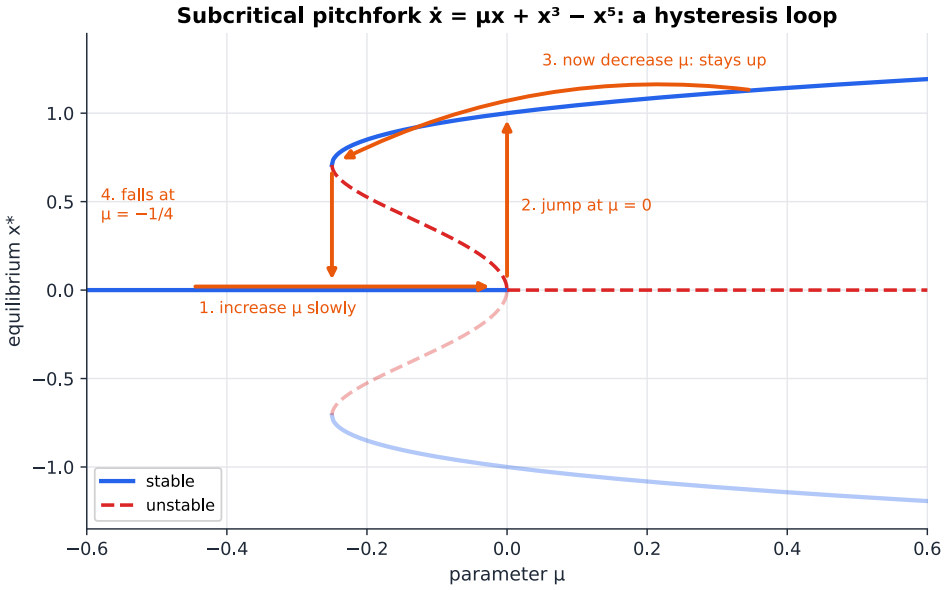
Bifurcation diagrams: equilibria (and, for Hopf, the cycle amplitude) against the parameter μ. Solid blue: stable; dashed red: unstable; grey arrows: the direction of flow. Saddle-node: a stable–unstable pair is created from nothing. Transcritical: two branches cross and exchange stability. Pitchfork: a symmetric equilibrium loses stability to two new stable ones. Hopf: a stable spiral gives birth to a limit cycle whose radius grows like $\sqrt{\mu}$.

Transcritical and pitchfork: when something forbids creation from nothing

Sometimes an equilibrium cannot disappear, because the model forbids it. Zero population, zero current or a perfectly upright beam are equilibria for *every* parameter value. Then the zero eigenvalue produces a different event.

- **Transcritical**, $\dot{x} = \mu x - x^2$: the branches $x = 0$ and $x = \mu$ cross at $\mu = 0$ and exchange stability. Laser and epidemic ($R_0 = 1$) thresholds have this form: below, "nothing happening" is stable; above, the nonzero state takes over.
- **Pitchfork**, $\dot{x} = \mu x - x^3$, needs a symmetry $x \to -x$. For $\mu > 0$ the symmetric state becomes unstable and two mirror-image stable states $\pm\sqrt{\mu}$ appear. A column buckles left or right, a powered-up flip-flop settles to 0 or 1, and imperfections too small to see decide which.

The cubic term $-x^3$ makes the pitchfork **supercritical**: the new states start at zero amplitude and grow smoothly. Flip its sign and the bifurcation turns **subcritical** and dangerous. The standard model is $\dot{x} = \mu x + x^3 - x^5$, in which the quintic term restrains the growth at large amplitude:



*The subcritical pitchfork $\dot{x} = \mu x + x^3 - x^5$. Raising μ past 0 destabilises $x = 0$ with no nearby stable state to go to, so the system jumps to the large-amplitude branch. Lowering μ again does not bring it back at 0: it stays up until the fold at $\mu = -1/4$, then falls. Between $-1/4$ and 0 both states are stable: a **hysteresis** loop.*

The nonzero equilibria satisfy $\mu + x^2 - x^4 = 0$, so $x^2 = \left(1 \pm \sqrt{1 + 4\mu}\right)/2$, which exist only for $\mu \geq -1/4$: the jump-back point is itself a saddle-node. Hysteresis is a memory: in the overlap, the state depends on history, not just on the present value of the knob. A Schmitt trigger is built to have it; a buckling shell or a collapsing grid has it whether you like it or not.

Hopf: the birth of a cycle

Ch. 83 left a mystery: as Van der Pol's μ is turned down through zero the limit cycle vanishes, so how is it born? When a complex pair of eigenvalues crosses the imaginary axis, the linearisation turns from a stable spiral to an unstable one. The nonlinear terms decide what happens to the outward-spiralling orbits. In polar coordinates the normal form is

$$\dot{r} = \mu r - r^3, \qquad \dot{\theta} = \omega.$$

The angle just turns at rate ω. The radius obeys a pitchfork-like equation on $r \geq 0$: for $\mu < 0$, $r = 0$ is the only equilibrium and it is stable; for $\mu > 0$ it is unstable, and $r^* = \sqrt{\mu}$ is a stable equilibrium of the radius, that is, a circular **limit cycle** of radius $\sqrt{\mu}$. Its stability follows from $\frac{d}{dr}(\mu r - r^3) = \mu - 3r^2 = -2\mu < 0$ at $r^* = \sqrt{\mu}$. Hopf's theorem (1942) says this is generic: when a pair crosses the axis with nonzero speed and a certain cubic coefficient (the **first Lyapunov coefficient**) is negative, a stable cycle of amplitude proportional to $\sqrt{\mu - \mu_c}$ is born, with period near $2\pi/\omega$.

> **Oscillator start-up, and the Van der Pol mystery solved**
>
> Take $\ddot{x} - (\mu - x^2)\dot{x} + x = 0$: the damping $-(\mu - x^2)$ is negative for small x once $\mu > 0$. The linearisation at the origin has eigenvalues $\mu/2 \pm j\sqrt{1 - \mu^2/4}$, crossing the imaginary axis at $\mu = 0$ with $\omega = 1$. Averaging the energy balance over one cycle of $x \approx a\cos t$ gives $\dot{a} = \frac{a}{2}\left(\mu - a^2/4\right)$, a Hopf normal form with stable amplitude
>
> $$a^* = 2\sqrt{\mu}.$$
>
> Numerically, the cycle amplitude is 0.200 at $\mu = 0.01$, 0.400 at $\mu = 0.04$ and 0.632 at $\mu = 0.1$, against $2\sqrt{\mu} = 0.2,\ 0.4,\ 0.632$.
>
> Now substitute $x = \sqrt{\mu}\,X$ (for $\mu > 0$). Every term picks up a factor $\sqrt{\mu}$, and the equation becomes $\ddot{X} - \mu(1 - X^2)\dot{X} + X = 0$: exactly the Van der Pol equation of Ch. 83. So Van der Pol's amplitude of 2 in X is the amplitude $2\sqrt{\mu}$ in x. The cycle is born at zero size at $\mu = 0$ and grows like the square root; the way Van der Pol wrote the equation simply hides this by measuring amplitude in units that shrink with μ.

This is how an electronic oscillator starts: past the gain where net damping changes sign, the amplitude grows from noise to a value proportional to the square root of the excess gain. Linear analysis tells you *whether* it starts, never *at what amplitude*, as the engineering note of Ch. 11, §11.9 warned.

If the first Lyapunov coefficient is positive the Hopf bifurcation is **subcritical**: an *unstable* cycle shrinks onto the equilibrium and the state jumps to whatever large-amplitude motion is available. Aircraft wing flutter can behave this way. So does the Lorenz system: at $\rho_H = \sigma(\sigma+\beta+3)/(\sigma-\beta-1) \approx 24.74$ the equilibria $C_\pm$ lose stability in a subcritical Hopf bifurcation, and there is nothing nearby to catch the orbit except the strange attractor of Ch. 84.

Period doubling: the bifurcation that only maps can do

A map $x_{n+1} = f(x_n, r)$ has one more way to lose stability. Its fixed point is stable while $|f'(x^*)| < 1$ (Ch. 83), so stability can be lost at $f' = +1$ (a saddle-node or relative, as for flows) or at $f' = -1$, where orbits overshoot with ever-growing alternation. That is a **flip** or **period-doubling bifurcation**, and it creates a 2-cycle.

The first period doubling of the logistic map

For $f(x) = rx(1-x)$, the fixed point $x^* = 1 - 1/r$ is stable for $1 < r < 3$ and loses stability at $r = 3$ with $f'(x^*) = -1$. For $r > 3$ there is a 2-cycle

$$p, q = \frac{r+1 \pm \sqrt{(r-3)(r+1)}}{2r},$$

which is stable for $3 < r < 1+\sqrt{6} \approx 3.4495$.

Proof. At the fixed point $f'(x^*) = r(1-2x^*) = r\big(1-2+2/r\big) = 2-r$, which lies in $(-1, 1)$ exactly when $1 < r < 3$, and equals -1 at $r = 3$.

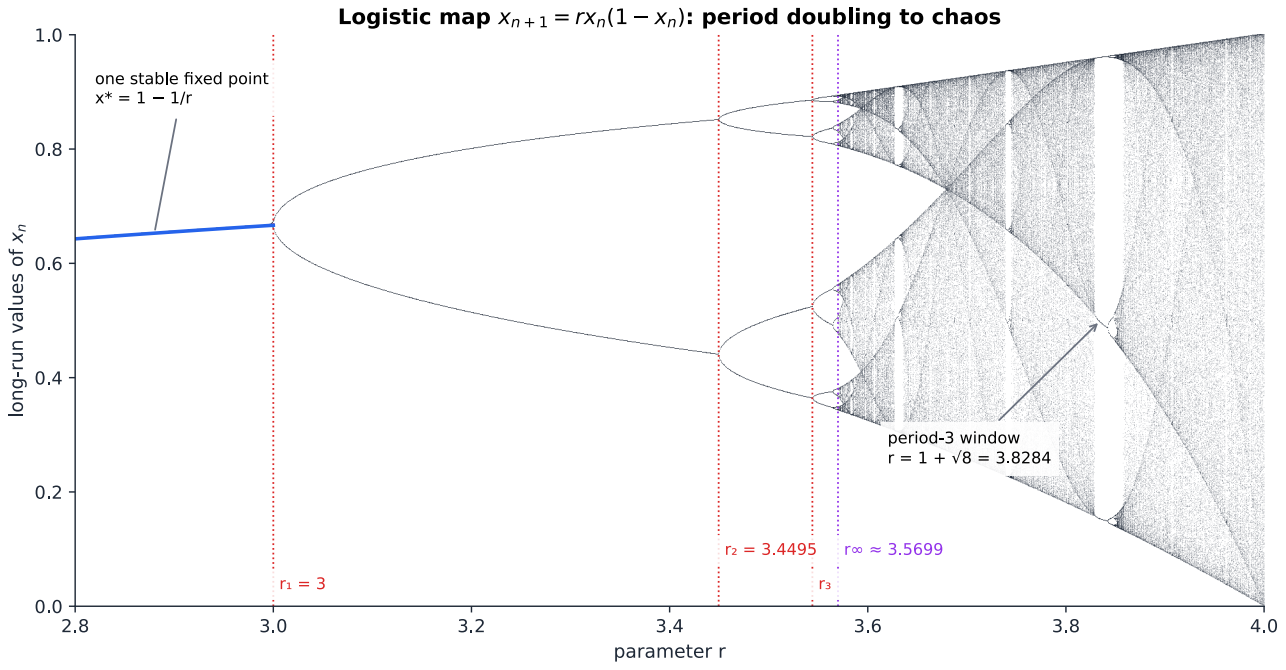
A 2-cycle is a pair with $f(p) = q$, $f(q) = p$, $p \neq q$. Subtracting $q = rp(1-p)$ from $p = rq(1-q)$ gives $p - q = r(q-p)(1-p-q)$, and dividing by $p - q \neq 0$ gives $p + q = (r+1)/r$. Adding the two equations gives $p + q = r(p+q) - r(p^2+q^2)$; substituting $p^2 + q^2 = (p+q)^2 - 2pq$ and $p + q = (r+1)/r$ gives $pq = (r+1)/r^2$. So p and q are the roots of $r^2 z^2 - r(r+1)z + (r+1) = 0$, which is the formula above. They are real and distinct exactly when $(r-3)(r+1) > 0$, that is, $r > 3$.

The cycle is a fixed point of $f \circ f$, with multiplier $(f\circ f)'(p) = f'(q)f'(p) = r^2(1-2p)(1-2q)$ by the chain rule. Expanding with the values of $p+q$ and pq:

$$r^2\big(1 - 2(p+q) + 4pq\big) = r^2 - 2r(r+1) + 4(r+1) = -r^2 + 2r + 4.$$

This equals $+1$ at $r = 3$ (the cycle is born from the fixed point) and decreases as r grows; it reaches -1 when $r^2 - 2r - 5 = 0$, at $r = 1+\sqrt{6}$. In between, its absolute value is below 1 and the cycle is stable. ■

At $r = 1+\sqrt{6}$ the 2-cycle's own multiplier hits -1, so it flips in turn and gives birth to a 4-cycle. Then 8, 16, 32: the **period-doubling cascade**.



The long-run values of the logistic map for each r (300 iterates plotted after 1000 discarded). One stable fixed point until $r_1 = 3$, a 2-cycle until $r_2 = 1+\sqrt{6}$, then 4, 8, ..., accumulating at $r_\infty \approx 3.5699$. Beyond, chaos, interrupted by windows of periodic behaviour; the widest is the period-3 window that opens at $r = 1+\sqrt{8} \approx 3.8284$.

The doublings come faster and faster. The first few happen at

n	r_n (period 2^n born)	$\frac{r_n - r_{n-1}}{r_{n+1} - r_n}$
1	3.000000	
2	3.449490	4.751
3	3.544090	4.656
4	3.564407	4.668
5	3.568759	4.665
∞	3.569946	$\delta = 4.6692\ldots$

(The last ratio uses $r_6 = 3.569692$.) The gaps shrink geometrically with ratio approaching **Feigenbaum's constant** $\delta = 4.6692$, so the infinitely many doublings fit into a finite interval and the period becomes infinite at r_∞. Past r_∞ the Lyapunov exponent of Ch. 84 turns positive (except in windows), and the orbit is chaotic.

Why does the cascade repeat? Look at $f \circ f$ near one point of the 2-cycle, just after it is born. It has a hump and a fixed point, and, flipped over and magnified, it looks like a small copy of f itself near its own fixed point. As r increases, the small copy goes through the same story as the original: its fixed point flips, which for f is the birth of the 4-cycle. Then f^4 contains a smaller copy again, and so on. Each copy is the previous one rescaled by a factor that tends to $\alpha \approx -2.5029$ in x and $\delta \approx 4.669$ in r. Feigenbaum turned this "copy of a copy" into an equation for the shape of the limiting map. This is where the story that Ch. 73 pointed to begins.

The period-3 window shows a different birth. At $r = 1 + \sqrt{8}$, the third iterate f^3 develops three new pairs of fixed points by saddle-node bifurcations: a stable 3-cycle and an unstable one, out of nothing, inside chaos. Just below $1 + \sqrt{8}$ the orbit lingers near the ghost of the 3-cycle for long stretches, then bursts out into chaos and back: **intermittency**, the bottleneck of part (b) of the saddle-node theorem, seen in a map.

> **? Why the same 4.669 everywhere?**
>
> The logistic map is not special. Any smooth map with a single quadratic hump, sin, $xe^{r(1-x)}$, a fitted model of a dripping tap, produces the same ratio $\delta = 4.6692\ldots$ and the same rescaling $\alpha = -2.5029\ldots$. Albert Libchaber measured period doubling in convecting liquid helium in 1980 and found ratios consistent with δ. The universality is explained by treating "take $f \circ f$ and rescale" as an operator on the space of all maps, and showing that it has a fixed point whose unstable eigenvalue is δ. That renormalisation idea, borrowed from the physics of phase transitions, is the subject of Ch. 92.

85.4 The algorithm

Two computational tools find bifurcations, and they answer different questions.

Brute force (the bifurcation diagram above) iterates for each parameter value, discards a transient and plots what remains. It shows attractors, chaotic ones included, but never unstable branches, misses attractors your start is not attracted to, and blurs near bifurcations, where transients become very long.

Continuation follows a branch of equilibria $g(\mathbf{x}, \mu) = \mathbf{0}$, stable or not, by stepping μ and correcting with Newton's method (Ch. 22, §22.4), monitoring the Jacobian's eigenvalues for sign changes. Stepping μ naively fails at a fold, where the branch turns back. **Pseudo-arclength continuation** parametrises the curve by its arclength s and treats μ as one more unknown. The code below traces the whole nose curve of §85.1, round the tip and down the lower branch, with $E = X = 1$ and load $p = P/P_{\max}$, so that $g(V, p) = V^4 - V^2 + p^2/4$.

```
import numpy as np

def g(V, p):                       # equilibrium condition of the line + load, E = X = 1
    return V**4 - V**2 + p**2 / 4

def grad(V, p):
    return np.array([4*V**3 - 2*V, p / 2])        # (dg/dV, dg/dp)

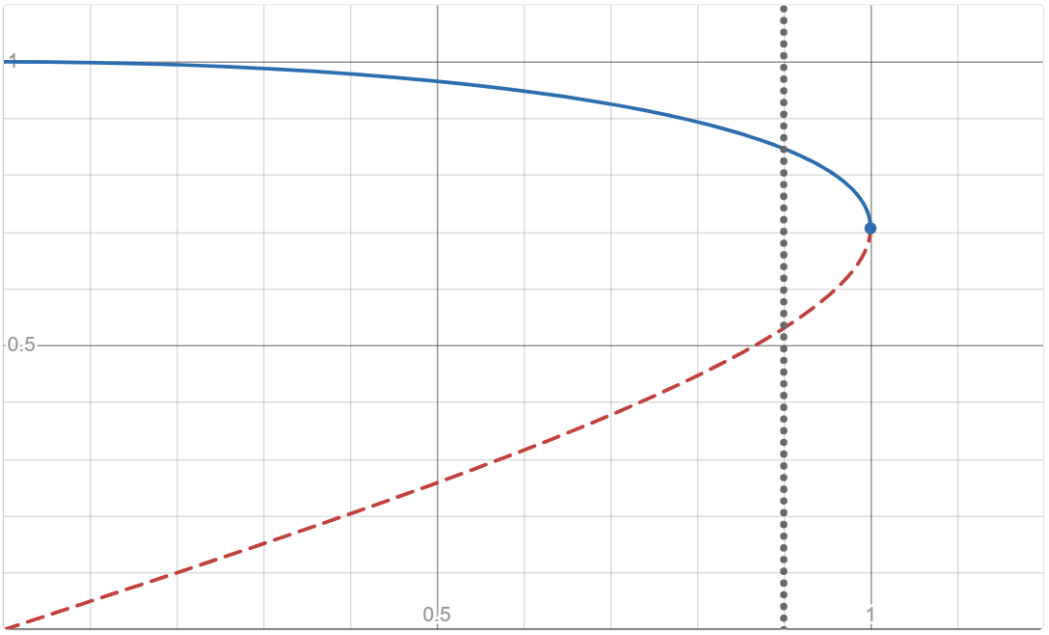
def continuation(V, p, ds=0.02, steps=80):
    t = np.array([0.0, 1.0])                      # initial tangent (dV, dp): increase load
    out = [(p, V)]
    for _ in range(steps):
        Vp, pp = V + ds * t[0], p + ds * t[1]      # predictor: step along the tangent
        for _ in range(20):                       # corrector: Newton on g = 0 plus arclength
            G = np.array([g(Vp, pp), t[0]*(Vp - V) + t[1]*(pp - p) - ds])
            J = np.array([grad(Vp, pp), t])
            dV, dp = np.linalg.solve(J, -G)
            Vp, pp = Vp + dV, pp + dp
        gV, gp = grad(Vp, pp)
        t_new = np.array([-gp, gV]); t_new /= np.linalg.norm(t_new)
        if t_new @ t < 0: t_new = -t_new           # keep moving the same way round the curve
        if t_new[1] * t[1] < 0:
            print(f"fold: load p = {pp:.4f}, voltage V = {Vp:.4f}")
        V, p, t = Vp, pp, t_new
        out.append((p, V))
    return np.array(out)

curve = continuation(V=1.0, p=0.0)
print(curve[::10].round(3))
```

It reports the fold one step after passing it, at $p = 0.9986$, $V = 0.688$ (exact: $p = 1$, $V = 0.707$); bisecting on the sign change of dp/ds pins it down. The augmented Jacobian (the gradient stacked on the tangent) stays invertible at the fold even though $\partial g/\partial V = 0$ there, which is the whole point. Each step costs one small linear solve per Newton iteration; for a grid model with 10^5 buses the same method uses sparse solvers (Ch. 24, §24.5). Packages such as AUTO and MatCont add automatic detection of Hopf points and continuation of periodic orbits.

85.5 The experiment

First the nose curve itself, both branches, with load on the horizontal axis as a fraction of $P_{\max}$ and voltage as a fraction of E.



The nose curve: normal operation (blue) and the low-voltage branch (red) merge at the fold $p = 1$. Move the dotted line from 0.9 toward 1 and watch how little the blue voltage changes compared with how fast the gap to the red branch closes; that gap is proportional to $\sqrt{1-p}$ near the tip.

Now draw the logistic bifurcation diagram yourself, and zoom.

```
import numpy as np
import matplotlib.pyplot as plt

r_min, r_max = 2.8, 4.0      # zoom: try 3.54, 3.575 or 3.82, 3.86
x_min, x_max = 0.0, 1.0      # and the matching x-range, e.g. 0.88, 0.90
n_r = 2000                   # parameter values
n_transient = 2000           # iterations discarded (raise it near bifurcations)
n_plot = 400                 # iterations plotted

r = np.linspace(r_min, r_max, n_r)
x = np.full(n_r, 0.5)
for _ in range(n_transient):
    x = r * x * (1 - x)
R, X = [], []
for _ in range(n_plot):
    x = r * x * (1 - x)
    keep = (x >= x_min) & (x <= x_max)

plt.xlim(r_min, r_max); plt.ylim(x_min, x_max)
plt.xlabel("r"); plt.ylabel("x"); plt.title("logistic map"); plt.show()
```

Things to try:

- Zoom into $3.54 \le r \le 3.575$, $0.88 \le x \le 0.90$. The picture repeats: a shrunken copy of the whole diagram. That is renormalisation made visible.
- Zoom into the period-3 window, $3.82 \le r \le 3.86$. Inside it, find a second period-doubling cascade (periods 6, 12, 24) and measure the first two ratios of its gaps. Are they close to 4.669?
- Set `n_transient = 50`. Near $r = 3$ and $r = 3.4495$ the branches smear out: critical slowing, seen as a slow-to-settle transient.

85.6 The challenge

1. **Intuition.** A thermostat with hysteresis switches the heater on at $19\,^\circ$C and off at $21\,^\circ$C. Sketch its "bifurcation diagram" (heater state against temperature) and explain why the two thresholds play the role of the two folds in the subcritical pitchfork figure. What would happen with no hysteresis?

2. **Derivation.** For $\dot{x} = \mu - x^2 + \varepsilon x^3$ with small $\varepsilon > 0$, show that a second fold appears far from the origin, find its location to leading order in ε, and sketch the resulting S-shaped curve. Then show that the pitchfork $\dot{x} = \mu x - x^3$ with a small imperfection h, $\dot{x} = h + \mu x - x^3$, no longer has a pitchfork at all but a smooth branch and a separate fold, and find the curve in the (μ, h) plane where folds occur.

3. **Implementation.** Modify the continuation code to trace the equilibria of $\dot{x} = \mu x + x^3 - x^5$ (equilibrium condition only, as a curve in (μ, x)) starting from $(\mu, x) = (0.5, 1.2)$ and moving toward smaller μ. Detect both folds and record the sign of $\partial f/\partial x$ on each part of the curve. Compare with the hysteresis figure.

4. **Open investigation.** Critical slowing should be visible in noisy data as rising variance and rising lag-1 autocorrelation as a fold approaches. Simulate $dx = (\mu - x^2)\,dt + \sigma\,dW$ with μ decreasing slowly toward 0 (Euler–Maruyama, Ch. 36), and compute both indicators in a sliding window. How early, and how reliably, do they warn? How do false alarms depend on the window length, the noise level and the speed at which μ changes? For real ecosystems and climate records this remains an open, much-debated question.

85.7 Loose threads

The hook asked whether an approaching cliff can be detected while the state still looks healthy. It can: near a saddle-node the equilibrium moves only like $\sqrt{\mu}$, but recovery time grows like $1/(2\sqrt{\mu})$. Bifurcations of equilibria happen only where an eigenvalue reaches the imaginary axis: a zero eigenvalue gives folds, transcritical and pitchfork bifurcations; a crossing pair gives Hopf's cycle of amplitude $\sqrt{\mu}$, which solved the Van der Pol mystery of Ch. 83. Maps can also flip, and the logistic map's flips cascade at a universal rate into chaos.

What the chapter left open:

- **Global bifurcations.** Cycles can also die by colliding with distant saddles (homoclinic bifurcations), which is how the Lorenz system's chaos is first assembled near $\rho \approx 13.9$; see Guckenheimer and Holmes below.
- **Two knobs at once.** With two parameters, curves of folds can meet at a **cusp**, the organising centre of hysteresis, and Hopf and fold curves can meet at points where cycles, tori and chaos are born together.
- **From local rules to global patterns.** In Ch. 86, the rule is discrete in space too, and changing one bit of the rule changes the world it creates.

? Tipping points in a noisy world

Critical slowing is clean in a deterministic model, but real systems are noisy and their parameters drift while you watch. Ecologists have reported rising variance and autocorrelation before lakes flipped from clear to turbid, and climate scientists have searched for the same signals before abrupt changes in ice-core records. When do such signals warn reliably, when do they cry wolf, and can noise tip a system over the rim before the valley vanishes, with no warning at all? These questions are taken up in Ch. 88.

? Bifurcations that draw pictures

Every bifurcation in this chapter happened to a handful of numbers. Let the state be a whole field, a chemical concentration over a surface, and an instability can choose a *shape*: Alan Turing showed in 1952 that two chemicals that react and diffuse at different rates can bifurcate from a uniform grey into spots or stripes of a definite wavelength. Why does diffusion, which smooths everything, create patterns, and how is the wavelength selected? That is a bifurcation of a partial differential equation, in Ch. 89.

Chapter 86 — Cellular Automata and Emergent Worlds

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 17, Ch. 22, Ch. 24, Ch. 83 · **Leads to:** Ch. 87, Ch. 88 · **Related:** Ch. 30, Ch. 73, Ch. 74, Ch. 81, Ch. 84 **Reading time:** ~25 min

86.1 The hook

Take a row of light bulbs, each either on or off. Once a second, every bulb looks at itself and its two immediate neighbours, and decides whether to be on or off in the next second. All bulbs use the same rule. There is no conductor, no memory beyond one second, no randomness, and nothing any bulb can see except three bits.

There are only $2^3 = 8$ possible neighbourhoods, and a rule is just a choice of on or off for each, so there are exactly $2^8 = 256$ such rules. You could print every one on a single sheet of paper. Surely, with so little to work with, the behaviour must be boring: everything dies out, or everything lights up, or some simple stripe repeats forever.

Start with a single bulb lit and run three of those rules. One draws a perfect fractal, the Sierpinski triangle, with no sign that anyone asked for it. One produces a pattern so disordered that its centre column was used for years as the random-number generator inside a commercial computer-algebra system. And one, which differs from its neighbours in the table by only a couple of bits, was proved in 2004 to be able to compute *anything any computer can compute*. Three bits of input per cell, and somewhere among the 256 rules sits a universal computer.

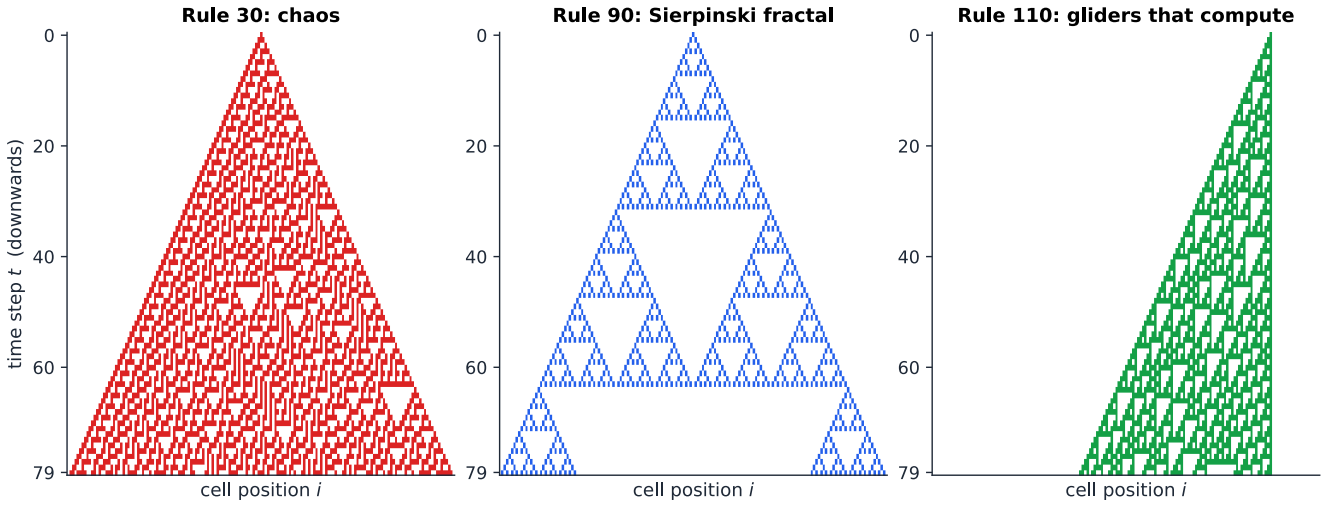
That is the paradox this chapter is about. How do rules that are purely local, tiny and deterministic produce patterns that are global, enormous and, in a precise sense, unpredictable? And if the rule is that simple, why can't we just *solve* it, the way we solve a linear difference equation?

86.2 The big idea

A **cellular automaton** (CA) is a dynamical system (Ch. 83) stripped to the bone. Space is a grid of cells. Time is a tick of a clock. Each cell holds one of a few states, and at every tick all cells update *simultaneously* by the same local rule, reading only the states in a small neighbourhood. That's the whole definition.

The analogy worth carrying is a stadium wave. Nobody in the crowd sees the wave. Each person follows one local rule ("stand up shortly after the person on your left stands, then sit down"), and a large-scale object, the wave, moves around the stadium at a definite speed, with a definite width, and survives collisions with stragglers. The wave isn't written anywhere in the rule. It is **emergent**: a pattern that belongs to the collective and has properties (speed, shape, persistence) that no individual has.

Cellular automata let us study emergence with nothing hidden. In a fluid or a brain we never know whether the interesting behaviour comes from details we left out. In a CA there are no details to leave out. If something interesting appears, the rule alone did it.



Three elementary cellular automata started from one live cell. Each row is the whole world at one instant; time runs downwards. Rule 30 (left) looks random, rule 90 (centre) is the Sierpinski triangle, and rule 110 (right) grows a lattice of interacting structures that can be made to compute.

Look at the figure the way a physicist looks at a bubble chamber. A one-dimensional CA leaves its entire history as a two-dimensional picture, the **space–time diagram**. Every pattern in that picture is something the rule did. The triangles in rule 90 nest inside one another forever; the speckle in rule 30 never settles; the diagonal stripes in rule 110 are moving particles, sometimes called *gliders*, that collide and either annihilate or create new ones.

Three intuitions carry the rest of the chapter.

1. **Locality limits speed.** A cell can only hear from its neighbours, so information moves at most one cell per tick. Every CA has a built-in speed of light, and the edges of the triangles above are exactly that light cone.
2. **Linearity makes things solvable.** Rule 90 says "new state = left XOR right". XOR is addition modulo 2, so rule 90 is a *linear* system, and linear systems obey superposition. That's why we will be able to predict its every cell exactly, in the same way we solve a linear difference equation with the Z-transform (Ch. 17).

3. **Nonlinearity plus locality breeds complexity.** Rule 30 is "left XOR (centre OR right)". That one OR breaks linearity, and with it every shortcut. Rule 110 goes further: its gliders are rich enough to store and process information.

86.3 The mathematics

Elementary cellular automata

Elementary cellular automaton

An **elementary cellular automaton** (ECA) is a map on configurations $x = (x_i)_{i \in \mathbb{Z}}$ with $x_i \in \{0,1\}$, given by

$$x_i^{t+1} = f\left(x_{i-1}^t,\, x_i^t,\, x_{i+1}^t\right)$$

for a fixed **local rule** $f : \{0,1\}^3 \to \{0,1\}$, applied to every i at once. On a finite ring of n cells, indices are read modulo n (periodic boundary).

Wolfram's numbering turns the rule into a byte. List the neighbourhoods in descending binary order, $111, 110, \dots, 000$, write the output bit under each, and read the eight output bits as a binary number. For rule 30:

neighbourhood (x_{i-1}, x_i, x_{i+1})	**111**	**110**	**101**	**100**	**011**	**010**	**001**	**000**
new x_i	0	0	0	1	1	1	1	0

and $00011110_2 = 30$. Equivalently, bit k of the rule number is the output for the neighbourhood whose binary value is k; that is exactly how the code in §86.4 reads it. In Boolean form, writing $\oplus$ for XOR,

$$\begin{aligned} \text{rule 30:}\quad & x_i^{t+1} = x_{i-1} \oplus (x_i \vee x_{i+1}), \\ \text{rule 90:}\quad & x_i^{t+1} = x_{i-1} \oplus x_{i+1}, \\ \text{rule 110:}\quad & x_i^{t+1} = (x_i \oplus x_{i+1}) \vee (x_i \wedge \neg x_{i-1}), \end{aligned}$$

each of which you can check against its eight-entry table in a minute (all three were checked by brute force).

Two symmetries cut the 256 rules down. Mirror reflection (swap left and right) and complementation (swap 0 and 1) map rules to rules with "the same" behaviour, and the 256 rules fall into 88 essentially different classes. Rule 110, for instance, is the mirror image of rule 124.

Result 1: the speed of light

Light cone

If two configurations x and y agree on the cells $a \le i \le b$ at time 0, then under any ECA they agree on $a + t \le i \le b - t$ at time t. Equivalently, the state of cell i at time t depends only on cells $i - t, \dots, i + t$ at time 0.

Proof. Induction on t. The case $t = 0$ is the hypothesis. If x^t and y^t agree on $[a + t,\ b - t]$, take any i with $a + t + 1 \le i \le b - t - 1$. Its neighbours $i - 1, i, i + 1$ all lie in $[a + t,\ b - t]$, so the local rule sees identical inputs and $x_i^{t+1} = y_i^{t+1}$. $\blacksquare$

That is why every pattern in the figure lives inside a triangle of slope one: a single live cell can't influence anything outside its cone. Rule 30 fills its cone entirely; rule 110 fills only the left half, because its rule happens to send information leftwards faster than rightwards. The same idea, a finite propagation speed set by the stencil, is the CFL condition for explicit PDE solvers (Ch. 22). A CA is, in a sense, a PDE solver that forgot to have a PDE.

Result 2: rule 90 is Pascal's triangle in disguise

Rule 90 is linear over the two-element field $\mathbb{F}_2 = \{0,1\}$ with addition $\oplus$. If x and y are two configurations, then applying rule 90 to $x \oplus y$ gives the XOR of the two separate results, because $(x_{i-1} \oplus y_{i-1}) \oplus (x_{i+1} \oplus y_{i+1}) = (x_{i-1} \oplus x_{i+1}) \oplus (y_{i-1} \oplus y_{i+1})$. Superposition holds, so it is enough to understand one live cell.

Encode a configuration as a Laurent polynomial with coefficients in $\mathbb{F}_2$, $X(z) = \sum_i x_i z^i$, the same bookkeeping trick as a generating function or a Z-transform. Shifting left and right is multiplication by z and z^{-1}, so one step of rule 90 is

$$X^{t+1}(z) = \left(z + z^{-1}\right) X^t(z), \qquad \text{hence} \qquad X^t(z) = \left(z + z^{-1}\right)^t X^0(z).$$

The single-seed solution of rule 90

Starting from one live cell at position 0, cell k is alive at time t if and only if $t + k$ is even and $\binom{t}{(t+k)/2}$ is odd. The number of live cells at time t is exactly

$$N(t) = 2^{s(t)},$$

where $s(t)$ is the number of 1s in the binary expansion of t.

Proof. With $X^0 = 1$, the binomial theorem gives $X^t(z) = \sum_{m=0}^{t} \binom{t}{m} z^{2m-t}$ with coefficients read modulo 2. Setting $k = 2m - t$ gives the first claim.

For the count, use the "freshman's dream", which is true in characteristic 2: $(a + b)^2 = a^2 + 2ab + b^2 = a^2 + b^2$, and by repeating it, $(a + b)^{2^m} = a^{2^m} + b^{2^m}$. Write $t = 2^{m_1} + 2^{m_2} + \cdots + 2^{m_s}$ with distinct $m_1 > m_2 > \cdots > m_s$. Then

$$\left(z + z^{-1}\right)^t = \prod_{r=1}^{s} \left(z^{2^{m_r}} + z^{-2^{m_r}}\right).$$

Expanding the product picks one of two signs from each factor, giving 2^s terms $z^{\pm 2^{m_1} \pm 2^{m_2} \pm \cdots \pm 2^{m_s}}$. These exponents are all distinct: two different sign choices first differ at some largest power 2^{m_r}, which changes the sum by $2 \cdot 2^{m_r} = 2^{m_r+1}$, while all smaller powers together can change it by at most $2(2^{m_r} - 1) < 2^{m_r+1}$. So no two terms cancel, and there are exactly $2^{s(t)}$ live cells. ■

So at $t = 63 = 111111_2$ the row has $2^6 = 64$ live cells, and one tick later, at $t = 64 = 1000000_2$, it collapses to just 2: the two lonely seeds at the bottom of the centre panel. Summing over the first 2^n rows gives 3^n live cells in total (729 for the 64 rows drawn), which is precisely the self-similar counting of the Sierpinski triangle, whose fractal dimension $\log 3 / \log 2 \approx 1.585$ you meet in Ch. 73. The fractal is the shadow of a binomial theorem.

> **Engineering note**
>
> Linear CAs over $\mathbb{F}_2$ are the spatial cousins of linear-feedback shift registers. Built-in self-test circuits in VLSI chips use rule-90/150 hybrid automata as pattern generators, because each cell needs only one XOR gate and neighbours are physically adjacent, so the wiring is short.

Result 3: worlds with no past

Run a CA forward and you get a future. Can you also run it backward? A configuration with no predecessor at all is called a **Garden of Eden**: it can be a starting state, but the rule can never *produce* it.

> **Gardens of Eden for rule 90 on a ring**
>
> On a ring of $n \geq 3$ cells, rule 90 is not invertible. When n is odd, exactly half of all 2^n configurations are Gardens of Eden; when n is even, exactly three quarters are.

Proof. On the ring, rule 90 is a linear map $\mathbf{A} : \mathbb{F}_2^n \to \mathbb{F}_2^n$, $(\mathbf{A}x)_i = x_{i-1} \oplus x_{i+1}$. Its kernel is the set of x with $x_{i-1} = x_{i+1}$ for all i, so the cells two apart agree. If n is odd, stepping by 2 around the ring visits every cell, so all cells are equal: the kernel is $\{00\ldots0,\ 11\ldots1\}$, of dimension 1. If n is even, the even-indexed cells must all agree and the odd-indexed cells must all agree, independently, which gives four kernel elements, dimension 2. By rank–nullity (Ch. 9), the image has dimension $n-1$ or $n-2$, so it contains 2^{n-1} or 2^{n-2} configurations. Everything outside the image is a Garden of Eden, a fraction $1/2$ or $3/4$. ■

Notice the logic: rule 90 is non-injective (two different states, like all-zeros and all-ones, both map to all-zeros), and *therefore* non-surjective. On a finite set that is trivial. The deep fact is that it stays true on infinite grids for every CA, linear or not:

> **Moore–Myhill Garden-of-Eden theorem (stated)**
>
> A cellular automaton on $\mathbb{Z}^d$ has Garden-of-Eden configurations if and only if it has two configurations that differ in finitely many cells but have the same image.

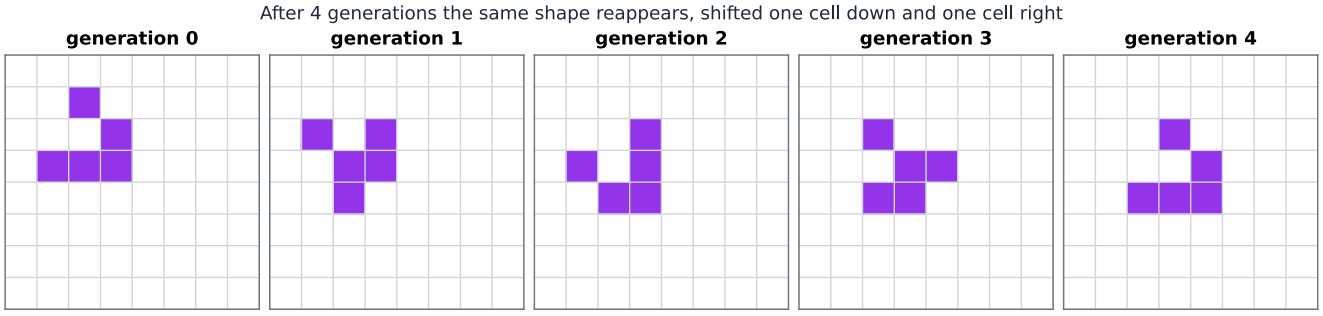
Conway's Game of Life has both, so it has Gardens of Eden, and people have found explicit ones. Information destruction (two pasts, one future) forces impossibility (some futures with no past). That trade-off is the discrete seed of the thermodynamic arrow of time.

Two dimensions: the Game of Life

In 1970 John Conway designed a two-dimensional CA on the square grid, with each cell reading its eight surrounding neighbours. The rule, written B3/S23, is:

- a dead cell with exactly 3 live neighbours is **born**;
- a live cell with 2 or 3 live neighbours **survives**;
- every other cell is dead at the next tick.

Out of this come still lifes (a 2×2 block never changes), oscillators (three in a row flips between horizontal and vertical with period 2), and the famous **glider**: five cells that, after four generations, reproduce their own shape shifted one cell diagonally.



A glider in Conway's Game of Life. The intermediate shapes are different, but generation 4 is generation 0 translated by one cell diagonally, so the glider travels at a quarter of the speed of light, $c/4$.

Gliders carry information across the grid. A **glider gun** (found by Bill Gosper in 1970) emits one every 30 generations, and colliding streams of gliders can be arranged to behave like AND, OR and NOT gates, wires and memory. Assemble enough of them and Life simulates a universal Turing machine. People have since built, inside Life, a working digital clock, a Life simulator running Life, and a pattern that computes the primes.

Wolfram's four classes and universality

Running all 256 elementary rules from random starts, Stephen Wolfram sorted their behaviour into four qualitative classes:

class	behaviour	examples
I	everything converges to a uniform state	rule 0, rule 32
II	settles into stable or periodic stripes	rule 4, rule 108
III	chaotic, aperiodic, random-looking	rule 30, rule 45
IV	localised structures that move and interact	rule 110, Life

Classes I–III map onto ideas from Ch. 83 and Ch. 84: fixed points, periodic orbits and chaos. Class III rules show sensitive dependence: flip one cell in rule 30 and the difference spreads rightwards at the full speed of light (one cell per tick) and leftwards at roughly a fifth of it, never healing. Class IV is new. It sits between order and chaos, and it is the class where computation lives.

Universality of rule 110 (Cook, 2004; stated)

With a suitable periodic background and finite initial pattern, rule 110 can simulate any Turing machine.

The proof shows that rule 110's gliders can emulate a *cyclic tag system*, a simple string-rewriting machine already known to be universal. It is long and ingenious, and its consequence is drastic. Universality plus the halting problem (Ch. 30) means that questions like "will this rule-110 pattern ever produce glider type X?" are **undecidable**: no algorithm answers them for all inputs. For such systems, there is in general no shortcut. The fastest way to learn what the automaton does in a million steps is to run it for a million steps. Wolfram calls this *computational irreducibility*.

That answers the hook's second question. We can solve rule 90 because it is linear: a closed form exists, and $N(t) = 2^{s(t)}$ lets you jump to step 10^{100} instantly. We cannot solve rule 110, and not merely because nobody has been clever enough. If a general closed form existed, it would decide the halting problem.

? Is rule 30 really random?

Rule 30's centre column starts $1, 1, 0, 1, 1, 1, 0, 0, 1, 1, \ldots$ and over the first 1000 steps it is 1 about 48% of the time, as a fair coin would be. Every statistical test anyone has run on it passes. Yet nobody has proved that the column is not eventually periodic, that 0s and 1s each occur with limiting frequency $\tfrac{1}{2}$, or that computing the nth bit requires about n steps of work. Wolfram offered prizes for each of the three in 2019, and they remain unclaimed. What it would even *mean* to prove "random-looking" is the subject of Ch. 81, where randomness is defined by what no efficient algorithm can tell apart.

When the averages lie: mean-field theory

Here is a tempting shortcut. Pretend each cell of Life is independently alive with probability p. Then a dead cell is born with probability $\binom{8}{3}p^3(1-p)^5$, a live cell survives with probability $\binom{8}{2}p^2(1-p)^6 + \binom{8}{3}p^3(1-p)^5$, and the density obeys a one-dimensional map

$$p_{t+1} = F(p_t) = 84\,p_t^3(1-p_t)^6 + 56\,p_t^4(1-p_t)^5.$$

This **mean-field** map has a stable fixed point at $p^* \approx 0.370$ (with $F'(p^*) \approx -0.08$, so convergence is fast) and an unstable threshold at $p \approx 0.192$ below which it predicts extinction. Now actually run Life from a random 35% soup. The density does not settle near 37%; it falls below 10% within about a hundred generations and keeps sinking for thousands more, to roughly 3% (on a 300×300 torus): scattered blocks, blinkers and the odd glider. Mean-field theory is wrong by an order of magnitude.

The error is the independence assumption. Live cells in Life are strongly *correlated*: they cluster into small structures with empty space between them. The whole point of emergence is that the parts are not independent, so any theory that averages them away throws away the phenomenon. You will meet the same failure, and the same partial rescue, in network epidemics (Ch. 87) and in critical phenomena (Ch. 88).

86.4 The algorithm

Updating a whole world at once

The only subtle point in simulating a CA is the word *simultaneously*. If you update cells one by one in a loop, overwriting as you go, cell $i+1$ sees the *new* value of cell i and you are simulating a different system. Always compute the next configuration from a frozen copy of the current one.

With NumPy the freeze comes for free: build the neighbourhood index for every cell in one vectorised expression and look the answers up in the rule table.

```
import numpy as np

def eca_step(x, rule):
    table = np.array([(rule >> k) & 1 for k in range(8)], dtype=np.uint8)
    left, right = np.roll(x, 1), np.roll(x, -1)      # periodic ring
    return table[4 * left + 2 * x + right]           # neighbourhood -> bit k of rule

def life_step(G):
    n = sum(np.roll(np.roll(G, a, 0), b, 1)
            for a in (-1, 0, 1) for b in (-1, 0, 1)) - G   # live-neighbour count
    return ((n == 3) | ((G == 1) & (n == 2))).astype(np.uint8)
```

`4*left + 2*x + right` is the neighbourhood read as a 3-bit binary number k, so `table[k]` is bit k of the rule number, exactly Wolfram's convention. For Life, the neighbour count is a sum of eight shifted copies of the grid; equivalently, a 2-D convolution with a 3×3 kernel of ones whose centre is zero, which is the same stencil idea as a finite-difference Laplacian.

Cost and tricks

One step costs $O(N)$ for N cells, so T steps cost $O(NT)$, and there is no way around this for irreducible rules. Engineers still find huge constant factors:

- **Bit packing.** Store 64 cells in one machine word and apply the Boolean formula for the rule with word-wide AND, OR and XOR. Rule 90 becomes `(x << 1) ^ (x >> 1)` and processes 64 cells per instruction.
- **Activity lists.** In Life most of the grid is empty and stays empty. Only cells next to a change can change, so track the active region.
- **HashLife.** Bill Gosper's algorithm memoises the evolution of quadtree blocks: a $2^k \times 2^k$ block determines its own centre 2^{k-2} generations later (light cone again!), and since repetitive patterns reuse the same blocks, it can leap billions of generations ahead for structured patterns. On random soup it gains nothing, which is computational irreducibility showing its teeth.

Failure cases

> **The boundary is part of the rule**
>
> A periodic ring of n cells is a *different dynamical system* from the infinite line. Once the light cone wraps around (after about $n/2$ steps for a single seed), the two sides interfere and the picture changes. Rule 90 on a ring of 2^m cells dies completely at $t = 2^{m-1}$: by the freshman's dream, $(z + z^{-1})^{2^{m-1}} = z^{2^{m-1}} + z^{-2^{m-1}}$, and on the ring $z^{2^m} = 1$, so the two terms are the same cell and cancel. Fixed-zero boundaries give yet another system. Always state the boundary condition, and make the grid much wider than the light cone if you want the infinite-line behaviour.

Other pitfalls: using signed `int8` and overflowing neighbour counts (fine for Life, since the maximum is 8, but not for automata with many states); and drawing conclusions from a single random seed, when classes III and IV can look alike for a few hundred steps.

86.5 The experiment

Part 1: your own space–time diagrams

Run this script, then change the knobs at the top.

```
import numpy as np
import matplotlib.pyplot as plt

RULE   = 30        # try 90, 110, 184, 54, 73, 45, 150
WIDTH  = 301       # number of cells (periodic ring)
STEPS  = 200       # number of time steps
RANDOM = False     # True: random start; False: single live cell
SEED   = 1

table = np.array([(RULE >> k) & 1 for k in range(8)], dtype=np.uint8)
rng = np.random.default_rng(SEED)
x = rng.integers(0, 2, WIDTH).astype(np.uint8) if RANDOM else np.zeros(WIDTH, np.uint8)
if not RANDOM:
    x[WIDTH // 2] = 1

rows = [x]
for _ in range(STEPS - 1):
    x = table[4 * np.roll(x, 1) + 2 * x + np.roll(x, -1)]
    rows.append(x)
grid = np.array(rows)

centre = grid[:, WIDTH // 2]
print(f"rule {RULE}: final density {grid[-1].mean():.3f}, "
      f"centre column mean {centre.mean():.3f}")

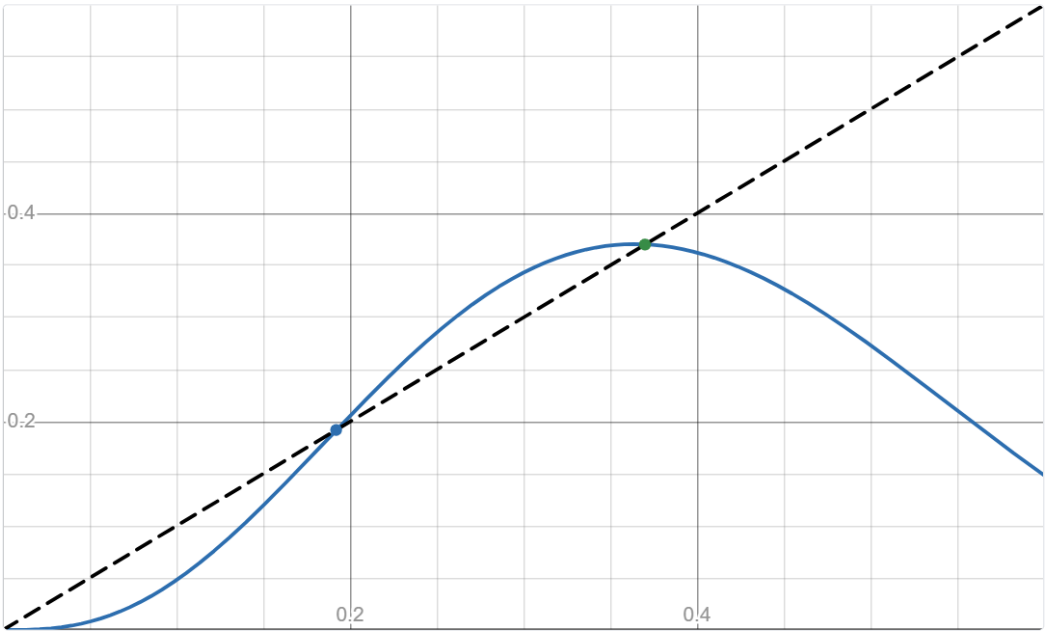
plt.figure(figsize=(8, 5))
plt.imshow(grid, cmap="Greys", interpolation="nearest", aspect="auto")
plt.title(f"Rule {RULE}")
plt.xlabel("cell")
plt.ylabel("time")
plt.show()
```

Things to try:

- Set `RULE = 90` and `WIDTH = 256` and watch the Sierpinski triangle wrap around and annihilate at $t = 128$, as the warning above predicts.
- Set `RANDOM = True` and compare rules 30 and 110. Rule 110's background settles into a periodic texture with gliders sliding over it; rule 30 never settles.
- Rule 184 is a traffic model: a 1 is a car that moves right if the cell ahead is empty. Start random with density below and above $\frac{1}{2}$ and look for traffic jams that move *backwards*.
- Flip one bit of a random start (`x[WIDTH//2] ^= 1` on a second copy) and plot the XOR of the two runs: that is the CA's version of the butterfly effect from Ch. 84.

Part 2: the mean-field map for Life

The density map from §86.3 is a one-dimensional iterated map, so a cobweb picture tells you everything the mean-field theory believes.



Mean-field density map $p_{t+1} = F(p_t)$ for the Game of Life (blue) against the diagonal. The blue curve crosses the diagonal at the two fixed points marked. The real Life soup ends near 3%, far below the stable point the curve predicts.

The polynomial is "born with exactly 3" plus "survive with 2 or 3". Change the rule and watch the fixed points move. HighLife (B36/S23) adds birth on 6 neighbours: add the term `28x^{6}(1-x)^{3}`, which is the probability $(1-x)$ that the cell was dead times $\binom{8}{6}x^6(1-x)^2$. Or try "Seeds" (B2/S, every live cell dies), whose map is just $(1-x)\binom{8}{2}x^2(1-x)^6 = 28x^2(1-x)^7$. Ask each time: does the mean-field prediction match what the real automaton does? Run the Life step from §86.4 to find out.

86.6 The challenge

1. **Intuition.** Without running any code, predict what rule 0, rule 255, rule 204 and rule 51 do from any starting configuration. (Hint: write out the eight-entry tables.) Then explain in one sentence why rule 184, the traffic rule, must conserve the number of 1s, and why no rule that conserves 1s can ever be in Wolfram's class I unless the density is 0 or 1.
2. **Derivation.** Rule 150 is $x_i^{t+1} = x_{i-1} \oplus x_i \oplus x_{i+1}$. Show that it is linear over $\mathbb{F}_2$, write its single-seed evolution as $\left(z^{-1}+1+z\right)^t X^0(z)$, and prove that the number of live cells at time 2^m is exactly 3. Then decide, for rings of n cells, for which n rule 150 is invertible, by computing its kernel as in Result 3.
3. **Implementation.** Write a program that classifies all 88 inequivalent elementary rules automatically. From 20 random starts on a ring of 400 cells, run 1000 steps and compute (a) the final density, (b) whether the configuration has become periodic in time, and (c) the spreading speed of a single flipped bit. Use these numbers to sort the rules into Wolfram's four classes, and list the rules your program cannot confidently place.
4. **Open investigation.** Search the space of two-dimensional "Life-like" rules (each is a pair of sets B/S of neighbour counts, so there are $2^{18} = 262144$ of them) for rules that support a glider. Starting from random soups of density 0.3, how often do spontaneously moving objects appear? Is there a simple statistic of the rule (the number of birth conditions, the mean-field fixed point, the rate of density decay) that predicts whether gliders exist? Nobody has a clean criterion.

86.7 Loose threads

The chapter showed that tiny local rules can be solvable (rule 90), random-looking (rule 30) or universal (rule 110 and Life), and that mean-field averaging fails precisely where things get interesting. It skipped three big questions on purpose.

? Does computation live at the edge of chaos?

Class IV sits between frozen order (classes I and II) and seething disorder (class III). In 1990 Chris Langton parametrised rules by λ, the fraction of neighbourhoods that map to a live state, and claimed that complex, computation-capable behaviour clusters near a critical λ, the way a magnet is most responsive at its critical temperature. Others reran the experiments and disputed the conclusion. Is there a phase transition in "rule space", and is it where adaptive systems, from cells to brains, tune themselves? The idea of self-tuned criticality returns in Ch. 88, and whether it holds up is still argued.

? Can a cellular automaton be a fluid?

Put particles on a hexagonal lattice, let them hop and collide by a few local rules that conserve number and momentum, and average over large blocks. In 1986 Frisch, Hasslacher and Pomeau showed that the averages obey the Navier–Stokes equations of fluid dynamics, even though nothing in the rules mentions viscosity or pressure. Why do the conservation laws and the lattice symmetry alone fix the continuum equations, and why does a square lattice give the *wrong* answer? That passage from discrete microscopic rules to continuum PDEs is a theme of Ch. 92.

Other threads:

- **Undecidability, made precise.** The claim that rule 110 has undecidable long-term behaviour rests on the halting problem and on reductions between machines, which Ch. 30 builds from scratch.

- **Procedural worlds.** Game designers use CAs (for instance, "a wall survives if 4 or more of its 8 neighbours are walls") to carve caves from noise in a few passes: Ch. 74.
- **From grids to networks.** A CA lives on a lattice where every cell has the same neighbours. Real systems, from power grids to social networks, have wildly uneven neighbourhoods, and the same local-rule thinking on an irregular graph is the subject of Ch. 87.
- **Reversible worlds.** Some CAs are invertible, so no information is ever lost. Physics at the microscopic level is reversible too. Whether reversible CAs can still be universal (they can) and what that has to do with the energy cost of computation is a story about Landauer's principle that Ch. 33 starts.

Chapter 87 — Network Science: The Shape of Complex Systems

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 11, Ch. 19, Ch. 27, Ch. 34 · **Leads to:** Ch. 88, Ch. 90 · **Related:** Ch. 10, Ch. 45, Ch. 86 **Reading time:** ~25 min

87.1 The hook

On average, your friends have more friends than you do.

This is not a statement about you. It is true for most people in almost every social network ever measured, from Facebook to high-school friendships to sexual-contact surveys. It sounds like a statistical insult, and it is a theorem, one we will prove in five lines.

Here is a second puzzle with the same root. Two cities each have a million people, and in both, the average person has six close contacts. A new virus arrives in each, with identical biology: same chance of passing per contact, same recovery time. In one city the outbreak fizzles. In the other it infects nearly half the population. Nothing differs except *who is connected to whom*.

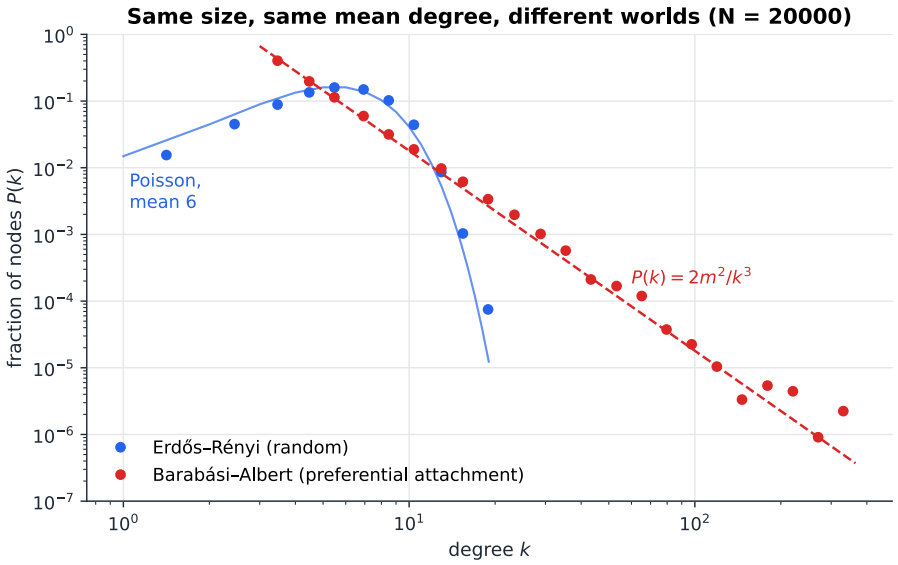
And a third. On a summer evening in Southeast Asia, thousands of male fireflies in a single tree begin to flash in unison. Nobody conducts them. Each firefly only adjusts its rhythm slightly toward the flashes it sees. Below a certain level of mutual influence, nothing happens; the tree twinkles at random. Above it, synchrony appears suddenly and spreads through the tree.

Three phenomena, one lesson. Once many parts interact, the **pattern of connections** is itself a variable, often the most important one. The question for this chapter: what can mathematics say about a system when you know the shape of its network but not the details of its parts?

87.2 The big idea

Chapter 27 treated a graph as a fixed object to be searched: find the shortest path, the best matching, the communities. Network science asks a different question. Real networks have millions of nodes, nobody designed them, and they grow and change. So instead of studying one graph, we study **families of random graphs** with the right statistics, and ask which large-scale properties are almost certain.

The single most revealing statistic is the **degree distribution** $P(k)$: the fraction of nodes with exactly k links. Two networks can share size and mean degree and still be different worlds.



Two networks of 20,000 nodes, both with mean degree 6. In the random (Erdős–Rényi) network, degrees cluster tightly around 6 and nobody has more than 18 links. In the preferential-attachment (Barabási–Albert) network, the distribution is a straight line on log–log axes, a power law, and the best-connected node has 365 links.

Picture the two as road maps. The Erdős–Rényi network is like rural roads: every village has a handful of connections and no village is special. The Barabási–Albert network is like an airline map: most airports have a few routes, and a few hubs have hundreds. In the second kind there is no "typical" scale, which is why it is called **scale-free**.

Three intuitions follow and organise the rest of the chapter.

1. **Thresholds are everywhere.** Add links to a sparse random network one by one and nothing much happens, until suddenly a single connected "giant component" spans the network. The same arithmetic governs whether a disease, a rumour or a power-grid failure spreads: an epidemic is a giant component of infections.
2. **Hubs dominate.** If you reach a node by following a link, you are more likely to land on a hub, simply because hubs have more links pointing at them. That one bias explains the friendship paradox and why scale-free networks are so vulnerable to epidemics.
3. **Coupling creates collective rhythm.** Oscillators that each nudge each other weakly can, above a critical coupling, lock into synchrony. Like the giant component, it appears abruptly at a threshold.

87.3 The mathematics

Random networks and the giant component

Erdős–Rényi random graph

$G(n,p)$ has n nodes, and each of the $\binom{n}{2}$ possible edges is present independently with probability p. Its mean degree is $c=(n-1)p$. For large n with c fixed, the degree of a node is Binomial$(n-1,p)\approx$ Poisson(c):

$$P(k)=e^{-c}\frac{c^k}{k!}.$$

The Poisson limit is the law of rare events from Ch. 19. Its variance equals its mean, so with $c=6$ almost all degrees lie between 1 and 13.

The key fact about sparse random graphs is that they are **locally tree-like**: short loops are rare, because closing a loop of length ℓ needs an unlikely extra edge, with probability about c/n. Near any node, the network looks like a branching family tree. That turns global connectivity into a branching-process calculation.

The giant component

In $G(n,c/(n-1))$ with $n\to\infty$, let S be the fraction of nodes in the largest connected component. Then S is the largest solution in $[0,1]$ of

$$S=1-e^{-cS}.$$

For $c\le 1$ the only solution is $S=0$ (all components are small); for $c>1$ there is a unique solution with $S>0$, a **giant component** containing a finite fraction of all nodes.

Derivation. Let u be the probability that a node is *not* in the giant component. A node avoids the giant component exactly when every one of its neighbours does, and in a tree-like network the neighbours' fates are independent. A node of degree k therefore avoids it with probability u^k, and averaging over the Poisson degree,

$$u=\sum_{k=0}^{\infty}e^{-c}\frac{c^k}{k!}u^k=e^{-c}e^{cu}=e^{-c(1-u)}.$$

(For Poisson degrees, the number of *further* neighbours of a node reached along an edge is again Poisson(c), so the same u appears on both sides.) Writing $S=1-u$ gives $S=1-e^{-cS}$.

Now look at the right-hand side $h(S)=1-e^{-cS}$. It is increasing and concave, with $h(0)=0$, $h'(0)=c$ and $h(1)<1$. If $c\le 1$, concavity puts $h(S)<cS\le S$ for every $S>0$, so the curve lies below the diagonal and only $S=0$ works. If $c>1$, the curve starts *above* the diagonal (slope $c>1$) and ends below it, so it crosses exactly once more in $(0,1)$. ■

The solution rises steeply: $S\approx 0.583$ at $c=1.5$, 0.797 at $c=2$, and 0.997 at $c=6$. (A simulation of $n=100{,}000$ nodes at $c=2$ gives 0.797.) The transition at $c=1$ is a genuine **phase transition**, like water freezing: as c crosses 1, the size of the largest cluster jumps from a vanishing fraction to a finite one. You will watch it happen in the experiment.

The tree-like picture also explains why random networks are **small worlds**. From a typical node, about c nodes are one step away, c^2 two steps away, and c^ℓ at distance ℓ. These run out of network when $c^\ell\approx n$, so typical distances are

$$\ell\approx\frac{\ln n}{\ln c}.$$

For $n=20{,}000$ and $c=6$ this gives 5.5, and the network in the figure has mean distance 5.8. Distances grow only *logarithmically* with size: that is the "six degrees of separation" phenomenon, explained by nothing more than branching.

Result 2: the friendship paradox

Pick a random node and look at its degree: on average, $\langle k\rangle$. Now pick a random *edge* and follow it to one of its ends. A node with k links is the end of k edges, so it is reached with probability proportional to k. The degree of a node reached along an edge has distribution $kP(k)/\langle k\rangle$, and its mean is

$$\langle k\rangle_{\text{neighbour}}=\sum_k k\cdot\frac{kP(k)}{\langle k\rangle}=\frac{\langle k^2\rangle}{\langle k\rangle}.$$

Friendship paradox

In any network, the mean degree of a node reached by following a random edge is at least the mean degree of a random node:

$$\frac{\langle k^2\rangle}{\langle k\rangle}=\langle k\rangle+\frac{\mathrm{Var}(k)}{\langle k\rangle}\ \ge\ \langle k\rangle,$$

with equality only when every node has the same degree.

Proof. $\langle k^2\rangle=\langle k\rangle^2+\mathrm{Var}(k)$ (Ch. 19). Divide by $\langle k\rangle>0$, and use $\mathrm{Var}(k)\ge 0$, with equality only for constant k. ■

The size of the paradox is the variance. For the random network in the figure, $\langle k\rangle=6$ and $\langle k^2\rangle/\langle k\rangle=7.0$: your friends have one more friend than you. For the scale-free network with the *same* mean degree, $\langle k^2\rangle/\langle k\rangle=19.5$: your friends have more than three times as many friends as you. The hubs are hiding in everyone's friend list.

Engineering note

The paradox is a sampling tool. To find well-connected nodes without knowing the network, pick random nodes and ask each for *a random neighbour*. During outbreaks, monitoring the friends of randomly chosen people detects epidemics earlier than monitoring the people themselves, and "acquaintance immunisation" (vaccinate a random friend of a random person) protects a scale-free population far better than random vaccination.

Result 3: where power laws come from

The Erdős–Rényi model can never produce a hub with 365 links: the Poisson tail falls faster than exponentially. In 1999 Barabási and Albert proposed a mechanism with two ingredients that real networks (the web, citations, airline routes) clearly have: **growth** and **preferential attachment**, "the rich get richer".

Barabási–Albert model

Start with a few connected nodes. At each time step add one new node with m edges, and attach each edge to an existing node i with probability proportional to its degree, $k_i / \sum_j k_j$.

Degree exponent of the BA model

In the continuum (mean-field) approximation, the BA model produces a degree distribution $P(k) \approx 2m^2/k^3$ for $k \geq m$: a power law with exponent 3.

Derivation. After t steps there are about t nodes and mt edges, so $\sum_j k_j = 2mt$. Treat k_i as a continuous function of time. Node i gains links from each of the m new edges with probability $k_i/(2mt)$, so

$$\frac{dk_i}{dt} = m \cdot \frac{k_i}{2mt} = \frac{k_i}{2t}, \qquad k_i(t_i) = m,$$

a separable ODE with solution $k_i(t) = m\sqrt{t/t_i}$, where t_i is the node's birth time. Old nodes are big; that's the whole mechanism. A node has degree below k exactly when it was born late enough: $k_i(t) < k \iff t_i > m^2 t/k^2$. Birth times are uniform on $[0, t]$, so

$$P(k_i < k) = 1 - \frac{m^2}{k^2}, \qquad P(k) = \frac{d}{dk} P(k_i < k) = \frac{2m^2}{k^3}.$$

■

The dashed line in the figure is $2m^2/k^3$ with $m = 3$, and the simulated network sits right on it. The important consequence is the second moment. With $P(k) \propto k^{-3}$, $\langle k^2 \rangle \approx \int_m^{k_{\max}} k^2 \cdot 2m^2 k^{-3}\, dk = 2m^2 \ln(k_{\max}/m)$, which grows without bound as the network grows. For exponents between 2 and 3, common in real networks, it grows like a power of n. **The variance of a scale-free network is effectively infinite.** Every result below that depends on $\langle k^2 \rangle$ changes character.

? Are real networks actually scale-free?

Power laws are easy to see and hard to prove. A straight line on a log–log plot is weak evidence: log-normal and stretched-exponential distributions mimic it over two decades. In 2019 Broido and Clauset fitted nearly a thousand real networks with careful likelihood tests and found strong power laws in only a small minority, setting off a fierce debate that is not settled. How would you even test the claim? The tools (maximum-likelihood fits, goodness-of-fit and likelihood-ratio tests) are in Ch. 20; the verdict on the world's networks is still an open question.

Contagion: an epidemic is a giant component

The simplest epidemic model on a network is **SIR**: each node is Susceptible, Infected or Recovered. An infected node passes the infection along each of its edges with some probability per unit time, and recovers (permanently immune) at some rate. The well-mixed version, where everyone meets everyone, is the classic system of ODEs $\dot{S} = -\beta SI$, $\dot{I} = \beta SI - \gamma I$, $\dot{R} = \gamma I$ (Ch. 11), with its famous threshold $R_0 = \beta/\gamma > 1$. On a network, the threshold moves.

Collapse the timing into one number: the **transmissibility** T, the probability that an infected node infects a given neighbour before recovering. Then an outbreak is just a random subgraph: keep each edge with probability T, and the people eventually infected are the component of the kept-edge network that contains patient zero. A large epidemic is possible exactly when the kept-edge network has a giant component.

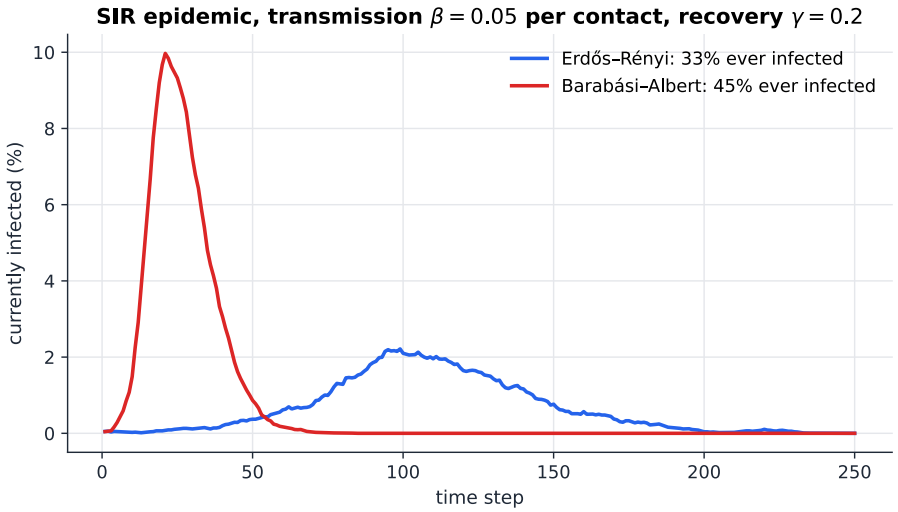
Now use the friendship-paradox calculation. Follow the infection down an edge to a newly infected node. That node was reached along an edge, so its mean degree is $\langle k^2 \rangle / \langle k \rangle$; one of its edges leads back to where the infection came from, which leaves $\langle k^2 \rangle / \langle k \rangle - 1$ onward edges, each transmitting with probability T. In a tree-like network the infection is a branching process with mean offspring

$$R = T\, \frac{\langle k^2 \rangle - \langle k \rangle}{\langle k \rangle},$$

and a branching process survives with positive probability exactly when its mean offspring exceeds 1. So the **epidemic threshold** is

$$T_c = \frac{\langle k \rangle}{\langle k^2 \rangle - \langle k \rangle}.$$

For a Poisson network with mean c, $\langle k^2 \rangle = c^2 + c$, so $T_c = 1/c$, which is the giant-component condition again with c replaced by Tc. For the two networks in the figure: $T_c \approx 0.167$ for the random network and $T_c \approx 0.054$ for the scale-free one.



The same disease on the two networks of the first figure (ten random initial cases, one realisation each). Per step, an infected node infects each susceptible neighbour with probability 0.05 and recovers with probability 0.2, giving transmissibility $T \approx 0.208$. On the random network $R \approx 1.25$ and the outbreak smoulders; on the scale-free network $R \approx 3.9$ and it explodes through the hubs, peaks around step 20, and reaches 45% of nodes.

That is the answer to the two-cities puzzle in the hook. Same biology, same average contacts, different variance. And for a scale-free network with exponent at most 3, $\langle k^2 \rangle \to \infty$ as the network grows, so $T_c \to 0$: **there is no epidemic threshold at all**. However weakly a pathogen spreads, a large enough scale-free network can sustain it, because the hubs act as amplifiers. Pastor-Satorras and Vespignani pointed this out in 2001 for computer viruses, which had puzzled everyone by persisting for years at low prevalence. The cure follows from the same algebra: target the hubs, the nodes that make $\langle k^2 \rangle$ large.

? The threshold is an eigenvalue

The formula $T_c = \langle k \rangle / (\langle k^2 \rangle - \langle k \rangle)$ only uses the degree distribution, as if the network were otherwise random. For a *particular* network, with its clustering, communities and correlations, a different number controls the threshold: the largest eigenvalue $\lambda_{\max}$ of the adjacency matrix $\mathbf{A}$, with the threshold near $T\lambda_{\max} = 1$. For the random network above $\lambda_{\max} \approx 7.17$, close to $\langle k^2 \rangle / \langle k \rangle = 7.0$; for the scale-free one $\lambda_{\max} \approx 22.6$ versus 19.5. Why should the top eigenvalue of a matrix of 0s and 1s decide whether a disease dies out, and what does its eigenvector say about *where* to vaccinate? The Perron–Frobenius theory behind it is in Ch. 90.

Synchronisation: the Kuramoto model

Now replace "infected or not" by a phase. Give each node an oscillator with angle θ_i and its own natural frequency ω_i, drawn from a distribution $g(\omega)$ that is symmetric about 0 (we can always rotate to a frame where the mean frequency is 0). Each oscillator speeds up or slows down toward the others:

$$\frac{d\theta_i}{dt} = \omega_i + \frac{K}{N} \sum_{j=1}^{N} \sin\left(\theta_j - \theta_i\right).$$

This is Kuramoto's model (1975), here on the complete graph; on a general network the sum runs over neighbours. To measure synchrony, average the oscillators as unit phasors in the complex plane, exactly as in a phasor diagram for AC circuits:

$$r\, e^{j\psi} = \frac{1}{N} \sum_{j=1}^{N} e^{j\theta_j}.$$

The **order parameter** $r \in [0, 1]$ is the length of the average phasor: $r \approx 0$ when phases are scattered, $r = 1$ when all oscillators point the same way.

Multiply the definition by $e^{-j\theta_i}$ and take imaginary parts: $r \sin(\psi - \theta_i) = \frac{1}{N} \sum_j \sin(\theta_j - \theta_i)$. So the model becomes

$$\frac{d\theta_i}{dt} = \omega_i + Kr \sin\left(\psi - \theta_i\right).$$

Each oscillator feels *only the mean field*: a pull of strength Kr toward the collective phase ψ. This is the feedback at the heart of synchrony. More order means a stronger pull, and a stronger pull creates more order.

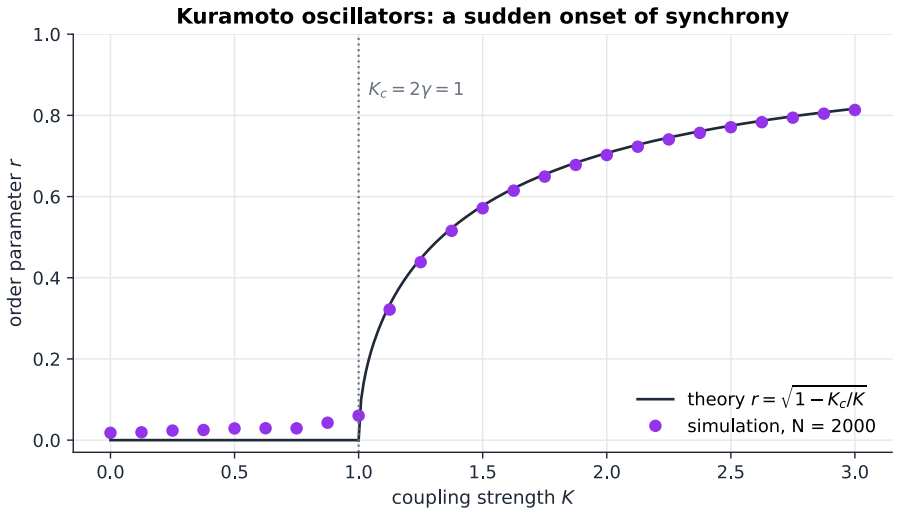
Suppose a steady state exists with constant r and $\psi = 0$. An oscillator with $|\omega_i| \le Kr$ can sit at the fixed point $\sin\theta_i = \omega_i / (Kr)$: it is **locked**. One with $|\omega_i| > Kr$ drifts forever. By symmetry of g the drifting ones contribute nothing to the average phasor, while a locked oscillator with $\omega = Kr \sin\theta$ contributes $\cos\theta$. Changing variables from ω to θ gives the **self-consistency equation**

$$r = \int_{-\pi/2}^{\pi/2} \cos\theta \; g\left(Kr \sin\theta\right) Kr \cos\theta \, d\theta = Kr \int_{-\pi/2}^{\pi/2} \cos^2\theta \; g\left(Kr \sin\theta\right) d\theta.$$

$r = 0$ always solves it (incoherence). A nonzero solution branches off when, dividing by r and letting $r \to 0$, $1 = Kg(0) \int_{-\pi/2}^{\pi/2} \cos^2\theta \, d\theta = Kg(0)\pi/2$. That is

$$K_c = \frac{2}{\pi g(0)}.$$

For the Lorentzian distribution $g(\omega) = \gamma / \left(\pi(\omega^2 + \gamma^2)\right)$, $g(0) = 1/(\pi\gamma)$, so $K_c = 2\gamma$, and the integral can be done exactly to give $r = \sqrt{1 - K_c/K}$ for $K > K_c$.



Simulated order parameter (purple, 2,000 oscillators with Lorentzian frequencies, $\gamma = 0.5$) against the exact large-N theory (black). Below $K_c = 1$ the phases stay scattered and r is only finite-size noise of order $1/\sqrt{N}$; above it, synchrony switches on with the square-root shape of a pitchfork bifurcation (Ch. 85).

The fireflies, the pacemaker cells of your heart, the generators of a power grid and the pedestrians who made London's Millennium Bridge sway on its opening day in 2000 all follow this script: a population of slightly different oscillators, a coupling that grows with the order it produces, and a threshold.

Self-consistency is not stability

The argument above found a *candidate* steady state. It did not show that the incoherent state $r = 0$ is stable below K_c, nor that the partially locked state is stable above it, and for $N = \infty$ both questions turn out to be surprisingly delicate. The simulation agrees with the theory, but agreement is evidence, not proof.

87.4 The algorithm

Building random networks without $O(n^2)$ work

Naively, $G(n, p)$ needs a coin flip for each of $\binom{n}{2}$ pairs, which for $n = 10^6$ is 5×10^{11} flips. Instead, draw the *number* of edges $M \sim \text{Binomial}(\binom{n}{2}, p)$, then draw M random pairs. This costs $O(n + M)$, produces a handful of self-loops and duplicate edges (which you discard; there are $O(1)$ of them in expectation), and is how the figure's networks were made.

For preferential attachment, the trick is a list in which every node appears once per unit of degree. Choosing a uniformly random entry of that list *is* choosing a node with probability proportional to degree, so each new edge costs $O(1)$.

```
def barabasi_albert(n, m, rng):
    repeated, edges, targets = [], [], list(range(m))
    for new in range(m, n):
        edges += [(new, t) for t in targets]
        repeated += targets + [new] * m          # one entry per unit of degree
        chosen = set()
        while len(chosen) < m:                   # m distinct targets
            chosen.add(repeated[rng.integers(len(repeated))])
        targets = list(chosen)
    return edges
```

The **configuration model** is the general tool: choose any degree sequence $k_1, \dots, k_n$, give node i exactly k_i "stubs", shuffle all stubs and pair them up. It produces a random network with exactly the degrees you asked for and nothing else, which makes it the natural null model for testing whether a real network's structure is more than its degrees.

Simulating dynamics on networks

Store the adjacency matrix in sparse form (only the $2M$ nonzeros). One step of discrete-time SIR is then one sparse matrix–vector product: $\mathbf{A}\mathbf{i}$ counts each node's infected neighbours n_i, and a susceptible node is infected with probability $1 - (1 - \beta)^{n_i}$. Cost: $O(n + M)$ per step. For exact continuous-time dynamics, treat the epidemic as a continuous-time Markov chain (Ch. 36) and use the Gillespie algorithm, which draws an exponential waiting time and jumps directly from one event to the next.

For Kuramoto on the complete graph, never evaluate the double sum, which costs $O(N^2)$. Compute the order parameter $re^{j\psi}$ in $O(N)$ and use the mean-field form; one Euler step is

```
z = np.exp(1j * theta).mean()                    # r * exp(j psi)
theta += dt * (omega + K * np.abs(z) * np.sin(np.angle(z) - theta))
```

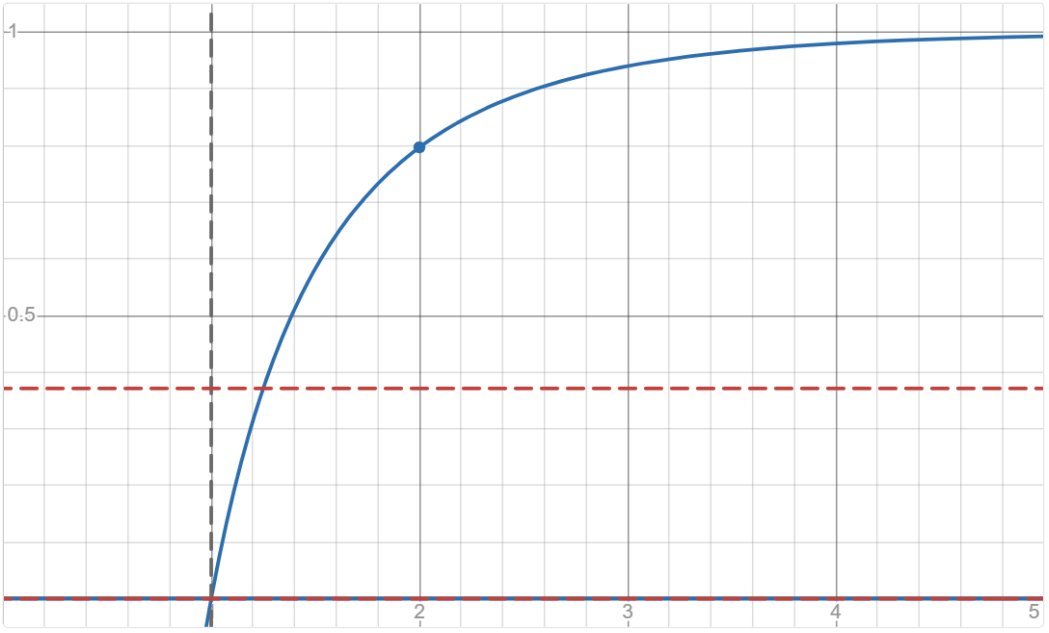
Failure cases

- **Stochastic die-out.** Even above threshold, an epidemic started from one case can die in the first few generations by bad luck; for a branching process the extinction probability is the smallest root of a generating-function equation. Always average over many seeds and report the *conditional* size of large outbreaks separately.
- **Finite-size rounding.** At $c = 1$ or $T = T_c$, the "transition" in a finite network is smeared over a window that shrinks only like a power of n. Theory is a limit; simulations live at finite n.
- **Stiffness and time step.** Oscillators with huge natural frequencies (the Lorentzian has heavy tails) rotate fast; an Euler step that is fine for the locked core can alias for them. They don't affect r much because they drift anyway, but check by halving `dt`.
- **The hub cutoff.** In a scale-free network of size n the largest degree grows like $\sqrt{n}$ (for exponent 3), so $\langle k^2 \rangle$ grows like $\ln n$, slowly. A scale-free network of a few thousand nodes can look as if it has a threshold.

87.5 The experiment

Part 1: watch the giant component appear

The equation $S = 1 - e^{-cS}$ is an implicit curve in the (c, S) plane, and Desmos draws implicit curves directly. Here x plays the role of the mean degree c and y the giant-component fraction S.



The blue curve is the solution set of $S = 1 - e^{-cS}$: the trivial branch $S = 0$ and the giant branch that leaves it at $c = 1$. The red dashed line asks the same question at the single value $c = 1.25$, the Tc of the random-network epidemic: its height, about 0.37, is the predicted final epidemic size there.

Change `1.25` in the red line to `0.9` (it collapses onto $y = 0$: no outbreak), then to `3`. Replace the blue equation by `y=1-e^{-2xy}` and explain why the transition moves to $x = 0.5$.

Part 2: an epidemic on a network you design

This script builds a configuration-model network with either Poisson or power-law degrees, then runs SIR on it. It uses only NumPy.

```
import numpy as np
import matplotlib.pyplot as plt

N, BETA, GAMMA, STEPS = 20000, 0.05, 0.2, 300
DEGREES = "powerlaw"      # "poisson" or "powerlaw"
rng = np.random.default_rng(0)

if DEGREES == "poisson":
    k = rng.poisson(6, N)
else:                     # Pareto tail, exponent ~3, minimum degree 3
    k = np.floor(3 * (1 - rng.random(N)) ** (-1 / 2)).astype(int)
k[0] += k.sum() % 2       # total number of stubs must be even
stubs = rng.permutation(np.repeat(np.arange(N), k))
u, v = stubs[0::2], stubs[1::2]
keep = u != v             # drop self-loops
u, v = u[keep], v[keep]
print(f"mean degree {k.mean():.2f}, <k^2>/<k> {np.mean(k**2)/k.mean():.1f}, max {k.max()}")

S = np.ones(N, bool); I = np.zeros(N, bool)
first = rng.choice(N, 10, replace=False); S[first] = False; I[first] = True
curve = []
for t in range(STEPS):
    n_inf = np.bincount(u[I[v]], minlength=N) + np.bincount(v[I[u]], minlength=N)
    new = S & (rng.random(N) < 1 - (1 - BETA) ** n_inf)
    rec = I & (rng.random(N) < GAMMA)
    S &= ~new
    I = (I | new) & ~rec
    curve.append(I.mean())

print(f"ever infected: {1 - S.mean():.1%}")
plt.plot(100 * np.array(curve))
plt.xlabel("time step"); plt.ylabel("infected (%)")
plt.title(f"SIR on a {DEGREES} network"); plt.show()
```

Things to try:

- Switch `DEGREES` between `"poisson"` and `"powerlaw"`. The printout shows $\langle k^2\rangle/\langle k\rangle$; predict from T_c which network will have an outbreak before you look at the plot.
- Lower `BETA` to 0.02. Transmissibility drops to about 0.09, below the Poisson threshold $1/6$: the Poisson network should stay clean while the power-law one may still burn.
- **Vaccinate the hubs.** Before the loop, set `S[np.argsort(k)[-N//20:]] = False` to immunise the best-connected 5%. Then try 5% chosen at random. Then try "acquaintance immunisation": pick 5% of random nodes and vaccinate one random *neighbour* of each. Which works, and why does the friendship paradox predict it?
- Change the Pareto exponent: `-1/2` gives $P(k) \propto k^{-3}$; `-1/1.5` gives $k^{-2.5}$, with an even fatter tail.

87.6 The challenge

1. **Intuition.** Ten people stand in a ring, each holding hands with the two people next to them, so everyone has degree 2. Is there a friendship paradox? Now add one person in the middle who holds a ribbon to all ten. Without calculating, say whether the paradox appears, who feels it, and how strongly. Then explain why random vaccination is a poor strategy in this network.
2. **Derivation.** Generalise the giant-component argument to any degree distribution. Let $G_0(x) = \sum_k P(k)x^k$ and $G_1(x) = G_0'(x)/G_0'(1)$. Show that the probability u that an edge does not lead to the giant component satisfies $u = G_1(u)$, that $S = 1 - G_0(u)$, and that a giant component exists exactly when $\langle k^2\rangle > 2\langle k\rangle$ (the Molloy–Reed criterion). Check that you recover $S = 1 - e^{-cS}$ for Poisson degrees.
3. **Implementation.** Simulate the Kuramoto model on an Erdős–Rényi network (the sum runs over neighbours only, divided by the mean degree) with $N = 1000$ and Lorentzian frequencies of width $\gamma = 0.5$. Plot r against K for mean degrees 4, 10 and 50, and compare with the complete-graph curve. How sparse can the network be before synchrony needs much more coupling?
4. **Open investigation.** Take a scale-free network and give each oscillator a natural frequency *equal to its degree*. Increase K slowly from 0, record r, then decrease K slowly back to 0. Reports in the literature describe "explosive synchronisation", a sudden jump with hysteresis, in this setup. Can you reproduce it? How does the jump depend on the degree exponent and on the network size? Is there a correlation between frequency and degree weaker than equality that still produces it? There is no complete theory.

87.7 Loose threads

This chapter used two ideas over and over: networks look like trees locally, so branching processes predict thresholds; and following edges biases you toward hubs, so the second moment $\langle k^2\rangle$ controls everything. We took the degree distribution as the whole story and the complete graph as the arena for synchrony. Both choices hid a lot.

> **? Why does incoherence stay incoherent?**
>
> Below K_c the Kuramoto order parameter decays to zero. Yet if you linearise the infinite-N model around the incoherent state, the spectrum has no decaying eigenvalues at all, only a continuous spectrum sitting exactly on the imaginary axis. Something other than ordinary exponential stability is pulling r to zero: a phase-mixing effect first found for waves in plasmas, called Landau damping. How can a system relax without any damping mechanism, and why do the same mathematics describe galaxies and plasmas? That is a story for Ch. 92.

Other threads:

- **Communities and centrality.** Real networks are not uniformly random: they have dense communities and important nodes. Detecting communities with the eigenvectors of the graph Laplacian, and measuring importance by eigenvector centrality and PageRank, is in Ch. 27 and Ch. 34.
- **Robustness and attack.** Remove random nodes from a scale-free network and the giant component survives almost to the end; remove the hubs and it shatters after a few per cent. This is percolation on networks, and the Molloy–Reed machinery from challenge 2 predicts both numbers.
- **Clustering and small worlds.** Social networks have many triangles (your friends know each other), which random graphs lack. Watts and Strogatz showed in 1998 that rewiring a few links of a lattice keeps the triangles but collapses the distances. Triangles break the tree-like assumption behind every threshold in this chapter.
- **Games on networks.** Cooperation survives in the prisoner's dilemma far more easily when players interact only with neighbours on a network: Ch. 45.
- **From networks to complexity.** Thresholds, feedback through a mean field and the sudden appearance of collective order recur everywhere in Ch. 88, which asks whether they share one explanation.

Chapter 88 — Complexity Science: When the Whole Exceeds the Parts

> **Level 2 · Track I — Dynamical Systems, Chaos, and Complexity Builds on:** Ch. 14, Ch. 25, Ch. 34, Ch. 86, Ch. 87 · **Leads to:** Track J, Ch. 92, Ch. 98 · **Related:** Ch. 45, Ch. 51, Ch. 85 **Reading time:** ~25 min

88.1 The hook

Shortly after 3 p.m. on 14 August 2003, a heavily loaded transmission line in northern Ohio sagged in the summer heat and touched a tree that should have been trimmed. The line tripped, exactly as its protection was designed to do. Its current shifted to neighbouring lines, which grew hotter and sagged in turn. An alarm program in the local control room had silently stalled, so the operators did not see what was happening. Over the next hour more lines tripped, each one pushing load onto the rest, until shortly after 4 p.m. the cascade swept across the north-eastern United States and Ontario in about seven minutes. Some 50 million people lost power.

Nothing in that story is exotic. Every component did what it was built to do. The grid had redundancy precisely so that losing one line would not matter, and usually it doesn't. Almost every day, somewhere, a line trips and nothing happens. Very occasionally, the same small event takes down a continent.

Engineers who collected decades of blackout records found something stranger still. Plot how often blackouts of each size occur and there is no "typical" blackout. Small ones are common and big ones are rare, but the frequency falls off slowly, roughly like a power of the size, so that the catastrophic events are far more likely than a bell curve would ever allow. Earthquakes, forest fires, stock-market crashes and extinctions in the fossil record show the same heavy-tailed signature.

Why would systems as different as power grids and the Earth's crust share the statistics of their disasters? And why would a system built to be stable organise itself, without anyone intending it, to the brink of collapse?

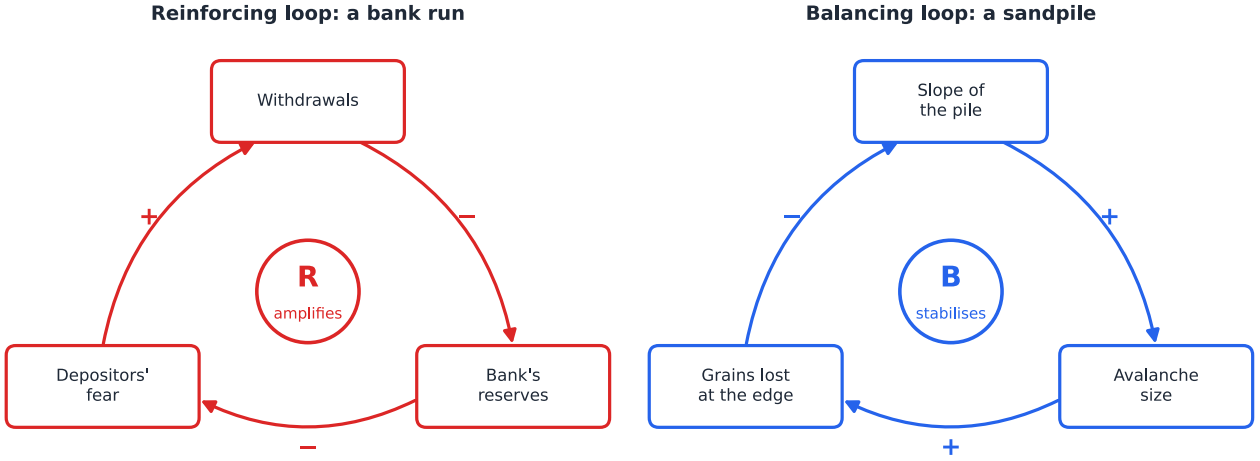
88.2 The big idea

"More is different," wrote the physicist Philip Anderson in 1972. Knowing everything about one water molecule tells you nothing about waves, whirlpools or ice. Knowing one neuron tells you nothing about a thought. **Complexity science** studies systems of many interacting parts whose collective behaviour has properties the parts don't have. Three words organise the field.

Emergence is the appearance of large-scale patterns from local interactions, as with the gliders of Ch. 86 and the synchrony of Ch. 87. An emergent pattern can be described by its own laws (a glider moves at $c/4$; a flock has a mean heading) without reference to the parts.

Self-organisation is emergence without a designer or a leader. A flock of starlings has no commander, an ant colony has no architect, and a market has no central planner, yet each produces coordinated structure. The organising force is the interactions themselves.

Feedback is the mechanism. When an effect circles back to influence its own cause, the loop either amplifies (positive, or *reinforcing*, feedback) or damps (negative, or *balancing*, feedback). Engineers know feedback from control theory (Ch. 14), where a balancing loop holds a motor at its set speed. In complex systems the loops are not designed, there are many of them, and they interact.



Loop polarity = product of the signs on its arrows: $(-)(-)(+) = +$ reinforces; $(+)(+)(-) = -$ balances

Causal-loop diagrams. Each arrow carries a sign: $+$ if more of the cause means more of the effect, $-$ if it means less. In a bank run (left), withdrawals drain reserves, falling reserves raise fear, and fear causes more withdrawals: two minus signs and a plus multiply to a reinforcing loop. In a sandpile (right), a steeper pile makes larger avalanches, which spill more grains off the edge, which lowers the slope: a balancing loop.

The analogy for the whole chapter is a sandpile on a table. Drop sand grains one at a time on a pile. At first the pile just grows. As it steepens, grains start to slide, small avalanches at first, occasionally large ones that spill sand over the edge. Eventually the pile reaches a slope it cannot exceed: add more sand and it sheds, on average, exactly what you add. At that point the pile is **critical**. Most grains do nothing; a few trigger slides that run across the entire pile. Nobody tuned the slope. The balancing loop in the figure found it.

That is the big idea of **self-organised criticality** (Bak, Tang and Wiesenfeld, 1987): slowly driven systems with thresholds and dissipation can drive *themselves* to a critical state, where events of all sizes occur and the size distribution is a power law. It is a candidate answer to the hook. The grid is loaded by growing demand (the slow drive), protected by trips (the threshold), and repaired and upgraded after failures (the dissipation). Its own feedback loops may push it to the edge.

88.3 The mathematics

Feedback in one line

Take a quantity x and a loop that returns a fraction g of any change to the input on the next round, so that a small deviation evolves as $\delta_{t+1} = g\,\delta_t$, and $\delta_t = g^t \delta_0$. The **loop gain** g is the product of the gains around the loop, which is why the *signs* on a causal-loop diagram multiply. If $g > 0$ the loop is reinforcing, if $g < 0$ it is balancing, and the deviation dies out exactly when $|g| < 1$. (For a balancing loop with $g < -1$, the correction overshoots by more than the error, and the system oscillates with growing amplitude: the mechanism behind the bullwhip effect in supply chains and an over-tuned thermostat.) This is the scalar case of the stability theory in Ch. 17.

In a complex system the gain is not fixed. It depends on the state, and the state depends on the gain. That loop-of-loops is what lets a system *find* its own critical point, and the cleanest place to see it is a pile of sand.

The Abelian sandpile

Bak–Tang–Wiesenfeld (Abelian) sandpile

Each site of an $L \times L$ grid holds $z_i \in \{0, 1, 2, \dots\}$ grains. A site with $z_i \geq 4$ is **unstable** and **topples**: it loses 4 grains and each of its four neighbours gains one. Grains sent off the edge of the grid are lost. A configuration with all $z_i \leq 3$ is **stable**. The dynamics: add one grain at a random site, then topple unstable sites until the configuration is stable. The total number of topplings is the **avalanche size** s.

Two things need proof before this is even a well-defined model. Does an avalanche always stop? And when several sites are unstable at once, does it matter which one topples first?

Avalanches are finite

On a finite grid with grains lost at the boundary, every avalanche ends after finitely many topplings.

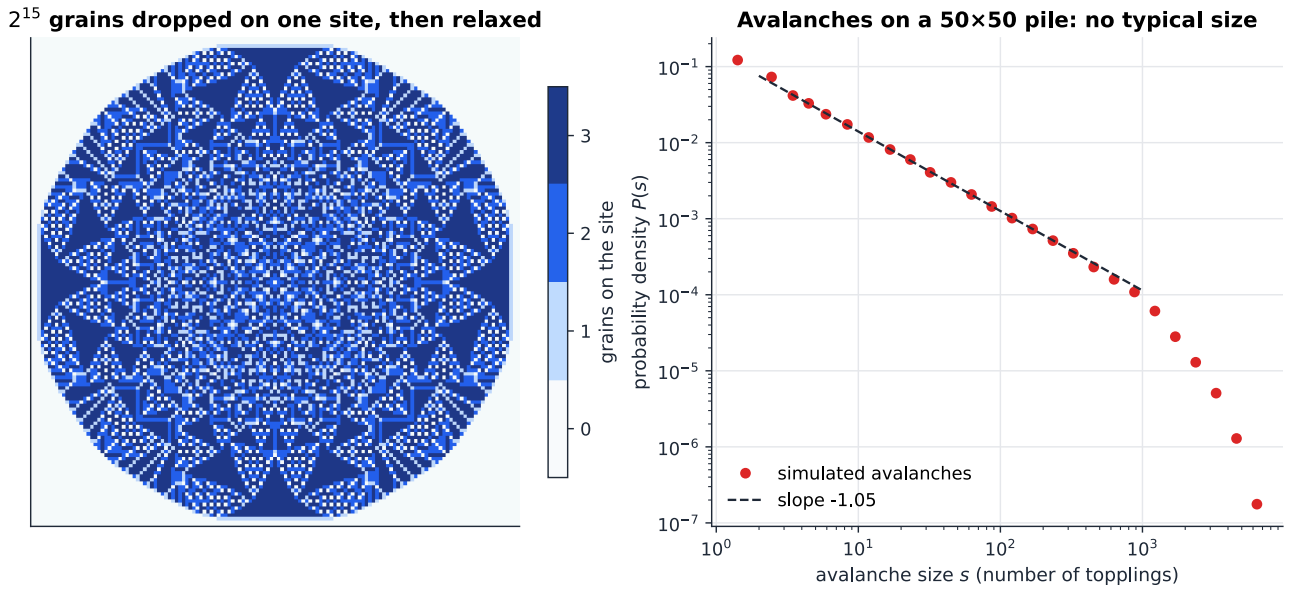
Proof. Suppose some avalanche never ends. There are finitely many sites, so some site a topples infinitely often. Each of its topplings gives a grain to each neighbour, so every neighbour of a receives infinitely many grains; a site that topples only finitely often can only gain grains from some point on, never lose them, so its height would grow without bound and it would have to topple again. Hence every neighbour of a also topples infinitely often, and by repeating the argument, so does every site of the connected grid, including a boundary site. But each toppling of a boundary site throws at least one grain off the grid, permanently, while the total number of grains is finite and only decreases during an avalanche. Infinitely many such losses are impossible. ■

The Abelian property

The final stable configuration, and the number of times each site topples, do not depend on the order in which unstable sites are toppled.

Proof sketch. The local step is that two topplings **commute**. Suppose sites a and b are both unstable. Toppling a can only *add* grains to b, so b is still unstable afterwards, and vice versa. Toppling a site is the same as subtracting a fixed vector Δ_a (minus 4 at a, plus 1 at each neighbour) from the configuration, and vector subtraction commutes: toppling a then b and toppling b then a both give $z - \Delta_a - \Delta_b$. So any two legal toppling sequences can be rearranged into one another by swapping neighbouring steps, provided both are finite. That each order is finite is the previous theorem. The full argument (a "least action" principle: any legal toppling sequence topples each site at most as often as any other sequence that reaches a stable configuration) turns the local swap into the global statement. ■

The name *Abelian* comes from this commutativity. Write S_a for "add a grain at a and stabilise". Then $S_a S_b = S_b S_a$: the order in which grains arrive doesn't matter either. It is a startlingly strong property for a model of disasters, and it is the key to every exact result about the sandpile.



Left: $2^{15} = 32{,}768$ grains placed on one site of a large grid and toppled to stability. The result is a disc of radius about 70 sites filled with intricate, self-similar structure, though the rule is just "four grains, topple". Right: dropping grains one at a time at random sites of a 50×50 pile, after it has reached its steady state, gives avalanches whose sizes follow a straight line on log–log axes for three decades, until the finite pile cuts them off.

Two facts in the figure deserve emphasis. In the driven pile, the mean height settles at about 2.1 grains per site, *whatever the initial condition*. Start empty, and the pile fills up until it gets there; start overfull, and the first avalanches shed the excess. That is the balancing loop made precise. And at that height the avalanches have no typical size: on this pile the distribution falls roughly like $s^{-1.05}$, and the largest avalanche toppled sites more than seven thousand times.

Result 3: why criticality means power laws

What does "critical" mean? Think of an avalanche as a **branching process**: each toppling sends grains to neighbours, and each of them may topple in turn. If each toppling triggers on average μ further topplings, avalanches die out quickly for $\mu < 1$ (subcritical), can run forever for $\mu > 1$ (supercritical), and sit on the knife edge for $\mu = 1$. The pile's feedback loop pushes μ toward 1 from both sides: below it, grains accumulate and the pile steepens, raising μ; above it, huge avalanches dump grains off the edge, lowering μ.

The simplest critical branching process can be solved exactly, and it shows where the power law comes from.

Total size of a critical binary branching process

Each event independently has either 0 or 2 offspring events, with probability $\frac{1}{2}$ each. The probability that the total number of events is $s = 2n + 1$ is

$$P(s) = \frac{C_n}{2^{2n+1}}, \qquad C_n = \frac{1}{n+1}\binom{2n}{n},$$

and for large s,

$$P(s) \approx \sqrt{\frac{2}{\pi}}\, s^{-3/2}.$$

Proof. A finished avalanche is a tree in which every node has 0 or 2 children: a *full binary tree*. A full binary tree with n internal nodes (those with two children) has $n + 1$ leaves, so $2n + 1$ nodes in all. Each internal node has probability $\frac{1}{2}$ (it chose "2") and each leaf has probability $\frac{1}{2}$ (it chose "0"), independently, so each particular tree has probability $2^{-(2n+1)}$. The number of full binary trees with n internal nodes is the Catalan number C_n (a standard count: splitting at the root gives $C_n = \sum_{i=0}^{n-1} C_i C_{n-1-i}$, the recurrence that defines the Catalan numbers, solved with a generating function in the style of Ch. 28). Multiplying gives $P(s) = C_n 2^{-(2n+1)}$.

For the asymptotics, Stirling's formula gives $\binom{2n}{n} \approx 4^n/\sqrt{\pi n}$, so $C_n \approx 4^n/(\sqrt{\pi}\, n^{3/2})$ and

$$P(s) \approx \frac{1}{2\sqrt{\pi}\, n^{3/2}} = \frac{1}{2\sqrt{\pi}} \left(\frac{s}{2}\right)^{-3/2} = \sqrt{\frac{2}{\pi}}\, s^{-3/2},$$

using $n \approx s/2$. ■

(Check: at $s = 101$ the exact value is 7.80×10^{-4} and the asymptotic formula gives 7.86×10^{-4}.) Two features of this answer are worth staring at. The probabilities add up to 1, so every avalanche ends; but the mean avalanche size $\sum_s s\, P(s)$ diverges, because $s \cdot s^{-3/2} = s^{-1/2}$ is not summable. *Every avalanche is finite and the average avalanche is infinite.* That is the mathematical signature of criticality, and the reason risk calculations based on averages fail for heavy-tailed systems.

Move off criticality and the power law acquires a cutoff. With "2 offspring" probability $p \neq \frac{1}{2}$, the same counting gives $P(s) = C_n p^n (1-p)^{n+1}$, and since $C_n \approx 4^n/(\sqrt{\pi} n^{3/2})$, the factor $(4p(1-p))^n$ appears. Because $4p(1-p) < 1$ whenever $p \neq \frac{1}{2}$, it decays exponentially: small avalanches still look like a power law, but there is now a typical largest size. Only at the critical point does the cutoff disappear. You will drag this cutoff around in the experiment.

The exponent $\frac{3}{2}$ is the **mean-field** value, exact for branching on a tree, or for sandpiles in high dimensions. The two-dimensional sandpile has different exponents, because avalanches there fold back and revisit sites. Simulations put them near the 1.05 in the figure for small piles, drifting with size, and nobody has computed them exactly.

? What is the sandpile's hidden algebra?

The Abelian property says that adding grains are commuting operations. Restrict them to the *recurrent* configurations, the ones the driven pile keeps returning to, and they form a finite **group**, with an identity element that is itself a striking fractal picture. The number of elements of this group equals the number of spanning trees of the grid, which in turn is the determinant of a reduced graph Laplacian. Why should a toy model of avalanches know how many spanning trees a graph has? The group structure is the language of Ch. 56, and the Laplacian is the matrix of Ch. 27; putting them together to count trees is a theorem you'll have to hunt down.

Self-organisation without a leader: flocking

A sandpile organises itself in *time*, toward a critical state. Flocks organise themselves in *space and direction*. In 1995 Tamás Vicsek and colleagues proposed the simplest model of collective motion.

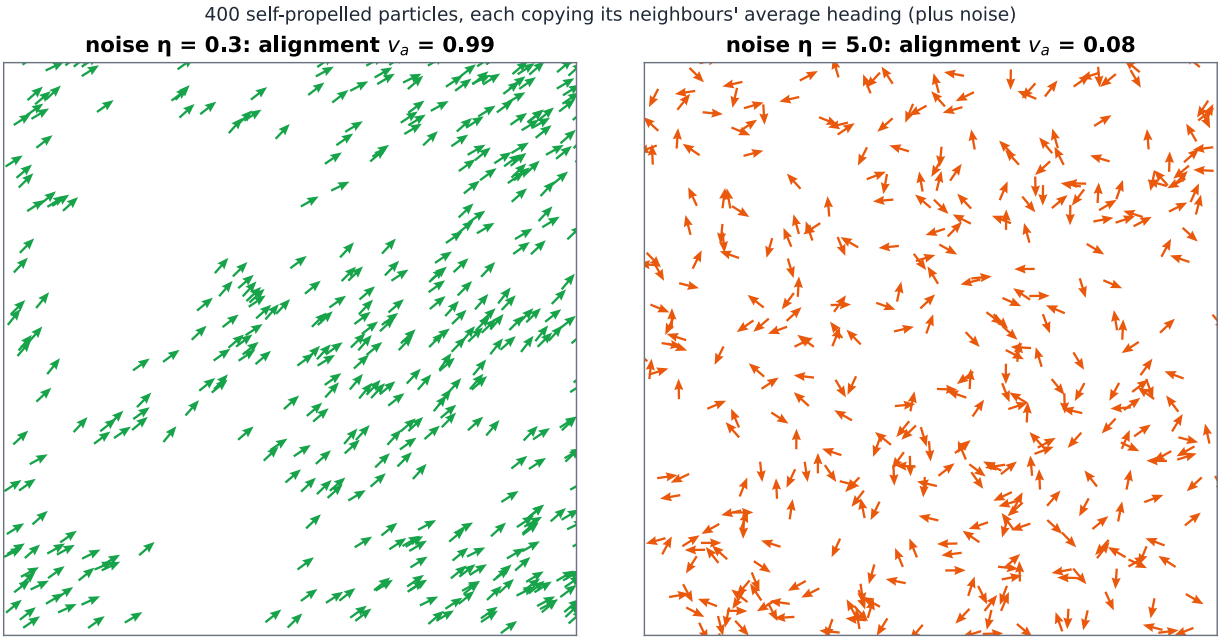
Vicsek model

N particles move in a periodic box at constant speed v. At each step, particle i adopts the average heading of all particles within distance r of it (itself included), plus noise:

$$\theta_i(t+1) = \operatorname{Arg}\left(\sum_{\|\mathbf{x}_j - \mathbf{x}_i\| < r} e^{j\theta_j(t)} \right) + \eta\,\xi_i(t), \qquad \mathbf{x}_i(t+1) = \mathbf{x}_i(t) + v \begin{pmatrix} \cos\theta_i(t+1) \\ \sin\theta_i(t+1) \end{pmatrix},$$

with ξ_i independent and uniform on $\left[-\frac{1}{2}, \frac{1}{2}\right]$. The **alignment** is $v_a = \left| \frac{1}{N} \sum_i e^{j\theta_i} \right|$.

The alignment v_a is the same average phasor as the Kuramoto order parameter of Ch. 87, and the logic is similar: a feedback between individual headings and the local average. The new ingredient is that the network of who-sees-whom is not fixed; it is rebuilt every step by the motion itself. Aligned neighbours travel together and stay neighbours, which strengthens their alignment. That is a reinforcing loop, and the noise is the dissipation that opposes it.



The Vicsek model with 400 particles in a 10×10 box (interaction radius 1, speed 0.03) after 600 steps. At low noise (left) a single flock forms with almost perfect alignment, $v_a = 0.99$, from random initial headings. At high noise (right) headings stay disordered and $v_a = 0.08$, close to the $1/\sqrt{N} = 0.05$ expected for random directions.

Between the two panels lies a phase transition at a critical noise η_c that depends on the density. Nobody in the flock knows the heading of the flock, and no particle is special. Order is a collective property, decided by a competition between the reinforcing loop of alignment and the randomising effect of noise.

Adaptive systems

In a sandpile and a flock the rules are fixed. In an **adaptive** system the parts change their rules in response to what the collective does, and the collective is made of those changing rules. Markets, immune systems, ecosystems and traffic are all of this kind.

The classic toy is Brian Arthur's El Farol bar problem (1994). One hundred people decide independently each week whether to go to a bar. The evening is pleasant if fewer than 60 go, and unpleasant otherwise. There is no correct prediction that everybody can follow: if everyone believes "few will go", everyone goes, and the belief is falsified. Arthur gave each agent a small bag of rules of thumb ("same as last week", "average of the last four weeks", "mirror image of last week around 50") and let each agent use whichever rule had recently predicted best. Attendance never settles, but it fluctuates around 60. The comfortable capacity is found by nobody and enforced by nobody: it emerges from a balancing loop between collective attendance and individual strategy choice.

The mathematics of adaptive populations, where strategies that do well become more common, is evolutionary game theory and the replicator equation of Ch. 45. Its phenomena are new: no equilibrium may exist, the system may cycle forever, and the "rules of the game" are themselves an outcome of the game.

> **Emergence is not magic**
>
> It is tempting to treat "emergent" as an explanation. It is a description. The gliders of Life, the power law of the sandpile and the order of the flock are all *consequences* of their rules and can be derived, simulated or bounded. What makes them emergent is that they are not visible in any single part's rule and are best described in a new vocabulary. Whenever you read that something "emerges", ask: from which interactions, through which feedback, and what would make it fail?

88.4 The algorithm

Toppling a sandpile

There are two ways to relax a sandpile, and the Abelian property says they give the same answer.

Parallel toppling topples every unstable site at once, and can even topple a site several times in one sweep: a site with z grains topples $\lfloor z/4 \rfloor$ times. With NumPy this is a few array operations per sweep:

```
def stabilise(z):
    """Relax a sandpile; grains falling off the edge are lost. Returns grid and avalanche size."""
    total = 0
    while True:
        t = z // 4                    # topplings at each site this sweep
        if not t.any():
            return z, total
        total += int(t.sum())
        z = z - 4 * t
        z[1:, :] += t[:-1, :]         # each toppling sends one grain to each neighbour
        z[:-1, :] += t[1:, :]
        z[:, 1:] += t[:, :-1]
        z[:, :-1] += t[:, 1:]
```

Sequential toppling with a **stack** of unstable sites does the same work site by site, and is faster when avalanches are small. Either way, the cost of an avalanche is proportional to its size, which for a critical pile is heavy-tailed: most grains cost nothing, and a few cost a large fraction of the pile. Placing N grains on one site is much worse than N separate drops, because the resulting disc has radius about $\sqrt{N}$ and every grain must be passed outward across it. For the figure's 2^{15} grains that is about 19 million single topplings, which the parallel version performs in about 6,000 sweeps.

Flocks in linear time

A naive Vicsek step compares every pair of particles, $O(N^2)$. Because the interaction radius r is fixed, divide the box into cells of side r and only compare particles in the same or adjacent cells. Each step then costs $O(N)$ at fixed density, which is the same **cell-list** idea used in molecular dynamics and physics engines (Ch. 72).

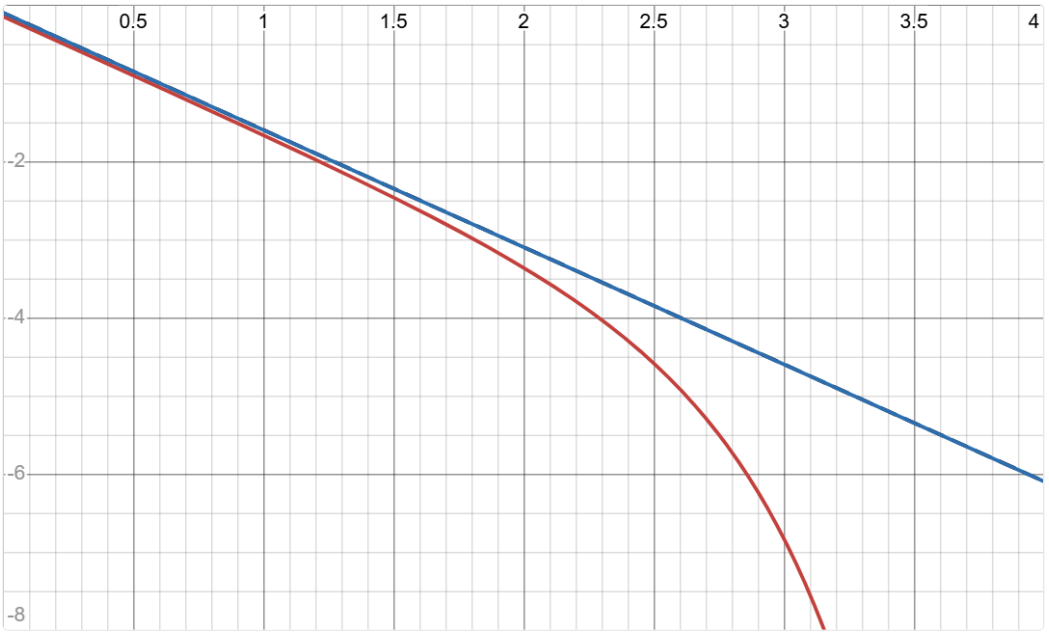
Failure cases

- **Transients.** A sandpile started empty spends thousands of grains just filling up. Measuring avalanches before it reaches its steady state (the figure discarded the first 10,000 grains) mixes two different statistics.
- **Fitting power laws by straight lines.** A least-squares line through a log–log histogram is biased, depends on the binning and ignores the cutoff. It is good enough for a picture, not for a claim. Use maximum-likelihood estimators and compare against alternative distributions.
- **Finite size.** Every simulated power law ends at a cutoff set by the system size. The honest test of criticality is **finite-size scaling**: check that the cutoff moves as a power of L as you simulate $L = 25, 50, 100, 200$.

88.5 The experiment

Part 1: the knife edge of criticality

On log–log axes, the size distribution of a branching process with "2 offspring" probability p is a straight line of slope $-\frac{3}{2}$ times an exponential cutoff. With $x = \log_{10} s$ and $y = \log_{10} P(s)$, the large-s approximation from §88.3 reads



Log–log avalanche-size distributions. Blue (critical, $p = 0.5$) lies exactly on the dashed power law of slope -1.5; red ($p = 0.55$, so each event triggers on average 1.1 more) bends down sharply after a few hundred events. A supercritical avalanche that has grown that large almost never stops, so large finite avalanches are rare; about 18% of these avalanches run forever.

The formula is $P(s) \approx (1-p)\,2^{1.5}\pi^{-1/2}s^{-3/2}\,(4p(1-p))^{s/2}$. Change `0.55` and `0.45` in the red line together to `0.51` and `0.49` and watch the cutoff move out to the right; the typical largest avalanche grows like $1/(p-\frac{1}{2})^2$. Then swap the two numbers in the red line, giving $p = 0.45$ and $1-p = 0.55$ (a subcritical process). The curve is nearly the same: on a log–log plot, sub- and supercritical processes look alike, and only the critical one has no scale at all.

Part 2: grow your own critical pile

```
import numpy as np
import matplotlib.pyplot as plt

L, GRAINS, BURN = 40, 40000, 8000      # pile size, grains to drop, grains to discard
rng = np.random.default_rng(0)
z = np.zeros((L, L), dtype=int)
sizes, heights = [], []

for g in range(GRAINS):
    i, j = rng.integers(0, L, 2)
    z[i, j] += 1
    s = 0
    while (t := z // 4).any():         # parallel toppling until stable
        s += t.sum()
        z -= 4 * t
        z[1:, :] += t[:-1, :]; z[:-1, :] += t[1:, :]
        z[:, 1:] += t[:, :-1]; z[:, :-1] += t[:, 1:]
    heights.append(z.mean())
    if g >= BURN and s > 0:
        sizes.append(s)

sizes = np.array(sizes)
print(f"final mean height {z.mean():.3f}, avalanches {len(sizes)}, largest {sizes.max()}")
bins = np.logspace(0, np.log10(sizes.max()), 25)
h, e = np.histogram(sizes, bins=bins)
c = np.sqrt(e[1:] * e[:-1]); ok = h > 0
fig, (a, b) = plt.subplots(1, 2, figsize=(10, 4))
a.plot(heights); a.set_xlabel("grains dropped"); a.set_ylabel("mean height")
b.loglog(c[ok], h[ok] / np.diff(e)[ok] / len(sizes), "o")
b.set_xlabel("avalanche size s"); b.set_ylabel("P(s)")
plt.show()
```

Things to try:

- The left plot shows the pile filling up and then *stopping* at a height near 2.1 by itself. Start instead from `z = 3 * np.ones((L, L), dtype=int)` (overfull and fragile). Where does it end up?
- Double `L` and compare the largest avalanche. A critical system's cutoff should grow with its size; a non-critical one would not.
- **Break the criticality.** Add dissipation inside the pile: after each toppling sweep, remove each grain with a small probability (for example `z -= (rng.random((L, L)) < 0.001) & (z > 0)` inside the `while` loop). The balancing loop now has a second exit, the pile settles lower, and the power law acquires a cutoff that no longer depends on `L`.
- Make sites topple only when they hold 5 grains while still sending out 4 (change `z // 4` to `z // 5` but keep `z -= 4 * t`). Where does the height settle now, and is the avalanche distribution still a power law?

88.6 The challenge

1. **Intuition.** A thermostat heats a room when it is below 20 °C, but the heater takes ten minutes to warm up and ten minutes to cool down. Draw the causal-loop diagram, mark the signs, and explain why the room temperature oscillates instead of settling, even though the loop is balancing. Then name one real complex system in which a delay turns a balancing loop into a source of boom-and-bust cycles.
2. **Derivation.** For the branching process with offspring 0 or 2 (probability $1-p$ and p), let q be the probability that an avalanche is finite. Show that $q = (1-p) + pq^2$, solve it, and prove that $q = 1$ for $p \le \frac{1}{2}$ and $q = (1-p)/p$ for $p > \frac{1}{2}$. Then show that the mean size of a finite avalanche is $1/(1-2p)$ for $p < \frac{1}{2}$, and explain what its divergence at $p = \frac{1}{2}$ means for anyone trying to estimate risk from past averages.
3. **Implementation.** Use the experiment's sandpile code to test the Abelian property directly. Start from one stable configuration, add 50 grains at 50 chosen sites, and stabilise after each grain. Then add the same 50 grains in a random different order, and finally add all 50 at once and stabilise once. Check that all three final configurations are identical and that the *total* number of topplings is the same in all three cases. Then break the property: make toppling send grains only to the right and down neighbours, and see whether order now matters.
4. **Open investigation.** Build the El Farol bar model: 100 agents, threshold 60, each with k random predictors chosen from a pool (for example weighted averages of the last few weeks), each using its recently most accurate predictor. Measure the mean and variance of attendance as you change k, the pool and the memory. Does attendance always hover near 60? When does it fluctuate wildly, and is there a "critical" amount of strategic diversity at which the fluctuations are largest? There is no complete theory.

88.7 Loose threads

This chapter offered a three-part vocabulary (emergence, self-organisation, feedback), one exactly solvable mechanism (the critical branching process and its $s^{-3/2}$ law), and two famous models (the sandpile and the flock). The real excitement is in what it left unresolved.

? How can a flock beat the theorem that forbids it?

In two dimensions, a magnet made of spins that align with their neighbours cannot have true long-range order at any positive temperature: thermal fluctuations always win at long distances (the Mermin–Wagner theorem). The Vicsek flock looks like the same system, alignment plus noise, yet simulations of huge flocks show genuine long-range order: particles at opposite ends of a very large flock agree on a heading. The difference is that Vicsek particles *move*, and moving carries information about orientation across the flock faster than diffusion could. In 1995 John Toner and Yuhai Tu built a continuum theory of flocks, the "hydrodynamics of active matter", to explain it. How motion defeats an equilibrium theorem is a question for Ch. 92.

? Is the brain poised at criticality?

In 2003 John Beggs and Dietmar Plenz recorded bursts of activity in slices of rat cortex and found "neuronal avalanches" whose sizes followed a power law with exponent close to $\frac{3}{2}$, the critical branching value derived in this chapter. A critical brain would have maximal dynamic range and information transmission, which makes the hypothesis attractive. But power laws can arise in many ways that have nothing to do with criticality, subsampling a network can create or destroy them, and twenty years of experiments have not settled whether the brain tunes itself to a critical point, hovers near one, or neither. This is an open problem; how researchers go about attacking such a question is the subject of Ch. 98.

Other threads:

- **The edge of chaos, revisited.** Ch. 86 asked whether computation concentrates at a transition between order and chaos. Self-organised criticality is a mechanism by which a system could *put itself* there. Whether adaptive systems in fact evolve toward criticality is part of the same unresolved debate.
- **From feedback loops to control.** A causal-loop diagram is a qualitative transfer-function block diagram. Making it quantitative, with gains, delays and stability margins, is the engineering of Ch. 14; choosing the feedback to optimise performance is Ch. 51.
- **Cascades on networks.** The 2003 blackout spread along a network, not a grid. Combining the thresholds of this chapter with the degree distributions of Ch. 87 gives models of cascading failure in which hubs are both the network's strength and its weak point.

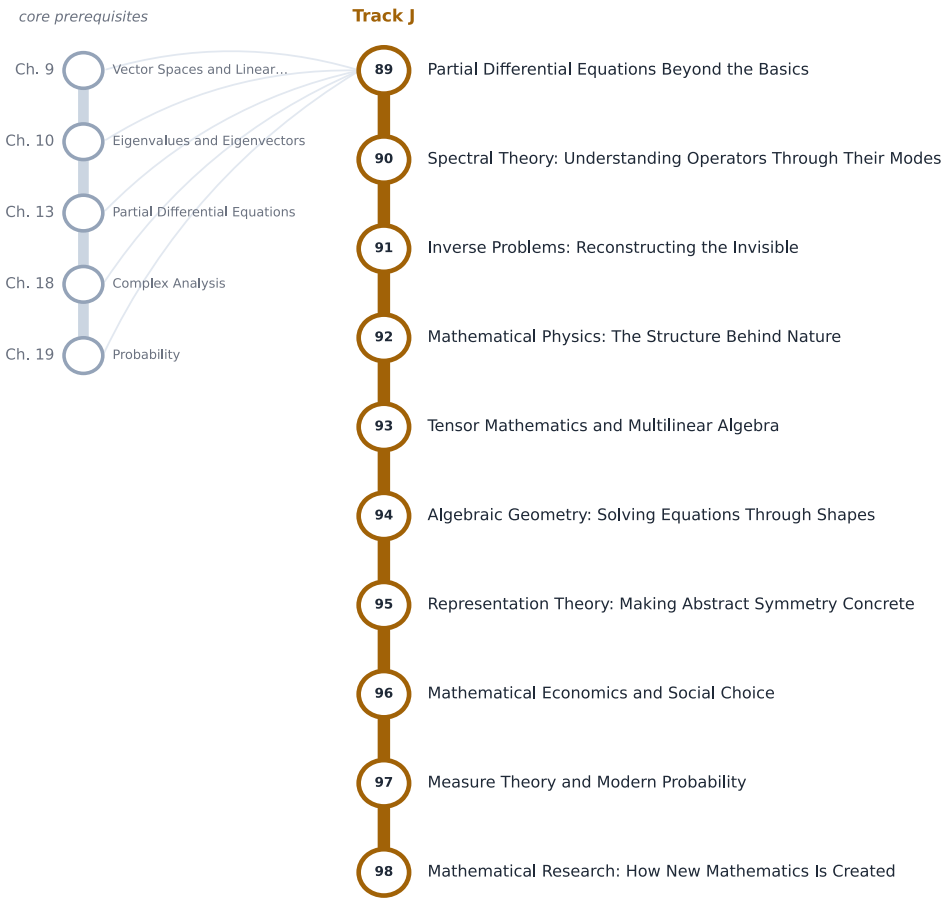
Level 3 — Research Frontier

Track J. Deeper territories to explore as your interests develop.

Track J — Mathematics at the Frontier

> **Level 3 — Research Frontier.** Not prerequisites for every programmer: the deeper territories to explore as your interests develop. The frontier is open-ended.



Suggested reading order for Track J. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 9 — Vector Spaces and Linear Transformations
- Ch. 10 — Eigenvalues and Eigenvectors
- Ch. 13 — Partial Differential Equations
- Ch. 18 — Complex Analysis
- Ch. 19 — Probability

Chapters

Ch.	Chapter	What it explores
89	Partial Differential Equations Beyond the Basics	Weak solutions, boundary-value problems, regularity.
90	Spectral Theory: Understanding Operators Through Their Modes	Eigenfunction expansions, operator spectra, applications to PDEs.
91	Inverse Problems: Reconstructing the Invisible	Parameter estimation, regularization, ill-posed problems.
92	Mathematical Physics: The Structure Behind Nature	Variational principles, symmetries, Hamiltonian mechanics.
93	Tensor Mathematics and Multilinear Algebra	Tensor products, multilinear maps, tensor decompositions.
94	Algebraic Geometry: Solving Equations Through Shapes	Polynomial varieties, ideals, coordinate rings.
95	Representation Theory: Making Abstract Symmetry Concrete	Group representations, characters, irreducible structures.
96	Mathematical Economics and Social Choice	Equilibrium, preference relations, welfare, voting theory.

Ch.	Chapter	What it explores
97	Measure Theory and Modern Probability	Sigma-algebras, measures, Lebesgue integration, convergence.
98	Mathematical Research: How New Mathematics Is Created	Conjectures, counterexamples, proof strategy, literature exploration.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 89 — Partial Differential Equations Beyond the Basics

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 13, Ch. 22, Ch. 61 · **Leads to:** Ch. 90, Ch. 91, Ch. 92 · **Related:** Ch. 36, Ch. 52, Ch. 60, Ch. 75 **Reading time:** ~30 min

89.1 The hook

Stretch a guitar string between two pegs and press it down with one fingertip. The string takes the shape of a tent: two straight segments meeting at a sharp corner under your finger. Every physicist in the world agrees this is the correct shape. Now ask what equation it solves.

The textbook answer is the equation of a loaded string, $-Tu''(x) = f(x)$, with tension T and load density f. But the tent has no second derivative at the corner. The slope jumps from one value to another, so u'' simply does not exist there. And the load of a fingertip is not a function at all: it is all concentrated at one point, a Dirac delta. The "solution" fails to be twice differentiable, the "data" fails to be a function, and yet nothing about the physics is in doubt.

This is not a curiosity. Look around an engineering office:

- A bar made of two materials glued together, copper on the left and steel on the right, carrying heat. The temperature is continuous, but its slope jumps at the glue line because the conductivity jumps. The heat equation $-(ku')' = f$ of §13.4 has no classical solution.
- An L-shaped room, or an L-shaped bracket under load. Near the inside corner the stress, which is a derivative of the displacement, is *infinite*. The solution exists; its gradient does not stay bounded.
- A shock wave in a supersonic flow: the density jumps across a surface. A traffic jam forms on a motorway: the car density jumps. Neither "solution" is even continuous.

Meanwhile, every serious engineering simulation code (structural analysis, electromagnetics, chip thermal design, crash testing) solves PDEs with exactly these features, on millions of unknowns, every day, and gets the right answer. What do those codes know that §13.3's separation of variables doesn't?

> **What does it mean for a function that can't be differentiated to *solve* a differential equation, and how can that weaker meaning be the foundation of the most successful numerical method in engineering?**

The answer is a shift of viewpoint that took mathematics from Riemann (1850s) to Sobolev (1930s) to Lax, Milgram and the engineers of the 1950s and 60s to complete. It is also the doorway to some of the hardest open problems in mathematics.

89.2 The big idea

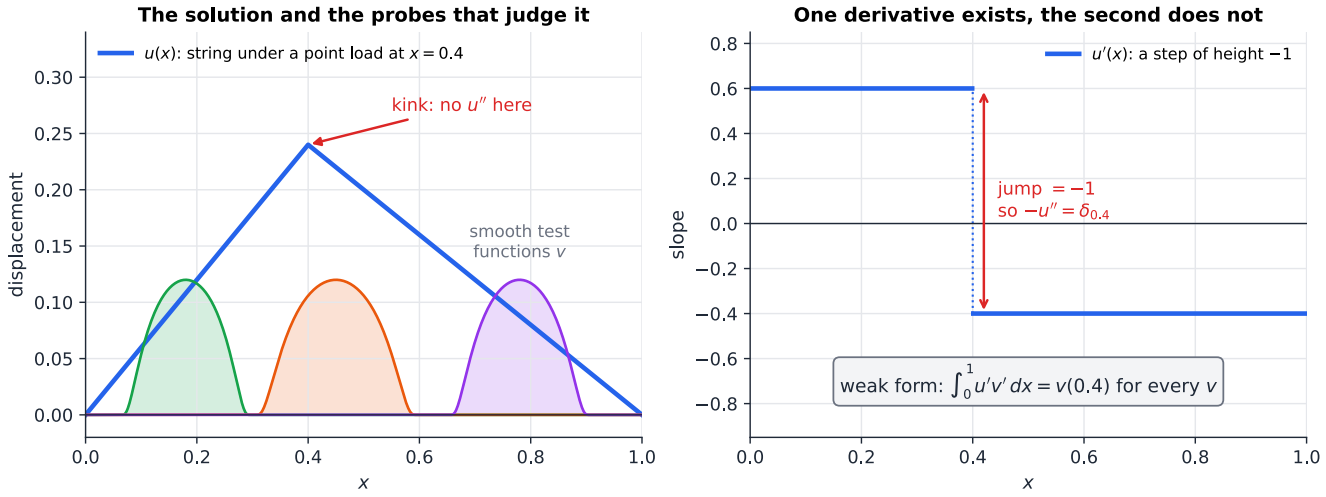
Judge a function by what it does to probes, not by its value at points. You cannot evaluate u'' at the corner of the tent. But you can ask a gentler question. Take any smooth "probe" function $v(x)$, a bump that vanishes at both ends of the string, and compute the integral $\int u''v\,dx$. Integrate by parts once:

$$-\int_0^1 u''\,v\,dx = \int_0^1 u'\,v'\,dx \qquad (v(0) = v(1) = 0).$$

The right-hand side only needs **one** derivative of u, and the tent has one: its slope is a step function, perfectly integrable. So we *define* "u solves $-u'' = f$" to mean

$$\int_0^1 u'\,v'\,dx = \int_0^1 f\,v\,dx \quad \text{for every probe } v.$$

The derivative has been moved off the rough unknown and onto the smooth probe. For the point load at $x = a$ the right side is just $v(a)$, and the tent passes this test. A function that passes it is a **weak solution**.



A weak solution is tested by integrals against smooth probes v, never at single points. The tent has a slope everywhere except one point, and that is enough to make $\int u'v' = v(0.4)$ meaningful and true.

An analogy: a referee who only watches replays averaged over a few seconds. A classical solution must be correct at every instant. A weak solution must be correct on average over every window, however small. A function can fail at isolated instants and still pass every averaged check, and for physics that is exactly right, because no instrument measures at a mathematical point.

The second idea: the solution is the cheapest shape. The weak equation is also the condition for a minimum. The string settles into the shape that minimizes its total energy, stretching energy minus the work done by the load:

$$E(v) = \tfrac{1}{2}\int_0^1 (v')^2\,dx - \int_0^1 f v\,dx.$$

The energy only involves v', never v''. So the natural home for the problem is the space of functions with **finite energy**: square-integrable functions with square-integrable first derivatives. That space, the **Sobolev space** H^1, was promised in Ch. 61's loose threads. It is a Hilbert space, so all the geometry of projection and orthogonality is available. Solving the PDE becomes "find the closest point" in a Hilbert space.

The third idea: regularity is earned, not assumed. Once a weak solution exists, you can ask how smooth it actually is. Often it is perfectly smooth and the whole detour was a formality. Sometimes, near a corner, a material interface or a shock, it is not, and knowing exactly *how* rough it is tells you how fast your simulation will converge. The modern theory of PDEs is largely this two-step programme: **first existence of a weak solution, then regularity**.

89.3 The mathematics

We work with the model boundary-value problem: find u on $(0,1)$ with

$$-(k(x)\,u')' = f \ \text{ on } (0,1), \qquad u(0) = u(1) = 0,$$

where the conductivity (or stiffness) satisfies $0 < k_{\min} \le k(x) \le k_{\max}$. Everything below extends, with harder analysis but the same ideas, to $-\nabla\cdot(k\nabla u) = f$ on a domain $\Omega \subset \mathbb{R}^d$.

Sobolev spaces

The space $H_0^1(0,1)$

A function $u \in L^2(0,1)$ has a **weak derivative** $w \in L^2(0,1)$ if $\int_0^1 u\,\varphi'\,dx = -\int_0^1 w\,\varphi\,dx$ for every smooth φ vanishing near 0 and 1. We write $u' = w$. The **Sobolev space** $H^1(0,1)$ is the set of $u \in L^2$ with a weak derivative in L^2, with inner product $\langle u, v\rangle_{H^1} = \int (uv + u'v')\,dx$. The subspace H_0^1 contains those with $u(0) = u(1) = 0$.

For the tent, the weak derivative is the step function, and the definition just says integration by parts still works when one factor has a corner. A function with a *jump* has no weak derivative in L^2: its derivative would have to be a delta. So H^1 functions in one dimension can have corners but not jumps. In fact they are always continuous, and here is the one-line reason. For $x < y$, by Cauchy–Schwarz (§9.8),

$$|u(y) - u(x)| = \left|\int_x^y u'\,dt\right| \le \sqrt{y-x}\;\|u'\|_{L^2}.$$

Finite energy forces Hölder continuity with exponent $\tfrac{1}{2}$. This is the simplest **Sobolev embedding theorem**. It is also where dimension starts to matter: in two dimensions the function $u = \ln\ln(1/r)$ near the origin has finite energy, $\int|\nabla u|^2 = 2\pi\int dr/(r\ln^2(1/r)) < \infty$, yet it is unbounded. A finite-energy membrane can have an infinitely tall spike. And conversely, the 2-D point-load solution $\ln(1/r)$ has *infinite* energy, $2\pi\int dr/r = \infty$: in a plane, a pin-point load is not an H^1 problem at all.

The weak formulation

Multiply the PDE by $v \in H_0^1$, integrate, and move one derivative across. The boundary term $[ku'v]_0^1$ vanishes because v does. This gives the problem we will actually solve.

Weak solution

$u \in H_0^1(0,1)$ is a **weak solution** if

$$a(u,v) = F(v) \quad \text{for all } v \in H_0^1, \qquad a(u,v) = \int_0^1 k\,u'v'\,dx, \quad F(v) = \int_0^1 f v\,dx.$$

Two quick facts justify the name. If u is a classical C^2 solution, it is a weak solution: that is the integration by parts we just did. Conversely, if a weak solution happens to be C^2 (and k is C^1), then integrating back gives $\int(-(ku')' - f)\,v = 0$ for all v, and a continuous function orthogonal to every probe is zero. So nothing is lost when solutions are smooth, and something is gained when they are not. For the two-material bar, the weak form automatically enforces the physically correct interface condition: the *flux* ku' is continuous across the glue line even though u' jumps.

Existence and uniqueness

Existence and uniqueness of the weak solution

If $0 < k_{\min} \le k \le k_{\max}$ and $f \in L^2(0,1)$, there is exactly one $u \in H_0^1$ with $a(u,v) = F(v)$ for all $v \in H_0^1$. It is also the unique minimizer of $E(v) = \tfrac{1}{2}a(v,v) - F(v)$ over H_0^1, and $\|u'\|_{L^2} \le \|f\|_{L^2}/k_{\min}$.

Proof. **Step 1, a Poincaré inequality.** For $v \in H^1_0$, $v(0) = 0$, so the embedding estimate with $x = 0$ gives $|v(y)| \le \sqrt{y}\,\|v'\| \le \|v'\|$. Squaring and integrating over $y \in (0,1)$:

$$\|v\|_{L^2} \le \|v'\|_{L^2}.$$

(The sharp constant is $1/\pi$; you will see why in Ch. 90.)

Step 2, a new inner product. Define $\langle u, v\rangle_a = a(u,v) = \int k u'v'$. It is symmetric and bilinear, and $\langle v,v\rangle_a \ge k_{\min}\|v'\|^2 \ge \frac{k_{\min}}{2}\|v\|^2_{H^1}$ by Step 1, so it is positive definite. It is also bounded above by $k_{\max}\|v\|^2_{H^1}$, so the "energy norm" $\|v\|_a = \sqrt{a(v,v)}$ is equivalent to the H^1 norm and H^1_0 is complete under it: a Hilbert space.

Step 3, Riesz. F is linear, and bounded in the energy norm: $|F(v)| \le \|f\|\,\|v\| \le \|f\|\,\|v'\| \le \|f\|\,\|v\|_a/\sqrt{k_{\min}}$. By the Riesz representation theorem (Ch. 61), every bounded linear functional on a Hilbert space is an inner product with a unique element: there is exactly one u with $\langle u, v\rangle_a = F(v)$ for all v. That is the weak equation. Taking $v = u$ gives $k_{\min}\|u'\|^2 \le \|f\|\|u'\|$, the stated bound.

Step 4, minimum energy. For any $w \in H^1_0$,

$$E(u+w) = E(u) + \underbrace{\big[a(u,w) - F(w)\big]}_{=0} + \tfrac{1}{2}a(w,w) \;\ge\; E(u),$$

with equality only if $a(w,w) = 0$, that is $w = 0$. ∎

Notice what did the work: not a formula, but geometry. The solution is the Riesz representer of the load, equivalently the point of H^1_0 that minimizes energy. Existence came from **completeness**. This is exactly where Dirichlet and Riemann went wrong in the 1850s. They "proved" existence for Laplace's equation by saying an energy bounded below must attain its minimum. Weierstrass gave a counterexample in 1870, an energy whose infimum is never attained in the space of smooth functions, and the "Dirichlet principle" was discredited for thirty years until Hilbert rescued it in 1900. The fix is to minimize over a complete space, H^1, and then prove the minimizer is smooth. That second step is the regularity theory.

For non-symmetric problems (add a convection term bu') the form a is no longer an inner product, and the **Lax–Milgram theorem** (1954) replaces Riesz: if a is bounded and coercive, $a(v,v) \ge \alpha\|v\|^2$, the weak problem is still uniquely solvable.

The point load, and Green's function

For $f = \delta_a$ the load is $F(v) = v(a)$. It is bounded on H^1_0 in one dimension, since $|v(a)| \le \|v'\|$, so the theorem applies even though $\delta_a \notin L^2$. The solution is the tent, which is the Green's function of §11.8:

$$G(x,a) = \begin{cases} x(1-a), & x \le a, \\ a(1-x), & x \ge a. \end{cases}$$

Check: G' is $1-a$ to the left of a and $-a$ to the right, a jump of -1. Using $v(0) = v(1) = 0$,

$$\int_0^1 G'v'\,dx = (1-a)\big[v(a) - v(0)\big] - a\big[v(1) - v(a)\big] = (1-a)v(a) + a\,v(a) = v(a).$$

The tent passes every test.

Boundary conditions: essential and natural

The weak form sorts boundary conditions into two kinds, a distinction that classical theory (§13.2) never makes.

Suppose the right end is not clamped but has a prescribed flux, $k(1)u'(1) = g$. Do *not* require $v(1) = 0$. The boundary term from integration by parts is now $k(1)u'(1)v(1) = g\,v(1)$, and the weak problem becomes: find u with $u(0) = 0$ such that

$$\int_0^1 k u'v'\,dx = \int_0^1 f v\,dx + g\,v(1) \quad \text{for all } v \text{ with } v(0) = 0.$$

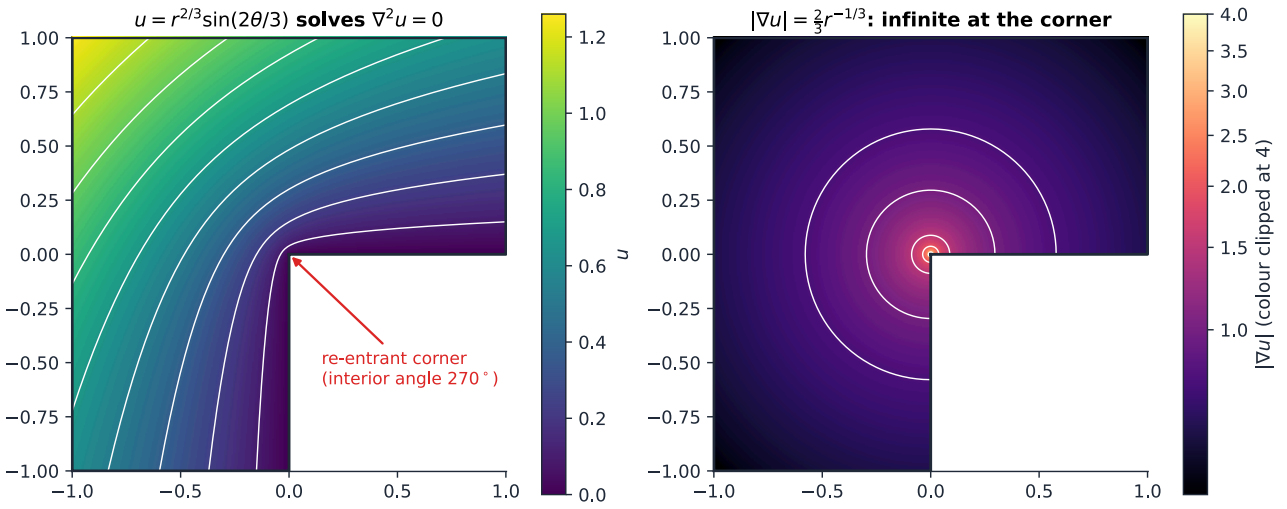
The Dirichlet condition $u(0) = 0$ had to be built into the space: it is **essential**. The Neumann condition never appears as a constraint at all; a weak solution that is smooth satisfies it automatically, because any mismatch $k(1)u'(1) - g$ would show up against probes with $v(1) \neq 0$. It is **natural**. In mechanics, displacements are essential and forces are natural; in electrostatics, potentials are essential and surface charges are natural.

Regularity: how smooth is the weak solution?

> **Elliptic regularity (stated)**
>
> If k is smooth and $f \in H^m$ (m derivatives in L^2), the weak solution lies in H^{m+2}: it gains two derivatives over the data. On a domain $\Omega \subset \mathbb{R}^d$ the same holds in the interior, and up to the boundary if the boundary is smooth or the domain is convex.

In one dimension you can see it directly: $ku' = -\int f + C$ is one derivative smoother than f, and u one more. The interesting cases are where the hypotheses fail:

- **Jumping coefficients.** The two-material bar has $u \in H^1$ but $u \notin H^2$: u' jumps at the interface. Regularity is limited by the material, not by the load.
- **Corners.** On the L-shaped domain, $u = r^{2/3}\sin(2\theta/3)$ is harmonic, vanishes on the two edges meeting at the re-entrant corner, and has $|\nabla u| = \frac{2}{3}r^{-1/3}$, which blows up. It lies in H^1 but not H^2. Generally, a corner of interior angle ω produces a singularity $r^{\pi/\omega}$, which is rougher than smooth exactly when $\omega > \pi$.



A perfectly smooth boundary value (zero) and a perfectly smooth equation (Laplace) still give an infinite gradient, purely because of geometry. Structural engineers know this as stress concentration at an inside corner, which is why such corners are rounded off with a fillet.

? Two derivatives for free, but only in the linear world

For $-\nabla \cdot (k\nabla u) = f$ with smooth k the theorem gives two derivatives for free. What if $k(x)$ is merely bounded and measurable, with no continuity at all, like a random composite? Then no derivatives are free, and in 1957–58 De Giorgi and Nash independently proved that weak solutions are *still* Hölder continuous, solving Hilbert's 19th problem. For *systems* of equations, such as elasticity, De Giorgi himself found a counterexample in 1968. For the 3-D Navier–Stokes equations, Leray proved in 1934 that weak solutions exist for all time. Whether they stay smooth, or whether a smooth flow can develop a singularity in finite time, is one of the seven Clay Millennium Problems, and it is open.

Other ways to be a solution

Integration by parts needs the equation to be in "divergence form", so that a derivative can be moved onto v. Two important families are not.

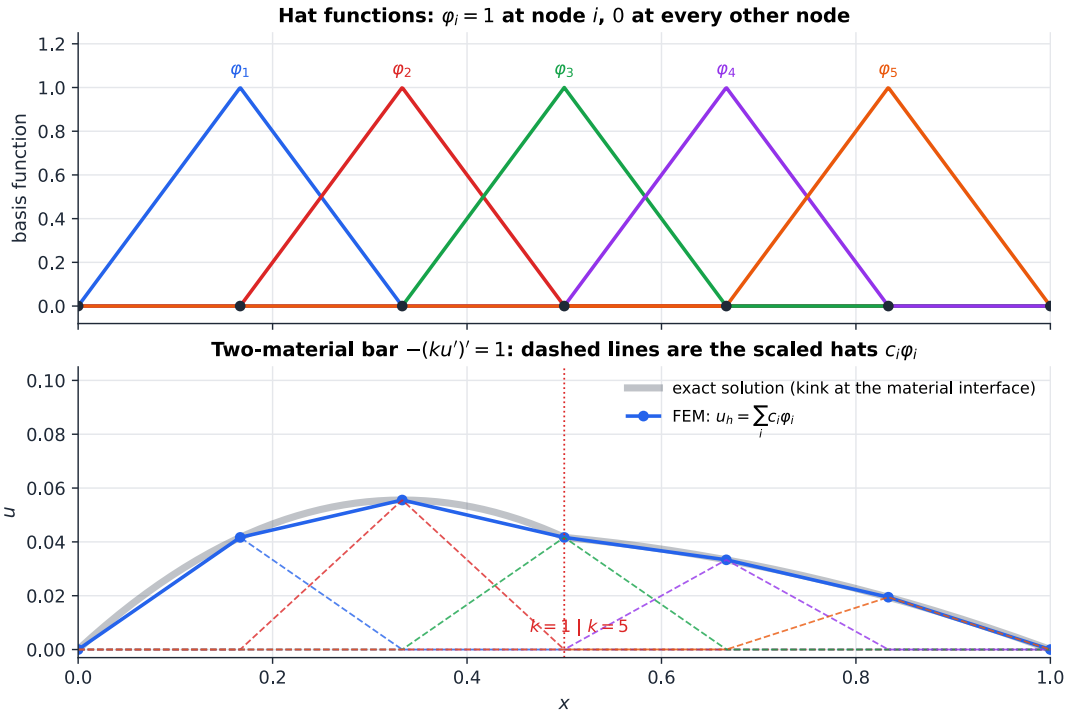
Viscosity solutions. The Hamilton–Jacobi–Bellman equation of Ch. 52 is nonlinear in u'. The simplest example is $|u'| = 1$ on $(-1, 1)$ with $u(\pm 1) = 0$: the travel time to the nearest exit, walking at unit speed. The true answer is $u = 1 - |x|$, with a kink in the middle. But the zigzag $\frac{1}{2} - \left||x| - \frac{1}{2}\right|$ also has $|u'| = 1$ everywhere except at three kinks, and so do infinitely many others. "Almost everywhere" is far too weak. Crandall and Lions (1983) found the right test: at a kink, compare u against smooth functions φ that touch it from above or from below, and demand an inequality on φ' there. The kink of $1 - |x|$ points upward and can only be touched from above, where the test passes. The zigzag's downward kink at 0 is touched from below by $\varphi \equiv 0$, where $|\varphi'| - 1 = -1 < 0$ violates the required inequality. So among all the almost-everywhere solutions exactly one survives, and it is the one obtained as the limit of $|u'| - 1 = \varepsilon u''$ as the "viscosity" $\varepsilon \to 0$.

Probabilistic solutions. The harmonic function with boundary values g is $u(\mathbf{x}) = E[g(\mathbf{W}_\tau)]$: start a Brownian motion at $\mathbf{x}$ and average g over the point where it first exits (Ch. 36). This needs no derivatives of u at all, and it is the seed of Monte Carlo PDE solvers that work in hundreds of dimensions, where no grid could ever fit.

89.4 The algorithm

The weak formulation is not only a theory. Replace "for all v in an infinite-dimensional space" by "for all v in a finite-dimensional subspace" and you have an algorithm. This is the **Galerkin method**, and with the right subspace it is the **finite element method** (FEM).

Step 1: choose a subspace. Split $[0, 1]$ into elements $[x_{i-1}, x_i]$ of width h. Let V_h be the continuous functions that are linear on every element and vanish at the ends. Its natural basis is the **hat functions**: φ_i equals 1 at node x_i, 0 at every other node, and is linear in between. Each hat lives on just two elements.



The FEM approximation is a sum of hats, $u_h = \sum_i c_i\varphi_i$, so its coefficients are its nodal values. With six elements the polygon already sits on the exact curve at every node.

Step 2: ask the weak equation only of the probes in V_h. Write $u_h = \sum_j c_j\varphi_j$ and demand $a(u_h, \varphi_i) = F(\varphi_i)$ for each i. That is a linear system

$$\mathbf{A}\mathbf{c} = \mathbf{b}, \qquad A_{ij} = \int_0^1 k\,\varphi_i'\varphi_j'\,dx, \qquad b_i = \int_0^1 f\,\varphi_i\,dx.$$

The **stiffness matrix A** is symmetric positive definite, because it is the Gram matrix of the energy inner product (§10.6). It is also sparse: $A_{ij} = 0$ unless the hats i and j overlap. For $k = 1$ and uniform h it is $\frac{1}{h}\,\mathrm{tridiag}(-1, 2, -1)$, the same matrix as the finite-difference scheme of §22.10. The two methods agree on easy problems and part company on hard ones: FEM handles jumping coefficients, curved boundaries, unstructured meshes and Neumann conditions with no special effort.

Step 3: assemble element by element. Real codes never form A_{ij} by thinking about pairs of hats. They loop over elements, compute a small element matrix, and add it into the global one:

```
import numpy as np

def fem_1d(k, f, n):
    """Linear finite elements for -(k u')' = f on (0,1), u(0) = u(1) = 0."""
    x = np.linspace(0, 1, n + 1)
    A = np.zeros((n + 1, n + 1)); b = np.zeros(n + 1)
    for e in range(n):                       # loop over elements [x_e, x_{e+1}]
        h = x[e + 1] - x[e]; mid = 0.5 * (x[e] + x[e + 1])
        Ke = k(mid) / h * np.array([[1, -1], [-1, 1]])   # element stiffness
        Fe = f(mid) * h / 2 * np.array([1, 1])           # element load (midpoint rule)
        idx = [e, e + 1]
        A[np.ix_(idx, idx)] += Ke; b[idx] += Fe
    inner = slice(1, n)                      # Dirichlet: drop the boundary nodes
    u = np.zeros(n + 1)
    u[inner] = np.linalg.solve(A[inner, inner], b[inner])
    return x, u

k = lambda x: 1.0 if x < 0.5 else 5.0       # two materials, interface at x = 0.5
f = lambda x: 1.0
x, u = fem_1d(k, f, 8)
print(np.round(u, 5))
```

With eight elements the output at $x = 0.5$ is 0.04167, which is the exact value $1/24$. In fact all nine nodal values are exact. That is not luck, and the reason is worth a proof.

> **Galerkin orthogonality and Céa's lemma**
>
> The FEM solution satisfies $a(u - u_h, v_h) = 0$ for every $v_h \in V_h$, and therefore
>
> $$\|u - u_h\|_a = \min_{v_h \in V_h} \|u - v_h\|_a.$$

Proof. Subtract $a(u_h, v_h) = F(v_h)$ from $a(u, v_h) = F(v_h)$, which holds because $V_h \subset H_0^1$. For any v_h, split $u - u_h = (u - v_h) + (v_h - u_h)$, where the second piece lies in V_h:

$$\|u-u_h\|_a^2 = a(u-u_h, u-v_h) + \underbrace{a(u-u_h, v_h-u_h)}_{=0} \le \|u-u_h\|_a \, \|u-v_h\|_a .$$

Divide by $\|u-u_h\|_a$. ■

So FEM is an **orthogonal projection** in the energy inner product: it finds the best approximation the subspace can offer, in exactly the sense of §9.9. The error is then a pure approximation question: how well can piecewise-linear functions approximate u? For $u \in H^2$ the interpolant has energy error $O(h)$, so FEM converges like h. For a rougher u it converges more slowly, and regularity theory tells you precisely how slowly.

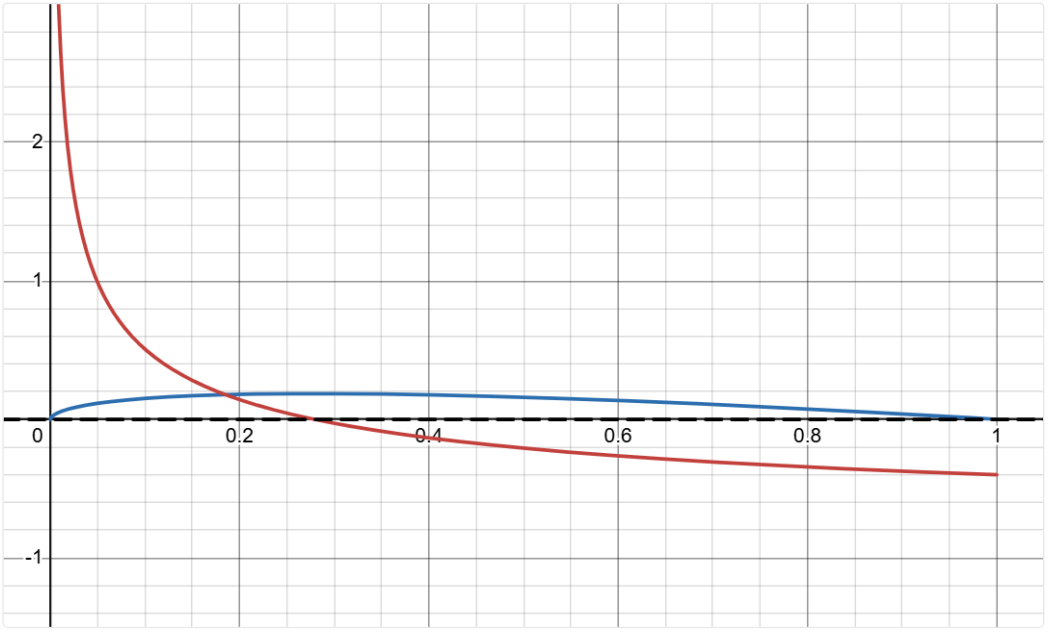
The nodal exactness follows too, for $k=1$. The Green's function $G_i = G(\cdot, x_i)$ is a tent with its kink at a node, so it lies in V_h. Since $a(G_i, w) = w(x_i)$ for every w, Galerkin orthogonality gives $u(x_i) - u_h(x_i) = a(G_i, u-u_h) = 0$. In one dimension FEM is exact at the nodes (when the load integrals are exact). In two dimensions Green's function has a logarithmic spike and no mesh contains it, so this miracle is lost.

Cost and failure modes.

- Assembly costs $O(n)$. The sparse SPD system can be solved by banded Cholesky in $O(n)$ in 1-D, and by preconditioned conjugate gradients or multigrid (§24.4) in higher dimensions. Multigrid is optimal: $O(n)$ for n unknowns.
- The condition number of $\mathbf{A}$ grows like h^{-2}. Fine meshes need good iterative solvers, not better pivoting.
- **Mesh quality.** In 2-D and 3-D the constant in "error $\le C\,h$" depends on element shape. Triangles with an angle near 180°, or the flat "sliver" tetrahedra of Ch. 75, make C enormous: the gradient of a linear function on a nearly degenerate element is wildly sensitive to its nodal values (the maximum-angle condition of Babuška and Aziz, 1976). That is why mesh generators fight so hard to remove slivers.
- **Locking.** For nearly incompressible materials (rubber) or thin plates, low-order elements become artificially stiff and the computed displacement is far too small, however fine the mesh. Coercivity holds, but with a constant that degenerates with the physical parameter. Mixed and discontinuous Galerkin methods were invented to escape this.

89.5 The experiment

When does a corner have finite energy? The function $u = x^\alpha - x$ vanishes at 0 and 1. Its energy $\int_0^1 (u')^2\,dx$ is finite exactly when $\int x^{2\alpha-2}\,dx$ converges at 0, that is when $\alpha > \tfrac12$. Change the exponent 0.6 in both lines to 0.51, then 0.5, then 0.4, and watch the derivative (red) shoot up near $x=0$.



$u = x^{0.6} - x$ (blue) is continuous and vanishes at both ends; its slope (red) is infinite at $x=0$ but square-integrable. Below $\alpha = \tfrac12$ the energy is infinite and u leaves H^1.

Regularity controls convergence. This script solves $-u'' = f$ by FEM with the exact solution $u = x^\alpha - x$, then measures the energy error $\|u' - u_h'\|$ as the mesh is halved. To keep the code short, the load integrals are computed exactly by integrating by parts against the known u.

```
import numpy as np

alpha = 2 / 3                       # knob: try 3, 1.5, 0.75, 0.6, 0.51
u  = lambda x: x**alpha - x         # exact solution, u(0) = u(1) = 0
du = lambda x: alpha * x**(alpha - 1) - 1

def fem(n):
    """Linear FEM for -u'' = f on (0,1); returns nodes and nodal values."""
    x = np.linspace(0, 1, n + 1); h = 1 / n
    A = (2 * np.eye(n - 1) - np.eye(n - 1, k=1) - np.eye(n - 1, k=-1)) / h
    # load b_i = int f phi_i = int u' phi_i'  (exact, by integration by parts)
    b = (2 * u(x[1:-1]) - u(x[:-2]) - u(x[2:])) / h
    U = np.zeros(n + 1); U[1:-1] = np.linalg.solve(A, b)
    return x, U

def energy_error(x, U, m=400):
    """|| u' - u_h' ||_L2, with a graded quadrature in every element."""
    err2 = 0.0
    t = (np.arange(m) + 0.5) / m
    for i in range(len(x) - 1):
        s = x[i] + (x[i + 1] - x[i]) * t**3          # cluster points near x[i]
        w = (x[i + 1] - x[i]) * 3 * t**2 / m
        slope = (U[i + 1] - U[i]) / (x[i + 1] - x[i])
        err2 += np.sum((du(s) - slope)**2 * w)
    return np.sqrt(err2)

prev = None
print("   n    energy error   rate")
for n in [8, 16, 32, 64, 128, 256]:
    x, U = fem(n)
    e = energy_error(x, U)
    rate = "" if prev is None else f"{np.log2(prev / e):6.3f}"
    print(f"{n:4d}   {e:.4e}   {rate}")
    prev = e
print("nodal error:", np.abs(U - u(x)).max())   # a 1-D surprise
```

For the smooth case $\alpha = 3$ the rate column reads 1.000: halving h halves the error. For $\alpha = \frac{2}{3}$ (the L-shaped corner exponent) it reads 0.167: halving h cuts the error by only 11%, and going from 8 to 256 elements improves it from 0.41 to 0.23. The rate is $\alpha - \frac{1}{2}$ exactly, a number set by the regularity of the solution and by nothing else. Meanwhile the last line prints a nodal error around 10^{-15}: the FEM solution is exact at the nodes, as proved in §89.4, and all of the error lives between them. Knobs to turn:

- Set `alpha` to 0.51. The method still converges, at a rate of 0.01. Would you notice convergence at all?
- Replace the uniform mesh by a graded one, `x = np.linspace(0, 1, n + 1)**3`, which crowds nodes toward the singularity (you will need to rewrite `A` and `b` element by element, as in §89.4). How much of the optimal rate comes back?
- Try `alpha = 1.5`. The solution is in H^1 but not quite H^2. What rate do you observe, and does the column settle?

89.6 The challenge

1. **Intuition.** Which of these belong to $H^1(-1,1)$: the tent $1 - |x|$; the step $\operatorname{sign}(x)$; $|x|^{1/3}$; $|x|^{2/3}$? For each one that fails, say in a sentence which physical quantity would be infinite if it were the displacement of a string.
2. **Derivation.** Write the weak form of the pure Neumann problem $-u'' = f$ on $(0,1)$, $u'(0) = u'(1) = 0$, over the whole of $H^1(0,1)$. Show that a solution can exist only if $\int_0^1 f\,dx = 0$, and that it is then unique up to an added constant. Interpret the condition for a heat-conducting rod with insulated ends.
3. **Implementation.** Solve $\nabla^2 u = 0$ on the L-shaped domain of §89.3 with boundary values taken from $u = r^{2/3}\sin(2\theta/3)$, using linear triangles or the five-point stencil of §22.10. Measure the maximum error and the energy error for $h = 2^{-3}, \dots, 2^{-7}$ and report the observed rates. Then refine only near the corner and see whether the rate recovers.
4. **Open investigation.** For $u = x^\alpha - x$, design an *adaptive* method: after each solve, estimate the error on every element (for instance, from the jump in u_h' between neighbours) and split the worst elements. Plot error against the number of elements N for uniform refinement and for your adaptive rule, for several α. Does your rule reach the rate N^{-1} of a smooth problem? Is there a grading that is optimal for every α at once, or must the mesh know the singularity?

89.7 Loose threads

The weak formulation turned a PDE into a question of Hilbert-space geometry, existence into the Riesz theorem, and numerical solution into orthogonal projection. Regularity theory told us when the weak solution is secretly classical, and when corners and material interfaces leave it rough. Two more clues are still on the table.

> **? Frequencies that are always too high**
>
> The same hat-function machinery computes vibration frequencies: replace $\mathbf{Ac} = \mathbf{b}$ by the generalized eigenproblem $\mathbf{Ac} = \lambda \mathbf{Mc}$, with the mass matrix $M_{ij} = \int \varphi_i \varphi_j$. For a string with ten elements the first three computed eigenvalues are 9.95, 40.79 and 95.58, against the exact $\pi^2 = 9.87$, $4\pi^2 = 39.48$ and $9\pi^2 = 88.83$. Every one is too high, and they stay too high on every mesh you try. Why can a Galerkin eigenvalue never undershoot? The answer is the min–max characterization of eigenvalues in Ch. 90, which is also where the Poincaré constant $1/\pi$ comes from.

? Running the problem backwards

This chapter assumed you know the material, $k(x)$, and want the temperature u. A thermal camera gives you the opposite: u measured on the surface, with noise, and the material unknown. Can k be recovered at all? In one dimension the answer is a qualified yes. For a 3-D body probed only by voltages and currents on its skin, which is electrical impedance tomography, it is the **Calderón problem**, and how unstable its solution is turns out to be the central difficulty. That is where Ch. 91 begins.

Further pointers:

- **Variational principles.** The energy $E(v)$ was a special case of an action functional. Why physics is so full of quantities that nature minimizes, and what symmetries of the functional tell you, is in Ch. 92.
- **Weak derivatives need Lebesgue.** "Square-integrable" and "almost everywhere" quietly used the Lebesgue integral. The full construction of Sobolev spaces as complete spaces needs Ch. 97.
- **High dimensions.** The random-walker formula of §89.3 has no grid. Its error depends on the number of samples, not the dimension, which is why Monte Carlo (Ch. 38) and, more recently, neural-network PDE solvers are being pushed into dimensions where FEM is hopeless. Proving when those neural solvers converge is active research.

Chapter 90 — Spectral Theory: Understanding Operators Through Their Modes

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 10, Ch. 13, Ch. 61, Ch. 89 · **Leads to:** Ch. 91, Ch. 92, Ch. 95 · **Related:** Ch. 27, Ch. 34, Ch. 38, Ch. 99 **Reading time:** ~30 min

90.1 The hook

In 1910 the physicist Hendrik Lorentz gave a series of lectures in Göttingen. He posed a problem that came out of the theory of black-body radiation: take a cavity of any shape, count how many standing electromagnetic waves it supports below a given frequency, and show that for high frequencies the count depends only on the cavity's *volume*, not its shape. David Hilbert, in the audience, is said to have predicted that he would not live to see it proved. His student Hermann Weyl proved it in 1911.

Fifty-five years later, Mark Kac turned Weyl's theorem into a question that every mathematician now knows by its title: *Can one hear the shape of a drum?* A drum is a membrane clamped along its rim. When struck, it vibrates in a superposition of standing modes, each with its own frequency. An ideal ear hears the complete list of frequencies, the **spectrum**, and nothing else. Weyl showed that this list reveals the drum's area. Later work showed it also reveals the perimeter, and the number of holes. So how much more does it reveal? Is the shape itself encoded in the sound?

This is not just a riddle about drums. The same question, "what does the list of eigenvalues tell me about the object?", sits underneath a remarkable range of things:

- A **graph's** Laplacian eigenvalues tell you whether the network has a bottleneck (Ch. 27), and Google-style ranking and spectral clustering are built on them.
- A **Markov chain's** second eigenvalue tells you how fast it forgets its starting point, which is how long a Monte Carlo simulation must run (Ch. 34, Ch. 38).
- An **atom's** spectrum, the frequencies of light it emits, was decoded into the energy levels of a Schrödinger operator. Spectroscopy reads the structure of matter from a list of numbers.
- A **bridge's** or **aircraft wing's** lowest natural frequencies decide whether wind or engines can shake it apart, which is the modal analysis of §10.8.

> **How much of an operator, and of the shape it lives on, can you recover from its spectrum alone? And when an operator has no eigenvectors at all, what is its spectrum made of?**

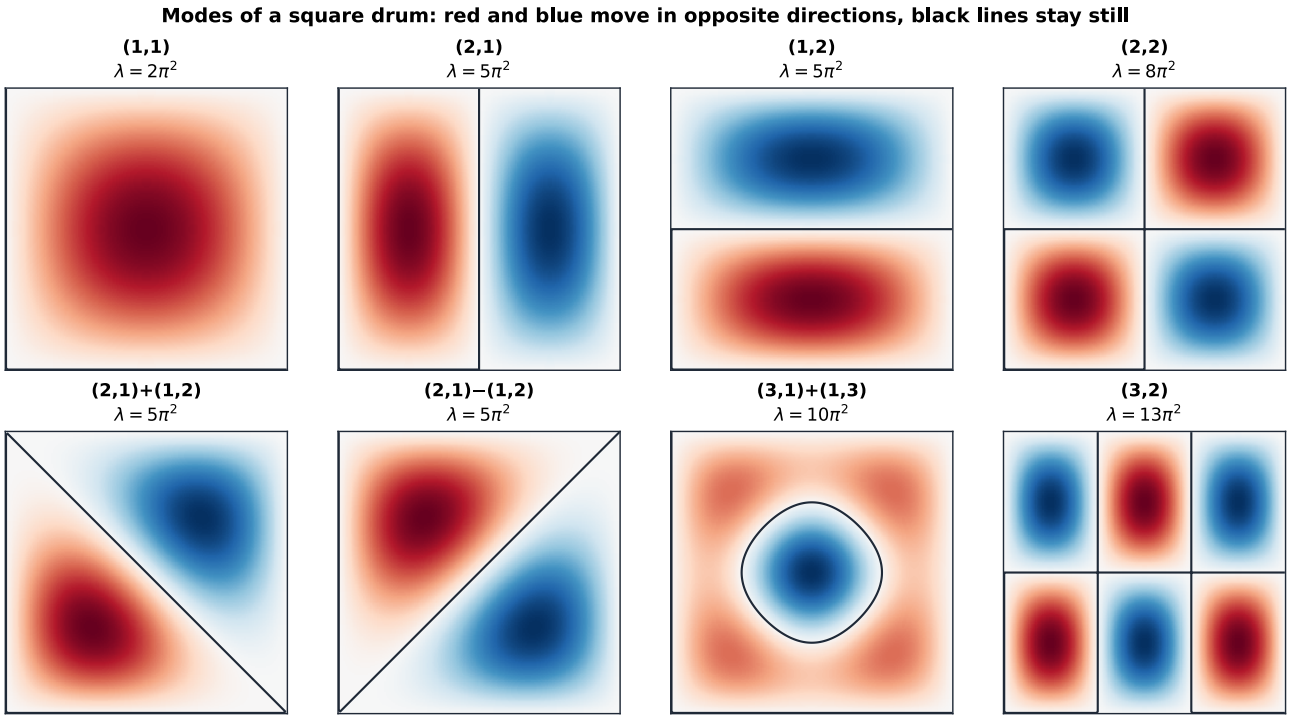
The second half of that question is where matrices stop being a good guide. The first half was answered for drums in 1992, and the answer is a surprise.

90.2 The big idea

An operator is an orchestra of modes. For a symmetric matrix the spectral theorem says: there is an orthonormal basis of eigenvectors, and in that basis the matrix just multiplies each coordinate by its eigenvalue (§10.5). Spectral theory is the same statement for operators on functions. For the Laplacian on a drum the "eigenvectors" are mode shapes, the **eigenfunctions** $\phi_k(x, y)$, and the eigenvalues are squared frequencies:

$$-\nabla^2 \phi_k = \lambda_k \phi_k \ \text{ inside the drum}, \qquad \phi_k = 0 \ \text{ on the rim}.$$

Once you know the modes, any question about the operator becomes a question about numbers. Heat flow multiplies mode k by $e^{-\lambda_k t}$. A struck membrane oscillates mode k as $\cos(\sqrt{\lambda_k}\, t)$. Solving $-\nabla^2 u = f$ divides mode k of f by λ_k. Every one of these is "apply a function to the eigenvalues". That is exactly why separation of variables works (§13.3).



Modes of the unit square, $\phi_{mn} = \sin(m\pi x)\sin(n\pi y)$ with $\lambda = \pi^2(m^2+n^2)$. Because the square is symmetric, $(2,1)$ and $(1,2)$ share an eigenvalue, and every combination of them is also a mode: the bottom row shows diagonal nodal lines and even a closed nodal curve, none of which appears in any single product of sines.

The low notes know the big picture; the high notes know the details. The lowest eigenvalue λ_1 is a single number that summarizes the drum's overall size and shape: how hard it is to bend. High eigenvalues come in a dense crowd, and their *density*, how many there are below λ, is controlled by the area. Between these extremes lies the subtle information: the perimeter, the corners, the holes, and possibly the shape.

When there are no modes. On a bounded drum the modes are a discrete list. On an infinite string there are no standing waves at all: a wave $e^{j\omega x}$ has the right shape but infinite energy, so it is not an eigenfunction. The spectrum does not disappear; it smears into a continuum. Spectral theory's deepest result says that even then, the operator is still "multiplication by a number" in a suitable sense, and the Fourier transform of Ch. 16 is the prototype.

90.3 The mathematics

Throughout, Ω is a bounded region in the plane, and $-\nabla^2$ acts on functions that vanish on its boundary $\partial\Omega$ (a **Dirichlet** drum). The inner product is $\langle u, v\rangle = \iint_\Omega u\, v\, dA$.

Self-adjointness: why the modes are real and orthogonal

The Dirichlet Laplacian is symmetric and positive

For smooth u, v vanishing on $\partial\Omega$: $\langle -\nabla^2 u, v\rangle = \langle u, -\nabla^2 v\rangle = \iint_\Omega \nabla u \cdot \nabla v\, dA$. Consequently its eigenvalues are real and positive, and eigenfunctions with different eigenvalues are orthogonal.

Proof. Green's first identity (§7.11) gives $\iint (-\nabla^2 u)v\, dA = \iint \nabla u\cdot\nabla v\, dA - \oint v\,\partial_n u\, ds$, and the boundary term vanishes because $v = 0$ there. The result is symmetric in u and v. If $-\nabla^2\phi = \lambda\phi$ with $\phi \neq 0$, take $u = v = \phi$: $\lambda\|\phi\|^2 = \iint |\nabla\phi|^2 > 0$, since a function with zero gradient that vanishes on the boundary is zero. If $-\nabla^2\phi = \lambda\phi$ and $-\nabla^2\psi = \mu\psi$, then $\lambda\langle\phi,\psi\rangle = \langle -\nabla^2\phi, \psi\rangle = \langle \phi, -\nabla^2\psi\rangle = \mu\langle\phi,\psi\rangle$, so $\lambda \neq \mu$ forces $\langle\phi,\psi\rangle = 0$. ∎

This is the matrix proof of §10.5 with the transpose replaced by integration by parts. What it does *not* give is existence: a matrix always has eigenvalues, an operator need not. For the drum, existence comes from Ch. 61's spectral theorem for compact self-adjoint operators, applied to the inverse $(-\nabla^2)^{-1}$, which solves the weak problem of Ch. 89. That inverse is compact because finite-energy functions on a bounded domain cannot oscillate arbitrarily fast without paying for it (Rellich's theorem). The conclusion:

Eigenfunction expansion (stated)

On a bounded domain, the Dirichlet Laplacian has eigenvalues $0 < \lambda_1 \le \lambda_2 \le \cdots \to \infty$, each of finite multiplicity, with an orthonormal basis of eigenfunctions ϕ_k of $L^2(\Omega)$. Every $f \in L^2(\Omega)$ satisfies $f = \sum_k \langle f, \phi_k\rangle\phi_k$, with convergence in the L^2 norm.

Applied to the heat equation. If $u_t = \nabla^2 u$ with $u = 0$ on the boundary and $u(\cdot,0) = f$, then

$$u(\cdot,t) = \sum_k e^{-\lambda_k t}\langle f,\phi_k\rangle\,\phi_k, \qquad \|u(\cdot,t)\| \le e^{-\lambda_1 t}\|f\|.$$

The inequality follows from Parseval: every coefficient shrinks by at least $e^{-\lambda_1 t}$. So λ_1 is the cooling rate, and in the long run $u \approx e^{-\lambda_1 t}\langle f,\phi_1\rangle\phi_1$: everything except the fundamental mode is forgotten. For an insulated (Neumann) body, $\lambda_1 = 0$ is the constant mode, the final uniform temperature, and the approach to it is governed by the **spectral gap** λ_2. Replace "temperature" by "probability" and this is the convergence of a Markov chain to equilibrium, which is why mixing-time

bounds in Ch. 38 are spectral-gap bounds.

The variational principle

Rayleigh quotient and min–max

Let $R(v) = \dfrac{\iint |\nabla v|^2 \, dA}{\iint v^2 \, dA}$ for nonzero v in $H_0^1(\Omega)$. Then

$$\lambda_1 = \min_{v \neq 0} R(v), \qquad \lambda_k = \min_{\dim S = k} \; \max_{v \in S,\, v \neq 0} R(v),$$

where S ranges over k-dimensional subspaces of $H_0^1(\Omega)$ (Courant–Fischer).

Proof of the first statement. Expand $v = \sum_k c_k \phi_k$. By orthogonality, $\iint v^2 = \sum c_k^2$. Because $\iint \nabla \phi_i \cdot \nabla \phi_k = \langle -\nabla^2 \phi_i, \phi_k \rangle = \lambda_i \delta_{ik}$, also $\iint |\nabla v|^2 = \sum \lambda_k c_k^2$. Hence

$$R(v) = \frac{\sum_k \lambda_k c_k^2}{\sum_k c_k^2} \;\geq\; \frac{\sum_k \lambda_1 c_k^2}{\sum_k c_k^2} = \lambda_1,$$

with equality for $v = \phi_1$. ■ The min–max formula is proved the same way: any k-dimensional S contains a nonzero v orthogonal to $\phi_1, \dots, \phi_{k-1}$ (a dimension count), and for that v the same estimate gives $R(v) \geq \lambda_k$; the subspace spanned by $\phi_1, \dots, \phi_k$ attains it.

This one principle settles several questions at once.

- **Poincaré's constant.** On $(0,1)$, $\lambda_1 = \pi^2$, so $\int v^2 \leq \pi^{-2} \int (v')^2$ for every $v \in H_0^1$: the sharp constant $1/\pi$ that Ch. 89 promised.
- **Cheap estimates.** Any trial shape gives an upper bound. For $v = x(1-x)$ on $(0,1)$, $R(v) = \frac{1/3}{1/30} = 10$, within 1.3% of $\pi^2 = 9.8696$, with no differential equation solved.
- **Galerkin eigenvalues are always too high.** A finite-element method restricts the subspaces S in the min–max formula to subspaces of V_h. Minimizing over fewer candidates cannot give a smaller minimum, so $\lambda_k^h \geq \lambda_k$ for every k and every mesh. That is the clue left open in Ch. 89, where ten elements gave $9.95 > \pi^2$.
- **Domain monotonicity.** If $\Omega_1 \subset \Omega_2$, every trial function for Ω_1 (extended by zero) is a trial function for Ω_2, so $\lambda_k(\Omega_2) \leq \lambda_k(\Omega_1)$. Bigger drums sound lower.
- **Bottlenecks.** For a dumbbell, two rooms joined by a thin corridor, a Neumann trial function that is $+1$ in one room and -1 in the other has tiny gradient energy, so λ_2 is tiny. Cheeger's inequality (1970) makes this two-sided: $\lambda_2 \geq h^2/4$, where h is the smallest ratio of "cut length" to "area cut off". A small gap *forces* a bottleneck. The graph version is the clue left open in Ch. 27.

Weyl's law: hearing the area

Let $N(\lambda)$ be the number of eigenvalues $\leq \lambda$, counted with multiplicity.

Weyl's law

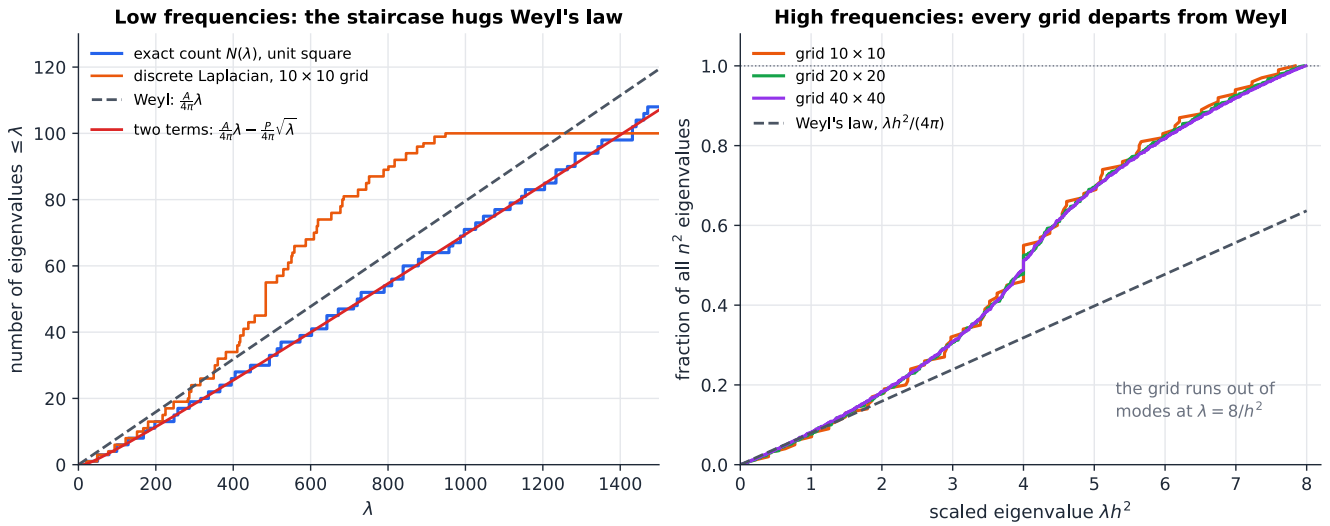
For a bounded plane domain of area A, $N(\lambda) \sim \dfrac{A}{4\pi}\,\lambda$ as $\lambda \to \infty$. In d dimensions, $N(\lambda) \sim \dfrac{\omega_d \, |\Omega|}{(2\pi)^d} \lambda^{d/2}$, where ω_d is the volume of the unit ball.

Proof for a rectangle $[0,a] \times [0,b]$. The eigenfunctions are $\sin(m\pi x/a)\sin(n\pi y/b)$ with $\lambda = \pi^2(m^2/a^2 + n^2/b^2)$, $m, n \geq 1$. So $N(\lambda)$ counts lattice points (m,n) with $m, n \geq 1$ inside the quarter-ellipse $E = \{m^2/a^2 + n^2/b^2 \leq \lambda/\pi^2,\ m, n \geq 0\}$, whose area is $\frac{\pi}{4} \cdot \frac{a\sqrt{\lambda}}{\pi} \cdot \frac{b\sqrt{\lambda}}{\pi} = \frac{ab}{4\pi}\lambda$. Attach to each counted point the unit square $[m-1, m] \times [n-1, n]$ that has it as its top-right corner. These squares do not overlap, and each lies inside E (moving down or left only decreases $m^2/a^2 + n^2/b^2$). So $N(\lambda) \leq \text{area}(E) = \frac{ab}{4\pi}\lambda$. Conversely, a point of E with positive coordinates lies in the square whose top-right corner is the lattice point just above and to the right of it. If the point is more than $\sqrt{2}$ from the curved edge, that corner is in E and is counted. So the squares cover all of E except a strip of width $\sqrt{2}$ along the curved edge, whose area is $O(\sqrt{\lambda})$. Hence $N(\lambda) = \frac{ab}{4\pi}\lambda + O(\sqrt{\lambda})$, and the leading term is $A\lambda/(4\pi)$. ■

The general case glues rectangles together, using domain monotonicity to squeeze the count from above and below. The $O(\sqrt{\lambda})$ correction is not random. If lattice points on the two axes were allowed, the count would overshoot the area by about half of the points lying on those axes, and there are about $\frac{(a+b)\sqrt{\lambda}}{\pi}$ of them. Excluding them ($m, n \geq 1$) leaves a net deficit of about $\frac{(a+b)\sqrt{\lambda}}{2\pi}$, which is the second term of Weyl's conjecture,

$$N(\lambda) \approx \frac{A}{4\pi}\lambda - \frac{P}{4\pi}\sqrt{\lambda},$$

where P is the perimeter. For the unit square at $\lambda = 10{,}000$ the true count is 764; one term predicts 795.8, two terms predict 763.9.



Left: the eigenvalue count of a square drum follows Weyl's law, and the two-term version almost exactly. A 10×10 finite-difference grid agrees at first, then overcounts and stops at 100 modes. Right: every grid, rescaled, follows the same curve, which bends away from Weyl long before its last mode at $\lambda = 8/h^2$. A discretization only hears the low notes correctly.

A cleaner way to hear the geometry is the **heat trace** $Z(t) = \sum_k e^{-\lambda_k t}$, which is determined by the spectrum. For a domain with a smooth boundary and g holes, as $t \to 0^+$,

$$Z(t) = \frac{A}{4\pi t} - \frac{P}{8\sqrt{\pi t}} + \frac{1-g}{6} + O(\sqrt{t}).$$

Area, perimeter and the number of holes can all be heard. (Corners add their own constants: for the square the constant is $\frac{1}{4}$, which you can check from $Z = \left(\sum_m e^{-\pi^2 m^2 t}\right)^2$.)

And the shape? In 1992 Carolyn Gordon, David Webb and Scott Wolpert built two different polygons, each assembled from seven congruent half-squares, with exactly the same spectrum. One cannot hear the shape of a drum. The proof is a transplantation: cut an eigenfunction on one drum into its seven pieces and reassemble them, with sign changes, on the other.

? Can one hear the shape of a *smooth* drum?

The Gordon–Webb–Wolpert drums have corners. Nobody knows whether two different smooth convex drums can share a spectrum. Zelditch (2009) proved that among analytic domains with one mirror symmetry, the spectrum does determine the shape, and Hezari and Zelditch later extended the result to nearly circular ellipses. The general question, which Kac really asked, is an open problem. The tools that might settle it come from billiards: the heat trace and its cousin, the wave trace, carry the lengths of periodic billiard paths inside the drum.

? The second term of Weyl's law

The two-term formula above is called Weyl's *conjecture*. Ivrii proved it in 1980, but only under a condition on billiards: the periodic trajectories bouncing around inside the drum must form a set of measure zero. Whether every domain satisfies this condition is unknown. It is open even for convex domains with smooth boundary in the plane. A question about counting musical notes is waiting on a question about pool tables.

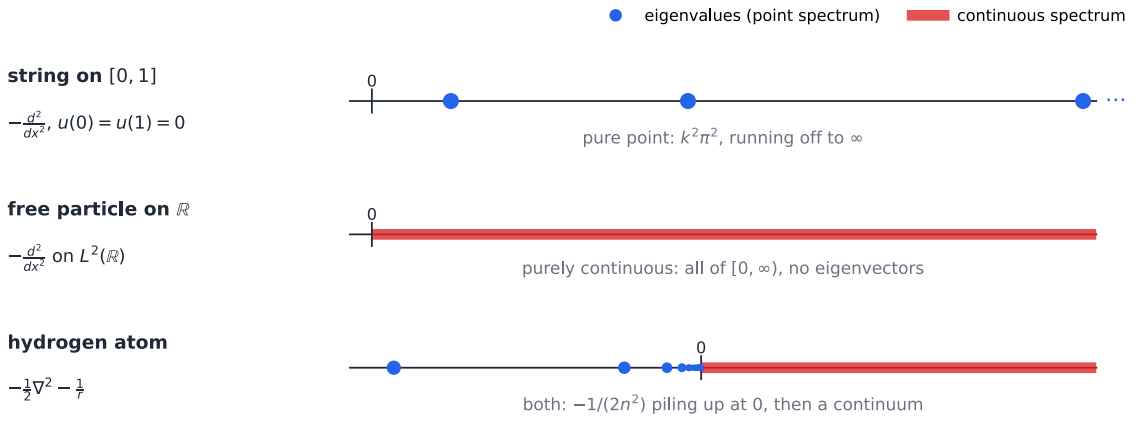
When there are no eigenvectors: continuous spectrum

On the whole line, $-d^2/dx^2$ acting on $L^2(\mathbb{R})$ has no eigenfunctions: the solutions of $-u'' = \lambda u$ are $e^{\pm j\sqrt{\lambda}x}$, or exponentials, none of them square-integrable. But the Fourier transform (§16.3) turns differentiation into multiplication, $\mathcal{F}\{-u''\} = \omega^2\,\mathcal{F}\{u\}$. In the frequency domain the operator is just "multiply by ω^2": diagonal, with a continuum of diagonal entries $[0, \infty)$ instead of a list. This is the general picture, and it answers the clue of Ch. 61.

Spectral theorem for self-adjoint operators, multiplication form (stated)

For every self-adjoint operator T on a Hilbert space $\mathcal{H}$, possibly unbounded, there is a measure space (M, μ), a real function g on M and a unitary map $U : \mathcal{H} \to L^2(M, \mu)$ with $UTU^{-1} =$ multiplication by g. Equivalently, $T = \int \lambda\, dE(\lambda)$ for a projection-valued measure E.

Eigenvalues are the atoms of the measure, where a single value of g carries positive weight; continuous spectrum is the rest. The physicist's "eigenstates" $|x_0\rangle$ and plane waves $e^{j\omega x}$ are not vectors in $\mathcal{H}$; they are the kernel of U, a coordinate system for the multiplication picture. Real operators often mix both kinds:



Point, continuous and mixed spectra. Hydrogen's bound states $-1/(2n^2)$ (in atomic units) are the spectral lines of the Balmer and Lyman series; the continuum above 0 is an electron that has escaped.

Beyond self-adjoint. For non-symmetric operators, such as convection-diffusion or the linearized equations of fluid flow, eigenvalues can be dangerously misleading. A flow whose eigenvalues all predict decay can still amplify a disturbance by a factor of thousands before decaying, which is one route to turbulence. The robust object is the **ε-pseudospectrum**, the set of z where $\|(T - zI)^{-1}\| > 1/\varepsilon$, introduced in Ch. 99's loose threads. For a normal operator it is just the ε-neighbourhood of the spectrum. For a non-normal one it can be enormously larger, and it, not the spectrum, predicts the transient growth.

90.4 The algorithm

Discretize a drum on an $n \times n$ grid and the Laplacian becomes a sparse symmetric matrix of size $N = n^2$. For a square it is a **Kronecker sum**, $\mathbf{A} = \mathbf{I} \otimes \mathbf{T} + \mathbf{T} \otimes \mathbf{I}$, where $\mathbf{T} = h^{-2}\,\mathrm{tridiag}(-1, 2, -1)$ is the 1-D second difference. Its eigenvalues are known exactly:

$$\lambda^h_{mn} = \frac{4}{h^2}\Big(\sin^2\frac{m\pi h}{2} + \sin^2\frac{n\pi h}{2}\Big), \qquad 1 \le m, n \le n_{\text{grid}}.$$

For small mh this is $\pi^2(m^2 + n^2)$ minus a correction of order h^2, so finite differences *underestimate* the low eigenvalues, the opposite of finite elements. For large m the formula saturates at $8/h^2$: the grid has no notes above that. This is why the right panel of the Weyl figure bends away.

You never want *all* N eigenvalues of a large drum. A dense symmetric eigensolver costs $O(N^3)$ time and $O(N^2)$ memory, so $N = 40{,}000$ already needs about 13 GB just to store the matrix. Engineers want the lowest few modes. The workhorse is **inverse iteration with a shift**: factor $\mathbf{A} - \sigma\mathbf{I}$ once, then repeatedly solve with it. Each solve multiplies the component along mode k by $1/(\lambda_k - \sigma)$, so the mode nearest σ wins.

```
import numpy as np
import scipy.sparse as sp
from scipy.sparse.linalg import splu, eigsh

n = 199; h = 1.0 / (n + 1)                      # interior grid of the unit square
T = sp.diags([-1.0, 2.0, -1.0], [-1, 0, 1], shape=(n, n)) / h**2
I = sp.identity(n)
A = (sp.kron(I, T) + sp.kron(T, I)).tocsc()     # 2-D Laplacian: a Kronecker sum

def inverse_iteration(A, sigma=0.0, iters=50, tol=1e-12):
    """Eigenpair of A nearest the shift sigma."""
    lu = splu(A - sigma * sp.identity(A.shape[0], format="csc"))   # factor once
    v = np.random.default_rng(1).standard_normal(A.shape[0])
    lam = 0.0
    for _ in range(iters):
        w = lu.solve(v)                         # w = (A - sigma I)^{-1} v
        v = w / np.linalg.norm(w)
        lam_new = v @ (A @ v)                   # Rayleigh quotient
        if abs(lam_new - lam) < tol * abs(lam_new): break
        lam = lam_new
    return lam_new, v

lam1, v1 = inverse_iteration(A)
print("inverse iteration:", lam1, " exact 2*pi^2 =", 2 * np.pi**2)
print("Lanczos, 6 smallest:", np.round(eigsh(A, k=6, sigma=0, which="LM")[0], 3))
```

On this 39,601-unknown problem, inverse iteration returns $\lambda^h_1 = 19.7388$ against the exact $2\pi^2 = 19.7392$. The last line uses the **Lanczos** method in shift-invert mode, which builds the best approximations from the whole Krylov space $\{\mathbf{v}, \mathbf{A}^{-1}\mathbf{v}, \mathbf{A}^{-2}\mathbf{v}, \dots\}$ instead of keeping only the latest vector. It finds $19.739,\ 49.345,\ 49.345,\ 78.95,\ 98.679,\ 98.679$: the double eigenvalues $5\pi^2$ and $10\pi^2$ appear twice, as they should.

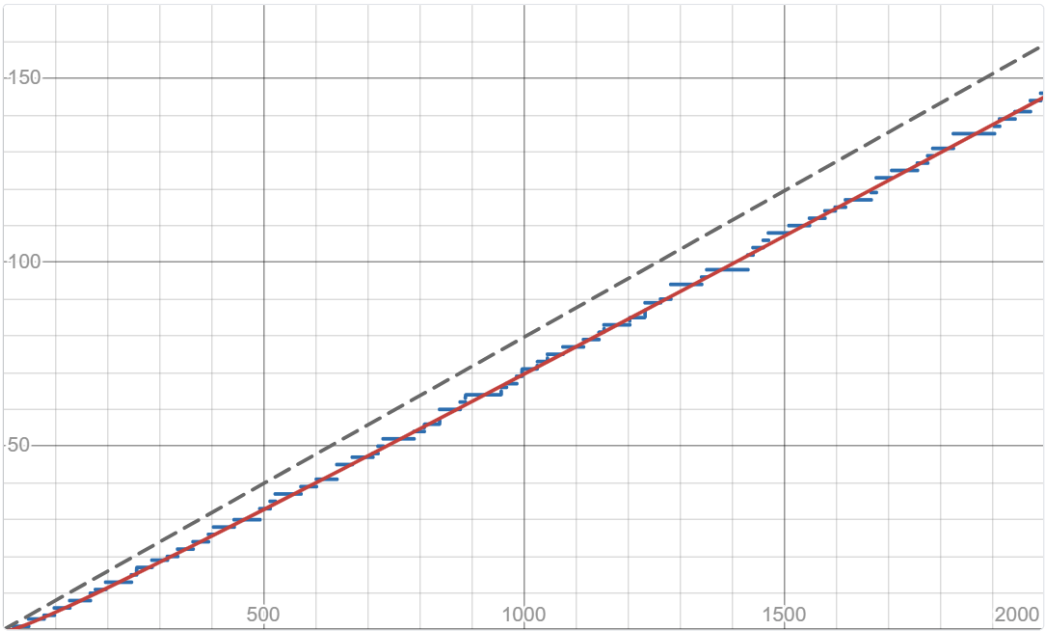
Cost and failure modes.

- Inverse iteration converges with ratio $|\lambda_1 - \sigma|/|\lambda_2 - \sigma|$ per step. A good shift makes it fast; a shift halfway between two eigenvalues makes it stall. Rayleigh-quotient iteration, which updates σ each step, converges cubically, at the price of refactoring every step.
- **Degenerate eigenvalues.** For $5\pi^2$ the solver returns *some* orthonormal pair from a two-dimensional eigenspace, and which pair depends on rounding and on the random start. Comparing "mode 2" between two runs, or between two meshes, can fail for this reason alone. Only the eigenspace is well defined.

- **Non-symmetric matrices.** For convection-dominated problems, eigenvalues of the matrix can sit far from those of the operator, and tiny perturbations move them a lot (the pseudospectra of §90.3). Check them, don't trust them.
- **Spectral pollution.** For operators with continuous spectrum, or for Maxwell's equations discretized with the wrong elements, Galerkin methods can produce eigenvalues that converge to nothing at all, sitting in a gap of the true spectrum. The min–max principle protects the bottom of the spectrum, never the interior. Detecting and avoiding pollution is current research.

90.5 The experiment

Hear the area and the perimeter. For an $a \times b$ rectangle the counting function is a finite sum of floor functions. With $a = b = 1$, the blue staircase is the exact $N(\lambda)$ and the red curve is the two-term Weyl law. Then make the drum long and thin with the same area: set $a = 4$, $b = 0.25$. In the sum, b is the factor in front of the square root and a is the base of `1^{2}`; in the Weyl curves, ab is `1\cdot1` and the perimeter $2(a + b)$ is `2(1+1)`. The one-term line does not move, because the area is unchanged; the staircase drops (at $\lambda = 2000$, from 146 modes to 131), and the perimeter term explains by how much.



Exact eigenvalue count of a rectangular drum (blue) against Weyl's law with one term (dashed) and two terms (red). The same area gives the same slope; the perimeter sets the offset.

Your own drum. This script builds the five-point Laplacian on any shape you can describe by a mask, computes all its eigenvalues with a dense solver, and compares the count with Weyl's law. The shapes live in $[-1, 1]^2$: a square of side 2, the L-shape of Ch. 89 (area 3), and the unit disk.

```
import numpy as np

n = 30                                  # knob: grid points per unit length
shape = "L"                             # knob: "square", "L" or "disk"
h = 1.0 / n
g = (np.arange(-n, n) + 0.5) * h        # cell centres covering [-1, 1]
X, Y = np.meshgrid(g, g)
masks = {"square": (np.abs(X) < 1) & (np.abs(Y) < 1),
         "L":      ~((X > 0) & (Y < 0)),
         "disk":   X**2 + Y**2 < 1}
area_perim = {"square": (4, 8), "L": (3, 8), "disk": (np.pi, 2 * np.pi)}
inside = masks[shape]
idx = -np.ones(X.shape, int); idx[inside] = np.arange(inside.sum())
N = inside.sum()

# five-point Dirichlet Laplacian on the cells inside the drum
A = np.zeros((N, N))
for i, j in zip(*np.nonzero(inside)):
    p = idx[i, j]; A[p, p] = 4 / h**2
    for di, dj in [(1, 0), (-1, 0), (0, 1), (0, -1)]:
        a, b = i + di, j + dj
        if 0 <= a < 2 * n and 0 <= b < 2 * n and inside[a, b]:
            A[p, idx[a, b]] = -1 / h**2
lam = np.linalg.eigvalsh(A)             # N x N dense: keep N below ~4000

print(f"{shape}: {N} unknowns; first eigenvalues:", np.round(lam[:6], 2))
Area, P = area_perim[shape]
print("   lambda   count   Weyl 1-term   Weyl 2-term")
for L in [50, 100, 200, 400, 800]:
    w1 = Area * L / (4 * np.pi); w2 = w1 - P * np.sqrt(L) / (4 * np.pi)
    print(f"{L:8d} {np.sum(lam <= L):7d} {w1:12.1f} {w2:12.1f}")
```

For the L-shape with $n = 30$ the first eigenvalue comes out as 9.08. The true value is 9.6397: this is the famous L-shaped membrane whose first mode is the MATLAB logo, computed to high accuracy by Fox, Henrici and Moler in 1967. The grid is crude, and because the grid's drum is effectively half a cell larger than the true one, its eigenvalues sit below the truth. At $\lambda = 400$ the count is 90, between the one-term (95.5) and two-term (82.8) predictions. Knobs to turn:

- Raise `n` to 35 (about 3,700 unknowns) and watch λ_1 creep toward 9.64. How fast? Compare with the square, whose exact λ_1 is $\pi^2/2 \approx 4.935$, and explain the difference using the corner singularity of Ch. 89.
- Look at `lam[1]` and `lam[2]` for the square and the disk. Which are degenerate, and which symmetry is responsible?
- Add your own mask: an annulus, a dumbbell, two disks joined by a thin channel. For the dumbbell, rerun with Neumann conditions (set each diagonal entry to the number of inside neighbours divided by h^2) and watch λ_2 collapse as the channel narrows.

90.6 The challenge

1. **Intuition.** Without computing, rank these drums of equal area by their fundamental frequency $\sqrt{\lambda_1}$: a disk, a square, an equilateral triangle, a $4 \times \frac{1}{4}$ rectangle. Which principle of §90.3 helps, and which pairs does it fail to decide?
2. **Derivation.** For the equilateral triangle and the square of the same area, compute the two-term Weyl predictions and say which drum has more modes below a large λ. Then verify the heat-trace constant $\frac{1}{4}$ for the unit square from $Z(t) = \left(\sum_{m\geq 1} e^{-\pi^2 m^2 t}\right)^2$, using $\sum_{m\geq 1} e^{-\pi^2 m^2 t} \approx \frac{1}{2\sqrt{\pi t}} - \frac{1}{2}$ for small t.
3. **Implementation.** Build the Gordon–Webb–Wolpert isospectral pair from seven half-squares each (look up their coordinates), discretize both with the script of §90.5 on triangular-friendly grids, and compare their first 20 eigenvalues. How close do two genuinely isospectral drums look after discretization, and can you tell them apart from a *non*-isospectral pair with the same area and perimeter?
4. **Open investigation.** Compute the first 2,000 eigenvalues of a rectangle with irrational aspect ratio and of a "stadium" (a rectangle with semicircular ends). Unfold each spectrum by subtracting the two-term Weyl law, form the gaps between consecutive eigenvalues, and plot their histograms. One histogram should look like e^{-s}; the other should vanish at $s = 0$. Which is which, and why might the shape of a billiard table decide whether eigenvalues repel each other?

90.7 Loose threads

Spectral theory turned operators into lists of numbers and the lists into geometry. The bottom of the spectrum measured stiffness, cooling rates and bottlenecks through the min–max principle. The density of the spectrum measured area, and its first correction, the perimeter. And when eigenvectors disappeared, the spectral theorem survived as "multiplication by a function". The challenge's last problem points at the most mysterious clue of all.

> **? Why do some spectra repel?**
>
> Unfold the eigenvalues of a rectangle and their gaps look like independent random numbers: a Poisson process, with many near-collisions. Do the same for a stadium, whose billiard paths are chaotic, and the gaps follow the statistics of eigenvalues of large random symmetric matrices, the Wigner surmise $\frac{\pi s}{2} e^{-\pi s^2/4}$, which vanishes at $s = 0$. Bohigas, Giannoni and Schmit conjectured in 1984 that this holds for every chaotic system, and the same statistics appear in heavy nuclei and in the zeros of the Riemann zeta function. Nobody has proved it for a single drum. The physics of it is in Ch. 92; the proof is an open problem.

Further pointers:

- **Inverse problems.** Singular values are the spectral theory of $\mathbf{K}^{\mathsf{T}}\mathbf{K}$, and the speed at which they decay decides whether an inverse problem is mildly or catastrophically unstable: Ch. 91.
- **Symmetry and degeneracy.** The double eigenvalue $5\pi^2$ is the square's rotation symmetry in disguise. In general, the multiplicities of a symmetric operator are the dimensions of the irreducible representations of its symmetry group: Ch. 95.
- **Graphs.** Everything here has a discrete twin. The graph Laplacian has a min–max principle, a Cheeger inequality and even isospectral pairs, and spectral clustering uses its second eigenvector to cut networks (Ch. 27, Ch. 87).

Chapter 91 — Inverse Problems: Reconstructing the Invisible

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 9, Ch. 10, Ch. 13, Ch. 61, Ch. 90 · **Leads to:** Ch. 92, Ch. 97 · **Related:** Ch. 24, Ch. 35, Ch. 76, Ch. 89 **Reading time:** ~30 min

91.1 The hook

On 24 April 1990 the Space Shuttle *Discovery* carried the Hubble Space Telescope into orbit. Its 2.4-metre primary mirror was the most precisely polished large mirror ever made. Within weeks the first images came back blurred. Stars that should have been sharp points were surrounded by a wide, faint halo. The investigation found that the mirror had been ground to the wrong shape: near its edge it was too flat by about 2.2 micrometres, roughly a fiftieth of the width of a human hair. A testing instrument used during polishing had been assembled with one lens about a millimetre out of place.

The error was tiny, but it was also *perfectly known*. Engineers could compute exactly how the faulty mirror spread the light of a point star, the **point-spread function**. Every Hubble image was therefore the true sky convolved with a known kernel. In principle, undoing the blur is just solving a linear system: the blurred image $\mathbf{g}$ equals $\mathbf{K}\mathbf{f}$, with $\mathbf{K}$ known, so $\mathbf{f} = \mathbf{K}^{-1}\mathbf{g}$. Astronomers spent three years doing exactly this kind of computation, until a servicing mission in December 1993 fitted corrective optics. They learned the hard way that the direct inverse is useless. Reconstructions came out as fields of violent speckle, with every pixel of sensor noise magnified into garbage.

Here is the same experience in one dimension. Take a signal with a box, a ramp and a bump; blur it with a narrow Gaussian; add noise of 1%, smaller than the line width on a plot. The blurring matrix is perfectly invertible. Its exact inverse returns a signal whose error is **273,000 times** the size of the signal itself.

And this is not an astronomy problem. It is the generic situation whenever you measure effects and want causes:

- **CT and MRI**: X-ray attenuations along lines, or Fourier samples, in; a tissue map out.
- **Seismic imaging**: echoes recorded at the surface in; rock layers kilometres down out.
- **Electrical impedance tomography**: voltages on the skin in; the conductivity of the lungs out.
- **Parameter estimation**: a step response in; the time constants of a circuit or a thermal model out (§25.8).

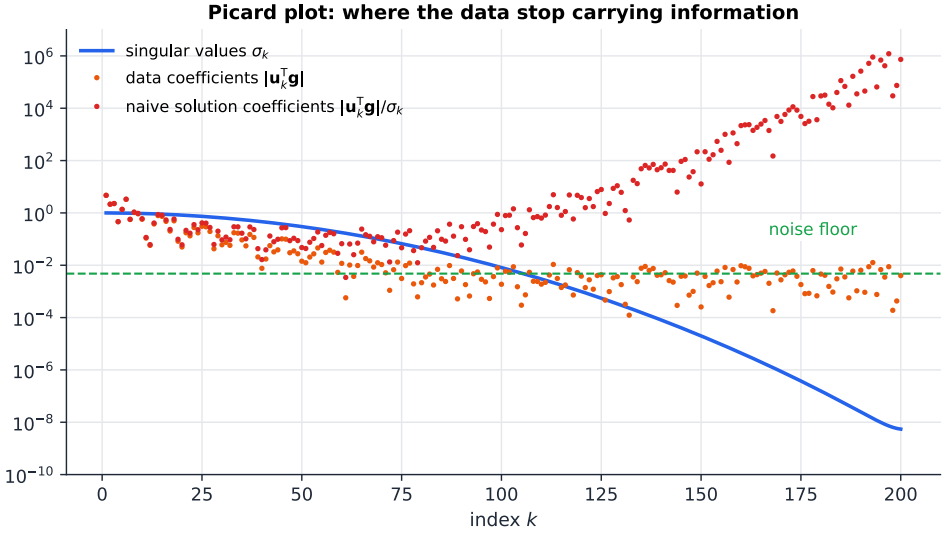
> **If you know the forward process exactly, why can't you just run it backwards? And if the exact inverse is worthless, what are you allowed to compute instead, and how do you know it isn't fiction?**

91.2 The big idea

Forward processes forget. Blurring averages neighbouring values together. Diffusion smears heat. A CT projection sums along a line. Physics is mostly smoothing, and smoothing destroys fine detail: two very different signals, one of them with a high-frequency wiggle added, produce almost identical measurements. The forward map is stable because it forgets. That same forgetting makes the inverse unstable: to recover the wiggle, the inverse must amplify the tiny trace it left in the data, and it amplifies the noise sitting in the same place just as much.

In the language of Ch. 13, the forward problem is well posed and the inverse problem is **ill posed**: its solution does not depend continuously on the data. Hadamard thought such problems were physically meaningless. A century later, they are most of medical imaging.

The singular value decomposition shows exactly where the forgetting happens. Write the forward matrix as $\mathbf{K} = \sum_k \sigma_k \mathbf{u}_k \mathbf{v}_k^{\mathsf{T}}$ (§10.7). Each input pattern $\mathbf{v}_k$ is mapped to output pattern $\mathbf{u}_k$, shrunk by σ_k. For a blur the $\mathbf{v}_k$ are oscillations of increasing frequency and the σ_k fall off a cliff. The exact inverse divides by σ_k, and in the components where σ_k is below the noise level it is dividing noise by almost nothing.



The Picard plot. Where the data coefficients (orange) still track the singular values (blue), the data carry information about $\mathbf{f}$. Beyond about $k = 60$ they hit the noise floor and carry only noise, and dividing by σ_k (red) inflates that noise by up to a million.

The cure is to want less. Since some components of $\mathbf{f}$ cannot be recovered, stop trying. Replace "find $\mathbf{f}$ with $\mathbf{Kf} = \mathbf{g}$" by "find a *reasonable* $\mathbf{f}$ that *nearly* fits the data". Reasonable means extra information you supply: the signal is not huge, or is smooth, or has few edges. That extra information is called **regularization**, and the art is in how much of it to add. An analogy: reading a smudged handwritten word. You cannot recover the ink exactly. You recover it by combining what is legible with what words usually look like, and if you trust your expectations too much you read the word you expected instead of the one that was written.

91.3 The mathematics

Throughout, the data are $\mathbf{g} = \mathbf{Kf} + \mathbf{e}$ with noise $\|\mathbf{e}\| \le \delta$, and $\mathbf{K} = \sum_k \sigma_k \mathbf{u}_k \mathbf{v}_k^{\mathsf{T}}$ with $\sigma_1 \ge \sigma_2 \ge \cdots > 0$. The same formulas hold for compact operators between Hilbert spaces, where $\sigma_k \to 0$ is forced (Ch. 61) and the inverse is unbounded rather than merely large.

Why the naive inverse explodes

Noise amplification

The naive solution is $\mathbf{K}^{-1}\mathbf{g} = \mathbf{f} + \sum_k \dfrac{\mathbf{u}_k^{\mathsf{T}}\mathbf{e}}{\sigma_k}\mathbf{v}_k$. Its worst-case error over all noise with $\|\mathbf{e}\| \le \delta$ is $\delta/\sigma_{\min}$. If the noise is white with variance η^2 per component, the expected squared error is $\eta^2 \sum_k \sigma_k^{-2}$.

Proof. Since $\{\mathbf{u}_k\}$ is orthonormal, $\mathbf{K}^{-1} = \sum_k \sigma_k^{-1}\mathbf{v}_k\mathbf{u}_k^{\mathsf{T}}$, and applying it to $\mathbf{Kf} + \mathbf{e}$ gives the formula. The error has coordinates $\mathbf{u}_k^{\mathsf{T}}\mathbf{e}/\sigma_k$ in the orthonormal basis $\{\mathbf{v}_k\}$, so its squared norm is $\sum_k (\mathbf{u}_k^{\mathsf{T}}\mathbf{e})^2/\sigma_k^2 \le \sigma_{\min}^{-2}\sum_k (\mathbf{u}_k^{\mathsf{T}}\mathbf{e})^2 = \delta^2/\sigma_{\min}^2$, with equality for $\mathbf{e} = \delta\mathbf{u}_{\min}$. For white noise, $E[(\mathbf{u}_k^{\mathsf{T}}\mathbf{e})^2] = \eta^2$ for each k. ∎

In the hook the condition number of $\mathbf{K}$ is 1.8×10^8, so 1% noise can become an error of over a million times the signal; the observed 2.7×10^5 is the typical case rather than the worst. Making the grid finer does not help. It adds more components with tiny σ_k, and in the continuum limit $\sigma_{\min} \to 0$.

How bad is bad? The decay of σ_k grades the difficulty. If $\sigma_k \sim k^{-p}$ the problem is **mildly ill posed**: differentiation is $p = 1$ (the Volterra operator of §61.4 has $\sigma_k = 2/((2k-1)\pi)$), and the CT scanner's Radon transform behaves like $p = \frac{1}{2}$ in two dimensions. If σ_k decays exponentially, the problem is **severely ill posed**: a Gaussian blur damps frequency ω by $e^{-s^2\omega^2/2}$, and running the heat equation backwards for time T requires undoing $e^{-k^2\pi^2 T}$. In a severely ill-posed problem, halving the noise buys only a few more recoverable components. That is why CT images are sharp and why nobody reconstructs the temperature history of a rod from its present state.

The Picard condition

A solution exists in the continuum only if $\sum_k (\mathbf{u}_k^{\mathsf{T}}\mathbf{g})^2/\sigma_k^2 < \infty$: the data coefficients must decay faster than the singular values. Exact data always satisfy it. Noisy data never do, because noise coefficients stop decaying. The Picard plot shows the index where the condition breaks, and that index is roughly how many components any method can hope to recover.

Tikhonov regularization

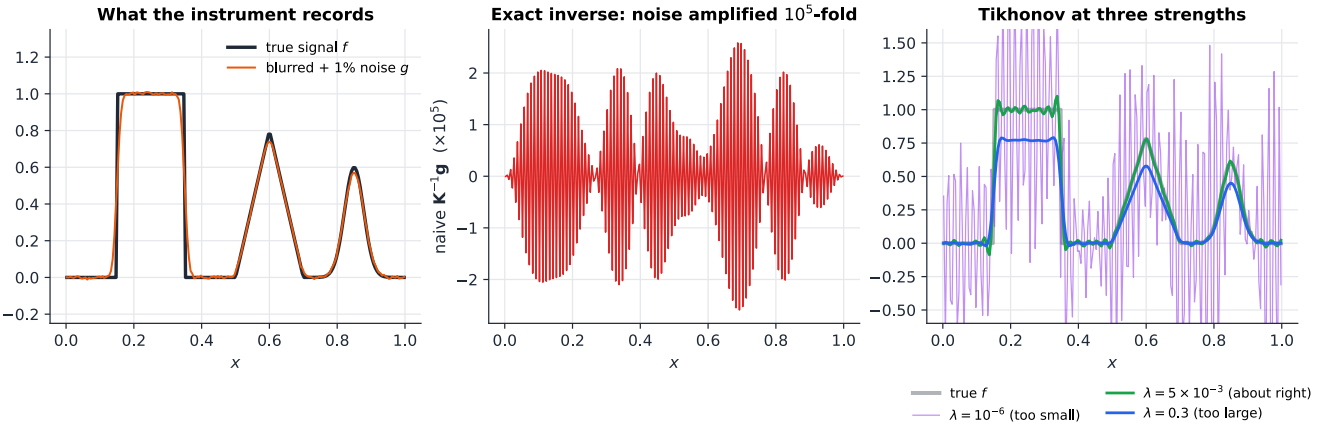
Andrey Tikhonov's 1963 proposal: instead of solving $\mathbf{Kf} = \mathbf{g}$, minimize

$$J_\lambda(\mathbf{f}) = \|\mathbf{Kf} - \mathbf{g}\|^2 + \lambda\|\mathbf{f}\|^2, \qquad \lambda > 0.$$

The first term asks for data fit, the second penalizes size, and λ sets the exchange rate. Setting the gradient to zero gives the regularized normal equations $(\mathbf{K}^{\mathsf{T}}\mathbf{K} + \lambda\mathbf{I})\mathbf{f}_\lambda = \mathbf{K}^{\mathsf{T}}\mathbf{g}$, which always have a unique solution because $\mathbf{K}^{\mathsf{T}}\mathbf{K} + \lambda\mathbf{I}$ is positive definite. It is ordinary least squares (§9.11) for the stacked system $\begin{bmatrix}\mathbf{K}\\ \sqrt{\lambda}\mathbf{I}\end{bmatrix}\mathbf{f} \approx \begin{bmatrix}\mathbf{g}\\ \mathbf{0}\end{bmatrix}$. In the SVD basis, $\mathbf{K}^{\mathsf{T}}\mathbf{K} + \lambda\mathbf{I}$ is diagonal with entries $\sigma_k^2 + \lambda$, so

$$\mathbf{f}_\lambda = \sum_k \underbrace{\frac{\sigma_k^2}{\sigma_k^2 + \lambda}}_{\text{filter factor}} \frac{\mathbf{u}_k^{\mathsf{T}}\mathbf{g}}{\sigma_k}\mathbf{v}_k.$$

Where $\sigma_k^2 \gg \lambda$ the filter factor is nearly 1 and the component is kept. Where $\sigma_k^2 \ll \lambda$ it is nearly 0 and the component is suppressed. Tikhonov is a smooth version of truncating the SVD, which Ch. 61 tried, with the cutoff at $\sigma_k \approx \sqrt{\lambda}$.



Deblurring a signal. The measurement (left) looks like the truth, yet the exact inverse (centre) is pure amplified noise. Tikhonov (right) with λ too small is still noise-dominated (relative error 116%); with $\lambda = 5 \times 10^{-3}$ the error is 9.8%; with $\lambda = 0.3$ the noise is gone but so are the corners and the peak heights (error 27%).

How good can it get?

The regularized solution has two errors with opposite appetites for λ, and the theorem below makes their trade exact. It needs one assumption about the truth, because without some smoothness of $\mathbf{f}$ no method can do better than arbitrarily badly.

Tikhonov error bound

Suppose $\mathbf{f} = \mathbf{K}^{\mathsf{T}}\mathbf{w}$ for some $\mathbf{w}$ (a **source condition**: $\mathbf{f}$ is smoother than a generic vector, in the sense the forward map defines). Then

$$\|\mathbf{f}_\lambda - \mathbf{f}\| \le \frac{\delta}{2\sqrt{\lambda}} + \frac{\sqrt{\lambda}}{2}\|\mathbf{w}\|,$$

and choosing $\lambda = \delta/\|\mathbf{w}\|$ gives $\|\mathbf{f}_\lambda - \mathbf{f}\| \le \sqrt{\delta\,\|\mathbf{w}\|}$.

Proof. Insert $\mathbf{g} = \mathbf{K}\mathbf{f} + \mathbf{e}$ into the filtered formula and use $\mathbf{u}_k^{\mathsf{T}}\mathbf{K}\mathbf{f} = \sigma_k \mathbf{v}_k^{\mathsf{T}}\mathbf{f}$:

$$\mathbf{f}_\lambda - \mathbf{f} = \sum_k \frac{\sigma_k}{\sigma_k^2 + \lambda}(\mathbf{u}_k^{\mathsf{T}}\mathbf{e})\,\mathbf{v}_k \;-\; \sum_k \frac{\lambda}{\sigma_k^2 + \lambda}(\mathbf{v}_k^{\mathsf{T}}\mathbf{f})\,\mathbf{v}_k.$$

Noise term. By the AM–GM inequality, $\sigma^2 + \lambda \ge 2\sigma\sqrt{\lambda}$, so every coefficient $\sigma_k/(\sigma_k^2+\lambda) \le 1/(2\sqrt{\lambda})$. The first sum therefore has norm at most $\|\mathbf{e}\|/(2\sqrt{\lambda}) \le \delta/(2\sqrt{\lambda})$.

Bias term. The source condition gives $\mathbf{v}_k^{\mathsf{T}}\mathbf{f} = \mathbf{v}_k^{\mathsf{T}}\mathbf{K}^{\mathsf{T}}\mathbf{w} = \sigma_k\,\mathbf{u}_k^{\mathsf{T}}\mathbf{w}$. So the second sum has coefficients $\lambda\sigma_k(\mathbf{u}_k^{\mathsf{T}}\mathbf{w})/(\sigma_k^2+\lambda)$, and by the same inequality $\lambda\sigma/(\sigma^2+\lambda) \le \sqrt{\lambda}/2$. Its norm is at most $\frac{\sqrt{\lambda}}{2}\|\mathbf{w}\|$.

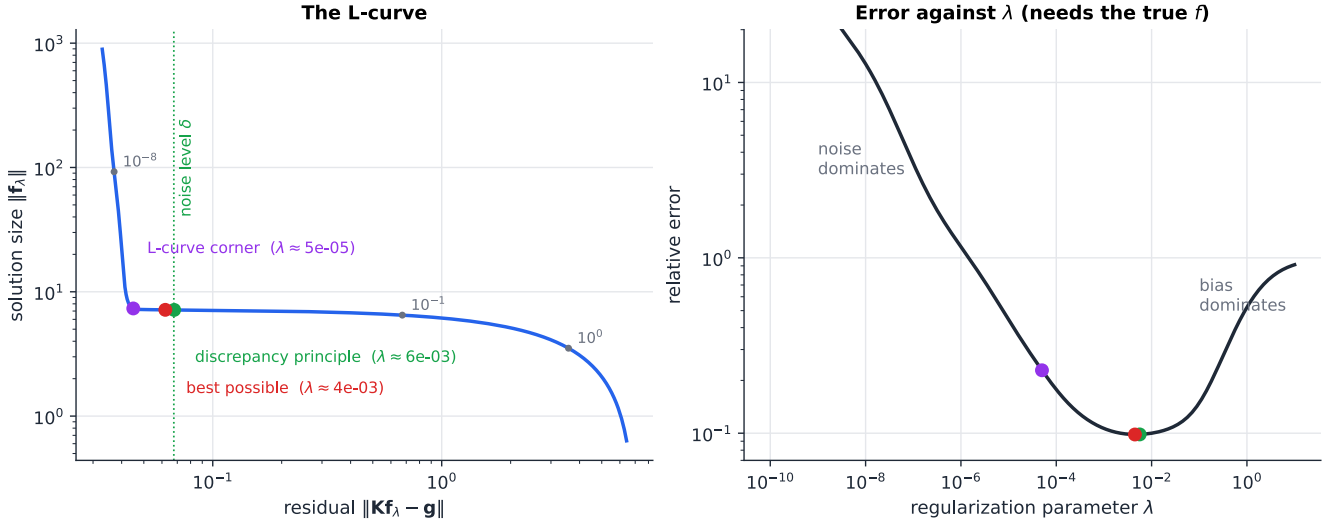
Balance. The sum $a/\sqrt{\lambda} + b\sqrt{\lambda}$ with $a = \delta/2$, $b = \|\mathbf{w}\|/2$ is minimized at $\lambda = a/b = \delta/\|\mathbf{w}\|$, where it equals $2\sqrt{ab} = \sqrt{\delta\|\mathbf{w}\|}$. ∎

Read the result carefully, because it is the central fact of the subject. With exact data ($\delta \to 0$) and λ chosen proportionally to δ, the reconstruction converges to the truth, so the method is a genuine **regularization**. But the error goes like $\sqrt{\delta}$, not δ: to gain one more correct digit you need two more digits of data accuracy. Stronger smoothness assumptions improve the exponent up to $\delta^{2/3}$ and no further for Tikhonov (its **saturation**). Ill-posedness is never fully cured; it is only negotiated.

Choosing λ from the data

The optimal λ in the theorem depends on $\|\mathbf{w}\|$, which describes the unknown truth. In practice λ must come from what you have.

- **The discrepancy principle** (Morozov, 1966). Do not fit the data better than the noise deserves: pick λ so that $\|\mathbf{K}\mathbf{f}_\lambda - \mathbf{g}\| = \tau\delta$ with $\tau \ge 1$. It needs the noise level δ, and with it, it provably achieves the optimal rate $O(\sqrt{\delta})$ under the source condition. In the hook's example it picks $\lambda \approx 5.6 \times 10^{-3}$ and an error of 9.8%, essentially the best possible.
- **The L-curve** (Hansen, 1992). Plot the solution size against the residual on log–log axes for all λ. Small λ gives large solutions with small residuals; large λ, the reverse. The curve has a corner where neither can be reduced without a large increase in the other, and the corner is the choice. It needs no knowledge of δ.
- **Generalized cross-validation** chooses λ so that the fit predicts each data point well when that point is left out. It also ignores δ.



Three ways of choosing λ on the same problem. The discrepancy principle, which knows δ, lands at the bottom of the error valley. The L-curve corner, which doesn't, picks $\lambda \approx 5 \times 10^{-5}$, about 100 times too small, and more than doubles the error to 23%.

Is there a rule that never needs δ and always works? No, and the reason is a theorem. **Bakushinskii's veto** (1984): for an ill-posed problem, any regularization method whose parameter is chosen from the data $\mathbf{g}$ alone, without knowledge of δ, fails to converge for some true solutions as $\delta \to 0$. The noise level is information that cannot be manufactured from the data. Heuristic rules like the L-curve and GCV still work very well in most practical cases, and understanding exactly when is an active line of research.

The Bayesian reading

Model the unknown as random, with a Gaussian prior $\mathbf{f} \sim \mathcal{N}(\mathbf{0}, \tau^2 \mathbf{I})$, and the noise as $\mathbf{e} \sim \mathcal{N}(\mathbf{0}, \eta^2 \mathbf{I})$. By Bayes' rule (Ch. 35) the posterior density is proportional to

$$\exp\Big(-\frac{\|\mathbf{K}\mathbf{f}-\mathbf{g}\|^2}{2\eta^2} - \frac{\|\mathbf{f}\|^2}{2\tau^2}\Big),$$

and its maximizer is exactly the Tikhonov solution with $\lambda = \eta^2/\tau^2$. The regularization parameter is a ratio of noise variance to signal variance, and the penalty $\|\mathbf{f}\|^2$ is a belief about what signals look like. Changing the penalty changes the belief: $\|\mathbf{D}\mathbf{f}\|^2$ with a difference matrix $\mathbf{D}$ says "smooth", the total variation $\|\mathbf{D}\mathbf{f}\|_1$ says "piecewise constant, with sharp edges", and $\|\mathbf{f}\|_1$ in a wavelet basis says "sparse", the idea behind compressed sensing (Ch. 76).

The Bayesian view gives something Tikhonov alone does not: an uncertainty. The posterior covariance $(\mathbf{K}^{\mathsf{T}}\mathbf{K}/\eta^2 + \mathbf{I}/\tau^2)^{-1}$ says which features of the reconstruction are determined by the data and which are only the prior talking. But it also creates the tension Ch. 61 warned about. In the Bayesian view λ is not tuned; it is fixed by η and τ. And the prior $\mathcal{N}(\mathbf{0}, \tau^2\mathbf{I})$ says each pixel is independent, so as the grid is refined, a "typical" signal under the prior becomes white noise, nothing like the box and bump we were reconstructing.

> **? A prior that survives refinement**
>
> A good prior should describe the same beliefs whether the signal is stored on 200 points or 200 million. That requires a probability measure on a space of *functions*, and on an infinite-dimensional space there is no uniform "Lebesgue" measure to write densities against. Gaussian measures with carefully decaying covariances work. In 2004 Lassas and Siltanen showed that the natural discretized total-variation prior, the edge-preserving favourite of image processing, does not: as the grid is refined, its reconstructions converge either to something blurry or to something meaningless, depending on how the prior is scaled. Which priors are "discretization invariant", and why, is a question about measures on function spaces: Ch. 97.

Nonlinear inverse problems and parameter estimation

Most real inverse problems are nonlinear: the data $\mathbf{g} = F(\mathbf{p}) + \mathbf{e}$ depend nonlinearly on parameters $\mathbf{p}$, such as the conductivity $k(x)$ of the rod in Ch. 89 or the time constants of a model. The workhorse is to linearize and regularize at each step. Gauss–Newton (§24.7) solves $\mathbf{J}\,\Delta\mathbf{p} \approx \mathbf{g} - F(\mathbf{p})$ with the Jacobian $\mathbf{J}$, and the Levenberg–Marquardt modification adds $\mu\|\Delta\mathbf{p}\|^2$: it is Tikhonov regularization applied to every linearized step. A new difficulty appears, **identifiability**: different parameters can produce *identical* data, not just similar data, and then no amount of regularization can tell them apart.

The model problem of the field is **Calderón's problem** (1980): recover the conductivity $\gamma(\mathbf{x})$ inside a body from all possible pairs of boundary voltages and boundary currents, the Dirichlet-to-Neumann map. Uniqueness was proved by Sylvester and Uhlmann in 1987 for smooth conductivities in three or more dimensions, and by Astala and Päivärinta in 2006 for any bounded conductivity in the plane. Stability is another matter: Mandache proved in 2001 that it can be at best *logarithmic*, so that improving the data accuracy from δ to δ^2 may only double the reconstruction accuracy. Impedance tomography is exponentially ill posed, however clever the algorithm.

> **? How rough can a conductivity be and still be heard?**
>
> In three dimensions uniqueness for Calderón's problem is known for Lipschitz conductivities (Caro and Rogers, 2016) and somewhat beyond, but not for merely bounded ones, which is what real tissue boundaries and composite materials look like. Whether two different bounded conductivities in 3-D can produce exactly the same boundary measurements is an open problem. So is a satisfying answer to the practical question: given logarithmic stability, how much prior information buys how much resolution in a real impedance scanner?

91.4 The algorithm

For a moderate problem, compute the SVD once, at $O(n^3)$ cost. After that, $\mathbf{f}_\lambda$ for any λ costs only $O(n^2)$, so scanning a hundred values of λ is cheap. That is what the experiment below does. Without an SVD, the stable way to compute one Tikhonov solution is the stacked least-squares problem, solved by QR rather than by forming $\mathbf{K}^{\mathsf{T}}\mathbf{K}$, which would square the condition number (§24.3). The discrepancy principle then becomes a one-dimensional root-finding problem in $\log\lambda$, because the residual $\|\mathbf{K}\mathbf{f}_\lambda - \mathbf{g}\|$ increases monotonically with λ.

```
import numpy as np

def tikhonov(K, g, lam):
    """argmin ||K f - g||^2 + lam ||f||^2, via a stacked least-squares problem (QR inside)."""
    n = K.shape[1]
    A = np.vstack([K, np.sqrt(lam) * np.eye(n)])
    b = np.concatenate([g, np.zeros(n)])
    return np.linalg.lstsq(A, b, rcond=None)[0]

def discrepancy(K, g, delta, tau=1.0, lo=1e-12, hi=1e2, steps=40):
    """Largest lam with ||K f_lam - g|| <= tau * delta, by bisection in log(lam)."""
    for _ in range(steps):
        mid = np.sqrt(lo * hi)
        if np.linalg.norm(K @ tikhonov(K, g, mid) - g) > tau * delta:
            hi = mid                    # residual too big: regularizing too much
        else:
            lo = mid
    return lo
```

On the hook's problem, `discrepancy` returns $\lambda = 5.6 \times 10^{-3}$ and a reconstruction with relative error 9.8%, matching the SVD scan.

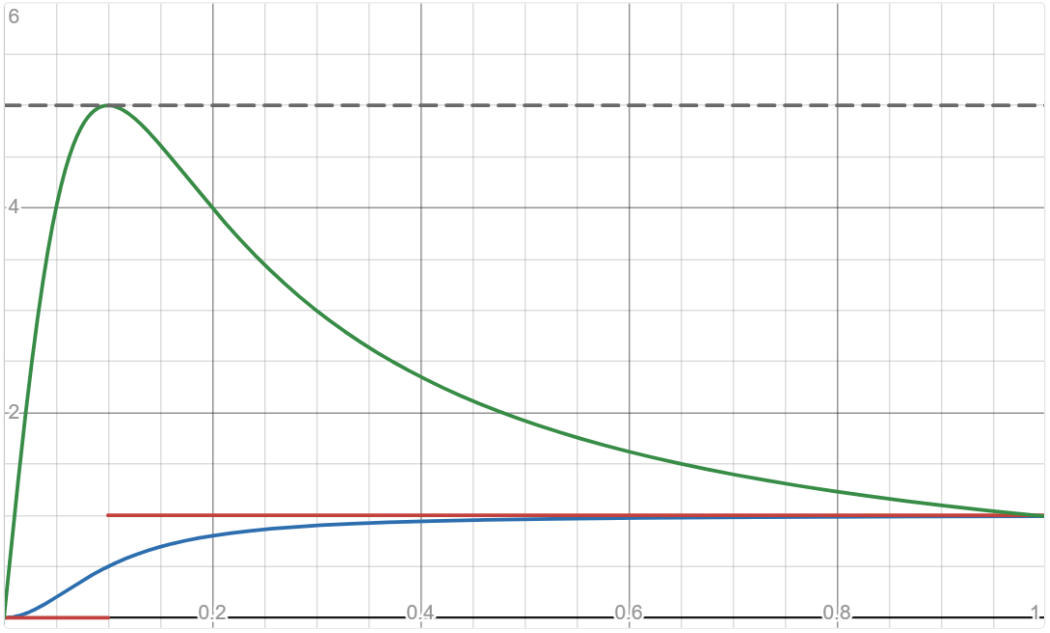
Large problems. A CT image of 512×512 pixels has $n \approx 2.6 \times 10^5$ unknowns, and $\mathbf{K}$ is never stored as a dense matrix: it is a routine that computes projections. Then the method of choice is an iterative least-squares solver such as CGLS or LSQR, which needs only products with $\mathbf{K}$ and $\mathbf{K}^{\mathsf{T}}$. These methods regularize by themselves. Early iterations pick up the large-σ_k components; later ones reach the small-σ_k, noise-dominated components. So the error first falls and then rises again, which is called **semi-convergence**, and the iteration count plays the role of $1/\lambda$. Stopping by the discrepancy principle is standard.

Failure modes.

- **The inverse crime.** If you generate synthetic data with the same discretized $\mathbf{K}$ that you then invert, the model is perfect and the reconstruction looks far better than it will on real data. Honest tests generate data on a finer grid, or with a different method, than the one used for inversion. The experiment below commits this crime on purpose; one of its knobs removes it.
- **Wrong noise model.** Astronomical images have Poisson photon noise, not Gaussian noise. The least-squares misfit is then the wrong measure, and the Richardson–Lucy iteration, which maximizes the Poisson likelihood and keeps intensities positive, was the tool astronomers actually used on Hubble's flawed images.
- **Wrong prior.** The penalty $\|\mathbf{f}\|^2$ rounds every edge, as the $\lambda = 0.3$ curve shows. Edge-preserving penalties such as total variation are better, but they are non-smooth and need convex-optimization algorithms (Ch. 47).
- **Boundary effects.** Near the ends of the interval, the blur averages over values the model assumes are zero. If the true scene continues beyond the edge, the reconstruction invents artefacts there.

91.5 The experiment

See the filter. The blue curve is Tikhonov's filter factor $\sigma^2/(\sigma^2+\lambda)$ with $\lambda = 0.01$, plotted against the singular value σ; the red step is truncated SVD with cutoff $\sigma = \sqrt{\lambda} = 0.1$. The green curve, $\sigma/(\sigma^2+\lambda)$, is how much Tikhonov amplifies noise in a component with singular value σ, and the dashed line is the bound $1/(2\sqrt{\lambda}) = 5$ from §91.3. Change `0.01` to `0.0001` everywhere (and the cutoff `0.1` to `0.01`, the bound `5` to `50`) and watch the filter sharpen while the noise amplification grows tenfold.



Tikhonov's filter (blue) keeps components with $\sigma \gg \sqrt{\lambda}$ and smoothly suppresses the rest, unlike the hard cut of truncated SVD (red). The amplification of noise (green) peaks exactly at $\sigma = \sqrt{\lambda}$, at the height the error bound uses.

Deblur it yourself. This script rebuilds the hook's example, prints the error for a range of λ, and lets the discrepancy principle choose.

```
import numpy as np

n, width, noise_level = 200, 0.01, 0.01   # knobs: grid, blur width, relative noise
rng = np.random.default_rng(0)
x = (np.arange(n) + 0.5) / n
K = np.exp(-(x[:, None] - x[None, :])**2 / (2 * width**2)) / (np.sqrt(2 * np.pi) * width * n)
f = ((x > 0.15) & (x < 0.35)) + 0.8 * np.maximum(0, 1 - np.abs(x - 0.6) / 0.1) \
    + 0.6 * np.exp(-((x - 0.85) / 0.04)**2)          # box, tent, bump
g_clean = K @ f
e = noise_level * np.linalg.norm(g_clean) / np.sqrt(n) * rng.standard_normal(n)
g = g_clean + e
delta = np.linalg.norm(e)

U, s, Vt = np.linalg.svd(K)
print(f"condition number {s[0] / s[-1]:.2e}")
rel = lambda fr: np.linalg.norm(fr - f) / np.linalg.norm(f)
print(f"naive inverse: relative error {rel(np.linalg.solve(K, g)):.2e}")

def tik(lam):                                       # Tikhonov through the SVD filter
    return Vt.T @ (s / (s**2 + lam) * (U.T @ g))

print("   lambda    residual/delta   rel. error")
for lam in [1e-8, 1e-6, 1e-4, 1e-3, 5e-3, 1e-2, 1e-1, 1]:
    fl = tik(lam)
    print(f"{lam:9.0e}   {np.linalg.norm(K @ fl - g) / delta:10.2f}   {rel(fl):10.3f}")

lams = np.logspace(-10, 1, 400)                     # discrepancy principle
res = np.array([np.linalg.norm(K @ tik(l) - g) for l in lams])
lam_d = lams[res <= delta].max()
print(f"discrepancy principle picks lambda = {lam_d:.1e}, error {rel(tik(lam_d)):.3f}")
```

With the default knobs the condition number is 1.83×10^{8} and the naive error is 2.73×10^{5}. The table's error column runs 12.8, 1.16, 0.178, 0.106, 0.098, 0.100, 0.149, 0.522 as λ grows: a valley with a flat floor between about 10^{-3} and 10^{-2}. The discrepancy principle picks $\lambda = 5.2 \times 10^{-3}$, with error 0.098. Knobs to turn:

- Set `noise_level` to 10^{-3} and then 10^{-4}. By how much does the best error improve each time? Compare with the $\sqrt{\delta}$ rate of the theorem: is this signal smooth enough to satisfy the source condition? (The box has jumps.)
- Double `width`. The problem becomes far more severely ill posed. How many singular values are now above the noise floor?
- Commit no crime: build the data with a finer kernel matrix (say $3n$ points, then average each group of three), and invert with the n-point `K`. How much worse is the best achievable error?
- Replace the penalty $\|\mathbf{f}\|^2$ by $\|\mathbf{D}\mathbf{f}\|^2$ with `D = np.diff(np.eye(n), axis=0)`, solving the normal equations $(\mathbf{K}^{\mathsf{T}}\mathbf{K} + \lambda \mathbf{D}^{\mathsf{T}}\mathbf{D})\mathbf{f} = \mathbf{K}^{\mathsf{T}}\mathbf{g}$ directly. Which features improve, and which get worse?

91.6 The challenge

1. **Intuition.** A thermometer at the midpoint of a rod records the temperature for one hour. Explain without equations why estimating the rod's *initial* temperature profile from this record is severely ill posed, while estimating a single unknown heat-loss coefficient from it is well posed. What is different about the number of unknowns compared with the number of components the data can carry?
2. **Derivation.** For truncated SVD with cutoff index r, $\mathbf{f}_r = \sum_{k \le r} \sigma_k^{-1} (\mathbf{u}_k^{\mathsf{T}}\mathbf{g})\mathbf{v}_k$, derive the analogue of the Tikhonov error bound under the source condition $\mathbf{f} = \mathbf{K}^{\mathsf{T}}\mathbf{w}$, and show that the best choice of r again gives an error of order $\sqrt{\delta}\|\mathbf{w}\|$. Then show that under the stronger condition $\mathbf{f} = (\mathbf{K}^{\mathsf{T}}\mathbf{K})\mathbf{z}$, truncated SVD reaches $O(\delta^{2/3})$ and keeps improving under still stronger conditions, while Tikhonov stalls at $\delta^{2/3}$. Find the step of the Tikhonov argument that causes the stall.
3. **Implementation.** Implement total-variation deblurring for the hook's signal: minimize $\|\mathbf{K}\mathbf{f} - \mathbf{g}\|^2 + \lambda \sum_i \sqrt{(f_{i+1} - f_i)^2 + \epsilon^2}$ by gradient descent or by lagged diffusivity (re-solve a weighted least-squares problem at each step). Compare its reconstruction of the box with Tikhonov's at the discrepancy-principle λ, and report both errors.
4. **Open investigation.** Train the simplest possible learned reconstructor: a linear map $\mathbf{f} \approx \mathbf{B}\mathbf{g}$ fitted by least squares on a thousand random training signals made of boxes and bumps. Compare it with Tikhonov on new signals of the same kind, then on signals of a different kind (a sine wave, a single spike). Then search for a small perturbation of the data, $\|\Delta\mathbf{g}\| \le \delta$, that maximizes the change in $\mathbf{B}\mathbf{g}$. Is the learned map more or less stable than Tikhonov, and does it trade stability for accuracy in any predictable way?

91.7 Loose threads

An inverse problem is a forward problem that forgot something. The SVD shows exactly which components were forgotten, regularization fills them in with assumptions, and the Tikhonov bound shows the price: errors that shrink like $\sqrt{\delta}$ at best, and a parameter whose choice needs information, the noise level, that the data cannot supply. The Bayesian reading turns the assumptions into explicit probability and buys honest error bars. Calderón's problem and the priors that survive refinement are still open. One more clue comes from the present day.

> **? Reconstructions that hallucinate**
>
> Since about 2017, neural networks trained on large image collections have produced MRI and CT reconstructions sharper than any regularization formula, from fewer measurements. In 2020 Antun, Renna, Poon, Adcock and Hansen showed that several such networks are unstable in a way Tikhonov never is. A tiny, carefully chosen perturbation of the measurements can make a lesion vanish or a false structure appear, and adding *more* measurements can make the result worse. Their follow-up work showed that, for some inverse problems, stable and accurate neural networks exist but no training algorithm can be guaranteed to find them. When a learned reconstructor can be trusted, and how to certify it on a particular scan, is an open problem with patients waiting on the answer.

Further pointers:

- **The physics behind the operators.** Most forward maps in this chapter, from blur to radiation transport to wave scattering, come from variational principles and conservation laws, and the symmetries of the physics decide which parameters can be identified: Ch. 92.
- **Uncertainty at scale.** Turning a posterior over a million unknowns into error bars needs sampling methods that work in high dimension, such as the preconditioned Crank–Nicolson MCMC, whose design comes straight from the infinite-dimensional view: Ch. 38.
- **Geometry from images.** Recovering depth from photographs, the inverse problem left open in Ch. 69, is nonlinear, and its ill-posedness shows up as near-degenerate camera configurations.

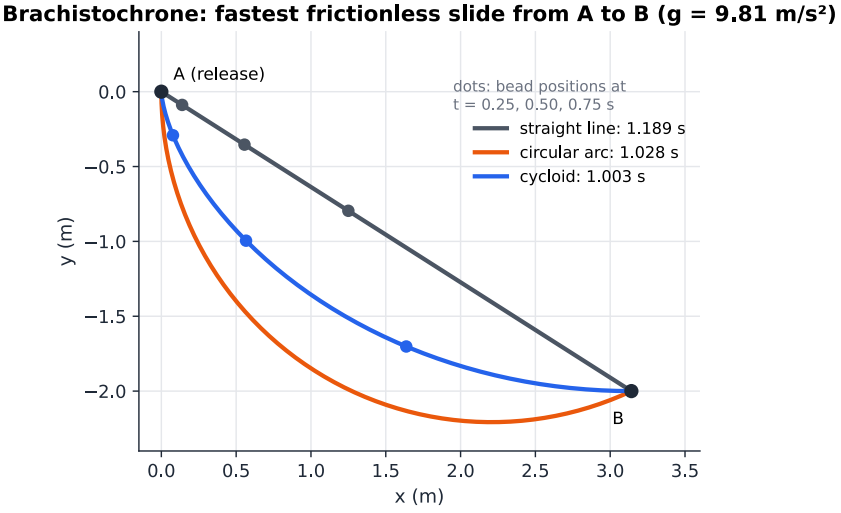
92.1 The hook

In June 1696 Johann Bernoulli published a challenge "to the sharpest mathematicians in the world". Two points A and B sit at different heights, with B lower and off to the side. A bead slides without friction along a wire from A to B, pulled only by gravity. What shape of wire gets it there fastest?

The straight line is the shortest path, but it is not the fastest. Take B to be π metres to the right of A and 2 metres below it. On the straight wire the bead takes **1.189 s**. Bend the wire into a circular arc that starts vertically and the bead wins, at **1.028 s**: it plunges first, builds up speed, and spends that speed on the longer route. The best wire of all takes **1.003 s**. It is a **cycloid**, the curve traced by a point on the rim of a rolling wheel. Newton is said to have solved it overnight and replied anonymously; Bernoulli recognised the lion "by his claw".



Three wires from A to B. The dots mark where each bead is after 0.25, 0.50 and 0.75 s. The cycloid bead drops steeply, gains speed early, and arrives first even though its wire is longer than the straight line.

The puzzle is old, but the idea inside it shaped the next three centuries of physics. The answer to "which *curve* is best?" is a differential equation, and nature seems to answer such questions all the time. Light crossing from air into water bends so as to minimise its travel time (Fermat). A planet follows the orbit that makes a certain integral, the **action**, stationary (Maupertuis, Euler, Lagrange, Hamilton). A clock in free fall follows the path through spacetime along which it ticks the most (Einstein).

Then, in 1918, Emmy Noether found something that is still astonishing. Once a law of motion is written as "make this integral stationary", every **continuous symmetry** of the integral hands you a **conserved quantity** for free. Laws that don't change from one day to the next force energy to be conserved. Laws that are the same everywhere force momentum to be conserved. Laws that look the same in every direction force angular momentum to be conserved.

> **Why should a symmetry, a statement about what does *not* matter, produce a number that never changes?**

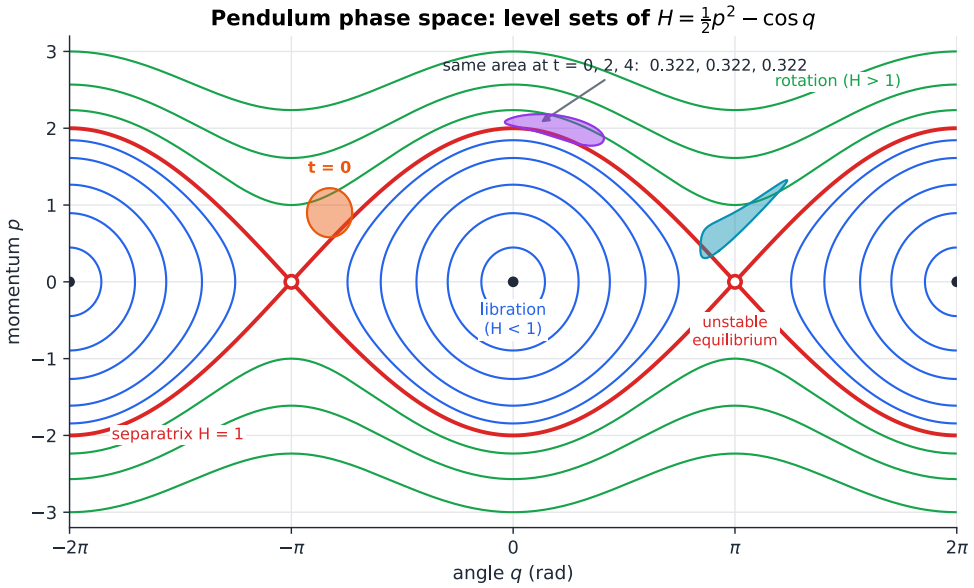
This chapter answers that question. It also follows the same structure into phase space, where it explains why some numerical integrators run stably for billions of steps, and to the edge of quantum mechanics.

92.2 The big idea

Idea 1: optimise over whole paths, not numbers. In calculus you minimise a function of a few numbers by setting a derivative to zero (§6.11). In the calculus of variations the unknown is a *whole function* $y(x)$, and the thing to minimise is a **functional**, a number computed from the entire curve, such as the bead's travel time. The trick is the same as in ordinary calculus. Wiggle the curve slightly, by $\varepsilon\,\eta(x)$, and demand that the first-order change vanish for *every* wiggle η. Because the wiggle is arbitrary, the condition holds at each point separately and becomes a differential equation.

Idea 2: a symmetry is a wiggle that costs nothing. Suppose moving the entire experiment 1 cm to the left changes nothing. That shift is a wiggle of the path that leaves the integral exactly unchanged, at every instant and not only to first order. Feed this special wiggle into the stationarity condition and it does not produce an equation for the path. It produces a statement that some combination of positions and velocities has zero time derivative. The symmetry is spent on buying a conservation law.

Idea 3: phase space is a place where volume is sacred. Hamilton rewrote mechanics using positions q *and* momenta p as equal partners. A state of the system is then a point in **phase space**, and the motion is a flow of that space. For a pendulum the flow runs along the level curves of the energy $H(q,p)$: closed ovals while it swings, wavy lines while it spins over the top, and the **separatrix** between them.



Pendulum phase space. Every trajectory runs along a level set of H. A disc of initial states (orange) is carried by the exact flow and sheared into crescents (purple at $t = 2$, teal at $t = 4$), but its area stays at 0.322 to six digits. This is Liouville's theorem.

An analogy: phase-space flow is like stirring paint into honey. You can stretch a blob into an arbitrarily thin thread, but never compress it. Facts as different as "a Hamiltonian system has no attractors" and the success of Hamiltonian Monte Carlo follow from this one incompressibility.

92.3 The mathematics

The Euler–Lagrange equation

Let $q(t) \in \mathbb{R}^n$ be a path with fixed endpoints $q(t_0) = q_0$ and $q(t_1) = q_1$, and let

$$S[q] = \int_{t_0}^{t_1} L\big(q(t), \dot q(t), t\big)\, dt$$

for a smooth function L, the **Lagrangian**.

Euler–Lagrange equations

If q makes S stationary among all smooth paths with the same endpoints, then for each $i = 1, \dots, n$

$$\frac{d}{dt}\frac{\partial L}{\partial \dot q_i} - \frac{\partial L}{\partial q_i} = 0.$$

Proof. Take any smooth $\eta(t)$ with $\eta(t_0) = \eta(t_1) = 0$ and compare q with $q + \varepsilon\eta$. Differentiating under the integral sign,

$$\frac{d}{d\varepsilon} S[q + \varepsilon\eta]\Big|_{\varepsilon = 0} = \int_{t_0}^{t_1} \sum_i \Big(\frac{\partial L}{\partial q_i}\eta_i + \frac{\partial L}{\partial \dot q_i}\dot\eta_i \Big)\, dt.$$

Integrate the second term by parts. The boundary term $\big[\sum_i \frac{\partial L}{\partial \dot q_i}\eta_i\big]_{t_0}^{t_1}$ vanishes because η vanishes at both ends, which leaves

$$0 = \int_{t_0}^{t_1} \sum_i \Big(\frac{\partial L}{\partial q_i} - \frac{d}{dt}\frac{\partial L}{\partial \dot q_i} \Big)\eta_i\, dt \quad \text{for every admissible } \eta.$$

If the bracket were nonzero at some time t^* in some component, say positive, it would stay positive on a small interval around t^*. Choose η_i to be a smooth bump supported inside that interval and every other component zero: the integral would then be positive, a contradiction. (This step is called the *fundamental lemma of the calculus of variations*.) ∎

Newton from a single function. For a particle of mass m in a potential $V(q)$, take $L = T - V = \tfrac{1}{2}m\|\dot q\|^2 - V(q)$. Then $\partial L/\partial \dot q = m\dot q$ and $\partial L/\partial q = -\nabla V$, so the Euler–Lagrange equation reads $m\ddot q = -\nabla V$: Newton's second law. The **principle of stationary action** packs mechanics into one scalar function, and it works in *any* coordinates. Write L in polar angles or a robot arm's joint angles, and the same recipe gives correct equations of motion without resolving a single force.

The brachistochrone, briefly. With y measured downward, a bead starting from rest has speed $\sqrt{2gy}$ by energy conservation, so the travel time is

$$T[y] = \int_0^X \frac{\sqrt{1 + y'^2}}{\sqrt{2gy}}\, dx.$$

The integrand $F(y, y')$ does not depend on x. For such integrands the Euler–Lagrange equation has a first integral, the **Beltrami identity** $F - y'\,\partial F/\partial y' = $ const, which here reduces to $y(1 + y'^2) = 2r$ for a constant r. Substituting $x = r(\theta - \sin\theta)$, $y = r(1 - \cos\theta)$ solves it: a cycloid. The bead's parameter turns out to be proportional to time, $\theta = t\sqrt{g/r}$, so reaching the bottom of an arch takes $\pi\sqrt{r/g}$, which is 1.003 s for $r = 1$ m. The Beltrami identity is our first conservation law from a symmetry. The integrand did not care about x, and something was conserved.

Noether's theorem

Now make that observation general. A **one-parameter symmetry** of L is a smooth family of transformations $q \mapsto q + \varepsilon K(q) + O(\varepsilon^2)$, generated by a vector field K, under which the Lagrangian does not change to first order:

$$\frac{d}{d\varepsilon} L\big(q + \varepsilon K(q),\ \dot q + \varepsilon \tfrac{d}{dt} K(q)\big)\Big|_{\varepsilon = 0} = \sum_i \Big(\frac{\partial L}{\partial q_i} K_i + \frac{\partial L}{\partial \dot q_i} \frac{dK_i}{dt} \Big) = 0.$$

Define the **momentum** conjugate to q_i as $p_i = \partial L / \partial \dot q_i$.

Noether's theorem (point symmetries)

If K generates a symmetry of L, then along every solution of the Euler–Lagrange equations the quantity

$$Q = \sum_i p_i\, K_i(q) = \sum_i \frac{\partial L}{\partial \dot q_i} K_i(q)$$

is constant in time.

Proof. Differentiate Q along a solution and use the product rule:

$$\frac{dQ}{dt} = \sum_i \Big(\frac{d}{dt}\frac{\partial L}{\partial \dot q_i} \Big) K_i + \sum_i \frac{\partial L}{\partial \dot q_i} \frac{dK_i}{dt}.$$

By the Euler–Lagrange equation the first bracket equals $\partial L / \partial q_i$. What remains is exactly the left-hand side of the symmetry condition, which is zero. ∎

That is the whole proof. The answer to the hook's question is now visible. The Euler–Lagrange equation says *forces equal the rate of change of momentum*. The symmetry condition says *the force along the direction K is cancelled by the way momentum feeds into K*. Put together, the momentum along K has nothing left to change it.

The three classical conservation laws

- **Translation.** N particles with $L = \sum_a \tfrac12 m_a \|\dot{\mathbf{x}}_a\|^2 - V$, where V depends only on differences $\mathbf{x}_a - \mathbf{x}_b$. Shifting every particle by $\varepsilon \hat{\mathbf{e}}$ leaves L unchanged, so $K = (\hat{\mathbf{e}}, \dots, \hat{\mathbf{e}})$ and $Q = \hat{\mathbf{e}} \cdot \sum_a m_a \dot{\mathbf{x}}_a$. Total momentum is conserved.
- **Rotation.** In the plane, rotating by ε moves (x, y) by $\varepsilon(-y, x)$. If V depends only on distances, $Q = p_x(-y) + p_y x = m(x\dot y - y\dot x)$. Angular momentum is conserved, which is Kepler's equal-area law.
- **Time translation.** If L has no explicit t, define the **energy function** $h = \sum_i p_i \dot q_i - L$. Then $dh/dt = -\partial L/\partial t = 0$ (differentiate and use Euler–Lagrange, exactly as above). For $L = T - V$ with T quadratic in $\dot q$, $h = T + V$. Energy is conserved.

Time translation needs the slightly larger version of the theorem that allows t to move too, but the computation is the same in spirit. The theorem also runs in reverse: in Hamiltonian form below, a conserved quantity *generates* a symmetry. The dictionary is two-way.

Not every conservation law is Noether's

Noether needs an action. Friction has none, which is why a damped oscillator has a time-independent law and still loses energy. Discrete symmetries such as reflections give selection rules rather than conserved numbers (Ch. 95).

Hamilton's equations and the incompressible flow

The **Legendre transform** trades velocities for momenta. Assuming $p = \partial L / \partial \dot q$ can be solved for $\dot q$, define the **Hamiltonian**

$$H(q, p) = \sum_i p_i \dot q_i - L(q, \dot q),$$

which is the energy function h written in terms of (q, p). Computing dH in two ways, and using the Euler–Lagrange equation, gives **Hamilton's equations**:

$$\dot q_i = \frac{\partial H}{\partial p_i}, \qquad \dot p_i = -\frac{\partial H}{\partial q_i}.$$

For the pendulum, with unit mass, length and g, $L = \tfrac12 \dot q^2 + \cos q$, $p = \dot q$, and $H = \tfrac12 p^2 - \cos q$. Two immediate consequences follow. First, $dH/dt = \sum_i (H_{q_i}\dot q_i + H_{p_i}\dot p_i) = \sum_i (H_{q_i}H_{p_i} - H_{p_i}H_{q_i}) = 0$, so trajectories stay on level sets, as in the figure. Second, and deeper:

Liouville's theorem

Let Φ_t be the flow of Hamilton's equations on $\mathbb{R}^{2n}$. For any region D of phase space, $\operatorname{vol}(\Phi_t(D)) = \operatorname{vol}(D)$ for all t.

Proof. Write the equations as $\dot z = F(z)$ with $z = (q, p)$ and $F = (\partial H/\partial p,\ -\partial H/\partial q)$. Its divergence is

$$\nabla \cdot F = \sum_i \Big(\frac{\partial^2 H}{\partial q_i \partial p_i} - \frac{\partial^2 H}{\partial p_i \partial q_i} \Big) = 0.$$

Let $J(t) = \partial \Phi_t(z_0)/\partial z_0$ be the Jacobian matrix of the flow. Differentiating $\dot z = F(z)$ with respect to the initial condition gives the linear equation $\dot J = DF(z(t))\, J$ with $J(0) = \mathbf{I}$. For any matrix solution of such an equation, $\frac{d}{dt} \det J = \operatorname{tr}(DF) \det J$ (Jacobi's formula; it follows from $\det(\mathbf{I} + h\mathbf{A}) = 1 + h \operatorname{tr}\mathbf{A} + O(h^2)$). Since $\operatorname{tr} DF = \nabla \cdot F = 0$, $\det J(t) = 1$ for all t, and the change-of-variables formula gives $\operatorname{vol}(\Phi_t(D)) = \int_D |\det J|\, dz_0 = \operatorname{vol}(D)$. ∎

The Hamiltonian flow preserves more than volume. Its Jacobian satisfies $J^{\mathsf{T}}\boldsymbol{\Omega} J = \boldsymbol{\Omega}$, with $\boldsymbol{\Omega} = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{I} & \mathbf{0} \end{pmatrix}$. Such a map is called **symplectic**. Geometrically, it preserves the sum of the oriented areas that any small 2-dimensional patch projects onto the n planes (q_i, p_i). In one degree of freedom "symplectic" and "area-preserving" coincide, which is the version you met in §72.3. In more dimensions it is far stronger: Gromov's **non-squeezing theorem** (1985) forbids a symplectic map from squeezing a ball of radius r into a cylinder $\{q_1^2 + p_1^2 < R^2\}$ with $R < r$, which a merely volume-preserving map could do.

Brackets, and the doorway to quantum mechanics

For any observable $f(q,p)$, the chain rule and Hamilton's equations give $\dot f = \{f, H\}$, where the **Poisson bracket** is

$$\{f, g\} = \sum_i \left(\frac{\partial f}{\partial q_i}\frac{\partial g}{\partial p_i} - \frac{\partial f}{\partial p_i}\frac{\partial g}{\partial q_i} \right), \qquad \{q_i, p_j\} = \delta_{ij}.$$

Noether's theorem now becomes beautifully symmetric. $\{Q, H\} = 0$ says both that Q is conserved along the flow of H, and (because the bracket is antisymmetric) that H is unchanged along the flow generated by Q, which is the symmetry. Momentum generates translations; angular momentum generates rotations; the Hamiltonian generates time evolution.

Dirac noticed that quantum mechanics keeps this algebra but replaces numbers by operators. The bracket $\{f,g\}$ becomes the commutator $[\hat f, \hat g]/(j\hbar)$, so $\{q,p\} = 1$ becomes

$$\hat X \hat P - \hat P \hat X = j\hbar\, \hat I.$$

Ch. 61 showed that no pair of *matrices* satisfies this, by taking traces. Could bounded operators on an infinite-dimensional Hilbert space do it? **Wielandt's argument** (1949) says no, in four lines. Suppose $XP - PX = c\,I$ with $c \neq 0$ and X, P bounded. By induction, $XP^n - P^nX = nc\,P^{n-1}$ for every $n \geq 1$. (Check it: $XP^{n+1} - P^{n+1}X = (XP^n - P^nX)P + P^n(XP - PX) = nc\,P^n + c\,P^n$.) Taking norms,

$$n|c|\,\|P^{n-1}\| \leq 2\|X\|\,\|P\|\,\|P^{n-1}\|.$$

If $P^{n-1} \neq 0$ for every n, dividing gives $n \leq 2\|X\|\|P\|/|c|$ for all n, which is absurd. If instead $P^m = 0$ for some m, the identity with $n = m$ gives $mc\,P^{m-1} = 0$, so $P^{m-1} = 0$; descending one power at a time eventually gives $c\,I = 0$, again absurd. ■ Position and momentum *must* be unbounded operators, with all the delicacy of domains that Ch. 61 warned about. The **Stone–von Neumann theorem** (1931) then says that, once the relation is stated in the robust exponentiated form $e^{ja\hat X}e^{jb\hat P} = e^{-jab\hbar}e^{jb\hat P}e^{ja\hat X}$, every irreducible solution is unitarily equivalent to the familiar one: $\hat X$ multiplies $\psi(x)$ by x and $\hat P = -j\hbar\, d/dx$. In this sense quantum mechanics of a particle is *unique*.

The uncertainty principle is Cauchy–Schwarz. Here is the signal-processing version promised in Ch. 76. Let $x(t)$ be a smooth signal with $\int |x|^2 dt = 1$, centred so that its mean time and mean frequency are zero, and decaying fast enough that $t|x(t)|^2 \to 0$ as $|t| \to \infty$. Define $\sigma_t^2 = \int t^2 |x|^2 dt$ and $\sigma_\omega^2 = \frac{1}{2\pi}\int \omega^2 |X(\omega)|^2 d\omega$, which equals $\int |x'(t)|^2 dt$ by Parseval's theorem (§16.7), since x' has transform $j\omega X$. Integrating by parts,

$$1 = \int |x|^2 dt = -\int t\,\frac{d}{dt}|x|^2\,dt = -2\,\mathrm{Re}\int t\,x^* x'\,dt \leq 2\Big(\int t^2|x|^2dt\Big)^{1/2}\Big(\int |x'|^2 dt\Big)^{1/2}.$$

So $\sigma_t\sigma_\omega \geq \tfrac12$, or $\sigma_t\sigma_f \geq 1/(4\pi)$ with $f = \omega/2\pi$. Equality in Cauchy–Schwarz needs $x' = -\lambda t\, x$ for a real $\lambda > 0$, whose solution is the Gaussian $e^{-\lambda t^2/2}$. Replace ω by $p/\hbar$ (a wavefunction's frequency is its momentum) and the same lines give Heisenberg's $\sigma_x\sigma_p \geq \hbar/2$. The physics is the Fourier transform. The quantum part is only the claim that a particle *is* a wave.

> **? Why does nature extremise anything?**
>
> A thrown ball does not try out paths and pick the best one, so why is mechanics a variational problem at all? Feynman's answer is that in quantum mechanics a particle takes *every* path, each weighted by the phase $e^{jS/\hbar}$. Paths far from stationary action cancel each other out, like a rapidly oscillating integrand, and only the neighbourhood of the classical path survives as $\hbar \to 0$. The trouble is that the "integral over all paths" has never been defined as a genuine integral in most cases of physical interest. For four-dimensional gauge theories, making it rigorous is the Yang–Mills existence and mass gap problem, one of the Clay Millennium Prize problems, and it is still **open**.

92.4 The algorithm

Liouville's theorem says the exact flow preserves area. An integrator that shares this property inherits much of the flow's long-term behaviour. The **Störmer–Verlet** or **leapfrog** method, for $H = \tfrac12 p^2 + V(q)$, is three shears: half a kick, a drift, and half a kick.

```
import numpy as np

def H(q, p):                      # pendulum, g/l = 1, unit mass and length
    return 0.5 * p**2 - np.cos(q)

def euler(q, p, h):               # explicit Euler: uses old q and old p
    return q + h * p, p - h * np.sin(q)

def leapfrog(q, p, h):            # Stormer-Verlet: kick, drift, kick
    p = p - 0.5 * h * np.sin(q)
    q = q + h * p
    p = p - 0.5 * h * np.sin(q)
    return q, p

for step in (euler, leapfrog):
    q, p, h = 1.0, 0.0, 0.1
    E0, worst = H(q, p), 0.0
    for n in range(100_000):      # 10,000 time units, about 1,500 swings
        q, p = step(q, p, h)
        worst = max(worst, abs(H(q, p) - E0))
    print(f"{step.__name__:9s} max |H - H0| = {worst:.2e}, final q = {q:.3f}")
```

Both methods cost about one force evaluation per step, since leapfrog's closing half-kick can be reused as the next step's opening one. Explicit Euler gains energy on every swing. Within four swings the pendulum is spinning over the top, and by the end the maximum energy error is about 330 and q has wound round to -1.9×10^{5} rad. Leapfrog's energy error never exceeds 1.1×10^{-3} over the whole run. It does not drift; it oscillates.

Why it works. Each substep is a shear of phase space: a kick changes p by an amount that depends only on q, and a drift changes q by an amount that depends only on p. Each shear has Jacobian determinant 1 and is symplectic, so their composition is too. The scheme is also **time-reversible**: run it with $-h$ from the end and you retrace the steps exactly. **Backward error analysis** (Benettin–Giorgilli 1994, Hairer–Lubich 1997) then gives the deep explanation of the shadow energy from Ch. 72. A symplectic method applied to an analytic Hamiltonian H is, up to an error of order $e^{-c/h}$, the *exact* flow of a modified Hamiltonian $\tilde{H} = H + h^2 H_2 + h^4 H_4 + \dots$, and the error stays exponentially small for times up to order $e^{c/h}$. The method conserves $\tilde{H}$ almost exactly, so it stays within $O(h^2)$ of the true energy surface for exponentially long times. For the harmonic oscillator, $H = \tfrac{1}{2}(p^2 + q^2)$, the series sums in closed form: leapfrog conserves $\tilde{H} = \tfrac{1}{2}p^2 + \tfrac{1}{2}(1 - h^2/4)q^2$ *exactly*, which you can check in two lines.

Hamiltonian Monte Carlo. This answers the question left open in Ch. 38. To sample from a density $\pi(q) \propto e^{-U(q)}$, add a fake Gaussian momentum and set $H = U(q) + \tfrac{1}{2}\|p\|^2$:

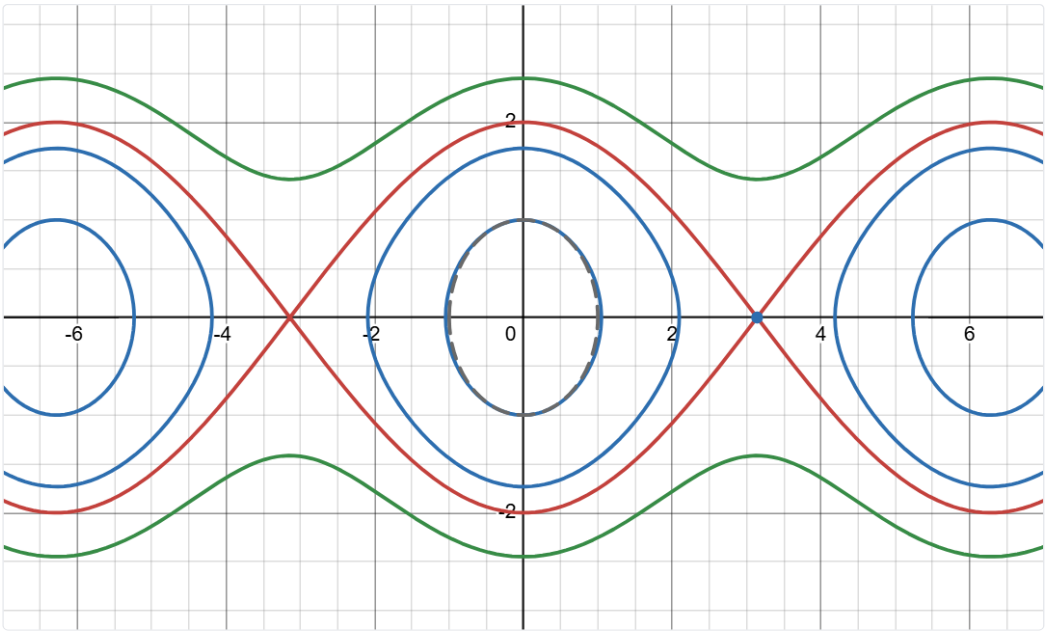
```
HMC step from q:
    draw p ~ N(0, I)
    (q*, p*) = L leapfrog steps of size h from (q, p) on H
    accept q* with probability min(1, exp(H(q, p) - H(q*, p*)))
```

Three properties of leapfrog make this rule exactly correct. *Volume preservation* removes any Jacobian factor from the acceptance ratio. *Reversibility* (flip p at the end) makes the proposal symmetric, as Metropolis needs. And the *small energy error* keeps acceptance near 1 even for long trajectories that cross the whole distribution. RK4 would need a Jacobian correction it cannot compute cheaply. For a product target in d dimensions, the leapfrog energy error adds up over the coordinates, and keeping the acceptance rate fixed requires $h \propto d^{-1/4}$ (Beskos et al., 2013). That is the $d^{1/4}$ cost quoted in Ch. 38.

Failure cases. Leapfrog is only second order and needs $h\omega < 2$ for an oscillator of frequency ω. Naive adaptive step sizes destroy its symplectic structure, and stiff or dissipative systems need other tools (§22.11).

92.5 The experiment

Phase portraits by hand. Every curve below is a level set $\tfrac{1}{2}p^2 - \cos q = E$ of the pendulum Hamiltonian, with x for q and y for p. The dashed grey ellipse is the small-angle approximation $\tfrac{1}{2}p^2 + \tfrac{1}{2}q^2 - 1 = E$ at the same energy $E = -0.5$.



Level sets of the pendulum Hamiltonian. Blue: swinging; red: the separatrix; green: spinning over the top. The dashed ellipse is the linearised pendulum.

Things to change:

- Change both -0.5 values to -0.9, then to 0.5. The ellipse and the true orbit agree for small swings and come apart as the energy approaches the separatrix. This is why a pendulum clock's period depends on its amplitude.
- Change the red level from 1 to 0.99 and to 1.01. A tiny change of energy changes the *kind* of motion. Near the separatrix the period becomes infinite, and this is where chaos first appears once the pendulum is pushed periodically.

Find the brachistochrone by brute force. This script never mentions cycloids or Euler–Lagrange. It cuts the wire into 40 straight segments, computes the exact travel time down each one (constant acceleration, so the time is length divided by mean speed), and moves the heights of the joints downhill in travel time.

```
import numpy as np

g, X, Y, N = 9.81, np.pi, -2.0, 40       # gravity, end point (X, Y), number of segments
x = np.linspace(0, X, N + 1)

def travel_time(y_inner):                # y_inner: (..., N-1) heights of the inner nodes
    y_inner = np.atleast_2d(y_inner)
    ends = np.ones((len(y_inner), 1))
    y = np.hstack([0 * ends, y_inner, Y * ends])
    v = np.sqrt(2 * g * np.maximum(-y, 0))           # speed from energy conservation
    L = np.hypot(np.diff(x), np.diff(y, axis=1))     # segment lengths
    return np.sum(2 * L / (v[:, :-1] + v[:, 1:]), axis=1)   # constant acceleration per segment

y = np.linspace(0, Y, N + 1)[1:-1]                   # start from the straight line
print(f"straight line : {travel_time(y)[0]:.4f} s")
eps, E = 1e-6, np.eye(N - 1)
for it in range(20000):                              # plain gradient descent
    grad = (travel_time(y + eps * E) - travel_time(y - eps * E)) / (2 * eps)
    y -= 0.02 * grad / max(1.0, np.abs(grad).max())
print(f"optimised path: {travel_time(y)[0]:.4f} s, lowest point y = {y.min():.3f}")
print(f"cycloid theory: {np.pi * np.sqrt(1 / g):.4f} s (radius 1)")
```

It starts at 1.1890 s on the straight line and settles at 1.0051 s, within 0.2% of the cycloid's 1.0030 s. The remaining gap is the cost of using 40 straight pieces. Things to change:

- Set `X = 2*np.pi`, so that B is far to the side. The optimiser now dips *below* B, to about $y = -2.49$, and climbs back up to it, in 1.4846 s. The exact cycloid (radius 1.275 m) bottoms out at -2.55 and takes 1.4804 s. Going downhill past your destination can be the fastest way to reach it.
- Increase `N` to 80 and watch the gap to theory shrink.
- Replace `2 * L / (v[:, :-1] + v[:, 1:])` by `L` and the same code finds the *shortest* path, the straight line. One functional per question.

92.6 The challenge

1. **Intuition.** A bead slides on a frictionless *helical* wire wound around a vertical axis, under gravity. Which of energy, vertical momentum and angular momentum about the axis are conserved? Now let the helix rotate about its axis at a constant rate. Which symmetry has been lost, and what conserved quantity takes the place of energy?
2. **Derivation.** For a particle in a central potential, $L = \tfrac{1}{2}m(\dot r^2 + r^2\dot\phi^2) - V(r)$, derive the Euler–Lagrange equations, use Noether to eliminate $\dot\phi$, and reduce the motion to a one-dimensional problem with an effective potential. Then derive the Beltrami identity $F - y'F_{y'} = \text{const}$ for an integrand $F(y, y')$ and show that it gives $y(1 + y'^2) = \text{const}$ for the brachistochrone.

3. **Implementation.** Write a leapfrog integrator for the Kepler problem, $H = \frac{1}{2}\|\mathbf{p}\|^2 - 1/\|\mathbf{q}\|$, starting on an orbit of eccentricity 0.6. Over 1,000 orbits, plot the energy error and the angular-momentum error for leapfrog and for RK4 at matched cost. Explain why leapfrog conserves angular momentum *exactly* (to rounding), while its energy merely oscillates.
4. **Open investigation.** Build the HMC sampler of §92.4 for a d-dimensional standard Gaussian. For $d = 10, 100, 1000$, find the step size h that gives an acceptance rate of about 65%, and test how h scales with d. Then repeat for a strongly correlated target such as Neal's funnel, where no single step size works everywhere. Can you design a position-dependent step or mass matrix that keeps the sampler exactly correct? (Riemannian-manifold HMC is one answer, and its cost is a live research question.)

92.7 Loose threads

The clock in orbit. The GPS mystery of Ch. 59 is a variational principle too. A free-falling clock follows the path through spacetime that makes its own elapsed time, the **proper time** τ, stationary. In a weak gravitational potential Φ and at speed $v \ll c$,

$$d\tau \approx \Big(1 + \frac{\Phi}{c^2} - \frac{v^2}{2c^2}\Big)dt, \qquad \text{so} \qquad -mc^2\int d\tau \approx \int \Big(\tfrac{1}{2}mv^2 - m\Phi\Big)dt - mc^2\int dt.$$

Stationary proper time is stationary Newtonian action, with $L = T - V$. The same formula also gives the GPS clock rates. With $GM = 3.986 \times 10^{14}\ \mathrm{m^3/s^2}$, Earth's radius 6,371 km and the orbital radius 26,561 km, the potential term makes the satellite clock gain 45.7 μs per day, and its orbital speed of 3.87 km/s makes it lose 7.2 μs per day. The net 38.5 µs per day is what the satellites correct for. As for *which* curvature matter controls: the Einstein equations $G_{\mu\nu} = \frac{8\pi G}{c^4}T_{\mu\nu}$ tie the **Ricci** part of the curvature, which governs how a small ball of test particles changes its *volume*, to energy and momentum. The remaining **Weyl** part is free: it carries tides and gravitational waves through empty space. "Why that one" has a Noether answer. Energy–momentum conservation, $\nabla_\mu T^{\mu\nu} = 0$, comes from the symmetry of physics under shifts of spacetime position. It can only be consistent if the geometric side is automatically divergence-free too. Lovelock proved (1971) that in four dimensions $G_{\mu\nu}$, plus a cosmological-constant term, is the *only* divergence-free symmetric tensor built from the metric and its first two derivatives. It is also what you get by applying Euler–Lagrange to the Einstein–Hilbert action $\int R\sqrt{-g}\,d^4x$. The curvature tensors themselves, and why they are tensors at all, are in Ch. 93.

Itô or Stratonovich? This is the physics answer to the mystery from Ch. 36. If the noise's correlation time is the *only* small timescale, the white-noise limit is Stratonovich (Wong–Zakai), natural for a circuit driven by thermal noise. Itô is right when the noise is non-anticipating by construction: a trader cannot react to tomorrow's price change. With *two* small timescales, such as a Brownian particle's inertia and its noise's correlation time, the limit depends on their ratio and can be neither convention (Kupferman, Pavliotis and Stuart, 2004); colloids diffusing near a wall show the resulting drift, matching the "anti-Itô" convention (Volpe et al., 2010).

? Do the tori survive?

A pendulum, a planet around a single sun, and any system with as many independent conserved quantities as degrees of freedom is **integrable**. Its phase space is foliated by invariant tori, and motion on each torus is perfectly regular. Add Jupiter's pull on the Earth and the extra conserved quantities are gone. Does the solar system then stay regular? Kolmogorov, Arnold and Moser proved that *most* tori survive a small enough perturbation, the ones whose frequencies are "sufficiently irrational", while the rest dissolve into thin layers of chaos. How irrational is sufficient, and what happens between the survivors, is the subject of Ch. 84.

? What is an electron, mathematically?

Noether turned each continuous symmetry into a conserved number. Wigner (1939) went much further. In quantum theory, the symmetry group of spacetime acts on the space of states by unitary operators, and an *elementary particle* is an **irreducible** piece of that action. Mass and spin, including the half-integer spin no classical object has, then come out as labels of the irreducible pieces, not as extra assumptions. Why the rotation group has a "double cover" that allows spin $\frac{1}{2}$, and how to classify irreducible representations at all, are the subject of Ch. 95.

Why a quantum verifier cannot be rewound. The zero-knowledge proofs of Ch. 82 copy a party's state and run it twice. Quantum states cannot be copied, and the reason is one line of linear algebra. Quantum evolution is a unitary, hence linear and inner-product-preserving, map U. Suppose some U cloned every state, $U(\psi \otimes \chi_0) = \psi \otimes \psi$, using a fixed blank state χ_0. Taking inner products of the results for two unit states ψ, φ gives $\langle\varphi,\psi\rangle = \langle\varphi,\psi\rangle^2$. So $\langle\varphi,\psi\rangle$ is 0 or 1: only states that are identical or perfectly distinguishable can be cloned, never a general superposition (Wootters–Zurek and Dieks, 1982). A classical memory can be copied freely, because a classical state is a point, not a vector in a space of superpositions. In quantum theory every state is such a vector, which is what makes copying impossible and measurement disturbing.

Two other threads go elsewhere. Pontryagin's costate in Ch. 51 is the momentum of a variational problem, and the Hamilton–Jacobi–Bellman equation of Ch. 52 is the Hamilton–Jacobi equation of mechanics in disguise. Replacing paths $q(t)$ by fields $u(x,t)$ turns Euler–Lagrange into the wave and Maxwell equations, whose spectra are the business of Ch. 90.

Chapter 93 — Tensor Mathematics and Multilinear Algebra

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 10 (§10.7 SVD), Ch. 99, Ch. 59 · **Leads to:** Ch. 94, Ch. 95, Ch. 98 · **Related:** Ch. 26, Ch. 92, Ch. 62 **Reading time:** ~30 min

93.1 The hook

Multiply two 2×2 matrices the way you learned at school:

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} = \begin{pmatrix} a_{11}b_{11} + a_{12}b_{21} & a_{11}b_{12} + a_{12}b_{22} \\ a_{21}b_{11} + a_{22}b_{21} & a_{21}b_{12} + a_{22}b_{22} \end{pmatrix}.$$

That takes eight multiplications. For more than a century nobody seriously asked whether eight was necessary. In 1969 Volker Strassen, trying to *prove* that it was, found seven:

$$\begin{aligned} M_1 &= (a_{11} + a_{22})(b_{11} + b_{22}), & M_2 &= (a_{21} + a_{22})\,b_{11}, & M_3 &= a_{11}(b_{12} - b_{22}), \\ M_4 &= a_{22}(b_{21} - b_{11}), & M_5 &= (a_{11} + a_{12})\,b_{22}, & M_6 &= (a_{21} - a_{11})(b_{11} + b_{12}), \\ M_7 &= (a_{12} - a_{22})(b_{21} + b_{22}), \end{aligned}$$

and then $c_{11} = M_1 + M_4 - M_5 + M_7$, $c_{12} = M_3 + M_5$, $c_{21} = M_2 + M_4$, $c_{22} = M_1 - M_2 + M_3 + M_6$. Expand and check: every unwanted cross term cancels. Applied recursively to blocks, saving one multiplication in eight turns n^3 into $n^{2.807}$ (Ch. 26).

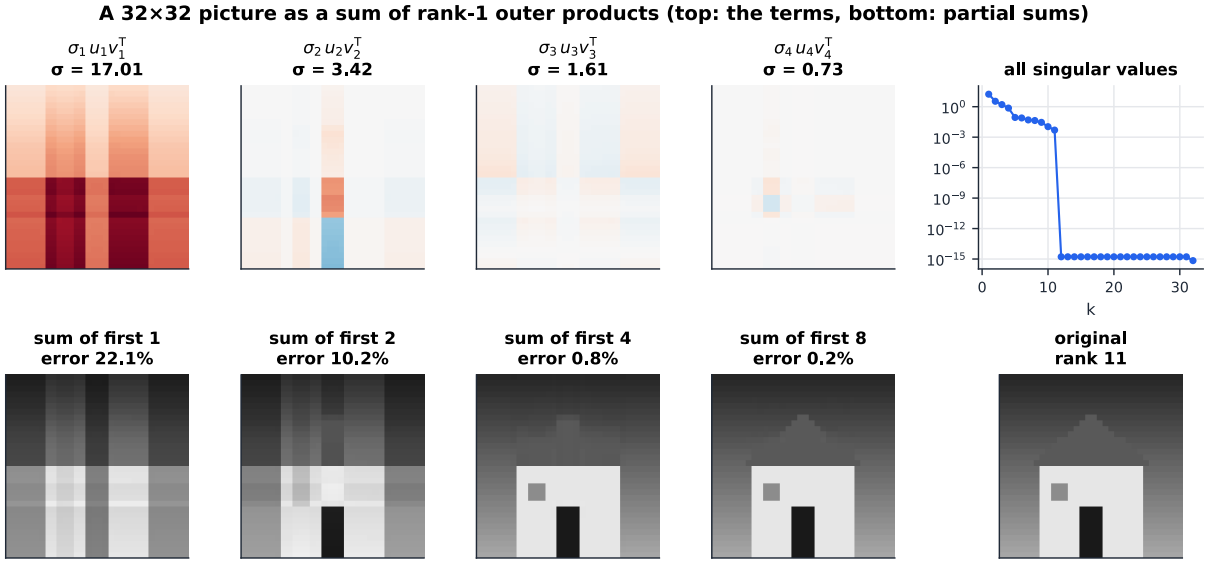
Two years later Winograd proved that seven is optimal for 2×2. For 3×3 matrices the best known algorithm (Laderman, 1976) uses 23 multiplications, the best lower bound is 19, and **nobody knows the true answer**. It is a question about 81 numbers that half a century of effort, and a reinforcement-learning system, has not settled.

The surprise this chapter builds on is that "how many multiplications?" is not really a question about algorithms. It asks for the **rank** of a certain three-dimensional array of zeros and ones. For a two-dimensional array, a matrix, rank is the most tractable number in linear algebra: Gaussian elimination computes it in a fraction of a second. Add a third index and computing rank becomes NP-hard, best approximations can fail to exist, and the answer can depend on whether you allow complex numbers.

> **Why does one extra index turn the easiest problem in linear algebra into one of the hardest?**

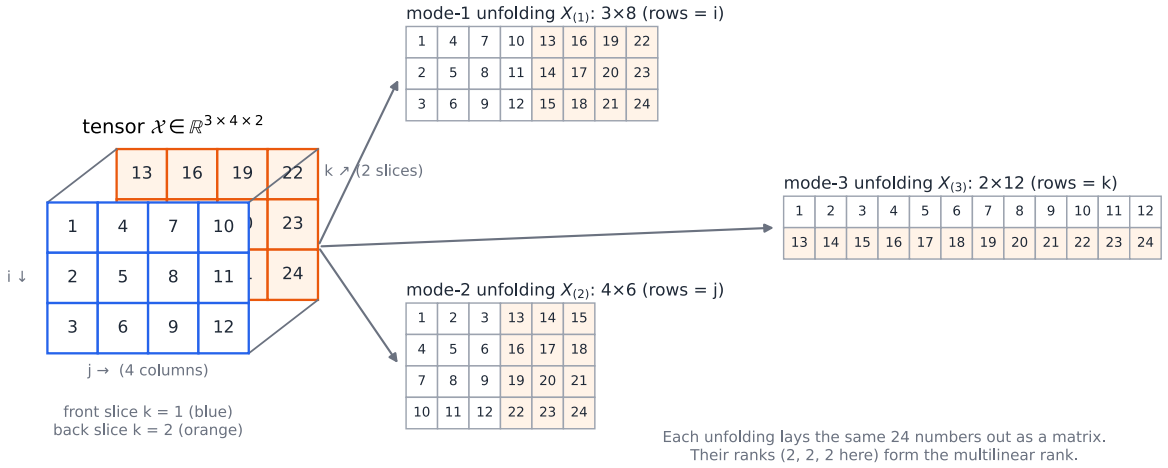
93.2 The big idea

A matrix is a sum of outer products. The singular value decomposition (§10.7) writes any matrix as $\mathbf{M} = \sum_k \sigma_k \mathbf{u}_k \mathbf{v}_k^{\mathsf{T}}$. Each term $\mathbf{u}\mathbf{v}^{\mathsf{T}}$ is the simplest possible matrix: every row is a multiple of the same row. The **rank** is the fewest such terms you need. Truncating the sum after r terms gives the best rank-r approximation (Eckart–Young), which is how a picture can be stored as a handful of vectors.



A 32×32 picture is a sum of outer products. Each term (top) is a "plaid" of one column pattern times one row pattern. Four of them reproduce the house to within 0.8%, and eleven reproduce it exactly: its rank is 11.

A tensor is a cube of numbers, and the same idea applies. An array $\mathcal{X}$ with entries x_{ijk} is a third-order tensor. The simplest cube is an outer product of three vectors, $(\mathbf{a} \otimes \mathbf{b} \otimes \mathbf{c})_{ijk} = a_i b_j c_k$. The **rank** of $\mathcal{X}$ is again the fewest such terms that sum to it. You can also slice the cube and lay the slices side by side, in three different ways. These **unfoldings** are ordinary matrices, and matrix tools apply to them.



A $3 \times 4 \times 2$ tensor and its three unfoldings. Each unfolding keeps one index as the row index and merges the other two into the column index.

The catch is that no unfolding tells you the tensor's rank. Each unfolding is a different "shadow" of the cube, and the cube can be far more complicated than any of its shadows.

An analogy for the tensor product. Suppose you want to multiply a vector by a vector and get *something*, demanding nothing except that the product be linear in each factor. The tensor product $\mathbf{v} \otimes \mathbf{w}$ is the most honest answer: it remembers that bilinearity and nothing else. Every other bilinear product (the dot product, the cross product, matrix multiplication, the determinant of a pair of columns) is obtained from it by one linear map. It is the universal "blank form" on which every bilinear operation is written.

93.3 The mathematics

Multilinear maps and the tensor product

Let V and W be vector spaces over a field K with bases $e_1, \dots, e_m$ and $f_1, \dots, f_n$. A map $B : V \times W \to X$ is **bilinear** if it is linear in each argument when the other is held fixed. Bilinear maps are *not* linear maps on $V \times W$: for example $B(2v, 2w) = 4B(v, w)$, not $2B(v, w)$. Ch. 99 asked for a single space that converts them into linear maps. Here it is.

Tensor product (concrete form)

$V \otimes W$ is the vector space with basis the mn symbols $e_i \otimes f_j$. For $v = \sum_i v_i e_i$ and $w = \sum_j w_j f_j$, define $v \otimes w = \sum_{i,j} v_i w_j \, e_i \otimes f_j$.

The map $(v, w) \mapsto v \otimes w$ is bilinear by construction. In coordinates an element of $V \otimes W$ is an $m \times n$ array, and $v \otimes w$ is the outer product $\mathbf{v}\mathbf{w}^{\mathsf{T}}$.

Universal property

For every bilinear map $B : V \times W \to X$ there is exactly one *linear* map $\tilde{B} : V \otimes W \to X$ with $\tilde{B}(v \otimes w) = B(v, w)$ for all v, w.

Proof. Existence: a linear map may be prescribed freely on a basis, so define $\tilde{B}(e_i \otimes f_j) = B(e_i, f_j)$ and extend linearly. Then, by bilinearity of B,

$$\tilde{B}(v \otimes w) = \sum_{i,j} v_i w_j \, \tilde{B}(e_i \otimes f_j) = \sum_{i,j} v_i w_j \, B(e_i, f_j) = B\Big(\sum_i v_i e_i, \sum_j w_j f_j\Big) = B(v, w).$$

Uniqueness: any such $\tilde{B}$ is forced to take the value $B(e_i, f_j)$ on each $e_i \otimes f_j$, and these elements form a basis. ■

The theorem also explains why the construction does not really depend on the bases. Any two spaces with the universal property are identified by a unique isomorphism that respects $\otimes$, by the standard argument of Ch. 62. Two consequences matter constantly.

Most tensors are not products. In coordinates $v \otimes w$ is a rank-1 matrix, so a general element of $V \otimes W$ is a *sum* $\sum_k v_k \otimes w_k$. The fewest terms needed is the matrix rank. In quantum mechanics, where the state space of two systems is $\mathcal{H}_1 \otimes \mathcal{H}_2$, a state that is not a single product is called **entangled**.

Linear maps are tensors, and upper and lower indices are vectors and covectors. The map $\varphi \otimes w \mapsto \big(v \mapsto \varphi(v)\, w\big)$ is an isomorphism $V^* \otimes W \cong \mathrm{Hom}(V, W)$, so a matrix *is* a tensor with one covector slot and one vector slot. Now change basis in V by $e'_a = \sum_i A^i{}_a e_i$. Components of a vector $v = \sum_i v^i e_i = \sum_a v'^a e'_a$ must transform by the *inverse* matrix, $v'^a = \sum_i (A^{-1})^a{}_i v^i$. Components of a covector, $\varphi_a = \varphi(e'_a) = \sum_i A^i{}_a \varphi_i$, transform by A itself. Physicists record the difference by writing vector indices up and covector indices down. An element of $V^{\otimes r} \otimes (V^*)^{\otimes s}$ has r upper and s lower indices, and its components pick up one factor of A^{-1} per upper index and one factor of A per lower index. On a manifold, with A the Jacobian of a coordinate change, this is exactly the "one Jacobian factor per index" rule for the metric in Ch. 59. A tensor in the physicist's sense is an element of a tensor product, and the transformation law is what that looks like in coordinates.

Rank, and matrix multiplication as a tensor

For three spaces, $U \otimes V \otimes W$ has basis $e_i \otimes f_j \otimes g_k$, its elements are $I \times J \times K$ arrays, and the **rank** of $\mathcal{T}$ is the least R with

$$\mathcal{T} = \sum_{r=1}^{R} \mathbf{u}_r \otimes \mathbf{v}_r \otimes \mathbf{w}_r .$$

This is the **CP decomposition** (canonical polyadic, also called CANDECOMP/PARAFAC). Write $\operatorname{vec}\mathbf{A}$ for the n^2 entries of $\mathbf{A}$ as one vector. Matrix multiplication $\mathbf{C} = \mathbf{A}\mathbf{B}$ is a bilinear map $K^{n^2} \times K^{n^2} \to K^{n^2}$, and by the universal property it corresponds to a tensor $\mathcal{M}_n$ with $n^2 \times n^2 \times n^2$ entries. Its entry is 1 at position $\big((a,b),(b,c),(a,c)\big)$, because $a_{ab}b_{bc}$ contributes to c_{ac}, and 0 elsewhere.

> **Multiplications = rank**
>
> $n \times n$ matrices can be multiplied by a bilinear algorithm that uses R multiplications if and only if $\operatorname{rank}\mathcal{M}_n \le R$.

Proof. A bilinear algorithm forms R products $m_r = (\mathbf{u}_r \cdot \operatorname{vec}\mathbf{A})(\mathbf{v}_r \cdot \operatorname{vec}\mathbf{B})$ and outputs $\operatorname{vec}\mathbf{C} = \sum_r m_r \mathbf{w}_r$. Read off the coefficient of $a_\alpha b_\beta$ in the γ-th output. The algorithm computes $c_\gamma = \sum_{\alpha,\beta} (\mathcal{M}_n)_{\alpha\beta\gamma} a_\alpha b_\beta$ exactly when

$$(\mathcal{M}_n)_{\alpha\beta\gamma} = \sum_{r=1}^{R} (\mathbf{u}_r)_\alpha (\mathbf{v}_r)_\beta (\mathbf{w}_r)_\gamma \quad \text{for all } \alpha,\beta,\gamma,$$

that is, when $\mathcal{M}_n = \sum_r \mathbf{u}_r \otimes \mathbf{v}_r \otimes \mathbf{w}_r$. Conversely, any such decomposition *is* an algorithm, with the vectors as its coefficients. ∎

The schoolbook method is the decomposition of $\mathcal{M}_2$ into its eight nonzero entries. Strassen's is a decomposition into seven rank-1 terms. For instance M_1 is $\mathbf{u}_1 = \mathbf{v}_1 = (1,0,0,1)$ (that is, $a_{11}+a_{22}$ and $b_{11}+b_{22}$), and since M_1 appears in c_{11} and c_{22}, $\mathbf{w}_1 = (1,0,0,1)$. Winograd's theorem says $\operatorname{rank}\mathcal{M}_2 = 7$. How such a finite rank becomes the asymptotic exponent $\omega \le \log_n R$ is proved in Ch. 98.

Where matrix intuition breaks

For matrices, the set of matrices of rank at most r is closed: a limit of rank-r matrices has rank at most r, because rank is detected by the vanishing of $(r+1)\times(r+1)$ minors, which are continuous functions. For tensors this fails.

> **A tensor that rank-2 tensors approximate arbitrarily well**
>
> Let $\mathbf{a},\mathbf{b}$ be linearly independent and $\mathcal{W} = \mathbf{a}\otimes\mathbf{a}\otimes\mathbf{b} + \mathbf{a}\otimes\mathbf{b}\otimes\mathbf{a} + \mathbf{b}\otimes\mathbf{a}\otimes\mathbf{a}$. Then $\mathcal{W}$ has rank 3, yet it is the limit of the rank-2 tensors
>
> $$\mathcal{T}_\varepsilon = \frac{1}{\varepsilon}\Big[(\mathbf{a}+\varepsilon\mathbf{b})^{\otimes 3} - \mathbf{a}^{\otimes 3}\Big] \qquad \text{as } \varepsilon \to 0.$$

Proof of the limit. Expand $(\mathbf{a}+\varepsilon\mathbf{b})^{\otimes 3}$ by multilinearity into eight terms. The ε^0 term is $\mathbf{a}^{\otimes 3}$, which cancels. The three ε^1 terms, divided by ε, are exactly $\mathcal{W}$. What remains is $\varepsilon(\mathbf{a}\otimes\mathbf{b}\otimes\mathbf{b} + \mathbf{b}\otimes\mathbf{a}\otimes\mathbf{b} + \mathbf{b}\otimes\mathbf{b}\otimes\mathbf{a}) + \varepsilon^2\mathbf{b}^{\otimes 3} \to 0$. With orthonormal $\mathbf{a},\mathbf{b}$, $\|\mathcal{T}_\varepsilon - \mathcal{W}\| = \varepsilon\sqrt{3+\varepsilon^2}$. That $\mathcal{W}$ itself has rank 3, not 2, takes a short but careful argument; see de Silva and Lim (2008). ∎

Look at the price of the approximation. The two rank-1 terms have norm about $1/\varepsilon$ each, and they nearly cancel. This is the **degeneracy** that makes CP fitting so treacherous. If you ask for the best rank-2 approximation of $\mathcal{W}$, there is none. The error can be made as small as you like, but never zero, and the factors blow up as you try. The least r such that $\mathcal{T}$ is a limit of rank-r tensors is called its **border rank**. The record exponents for matrix multiplication since 1979 have all come from border rank.

The other differences from matrices are just as stark:

property	matrices	tensors of order ≥ 3
computing rank	Gaussian elimination, polynomial time	NP-hard (Håstad 1990)
best rank-r approximation	always exists (Eckart–Young)	may not exist
rank over $\mathbb{R}$ vs $\mathbb{C}$	the same	can differ
rank of a random array	full, $\min(m,n)$, with probability 1	several "typical" ranks may each have positive probability
maximum rank	$\min(m,n)$	can exceed every side length

For instance, a random real $2\times2\times2$ tensor with Gaussian entries has rank 2 with probability $\pi/4 \approx 0.785$ and rank 3 otherwise. Over $\mathbb{C}$ it has rank 2 with probability 1. The dividing line is the sign of a single polynomial in the eight entries, Cayley's hyperdeterminant. Its exact role is a matter for Ch. 94.

> **? Which tensors have border rank r?**
>
> The tensors of border rank at most r form a closed set cut out by polynomial equations: it is an algebraic variety, called a **secant variety**. Its equations certify lower bounds. If such a polynomial does not vanish on $\mathcal{M}_n$, then $\mathcal{M}_n$ needs more than r terms, even approximately. Finding those polynomials is how Landsberg proved in 2006 that the border rank of $\mathcal{M}_2$ is also 7. For general n, nobody knows the equations, and proving that $\mathcal{M}_n$ has border rank much larger than n^2 is wide open. The language of varieties and ideals that this program needs starts in Ch. 94.

Answer from Chapter 59: the Riemann curvature tensor

Ch. 59 asked how an ant can compute the Gaussian curvature $K = \kappa_1\kappa_2$ from the metric alone. Here is the tensor answer. Carry a tangent vector $\mathbf{v}$ by parallel transport around a tiny loop spanned by two coordinate directions μ,ν, with coordinate area δA. It returns changed by $\delta v^\rho \approx -R^\rho{}_{\sigma\mu\nu} v^\sigma \, \delta A$ (the sign depends on the orientation convention), where

$$R^{\rho}{}_{\sigma\mu\nu} = \partial_\mu \Gamma^{\rho}_{\nu\sigma} - \partial_\nu \Gamma^{\rho}_{\mu\sigma} + \sum_{\lambda} \left(\Gamma^{\rho}_{\mu\lambda}\Gamma^{\lambda}_{\nu\sigma} - \Gamma^{\rho}_{\nu\lambda}\Gamma^{\lambda}_{\mu\sigma} \right).$$

Three facts carry the argument.

1. **It is a tensor.** The Christoffel symbols Γ are *not* tensors: they can be made zero at any one point by a clever choice of coordinates. Yet the combination above transforms with one Jacobian factor per index. It can be written without coordinates as $R(X,Y)Z = \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X,Y]} Z$, a failure of covariant derivatives to commute. So if it vanishes in one chart it vanishes in all, and it is a property of the geometry, not of the coordinates.
2. **It is built from the metric alone.** The Γ's come from first derivatives of g_{ij}, so R needs nothing but g and its first two derivatives. An insider can compute it.
3. **On a surface it is one number.** With all indices lowered, $R_{\rho\sigma\mu\nu}$ is antisymmetric in (ρ,σ) and in (μ,ν), symmetric under swapping the two pairs, and satisfies a cyclic identity. In n dimensions these symmetries leave $n^2(n^2-1)/12$ independent components, which is 1, 6 and 20 for $n = 2, 3, 4$. On a surface the single component is $R_{1212} = K\,(g_{11}g_{22} - g_{12}^2)$, so

$$K = \frac{R_{1212}}{\det g},$$

which depends only on g. That is the Theorema Egregium, and the reason behind Gauss's "page of brute calculation". The six components in three dimensions and the twenty in four are why one number no longer suffices there, and why Einstein's equations constrain only part of the curvature (Ch. 92).

93.4 The algorithm

Alternating least squares (CP-ALS). Fitting $\mathcal{T} \approx \sum_{r} \mathbf{u}_r \otimes \mathbf{v}_r \otimes \mathbf{w}_r$ is a nonconvex problem in all the factors at once. If you freeze $\mathbf{V} = [\mathbf{v}_1 \cdots \mathbf{v}_R]$ and $\mathbf{W}$, however, the model is *linear* in $\mathbf{U}$, and minimising the squared error over $\mathbf{U}$ is an ordinary least-squares problem (§9.11). Its normal equations have a pleasantly small matrix:

$$\mathbf{U}\left[(\mathbf{V}^{\mathsf T}\mathbf{V}) * (\mathbf{W}^{\mathsf T}\mathbf{W})\right] = \mathbf{G}, \qquad G_{ir} = \sum_{j,k} T_{ijk} V_{jr} W_{kr},$$

where $*$ is the entrywise product of two $R \times R$ matrices. (The left side is $\mathbf{U}$ times the Gram matrix of the columns of the Khatri–Rao product of $\mathbf{W}$ and $\mathbf{V}$.) Cycle through $\mathbf{U}$, $\mathbf{V}$, $\mathbf{W}$ and repeat:

```
import numpy as np

def cp_als(T, R, iters=500, lam=0.0, seed=0):
    rng = np.random.default_rng(seed)
    U, V, W = (rng.standard_normal((s, R)) for s in T.shape)
    reg = lam * np.eye(R)
    for _ in range(iters):
        U = np.einsum('ijk,jr,kr->ir', T, V, W) @ np.linalg.inv((V.T @ V) * (W.T @ W) + reg)
        V = np.einsum('ijk,ir,kr->jr', T, U, W) @ np.linalg.inv((U.T @ U) * (W.T @ W) + reg)
        W = np.einsum('ijk,ir,jr->kr', T, U, V) @ np.linalg.inv((U.T @ U) * (V.T @ V) + reg)
    return U, V, W
```

Each sweep costs $O(IJKR)$ for the three contractions plus $O(R^3)$ for the small solves. The error never increases from one update to the next, because each update is an exact minimisation over its block.

The Tucker form and the HOSVD. A different decomposition gives up the minimal number of terms in exchange for stability. Take the SVD of each unfolding, keep the leading r_1, r_2, r_3 left singular vectors as $\mathbf{Q}_1, \mathbf{Q}_2, \mathbf{Q}_3$, and project: $\mathcal{G} = \mathcal{T} \times_1 \mathbf{Q}_1^{\mathsf T} \times_2 \mathbf{Q}_2^{\mathsf T} \times_3 \mathbf{Q}_3^{\mathsf T}$, so that $\mathcal{T} \approx \mathcal{G} \times_1 \mathbf{Q}_1 \times_2 \mathbf{Q}_2 \times_3 \mathbf{Q}_3$. This is the **higher-order SVD** (De Lathauwer, De Moor and Vandewalle, 2000). It is computed by three ordinary SVDs, is never degenerate, and its error is within a factor $\sqrt{3}$ of the best possible for those sizes. The triple (r_1, r_2, r_3) of unfolding ranks is the **multilinear rank**, computable in polynomial time, unlike the CP rank. In the figure of §93.2 it is $(2, 2, 2)$. The price is a dense core $\mathcal{G}$ of size $r_1 r_2 r_3$, which grows exponentially with the number of indices. Tensor trains, also called matrix product states, are the modern fix for that.

Failure cases.

- *Wrong R.* Nothing in ALS tells you the rank. Too small and the fit stalls; too large and the factors become non-unique and can drift.
- *Degeneracy.* When the best rank-R approximation does not exist, as for $\mathcal{W}$, ALS drives pairs of factors to infinity with opposite signs while the error creeps down. The small ridge term `lam` in the code is the usual cure: it penalises large factors and keeps the problem well posed.
- *Swamps.* ALS can spend thousands of sweeps on a plateau where the error barely moves, then suddenly converge. Line searches, damped Gauss–Newton (Levenberg–Marquardt) and random restarts all help, but no method is guaranteed to work.
- *Uniqueness, the good news.* Unlike a matrix factorisation, which can always be rotated ($\mathbf{U}\mathbf{V}^{\mathsf T} = (\mathbf{U}\mathbf{Q})(\mathbf{V}\mathbf{Q})^{\mathsf T}$), a CP decomposition is usually *unique* up to scaling and reordering of its terms. Kruskal's theorem (1977) gives a sufficient condition. This is why chemists can separate the spectra of overlapping fluorescent compounds from a three-way array, and why psychometricians invented PARAFAC in the first place.

93.5 The experiment

Rediscover Strassen. This script builds the $4 \times 4 \times 4$ tensor $\mathcal{M}_2$ and asks CP-ALS for decompositions of rank 8, 7 and 6, from ten random starting points each. The regulariser starts at 10^{-3} and fades out.

```
import numpy as np

n = 2                                          # multiply n x n matrices
T = np.zeros((n * n, n * n, n * n))            # matrix multiplication tensor
for a in range(n):
    for b in range(n):
        for c in range(n):
            T[a * n + b, b * n + c, a * n + c] = 1   # c_ac += a_ab * b_bc

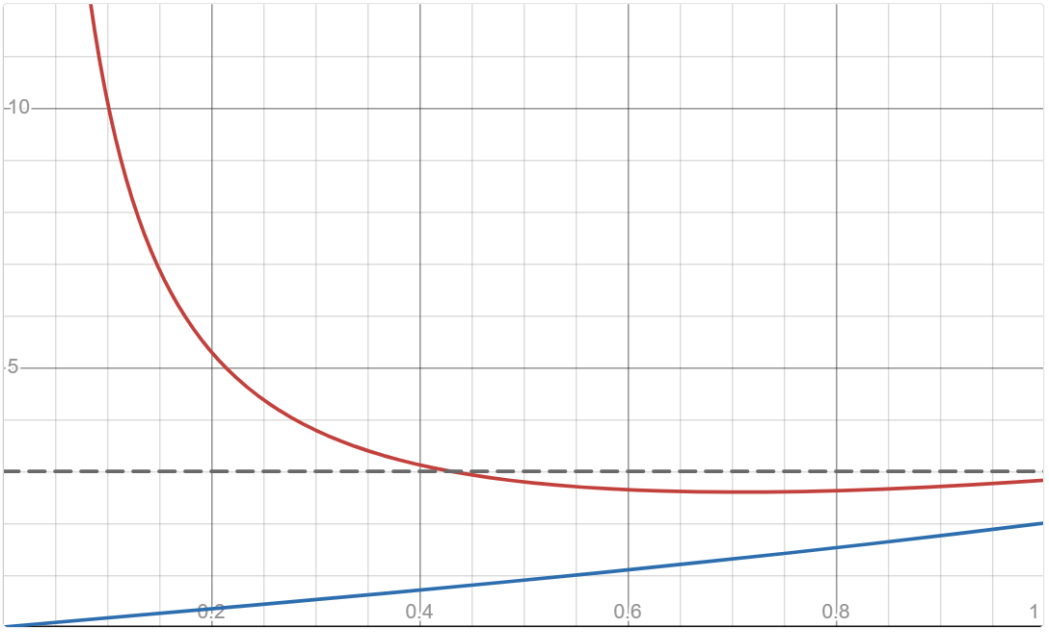
def cp_als(T, R, iters=3000, lam=1e-3, seed=0):
    rng = np.random.default_rng(seed)
    U, V, W = (rng.standard_normal((s, R)) for s in T.shape)
    for _ in range(iters):                     # each update is a linear least-squares solve
        U = np.einsum('ijk,jr,kr->ir', T, V, W) @ np.linalg.inv((V.T @ V) * (W.T @ W) + lam * np.eye(R))
        V = np.einsum('ijk,ir,kr->jr', T, U, W) @ np.linalg.inv((U.T @ U) * (W.T @ W) + lam * np.eye(R))
        W = np.einsum('ijk,ir,jr->kr', T, U, V) @ np.linalg.inv((U.T @ U) * (V.T @ V) + lam * np.eye(R))
        lam *= 0.995                           # fade out the regulariser
    approx = np.einsum('ir,jr,kr->ijk', U, V, W)
    return np.linalg.norm(T - approx)

for R in (8, 7, 6):
    errs = [cp_als(T, R, seed=s) for s in range(10)]
    print(f"rank {R}: best residual over 10 starts = {min(errs):.2e}, "
          f"successes = {sum(e < 1e-3 for e in errs)}/10")
```

On a typical run, rank 8 and rank 7 succeed from all ten starts, with residuals around 3×10^{-9}. Rank 6 fails every time, and the residual sticks at about 1.0. By de Groote's theorem (1978), every rank-7 decomposition is Strassen's algorithm in disguise, transformed by the symmetries of $\mathcal{M}_2$, so the script keeps rediscovering Strassen with messier real coefficients. Things to change:

- Print the factor matrices of a rank-7 solution and compute $\mathbf{U}^{\mathsf{T}}\mathbf{U}$. The columns are not orthogonal, unlike the SVD's. Can you rescale them to recover entries near $0, \pm 1$?
- Set `n = 3` and try `R = 23`, Laderman's count. Plain ALS usually stalls with a residual of a few percent. Add restarts, longer runs or a slower fade of `lam`, and see whether you can reach Laderman. Nobody knows whether `R = 22` is possible.
- Set `lam = 0` from the start and watch some rank-7 runs blow up or crawl: that is degeneracy and swamps in action.

Border rank in one picture. For $\mathcal{T}_\varepsilon$ in §93.3 with orthonormal $\mathbf{a}, \mathbf{b}$, the blue curve is the approximation error $\varepsilon\sqrt{3+\varepsilon^2}$ and the red curve is the size $(1+\varepsilon^2)^{3/2}/\varepsilon$ of each rank-1 term, with x playing the role of ε.



As $\varepsilon \to 0$ the error (blue) vanishes while the two rank-1 terms (red) blow up. The dashed line at 3 is the total size of the honest rank-3 decomposition: three unit terms.

Change the blue curve to $y = x^2$ to see what a second-order error would look like. Then try to invent a family whose error falls like ε^2 while its terms grow only like $1/\varepsilon$. (Hint: combine $(\mathbf{a} + \varepsilon\mathbf{b})^{\otimes 3}$ and $(\mathbf{a} - \varepsilon\mathbf{b})^{\otimes 3}$.)

93.6 The challenge

1. **Intuition.** Explain without computation why every unfolding of a rank-R tensor has matrix rank at most R. Then explain why the converse fails: the three unfoldings of $\mathcal{W}$ all have rank 2, yet $\mathcal{W}$ has rank 3.
2. **Derivation.** Prove that $V^* \otimes W \to \operatorname{Hom}(V, W)$, $\varphi \otimes w \mapsto (v \mapsto \varphi(v)w)$, is an isomorphism for finite-dimensional spaces, and that under it the rank of a tensor equals the rank of the linear map. Then show that the contraction $V^* \otimes V \to K$, $\varphi \otimes v \mapsto \varphi(v)$, corresponds to the trace, which gives a basis-free proof that the trace is basis-independent.
3. **Implementation.** Write the HOSVD of §93.4 and apply it to a $64 \times 64 \times 3$ colour image, or to a stack of 30 frames of a slowly changing synthetic video. Compare its storage and error with a separate SVD of each frame and with CP-ALS at equal storage. Which wins, and why?

4. **Open investigation.** For random real $2 \times 2 \times 2$ tensors the probability of rank 2 is $\pi/4$. Estimate by simulation the probabilities of each typical rank for random real $3 \times 3 \times 2$, $2 \times 2 \times 3$ and $3 \times 3 \times 3$ tensors, by deciding rank with a numerical test of your choice. How reliable is your test near the boundary between ranks, and can you find a closed form for any of these probabilities?

93.7 Loose threads

Two more mysteries lead beyond this chapter.

? What do the symmetries of $V^{\otimes n}$ decompose into?

The space $V \otimes V$ splits into symmetric tensors ($T_{ij} = T_{ji}$) and antisymmetric ones ($T_{ij} = -T_{ji}$). The determinant forms of Ch. 99 live in the fully antisymmetric part of $V^{\otimes n}$. For three or more factors these two pieces no longer account for everything, and the leftover parts are indexed by **Young diagrams**. Schur–Weyl duality says that the general linear group acting on each factor and the permutation group shuffling the factors split $V^{\otimes n}$ into irreducible pieces in perfectly matched pairs. Why the pieces are counted by partitions of n, and why those same pieces label the particle states of Ch. 92, is the subject of Ch. 95.

? Twenty-two multiplications?

The rank of $\mathcal{M}_3$ lies between 19 and 23, For 4×4 the classic count is Strassen applied twice, 49; AlphaTensor found 47 in arithmetic modulo 2, and the true rank is unknown. A single tensor of $9 \times 9 \times 9 = 729$ zeros and ones has resisted fifty years of human ingenuity and machine search. Settling its rank is an **open problem**. How finite gadgets like this feed the exponent ω, and how researchers attack such problems, is in Ch. 98.

The tensors of physics have also not been exhausted. The stress tensor of elasticity, the electromagnetic field tensor $F_{\mu\nu}$ and the curvature tensors above are all elements of tensor products of a tangent space and its dual. In each case, the symmetries of the tensor (symmetric, antisymmetric, the curvature identities) decide how many independent numbers the physics contains. Machine learning uses "tensor" more loosely, for any multi-index array, but its successes with low-rank structure are real: CP and tensor-train factorisations compress the weight arrays of neural networks, and attention layers are bilinear maps in disguise. Whether *generic* data have low tensor rank, and why the hard cases of the table in §93.3 rarely bite in practice, is an active research area with few theorems.

Chapter 94 — Algebraic Geometry: Solving Equations Through Shapes

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 1 (§1.4 polynomials), Ch. 56 (rings and fields), Ch. 18 · **Leads to:** Ch. 95, Ch. 78, Ch. 98 · **Related:** Ch. 57, Ch. 75, Ch. 82, Ch. 93 **Reading time:** ~30 min

94.1 The hook

A planar robot arm has its shoulder bolted to the origin, an upper arm of length 2 and a forearm of length 1. You want its hand at the point $(2, 1)$. Where must the elbow go?

The elbow (u, v) is at distance 2 from the shoulder and distance 1 from the hand:

$$u^2 + v^2 = 4, \qquad (u-2)^2 + (v-1)^2 = 1.$$

Subtract the two equations and the squares cancel, leaving the line $2u + v = 4$. Substitute $v = 4 - 2u$ back into the first equation to get $5u^2 - 16u + 12 = 0$, so $u = 2$ or $u = 1.2$. The two elbows are $(2, 0)$ ("elbow down") and $(1.2, 1.6)$ ("elbow up"). Every robotics engineer knows this answer.

Now look at it as a mathematician would. Each equation has degree 2: each describes a **conic**. There is a famous theorem, stated by Newton and Bézout and proved properly much later, that two curves of degrees d and e meet in **exactly** de **points**. For two conics that means four. An ellipse and a hyperbola really do meet in four points. But two different circles *never* meet in more than two. You can slide them about as you like and you will never find a third intersection.

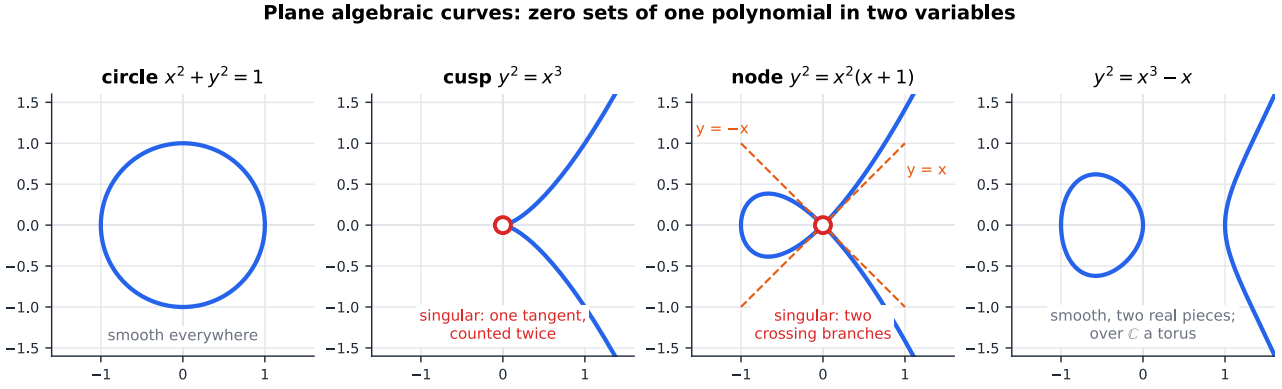
So either Bézout's theorem is false, or two intersection points of every pair of circles are hiding somewhere.

> **Where are the two missing intersection points of two circles?**

Answering it means changing what "point" means. Allow complex coordinates and add points at infinity, and polynomial equations stop behaving erratically and start obeying exact counting laws. That change of viewpoint, from equations to the *shapes* they define and back, is algebraic geometry. It now underlies robot kinematics, computer-aided design, elliptic-curve cryptography and the proof of Fermat's Last Theorem.

94.2 The big idea

Idea 1: an equation is a shape. The set of points where a polynomial vanishes is a geometric object: $x^2 + y^2 - 1 = 0$ is a circle, $y^2 - x^3 = 0$ is a curve with a sharp point. Such zero sets are called **varieties**. Their geometry, such as how many pieces they have, where they are pointed or self-crossing, and how they meet, tells you about the equations. In return, algebra about the polynomials, such as factoring, substituting and eliminating, tells you about the shapes.



Four plane curves. The cusp and the node have singular points, circled in red, where the curve fails to look like a smooth line. The last curve is an elliptic curve. Its real points form two pieces, but its complex points, together with one point at infinity, form a single torus.

Idea 2: the shape doesn't care which equations you wrote. The circle is described by $x^2 + y^2 - 1 = 0$, but equally by $(x^2 + y^2 - 1)(x^2 + 1) = 0$, or by any system of equations whose consequences are the same. What actually determines the shape is the set of *all* polynomials that follow from the equations by adding and multiplying. That set is an **ideal**, and ideals are the algebraic shadows of shapes.

Idea 3: functions on the shape form a ring, and the ring knows everything. On the circle, x^2 and $1 - y^2$ are the same function, because they agree at every point. Identify polynomials that agree on the shape and you get the **coordinate ring**: the algebra of polynomial functions on the variety. Two shapes are "the same" exactly when their coordinate rings are the same ring. Geometry turns into ring theory, and the ring theory of Ch. 56 gets a picture.

An analogy: a variety is a building, and its coordinate ring is the complete set of measurements you could take inside it. Two buildings that give identical answers to every possible measurement are, for every practical purpose, the same building.

94.3 The mathematics

Fix a field k, usually $\mathbb{R}$ or $\mathbb{C}$, and the polynomial ring $k[x_1, \ldots, x_n]$.

Affine variety and ideal

For polynomials $f_1, \dots, f_m$, the **affine variety** they define is

$$V(f_1, \dots, f_m) = \{\mathbf{a} \in k^n : f_1(\mathbf{a}) = \cdots = f_m(\mathbf{a}) = 0\}.$$

The **ideal** they generate is $\langle f_1, \dots, f_m \rangle = \{h_1 f_1 + \cdots + h_m f_m : h_i \in k[x_1, \dots, x_n]\}$.

Every element of the ideal vanishes wherever all the f_i do. So $V(f_1, \dots, f_m)$ depends only on the ideal, and any other generators of the same ideal describe the same set. The robot arm's trick of subtracting equations was a change of generators: $\langle f_1, f_2 \rangle = \langle f_1,\ f_1 - f_2 \rangle$. Two set operations have one-line algebraic counterparts: $V(f) \cup V(g) = V(fg)$ (a product vanishes when a factor does) and $V(f) \cap V(g) = V(f, g)$.

Going the other way, from a set $X \subseteq k^n$ to polynomials, gives the ideal $I(X)$ of all polynomials vanishing on X. Two classical theorems make the dictionary work.

- **Hilbert's basis theorem (1890).** Every ideal of $k[x_1, \dots, x_n]$ is generated by finitely many polynomials. So every variety, even one described by infinitely many equations, is cut out by finitely many.
- **Hilbert's Nullstellensatz (1893).** Over $\mathbb{C}$, or any algebraically closed field: $V(J) = \varnothing$ only if $1 \in J$, and in general $I(V(J))$ is the **radical** $\sqrt{J} = \{f : f^r \in J \text{ for some } r\}$.

The Nullstellensatz fails over $\mathbb{R}$: $x^2 + y^2 + 1$ has no real zeros, yet $1 \notin \langle x^2 + y^2 + 1 \rangle$. This is the first sign that the reals are the wrong place to count solutions, just as the real numbers were the wrong place to count roots of $x^2 + 1$ (Ch. 1).

Smooth and singular points

A point $\mathbf{a}$ of the plane curve $V(f)$ is **singular** if $\nabla f(\mathbf{a}) = \mathbf{0}$. At a non-singular point the implicit function theorem (Ch. 6) makes the curve locally the graph of a smooth function. At a singular point it can fail.

- **Cusp**, $f = y^2 - x^3$. Here $\nabla f = (-3x^2, 2y)$, which vanishes only at the origin, and the origin lies on the curve. Near it, the lowest-order part of f is y^2: one tangent line $y = 0$, counted twice. The curve arrives along it from both sides and turns back.
- **Node**, $f = y^2 - x^2(x+1) = y^2 - x^2 - x^3$. Here $\nabla f = (-2x - 3x^2,\ 2y)$, which vanishes at $(0, 0)$ and at $(-\tfrac{2}{3}, 0)$. Only the origin lies on the curve. The lowest-order part, $y^2 - x^2 = (y - x)(y + x)$, gives two distinct tangent lines $y = \pm x$: two branches cross.

For the family $y^2 = x^3 + ax + b$, the curve is singular exactly when the cubic $x^3 + ax + b$ has a repeated root, that is, when $4a^3 + 27b^2 = 0$. The cusp is $a = b = 0$. For $a = -3$, $b = 2$ the discriminant is $4(-3)^3 + 27 \cdot 2^2 = -108 + 108 = 0$, and indeed $x^3 - 3x + 2 = (x - 1)^2(x + 2)$: the curve $y^2 = x^3 - 3x + 2$ has a node at $(1, 0)$, just like the one in the figure. When the discriminant is nonzero the curve is smooth, and it is an **elliptic curve**, the object behind Ch. 78.

The coordinate ring

Coordinate ring

The **coordinate ring** of a variety $X \subseteq k^n$ is $k[X] = k[x_1, \dots, x_n]/I(X)$: polynomials, with two identified when they agree at every point of X.

A **polynomial map** $\phi : X \to Y$ between varieties is one given by polynomials in the coordinates. It induces the **pullback** $\phi^* : k[Y] \to k[X]$, $g \mapsto g \circ \phi$, a ring homomorphism. The arrows reverse direction. The central fact, which we state rather than prove, is that this correspondence is perfect: polynomial maps $X \to Y$ correspond exactly to k-algebra homomorphisms $k[Y] \to k[X]$. In particular X and Y are **isomorphic**, meaning there are polynomial maps both ways that are mutually inverse, if and only if $k[X] \cong k[Y]$.

The parabola is a line

The parabola $P = V(y - x^2)$ and the line k are isomorphic via $t \mapsto (t, t^2)$ and its inverse $(x, y) \mapsto x$, both polynomial. Correspondingly $k[x, y]/\langle y - x^2 \rangle \cong k[t]$: replace each y by x^2.

The cusp looks just as tame at first. The map $t \mapsto (t^2, t^3)$ is a bijection from the line onto $V(y^2 - x^3)$, and it is polynomial. Is the cusp a line too?

The cusp is not a line

There is no polynomial map from the cusp $C = V(y^2 - x^3)$ to the line that inverts $\phi(t) = (t^2, t^3)$. In fact C is not isomorphic to the line by any polynomial maps.

Proof of the first claim. An inverse would be a polynomial $h(x, y)$ with $h(t^2, t^3) = t$ for all t. But every monomial $x^a y^b$ becomes t^{2a+3b}, and $2a + 3b$ takes the values $0, 2, 3, 4, 5, \dots$ and *never* the value 1. So $h(t^2, t^3)$ has no t^1 term and cannot equal t. ∎

The same computation shows what the coordinate ring of the cusp *is*. Pulling back along ϕ identifies $k[C]$ with $k[t^2, t^3]$, the polynomials in t with no linear term. That ring is not $k[t]$. The quickest invariant that tells them apart is the dimension of the tangent space $\mathfrak{m}/\mathfrak{m}^2$ at the origin: it is 2 for the cusp, spanned by x and y, and 1 at every point of a line. So no isomorphism of any kind exists. The singularity is visible in the algebra as a "missing" function, $t = y/x$, which is defined on the cusp away from the origin but is not a polynomial.

Bézout's theorem, and the missing points

Two lines can be parallel, a circle and a line can miss each other, and a tangent line meets a parabola only once. To count intersections exactly, three repairs are needed.

1. **Complex points.** A circle and a line that "miss" meet at complex conjugate points.

2. **Points at infinity.** Parallel lines meet at infinity. Formally, the **projective plane** $\mathbb{P}^2$ is the set of nonzero triples $(x : y : z)$ up to scaling. The ordinary point (x, y) is $(x : y : 1)$, and the points with $z = 0$ form the line at infinity. A curve $f(x, y) = 0$ of degree d becomes the homogeneous equation $F(x, y, z) = z^d f(x/z, y/z) = 0$.
3. **Multiplicity.** A tangency counts twice, just as a double root of a polynomial counts twice.

Bézout's theorem

Two projective plane curves of degrees d and e over $\mathbb{C}$ with no common component meet in exactly de points, counted with multiplicity.

The general proof needs the resultant or intersection theory. The case $d = 1$ is a short argument that shows exactly why the three repairs are needed.

Proof for a line and a curve. Parametrise the projective line through two distinct points P and Q as $sP + tQ$, with $(s : t) \in \mathbb{P}^1$. Substituting into the homogeneous F of degree d gives $g(s, t) = F(sP + tQ)$, a homogeneous polynomial of degree d in (s, t). If $g \equiv 0$, the line is a component of the curve. Otherwise g factors over $\mathbb{C}$ into d linear factors $\prod_{i=1}^{d}(\beta_i s - \alpha_i t)$, by the fundamental theorem of algebra (Ch. 18) applied to $g(s, 1)$ together with the factors of t that account for roots "at $s = \infty$". Each factor is a point $(\alpha_i : \beta_i)$ of the line lying on the curve, and repeated factors are tangencies. So there are exactly d intersection points counted with multiplicity. ■

Without complex numbers, g might have no real factors. Without the projective line, the factors of t would be roots "at infinity" and would be lost. Without multiplicity, repeated factors would be undercounted. The theorem is clean only after all three repairs.

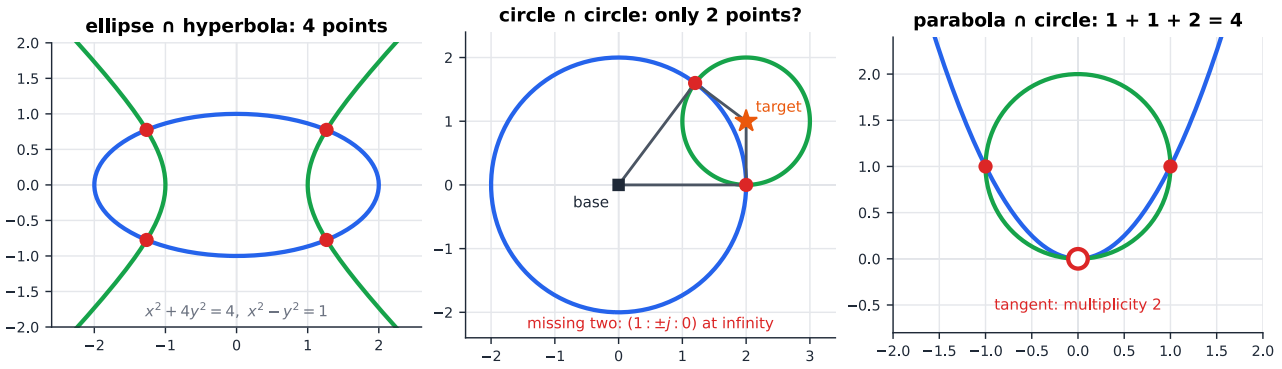
The answer to the hook. Any circle has equation $x^2 + y^2 + Dx + Ey + F = 0$, which homogenises to

$$x^2 + y^2 + Dxz + Eyz + Fz^2 = 0.$$

On the line at infinity, $z = 0$, this reduces to $x^2 + y^2 = 0$, that is, $(x + jy)(x - jy) = 0$. So *every circle*, whatever its centre and radius, passes through the two points

$$I = (1 : j : 0), \qquad J = (1 : -j : 0),$$

the **circular points at infinity**. Two circles share these two points, which leaves $4 - 2 = 2$ finite intersections. That is why the robot arm has at most two elbow positions, and why subtracting the two circle equations killed both squares: the difference of two circle equations has no $x^2 + y^2$ term, so it is a line, the line through the two finite intersections. Conversely, a conic through I and J is a circle. That is how projective geometers define a circle.



Bézout's count for conics. Left: four ordinary points. Middle: the robot arm's two circles meet at two real points; the other two are the circular points at infinity, shared by every circle. Right: $y = x^2$ and $x^2 + (y - 1)^2 = 1$ touch at the origin with multiplicity 2 and cross at $(\pm 1, 1)$, so $2 + 1 + 1 = 4$.

? Why is the chord-and-tangent rule associative?

Bézout says a line meets a cubic curve in exactly three points. On an elliptic curve that lets you "add" two points P and Q: draw the line through them, find the third intersection, and reflect it. Commutativity is obvious, since the line through P and Q is the line through Q and P. But why should $(P + Q) + R = P + (Q + R)$? Checked by brute algebra, it is a famously ugly computation. The conceptual proof uses Bézout again, this time for two cubics meeting in nine points: if eight of those points lie on a third cubic, so does the ninth. Why that is true, and how the group law becomes the backbone of modern cryptography, is in Ch. 78.

94.4 The algorithm

Gröbner bases: Gaussian elimination for polynomials. For linear equations, elimination (§8.7) turns any system into a triangular one: the last equation involves one unknown, the one before it two, and so on. A **Gröbner basis** does the same for polynomial systems. Fix a *monomial order*, a rule for which term of a polynomial is "leading". In **lex order** with $u > v$, any term containing a higher power of u wins. Then:

```
Buchberger(F):                    # F = list of polynomials generating the ideal
    G = F
    repeat:
        for each pair (f, g) in G:
            m = lcm(LT(f), LT(g))              # least common multiple of the leading terms
            S = (m / LT(f)) * f − (m / LT(g)) * g    # the S-polynomial cancels the leading terms
            r = remainder of S on division by G
            if r != 0: add r to G
    until no pair produces a new remainder
    return G
```

Buchberger's theorem (1965) says the loop always stops, by Hilbert's basis theorem, and that the result G generates the same ideal. With G in hand, every polynomial has a *unique* remainder on division by G. So $f \in \langle F \rangle$ if and only if its remainder is 0, and the ideal membership problem is solved. In lex order, the **elimination theorem** says the elements of G that involve only the last variable generate all consequences in that variable alone: the system has been triangularised.

The robot arm, by Buchberger. With $f_1 = u^2 + v^2 - 4$ and $f_2 = (u-2)^2 + (v-1)^2 - 1 = u^2 - 4u + v^2 - 2v + 4$, both leading terms are u^2. The S-polynomial is $f_1 - f_2 = 4u + 2v - 8$, which we halve to $g = 2u + v - 4$. Dividing f_1 by g (substitute $u = (4 - v)/2$) leaves the remainder $\tfrac{1}{4}(5v^2 - 8v)$. The reduced Gröbner basis is

$$\{\, 2u + v - 4,\;\; 5v^2 - 8v \,\}:$$

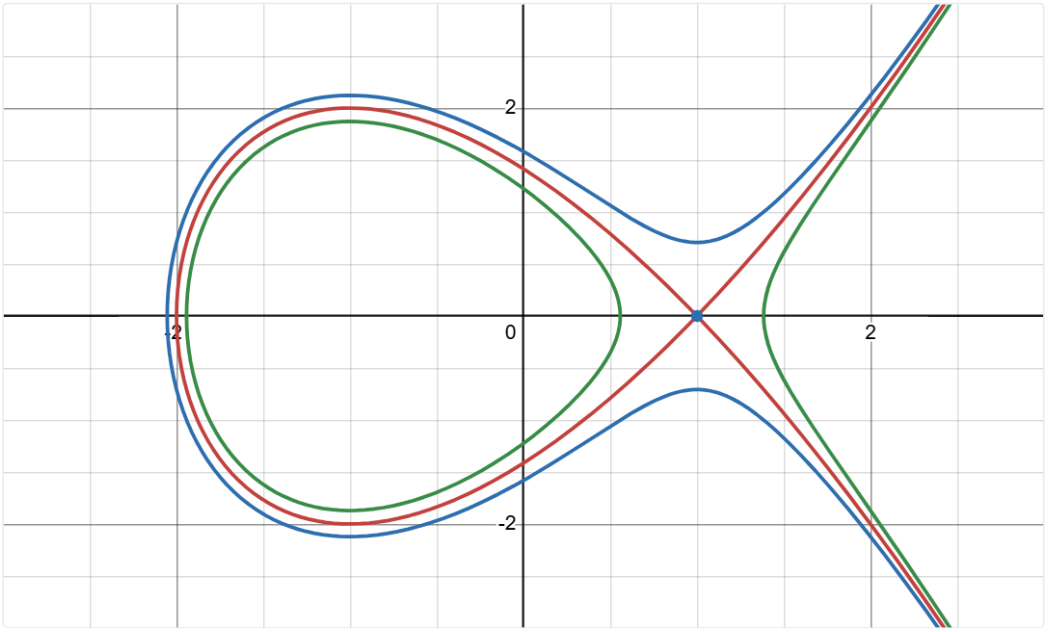
a quadratic in v alone, $v(5v - 8) = 0$, and then a linear equation for u. These are the two elbows, $(2, 0)$ and $(1.2, 1.6)$, found by the same steps a person would take, but now as an algorithm that works for any number of equations and unknowns.

Costs and failure modes. Gröbner bases are exact and complete, and computer algebra systems compute them routinely for kinematics and geometric constraint problems. Their worst case is brutal, though: the degrees in a Gröbner basis can be doubly exponential in the number of variables. Over floating-point numbers they are numerically fragile, because whether a coefficient is exactly zero changes the answer. Engineers who need *numbers* rather than formulas often use **resultants** instead (§94.5), or **homotopy continuation**. That method starts from a simple system whose $de\cdots$ solutions are known, by Bézout, and deforms it into the target system while tracking every solution path with an ODE solver (§22.9). The general six-joint robot arm has 16 inverse-kinematics solutions, a count found this way and then proved.

> **? Doubly exponential, yet it works**
>
> Mayr and Meyer (1982) built ideals for which *any* algorithm deciding ideal membership needs space exponential in the number of variables, and Gröbner bases with doubly exponential degrees. Yet the systems that come from engineering are solved in seconds. Is the worst case rare, or are real problems special? How problems can be provably hard in the worst case and easy in practice is a theme of Ch. 30.

94.5 The experiment

Watch singularities form. Desmos plots implicit equations directly. The curve $y^2 = x^3 - 3x + b$ is shown for $b = 2$, where it has a node, together with two nearby smooth members of the same family.



At $b = 2$ (red) the loop and the branch touch at the node $(1, 0)$. Slightly above (blue, $b = 2.5$) they merge into one smooth piece. Slightly below (green, $b = 1.5$) they separate into an oval and a branch.

Things to change:

- Replace $-3x$ by $0x$ and set all three constants to 0, 0.3 and -0.3. The red curve becomes the cusp $y^2 = x^3$. Its neighbours are smooth, but they do not split into two pieces.

- The singular curves are those with $4a^3 + 27b^2 = 0$. Use this to predict, then check, which b gives a node when $a = -12$.
- Add the lines `x^2+y^2=4`, `(x-2)^2+(y-1)^2=1` and `2x+y=4` to see the robot arm: the two circles and the line through their two finite intersections.

Count every intersection. This script finds *all* common points of two conics $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$, complex ones included. It eliminates y with the **resultant** of the two quadratics in y, a polynomial in x alone that vanishes exactly where they share a root, and then recovers y.

```
import numpy as np
P = np.poly1d

def intersect(c1, c2, tol=1e-4):
    """Common points of two conics A x^2 + B xy + C y^2 + D x + E y + F = 0."""
    def in_y(c):                                # coefficients of y^2, y^1, y^0 as polys in x
        A, B, C, D, E, F = c
        return P([C]), P([B, E]), P([A, D, F])
    a2, a1, a0 = in_y(c1)
    b2, b1, b0 = in_y(c2)
    res = (a2 * b0 - a0 * b2)**2 - (a2 * b1 - a1 * b2) * (a1 * b0 - a0 * b1)   # resultant in y
    res = P(np.where(abs(res.coeffs) < 1e-12, 0, res.coeffs))
    print("  resultant has degree", res.order, "in x")
    pts = []
    for x in np.unique(np.round(res.roots, 5)):   # each x may carry several points
        for y in np.unique(np.round(np.roots([a2(x), a1(x), a0(x)]), 5)):
            if abs(b2(x) * y**2 + b1(x) * y + b0(x)) < tol * (1 + abs(x)**2 + abs(y)**2):
                pts.append((complex(x), complex(y)))
    return pts

ellipse   = (1, 0, 4, 0, 0, -4)        # x^2 + 4y^2 = 4
hyperbola = (1, 0, -1, 0, 0, -1)       # x^2 - y^2 = 1
circle1   = (1, 0, 1, 0, 0, -4)        # x^2 + y^2 = 4
circle2   = (1, 0, 1, -4, -2, 4)       # (x-2)^2 + (y-1)^2 = 1

for name, c1, c2 in [("ellipse & hyperbola", ellipse, hyperbola),
                     ("two circles", circle1, circle2)]:
    print(name)
    for x, y in intersect(c1, c2):
        print(f"   x = {x.real:+.4f}{x.imag:+.4f}j,  y = {y.real:+.4f}{y.imag:+.4f}j")
```

For the ellipse and hyperbola the resultant has degree 4 and the script prints the four points $(\pm 1.2649, \pm 0.7746)$, which are $(\pm\sqrt{8/5}, \pm\sqrt{3/5})$. For the two circles the resultant collapses to degree 2: two solutions, the elbows $(1.2, 1.6)$ and $(2, 0)$. The lost degree *is* the pair of circular points at infinity. Things to change:

- Replace the hyperbola by the circle $(x-4)^2 + y^2 = 1$, `(1, 0, 1, -8, 0, 15)`, which misses the ellipse entirely in the real plane. The script still finds four points: $(8/3, \pm 0.8819j)$ and $(8, \pm 3.8730j)$.
- Give `circle2` a different x^2 coefficient, for instance `(1.1, 0, 1, -4, -2, 4)`. It is now an ellipse, it no longer passes through $(1 : \pm j : 0)$, and the resultant degree jumps back to 4. The two new solutions are huge, about $(38.4 \mp 20.9j,\ -20.9 \mp 38.3j)$, with $y/x \approx \mp j$: the points that were at infinity have come in from $(1 : \mp j : 0)$. Try `1.01` and watch them recede.
- Make two conics tangent, for instance $y = x^2$ and $x^2 + (y-1)^2 = 1$, `(1, 0, 0, 0, -1, 0)` and `(1, 0, 1, 0, -2, 0)`. Only three points print. Print `res.roots` to see the fourth: $x = 0$ appears twice.

94.6 The challenge

1. **Intuition.** Three generic quadric surfaces in space meet in $2 \cdot 2 \cdot 2 = 8$ points. Three spheres, as in GPS trilateration, meet in at most 2. Where are the other six? (Hint: what does every sphere have in common at infinity?)
2. **Derivation.** Over $\mathbb{C}$, show that the substitution $u = x + jy$, $v = x - jy$ turns the circle $x^2 + y^2 = 1$ into the hyperbola $uv = 1$, and deduce that its coordinate ring is $\mathbb{C}[u, u^{-1}]$. Then use the lines through $(-1, 0)$ to derive the rational parametrisation $x = (1 - t^2)/(1 + t^2)$, $y = 2t/(1 + t^2)$, and show that it gives every Pythagorean triple.
3. **Implementation.** Extend the resultant script to two *cubic* curves, using the 6×6 Sylvester determinant (evaluated at enough values of x and interpolated) to get a resultant of degree 9. Verify Bézout's count of 9 on random cubics, then find a pair of cubics for which the degree drops, and identify the common points at infinity.
4. **Open investigation.** Draw the six coefficients of each of two conics independently from a standard Gaussian. Estimate by simulation the probabilities that they meet in 0, 2 or 4 real points. Then try two random curves of degree d for $d = 2, \dots, 6$ and plot the average number of real intersection points against d. For one special distribution (Kostlan's) the expected count is exactly $\sqrt{de}$ (Shub and Smale, 1993). How does your distribution compare, and can you guess its growth rate?

94.7 Loose threads

Why SNARKs trust random points. The zero-knowledge proof systems of Ch. 82 encode a whole computation as an identity between polynomials and then check it at one random point. The geometric fact behind this is that a hypersurface is *thin*. The **Schwartz–Zippel lemma** says that if $f \neq 0$ has total degree d and $\mathbf{r}$ is drawn uniformly from S^n for a finite set S, then $P(f(\mathbf{r}) = 0) \leq d/|S|$. The proof is a short induction. For $n = 1$, a nonzero polynomial of degree d has at most d roots. For $n > 1$, write $f = \sum_{i \leq k} x_1^i f_i(x_2, \dots, x_n)$ with $f_k \neq 0$. By induction, $f_k(r_2, \dots, r_n) = 0$ with probability at most $(d-k)/|S|$. Otherwise f is a nonzero polynomial of degree k in x_1, which vanishes at r_1 with probability at most $k/|S|$. Adding the two gives $d/|S|$. Over a field with $q \approx 2^{255}$ elements, a false identity of degree a million survives a random test with probability below 2^{-235}. Seen this way, a variety is a set of measure almost zero, and a random point almost surely lies off it.

Fermat's Last Theorem. Ch. 57 asked how geometry enters Fermat's problem. A solution of $a^n + b^n = c^n$ in positive integers is a rational point $(a/c, b/c)$ on the curve $x^n + y^n = 1$. The **genus** of a smooth curve, the number of holes in its complex points viewed as a surface, controls how many rational points it can have. Genus 0 curves, like the circle, have none or infinitely many, which is why there are infinitely many Pythagorean triples. Genus 1 curves are elliptic curves, whose rational points form a finitely generated group. Curves of genus at least 2 have only *finitely* many rational points (Faltings, 1983). The Fermat curve has genus $(n-1)(n-2)/2$, which is at least 3 once $n \geq 4$, so Faltings already gives finitely many solutions. Wiles' proof (1995) that there are *none* goes through an elliptic curve, Frey's curve $y^2 = x(x - a^n)(x + b^n)$, which would be too strange to exist if a solution did.

? Can every singularity be smoothed away?

The cusp can be repaired. Substitute $y = tx$ into $y^2 = x^3$ and divide by x^2: the result is $t^2 = x$, a smooth parabola. This "blow-up" replaces the singular point by the directions of approach to it. Hironaka proved in 1964, in a 200-page paper that earned a Fields Medal, that every variety over a field of characteristic 0, such as $\mathbb{R}$ or $\mathbb{C}$, can be made smooth by repeated blow-ups. Over fields of characteristic p, the setting of cryptography and coding theory, the same statement is known only in dimension at most 3. In higher dimensions it is an **open problem**, and one of the most sought-after in the field.

The other threads lead into the rest of the track. The variety of tensors of border rank at most r from Ch. 93 is a secant variety, and finding its equations is algebraic geometry at the research frontier. Symmetry groups acting on varieties, and on the coordinate rings that describe them, bring in the representation theory of Ch. 95. Grothendieck's reformulation of the whole subject, which replaces varieties by "schemes" so that any commutative ring has a geometry, shows how mathematicians build new language when the old one runs out (Ch. 98).

Chapter 95 — Representation Theory: Making Abstract Symmetry Concrete

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 9, Ch. 10, Ch. 15, Ch. 56, Ch. 99 · **Leads to:** Ch. 92, Ch. 93, Ch. 94 · **Related:** Ch. 62, Ch. 90, Ch. 79 **Reading time:** ~30 min

95.1 The hook

In 1978 John McKay, a group theorist at Concordia University, was reading a paper on number theory and noticed a coefficient. The paper was about the **j-function**, a function of a complex variable studied since the nineteenth century, which has a series expansion beginning

$$j(q) = \frac{1}{q} + 744 + 196884\,q + 21493760\,q^2 + 864299970\,q^3 + \cdots$$

McKay knew the number 196883 from a completely different world. It was the smallest dimension in which the **Monster**, the largest sporadic finite simple group (Ch. 56), with about 8×10^{53} elements, can act by rotations without acting trivially. He wrote to John Thompson, who checked the next coefficient:

$$\begin{aligned} 196884 &= 1 + 196883, \\ 21493760 &= 1 + 196883 + 21296876, \\ 864299970 &= 2 \cdot 1 + 2 \cdot 196883 + 21296876 + 842609326. \end{aligned}$$

Every number on the right is the dimension of one of the Monster's "irreducible representations". A function from complex analysis, which knows nothing about groups, was spelling out the building blocks of the biggest exceptional symmetry object in mathematics. John Conway called this **monstrous moonshine**, meaning crazy talk.

To even say what these numbers *are* you need one idea. A group is an abstract table of how symmetries combine. A **representation** turns each symmetry into a matrix, so that combining symmetries becomes multiplying matrices. Then the full power of linear algebra (eigenvalues, traces, change of basis) can be aimed at the group. And just as a signal splits into sine waves that cannot be split further, a representation splits into irreducible pieces. The Monster has exactly 194 of them, and the smallest non-trivial one has dimension 196883.

You've already met a representation without being told. The DFT of Ch. 15 turns every circular convolution into a diagonal matrix. Why? Not because of some property of $e^{j\theta}$. It's because convolution commutes with shifting, and the shifts form a group. This chapter explains that sentence, and it shows that the same reasoning works for the symmetries of a square, of a molecule, or of the Monster.

95.2 The big idea

Take a symmetric object, say four equal masses at the corners of a square joined by identical springs. You want its vibration modes. The honest way is to write the 8×8 stiffness matrix and find its eigenvectors (§10.8). The clever way is to notice that the square has eight symmetries (four rotations, four reflections). The stiffness matrix commutes with all of them, because rotating the square and then letting it vibrate is the same as letting it vibrate and then rotating it.

Here is the key fact. **If a matrix commutes with a group of symmetries, then it cannot mix vectors that transform in genuinely different ways under the group.** So you first sort the space of motions into "transformation types", the irreducible representations, and the matrix becomes block-diagonal *before you compute anything about it*. The symmetry does the work.

The analogy is a prism. White light enters, and the prism sorts it by frequency because a prism treats every frequency differently but each one consistently. A group splits a vector space by "symmetry type" in the same way. For the cyclic group of shifts the types are exactly the frequencies, which is why Fourier analysis is the representation theory of $\mathbb{Z}_n$.

Two more ideas make the theory practical:

1. **Characters.** The trace of a matrix doesn't change under change of basis. So the function $g \mapsto \operatorname{tr} \rho(g)$, the **character**, is a basis-free fingerprint of a representation. Remarkably, it determines the representation completely.
2. **Orthogonality.** The characters of the irreducible representations are orthonormal vectors, in the same way that sampled sinusoids are. So to find how many times a type appears, you take an inner product, just like computing a Fourier coefficient.

95.3 The mathematics

Throughout, G is a finite group and vector spaces are over $\mathbb{C}$. Groups, homomorphisms and conjugacy were set up in Ch. 56; invariant subspaces and direct sums in Ch. 99.

Representation, subrepresentation, irreducible

A **representation** of G on a finite-dimensional space V is a homomorphism $\rho : G \to \mathrm{GL}(V)$, so $\rho(gh) = \rho(g)\rho(h)$ and $\rho(e) = \mathbf{I}$. Its **dimension** is $\dim V$. A subspace $W \subseteq V$ is **invariant** if $\rho(g)W \subseteq W$ for all g. The representation is **irreducible** if its only invariant subspaces are $\{0\}$ and V. Two representations are **equivalent** if some invertible $\mathbf{P}$ satisfies $\mathbf{P}\rho(g)\mathbf{P}^{-1} = \rho'(g)$ for every g, the same change of basis for all of them at once. The **character** is $\chi_\rho(g) = \operatorname{tr} \rho(g)$. It is constant on conjugacy classes, since $\operatorname{tr}(\mathbf{ABA}^{-1}) = \operatorname{tr} \mathbf{B}$.

Three examples to hold on to:

- **The trivial representation:** $\rho(g) = 1$ for all g, on $\mathbb{C}^1$.
- **Permutation representations:** if G permutes a set X, let $\rho(g)$ be the permutation matrix on $\mathbb{C}^X$. Its character $\chi(g)$ counts the points of X that g fixes. The **regular representation** is the case $X = G$, with G acting on itself by left multiplication.
- **Characters of $\mathbb{Z}_n$:** for each $k = 0, \dots, n-1$, the map $\chi_k(m) = e^{2\pi jkm/n}$ is a homomorphism $\mathbb{Z}_n \to \mathbb{C}^\times$, a one-dimensional representation.

Result 1: everything breaks into irreducibles

> **Maschke's theorem**
>
> If W is an invariant subspace of a representation V of a finite group, then W has an invariant complement W', with $V = W \oplus W'$. Hence every representation is a direct sum of irreducible ones.

Proof. Start with any inner product $\langle \cdot, \cdot \rangle_0$ on V and average it over the group:

$$\langle \mathbf{u}, \mathbf{v} \rangle = \frac{1}{|G|} \sum_{g \in G} \langle \rho(g)\mathbf{u}, \rho(g)\mathbf{v} \rangle_0.$$

This is again an inner product (a positive sum of inner products). It is **invariant**: replacing $\mathbf{u}, \mathbf{v}$ by $\rho(h)\mathbf{u}, \rho(h)\mathbf{v}$ turns $\rho(g)$ into $\rho(gh)$, and as g runs over G so does gh, so the sum is unchanged. Every $\rho(h)$ is therefore unitary for $\langle \cdot, \cdot \rangle$.

Let $W' = W^\perp$ for this inner product. If $\mathbf{w}' \in W'$ and $\mathbf{w} \in W$, then

$$\langle \rho(h)\mathbf{w}', \mathbf{w} \rangle = \langle \mathbf{w}', \rho(h)^{-1}\mathbf{w} \rangle = \langle \mathbf{w}', \rho(h^{-1})\mathbf{w} \rangle = 0,$$

since $\rho(h^{-1})\mathbf{w} \in W$. So $\rho(h)\mathbf{w}' \in W'$, and W' is invariant. Repeat inside W and W'. Dimensions drop each time, so the process ends with irreducible pieces. ∎

The averaging trick is the whole proof, and it is also where finiteness was used: we divided by $|G|$. For the group $\mathbb{Z}$ acting on $\mathbb{C}^2$ by powers of $\left[\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right]$, the line spanned by $(1, 0)$ is invariant and has no invariant complement. That is the Jordan block of Ch. 99 refusing to split.

Result 2: Schur's lemma, the engine

> **Schur's lemma**
>
> Let V, W be irreducible representations and $\mathbf{T} : V \to W$ a linear map with $\mathbf{T}\rho_V(g) = \rho_W(g)\mathbf{T}$ for all g (an **intertwiner**). (a) Either $\mathbf{T} = 0$ or $\mathbf{T}$ is invertible; so if V and W are not equivalent, $\mathbf{T} = 0$. (b) If $V = W$, then $\mathbf{T} = \lambda \mathbf{I}$ for some scalar λ.

Proof. (a) The kernel of $\mathbf{T}$ is invariant: if $\mathbf{T}\mathbf{v} = 0$ then $\mathbf{T}\rho_V(g)\mathbf{v} = \rho_W(g)\mathbf{T}\mathbf{v} = 0$. By irreducibility it is $\{0\}$ or V. Likewise the image is invariant in W, so it is $\{0\}$ or W. If $\mathbf{T} \neq 0$ the kernel is $\{0\}$ and the image is W, so $\mathbf{T}$ is invertible.

(b) Over $\mathbb{C}$, $\mathbf{T}$ has an eigenvalue λ (Ch. 10). Then $\mathbf{T} - \lambda\mathbf{I}$ is also an intertwiner, and it isn't invertible. By (a) it is zero. ∎

Here is the engineering payoff, the precise form of the big idea:

> **Symmetric operators are block-diagonal**
>
> Suppose $V = V_1 \oplus \cdots \oplus V_r$ with the V_i irreducible and pairwise inequivalent, and $\mathbf{K}$ commutes with every $\rho(g)$. Then $\mathbf{K}$ maps each V_i into itself and acts on it as a scalar λ_i. In other words, the V_i are eigenspaces of $\mathbf{K}$, found without knowing $\mathbf{K}$.

Proof. Let π_i be the projection onto V_i along the other pieces. It commutes with $\rho(g)$ because each piece is invariant. The map $\pi_i \mathbf{K}|_{V_k} : V_k \to V_i$ is an intertwiner. By Schur (a) it vanishes for $i \neq k$, so $\mathbf{K}V_k \subseteq V_k$. By Schur (b) it is a scalar for $i = k$. ∎

When some irreducible type appears m times, the same argument gives an $m \times m$ block, which is still a huge saving. The square of springs has an 8-dimensional configuration space. Symmetry splits it into pieces of dimension at most 2, with the 2-dimensional type appearing twice. You are left with one 2×2 eigenproblem and a few scalars, instead of an 8×8 one.

Result 3: Fourier analysis is the case $G = \mathbb{Z}_n$

> **The DFT diagonalises every shift-invariant operator**
>
> Let $\mathbf{S}$ be the cyclic shift on $\mathbb{C}^n$ and $\mathbf{C}$ any matrix with $\mathbf{CS} = \mathbf{SC}$. Then each vector $\mathbf{f}_k = (e^{2\pi jkm/n})_{m=0}^{n-1}$ is an eigenvector of $\mathbf{C}$. The matrices commuting with $\mathbf{S}$ are exactly the circular convolutions $\mathbf{x} \mapsto h \circledast \mathbf{x}$, and the eigenvalue on $\mathbf{f}_k$ is the DFT coefficient $\hat{h}[k] = \sum_m h[m] e^{-2\pi jkm/n}$.

Proof. Write $(\mathbf{S}\mathbf{x})[m] = x[m-1]$, indices mod n. Then $\mathbf{S}\mathbf{f}_k = e^{-2\pi jk/n}\mathbf{f}_k$. The n eigenvalues $e^{-2\pi jk/n}$ are distinct, so each eigenspace of $\mathbf{S}$ is the line through $\mathbf{f}_k$. These lines are the n one-dimensional representations of $\mathbb{Z}_n$, pairwise inequivalent, so the block-diagonal theorem says $\mathbf{C}\mathbf{f}_k = \lambda_k \mathbf{f}_k$. (You can also see it directly: $\mathbf{CS}\mathbf{f}_k = \mathbf{SC}\mathbf{f}_k$ says $\mathbf{C}\mathbf{f}_k$ is again an eigenvector of $\mathbf{S}$ with the same eigenvalue.)

If $\mathbf{C}$ commutes with $\mathbf{S}$, set $h = \mathbf{C}\boldsymbol{\delta}$, the image of the unit impulse. Every $\mathbf{x} = \sum_k x[k]\mathbf{S}^k\boldsymbol{\delta}$, so $\mathbf{C}\mathbf{x} = \sum_k x[k]\mathbf{S}^k h = h \circledast \mathbf{x}$. Finally, $(h \circledast \mathbf{f}_k)[m] = \sum_i h[i] e^{2\pi jk(m-i)/n} = \hat{h}[k]\, f_k[m]$. ∎

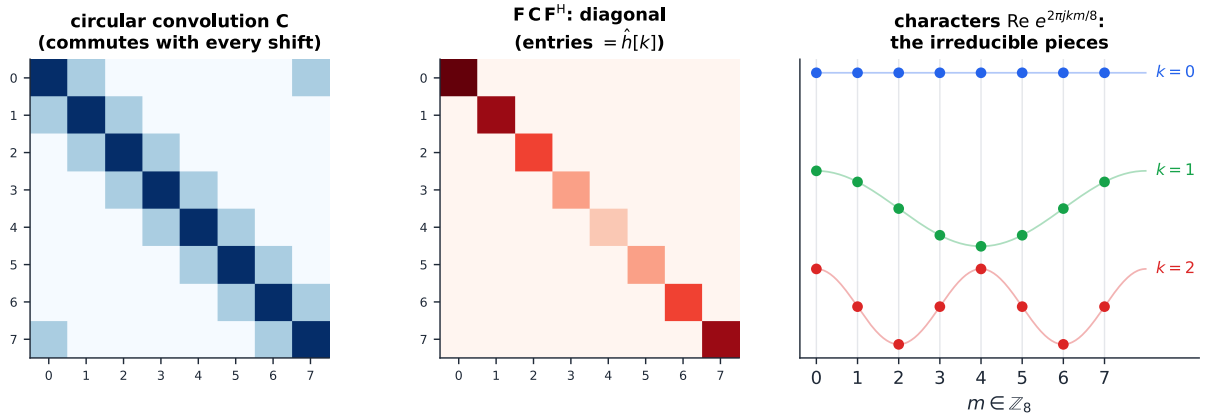

Figure 95.1 — Convolution on $\mathbb{Z}_8$ commutes with shifts, so in the basis of characters (right) it becomes diagonal (middle). The convolution theorem of §16.5 is Schur's lemma for an abelian group.

For an abelian group every irreducible representation is one-dimensional (by Schur (b), each $\rho(g)$ commutes with everything, so it is a scalar, and every line is invariant). For a non-abelian group some irreducibles must be bigger, and "frequencies" become small matrices. That is the only genuinely new phenomenon, and it is where the theory gets its depth.

Characters and the character table

The following facts follow from Schur's lemma by averaging intertwiners over the group. We state them; Serre's book in the reading list proves them in about ten pages.

Character theory of a finite group

Define $\langle \chi, \psi \rangle = \frac{1}{|G|} \sum_{g} \chi(g)\overline{\psi(g)}$.

1. The irreducible characters $\chi_1, \dots, \chi_r$ are orthonormal: $\langle \chi_i, \chi_k \rangle = \delta_{ik}$.
2. Their number r equals the number of conjugacy classes of G.
3. If $V \cong \bigoplus_i V_i^{\oplus m_i}$, then $m_i = \langle \chi_V, \chi_i \rangle$. So two representations with the same character are equivalent.
4. The regular representation contains each V_i exactly $d_i = \dim V_i$ times, so $\sum_i d_i^2 = |G|$.

Fact 4 is a quick consequence of fact 3. The regular character is $|G|$ at e and 0 elsewhere (only the identity fixes a group element under left multiplication). So $m_i = \frac{1}{|G|}|G|\,\overline{\chi_i(e)} = d_i$, and comparing dimensions gives $|G| = \sum_i d_i \cdot d_i$.

Example: S_3. The symmetric group on three letters has 6 elements in three classes: the identity, three transpositions, two 3-cycles. So it has three irreducibles, and $d_1^2 + d_2^2 + d_3^2 = 6$ forces dimensions $1, 1, 2$. Two are easy: the trivial character, and the sign of a permutation. For the third, S_3 permutes the corners of a triangle, giving a 3-dimensional permutation representation with character $(3, 1, 0)$ (fixed points). It contains the trivial representation once (the all-ones vector), and what remains is the 2-dimensional rotations-and-reflections of the triangle's plane, with character $(3, 1, 0) - (1, 1, 1) = (2, 0, -1)$.

irreducible	e (1 element)	(1 2) (3 elements)	(1 2 3) (2 elements)
trivial χ_1	1	1	1
sign χ_2	1	-1	1
standard χ_3	2	0	-1

class sizes weight the sum

rows are orthogonal: $\langle \chi_2, \chi_3 \rangle = \frac{1}{6}(1 \cdot 2 \cdot 1 + 3 \cdot (-1) \cdot 0 + 2 \cdot 1 \cdot (-1)) = 0$
first column: $1^2 + 1^2 + 2^2 = 6 = |S_3|$

Figure 95.2 — The character table of S_3. Rows are orthonormal once each column is weighted by its class size, and the first column's squares add up to the group order.

Example: the square, D_4. The eight symmetries fall into five classes: $\{e\}$, $\{r^2\}$, $\{r, r^3\}$, the two edge flips, and the two diagonal flips. So there are five irreducibles, and $8 = 1 + 1 + 1 + 1 + 2^2$. Let D_4 permute the four corners. A diagonal flip fixes two corners and everything else except e fixes none, so the character is 4 at e, 2 on diagonal flips and 0 elsewhere. Taking inner products with the five irreducible characters gives multiplicities $1, 0, 1, 0, 1$: the corner space is trivial $\oplus$ one sign-like line $\oplus$ the 2-dimensional irreducible.

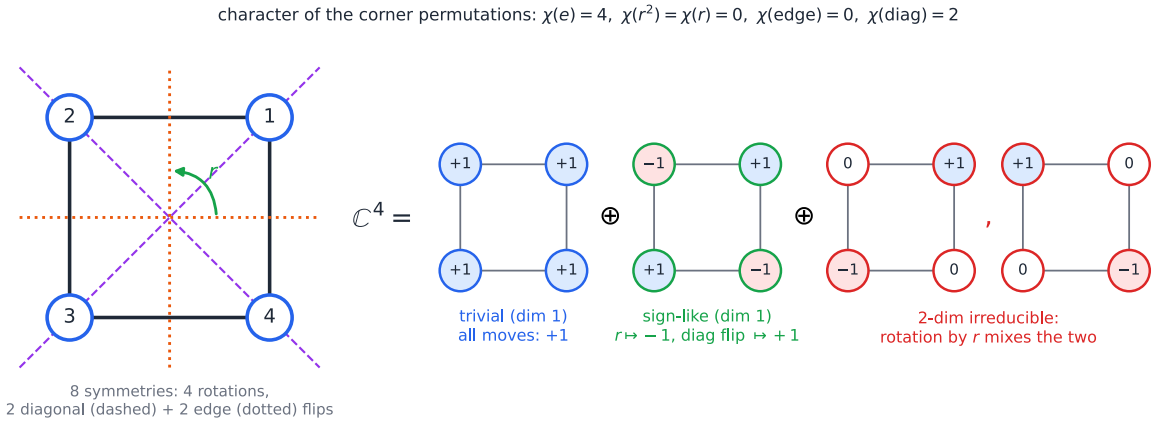

Figure 95.3 — The eight symmetries of the square act on functions of its corners. The space splits into three pieces. Any symmetric operator, such as a spring network's stiffness matrix, must respect this split.

Why one matrix is tame and two are wild

Ch. 99 left a puzzle. One linear map T on V, up to change of basis, is classified by Jordan form. Two maps S, T changed by the *same* basis have no such list. Representation theory explains the difference by changing what we represent. A single T is a representation of the polynomial ring $\mathbb{C}[x]$ (let x act as T). That ring is a principal ideal domain, and the structure theorem for its modules is exactly the Jordan form: the indecomposable pieces are the Jordan blocks, one family per eigenvalue and size.

A pair (S, T) is a representation of the free algebra $\mathbb{C}\langle x, y\rangle$, in which $xy \neq yx$. Every finite-dimensional algebra is a quotient of a free algebra, and with a little coding one can embed the representations of *any* finite-dimensional algebra (triples, quadruples of matrices, anything) into pairs. A classification of pairs would therefore contain every other classification problem of linear algebra. That is what **wild** means. Drozd proved in 1979 that every finite-dimensional algebra is either *tame* (indecomposables come in finitely many one-parameter families in each dimension) or wild, never both.

The sharpest picture uses **quivers**, directed graphs with a vector space at each vertex and a matrix on each arrow. Gabriel's theorem (1972) says that a connected quiver has only finitely many indecomposable representations exactly when its underlying graph is one of the Dynkin diagrams A_n, D_n, E_6, E_7, E_8. Two vertices joined by two arrows, Kronecker's "pencils of matrices" $\lambda\mathbf{A} + \mu\mathbf{B}$, are tame. One vertex with two loops, our pair (S, T), is wild.

> **? The same five letters, everywhere**
>
> The list A_n, D_n, E_6, E_7, E_8 that decides which quivers are classifiable is also the list of simple Lie algebras with one root length, of the finite subgroups of $\mathrm{SU}(2)$ (the symmetries of the Platonic solids, doubled), and of the simplest singular points of surfaces, such as $x^2 + y^3 + z^5 = 0$. The **McKay correspondence** links the last two through representations. Why should a polynomial singularity know about the icosahedron? The geometry of resolving singularities is in Ch. 94.

95.4 The algorithm

Given a representation as a list of matrices, how do you split it? Character theory turns the job into inner products and projections.

```
decompose(G, rho, irreducible characters chi_1..chi_r):
    chi = [trace(rho(g)) for g in G]                # O(|G| d)
    for each i:
        m_i = (1/|G|) * sum_g chi(g) * conj(chi_i(g))  # multiplicity
        P_i = (d_i/|G|) * sum_g conj(chi_i(g)) * rho(g) # projector, O(|G| d^2)
        V_i-part = column space of P_i              # dimension m_i * d_i
```

The projector formula $\mathbf{P}_i = \frac{d_i}{|G|} \sum_g \overline{\chi_i(g)}\, \rho(g)$ comes from the same averaging as Maschke's proof. It commutes with every $\rho(h)$, so by Schur it is a scalar on each irreducible piece, and orthogonality makes that scalar 1 on type i and 0 on every other type. For $G = \mathbb{Z}_n$ this is exactly the DFT: $\mathbf{P}_k$ projects onto the k-th frequency.

Costs and pitfalls:

- **Group size.** The sums run over $|G|$ elements. For S_{10} that is 3.6 million matrices. Summing over conjugacy classes (character values are constant on them) helps for multiplicities, though not for projectors.
- **Fast transforms.** The FFT computes all n projections of $\mathbb{Z}_n$ in $O(n \log n)$ by exploiting the subgroup chain $\mathbb{Z}_n \supset \mathbb{Z}_{n/2} \supset \cdots$. Clausen, Diaconis and Rockmore built analogous fast Fourier transforms for S_n and other non-abelian groups, and they are used to analyse ranked data such as elections and preference surveys.
- **Finding the character table.** If you don't know the χ_i, the Burnside–Dixon–Schneider algorithm finds them as simultaneous eigenvectors of class-multiplication matrices, which is linear algebra again. Computer algebra systems (GAP, Magma) store tables for thousands of groups, including the Monster's 194×194 table.
- **Numerical stability.** Floating-point projectors have rank only approximately $m_i d_i$. Use an SVD with a tolerance (§10.7) rather than Gaussian elimination to extract the subspace.

95.5 The experiment

The script builds the eight 4×4 permutation matrices of D_4 acting on corners, computes the character, and finds multiplicities and projector ranks for all five irreducibles. Then it checks that the DFT diagonalises a random circulant matrix.

```
import numpy as np

# D4 acting on the 4 corners of a square (corners 0,1,2,3 counter-clockwise)
def perm_matrix(p):                      # p[i] = where corner i goes
    P = np.zeros((4, 4)); P[p, range(4)] = 1; return P

r = perm_matrix([1, 2, 3, 0])            # rotate by 90 degrees
s = perm_matrix([0, 3, 2, 1])            # flip in the diagonal through corner 0
group = [np.linalg.matrix_power(r, k) @ f for k in range(4) for f in (np.eye(4), s)]

chi = np.array([np.trace(g) for g in group])          # character of this rep
print("character of corner rep:", chi)

# characters of the 5 irreducibles, element by element (same order as `group`)
signs_r = np.array([(-1) ** k for k in range(4) for _ in (0, 1)])
is_flip = np.array([f for _ in range(4) for f in (0, 1)])
diag = np.array([k % 2 == 0 for k in range(4) for _ in (0, 1)]) & (is_flip == 1)
irreps = {
    "A1 trivial": np.ones(8),
    "A2 (flips -1)": np.where(is_flip, -1, 1),
    "B1 (r -1, diag +1)": np.where(is_flip, np.where(diag, 1, -1), signs_r),
    "B2 (r -1, edge +1)": np.where(is_flip, np.where(diag, -1, 1), signs_r),
    "E  (2-dim)": np.array([np.trace(np.linalg.matrix_power(np.array([[0, -1], [1, 0]]), k)) * (1 - f)
                            for k in range(4) for f in (0, 1)]),
}
for name, x in irreps.items():
    mult = np.dot(chi, x) / len(group)                # <chi, chi_i>
    P = sum(xi * g for xi, g in zip(x, group)) * x[0] / len(group)
    print(f"{name:20s} multiplicity {mult:+.0f}   projector rank {np.linalg.matrix_rank(P)}")

# Fourier on Z_n: any matrix commuting with the cyclic shift is diagonalised by the DFT
n = 8
h = np.random.default_rng(1).normal(size=n)          # try your own filter here
C = np.array([[h[(i - k) % n] for k in range(n)] for i in range(n)])
F = np.fft.fft(np.eye(n)) / np.sqrt(n)
D = F @ C @ F.conj().T
print("largest off-diagonal entry:", np.abs(D - np.diag(np.diag(D))).max())
print("diagonal equals fft(h):", np.allclose(np.diag(D), np.fft.fft(h)))
```

Running it prints multiplicities $1, 0, 1, 0, 1$ with projector ranks $1, 0, 1, 0, 2$, and an off-diagonal residue around 10^{-16}. Things to change:

- **Act on edges instead of corners.** Replace `r` and `s` by the permutations of the four edges (number them so edge i joins corners i and $i+1$). Predict the character, and therefore the decomposition, before you run it. Which irreducible swaps in?
- **Act on motions.** Build the 8×8 representation on corner displacements $(\Delta x_i, \Delta y_i)$: each symmetry permutes the corners *and* rotates each displacement vector, so it is a Kronecker product of a permutation and a 2×2 rotation. Show that its character is the product of the two characters, and decompose it. You have just predicted the mode shapes of the spring square of §95.2.
- **Break the symmetry.** Make one entry of `h` depend on position (a non-circulant matrix). Watch the off-diagonal residue jump from 10^{-16} to order one.

95.6 The challenge

1. **Intuition.** A matrix commutes with all eight symmetries of the square. Without computing anything, how many distinct eigenvalues can it have on the corner space $\mathbb{C}^4$ at most? Why might it have fewer?
2. **Derivation.** Show that the number of one-dimensional representations of a finite group G equals $|G/[G,G]|$, where $[G,G]$ is the subgroup generated by all commutators $ghg^{-1}h^{-1}$. Check your formula on S_3 and D_4.
3. **Implementation.** Write code that, given generating permutations of a group, produces all its elements and its conjugacy classes, and then finds the dimensions of its irreducibles from $\sum d_i^2 = |G|$ together with the number of classes. Run it on the rotation group of the cube (order 24), and decide whether these two constraints alone always pin down the dimensions.
4. **Open investigation.** Take a random walk on S_n by repeatedly swapping two random cards of a deck. Diaconis and Shahshahani used the characters of S_n to show that the walk mixes after about $\frac{1}{2} n \ln n$ swaps. Simulate the distance to uniform for $n = 6, 8, 10$ and look for a sudden "cutoff". Is there a general way to predict from a group's character table alone when a random walk on it shows a cutoff? This is a research question, and no general answer is known.

95.7 Loose threads

The hook asked why a function from complex analysis spells out the dimensions of the Monster's representations. We've built the dictionary for even asking. A representation is a group written in matrices. Maschke's averaging splits every representation into irreducibles. Schur's lemma says symmetric operators are scalars on each irreducible type, which is why Fourier analysis diagonalises convolution and why symmetry predicts mode shapes. And characters, orthogonal like sinusoids, count the pieces.

Moonshine itself needed far more. Conway and Norton conjectured in 1979 that the j-function is the "graded dimension" of an infinite-dimensional representation $V^\natural = V_0 \oplus V_1 \oplus V_2 \oplus \cdots$ of the Monster, and that replacing dimensions by traces of other elements gives other classical functions. Frenkel, Lepowsky and Meurman constructed $V^\natural$ in 1988 from the Leech lattice. Richard Borcherds proved the conjecture in 1992 using a "no-ghost theorem" borrowed from string theory, and won a Fields Medal.

? Why does string theory know about the Monster?

Borcherds' proof works, but many mathematicians feel it explains *how* rather than *why*. $V^\natural$ is the state space of a two-dimensional quantum field theory, and the Monster is its symmetry group. Newer "umbral" and "Mathieu" moonshines link other sporadic groups to other functions (one discovered in 2010 from the K3 surfaces of string theory), and for most of them the representations have been shown to exist without anyone writing them down. A conceptual reason why sporadic groups and modular functions are linked remains an open problem. Symmetry in physics, the doorway to this story, is in Ch. 92.

We also stayed with finite groups. For the circle group $\mathbb{R}/2\pi\mathbb{Z}$ the irreducibles are $e^{jk\theta}$, and decomposing functions into them is the Fourier series of Ch. 15. For the line $\mathbb{R}$ there is a continuum of characters $e^{j\omega t}$, and you get the Fourier transform. For the rotation group $\mathrm{SO}(3)$ the irreducibles have dimensions $1, 3, 5, 7, \ldots$, and they are the spherical harmonics behind atomic orbitals and antenna radiation patterns.

? Fourier analysis on groups that do not commute

For a compact group such as $\mathrm{SO}(3)$, the Peter–Weyl theorem says the matrix entries of the irreducible representations form an orthonormal basis of $L^2(G)$, a non-commutative Fourier series. For non-compact, non-abelian groups such as the Lorentz group of relativity, the unitary irreducibles (the ones quantum mechanics needs) are infinite-dimensional and the "spectrum" can have continuous parts. How a spectrum can be partly a list and partly a continuum, and what an operator's spectrum even is, is the business of Ch. 90.

Further out lies the **Langlands program**, a web of conjectures, proved only in pieces, predicting that representations of symmetry groups of number fields correspond to automorphic functions generalising the j-function. Wiles' proof of Fermat's Last Theorem was one corner of it. And tensor products of representations, which is how two spin-$\frac{1}{2}$ particles combine into spin 0 and spin 1, are taken up in Ch. 93.

Chapter 96 — Mathematical Economics and Social Choice

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 6, Ch. 23, Ch. 42, Ch. 44 · **Leads to:** Ch. 97, Ch. 98 · **Related:** Ch. 39, Ch. 41, Ch. 43, Ch. 47, Ch. 30 **Reading time:** ~30 min

96.1 The hook

In 1951 a young economist named Kenneth Arrow published two results that seem to contradict each other.

The first was a mathematical version of Adam Smith's "invisible hand". Let millions of selfish people trade at market prices, each caring only about their own basket of goods. If prices settle where supply meets demand, the outcome is **Pareto efficient**: no central planner, however wise, could rearrange the goods to make one person better off without making someone else worse off. Selfish choices, aggregated by prices, give a collectively optimal result.

The second was his doctoral thesis, *Social Choice and Individual Values*. It asked whether a society could aggregate its members' preferences by *voting*, and it said no. Any rule that turns individual rankings of three or more options into a social ranking, respects unanimity, and judges each pair of options by individual opinions on that pair alone, must be a **dictatorship**: one voter's ranking decides everything.

So markets aggregate preferences perfectly and ballots cannot aggregate them at all. Arrow shared the 1972 Nobel prize largely for these two results, and it is not obvious that they can both be true. Hasn't a market just counted votes in dollars?

This chapter proves both theorems, and on the way it settles several debts left by the game-theory track: why Gibbard–Satterthwaite forces a dictator (Ch. 42), why no trading rule can be efficient and balanced at once, and why haggling ends at the Nash bargaining solution (Ch. 44). The answer to the hook turns out to be about *information*. A price carries more than a vote does, and it asks for less.

96.2 The big idea

Start with one person. Economics doesn't assume we can measure happiness. It assumes only that you can *compare*: given two bundles, you prefer one, or the other, or you're indifferent. A utility function is merely a way of writing those comparisons as numbers, and any increasing relabelling of it ($u \mapsto u^3$, $u \mapsto \ln u$) describes the same person. Utility is **ordinal**.

Now two people, Ann and Bob, and two goods, apples and bread. Draw a rectangle whose width is the total number of apples and whose height is the total bread. A point inside is a way to split everything: measure Ann's holdings from the bottom-left corner and Bob's from the top-right. This is the **Edgeworth box**, and every question about two-person exchange becomes geometry inside it.

Through the starting point (the **endowment**) runs one of Ann's indifference curves and one of Bob's. Between them is a lens of allocations that *both* prefer. Trading inside the lens helps both. Trading stops being mutually helpful only when the two indifference curves touch without crossing, that is, when their slopes (the rates at which each would swap apples for bread) are equal. The locus of all such tangencies is the **contract curve**, the set of Pareto-efficient splits.

A price line through the endowment is a budget: at price ratio p, Ann can sell apples for bread along it. Each person picks their favourite point on the line, so each sets their own rate of substitution equal to the *same* price. That is why markets hit the contract curve. Everyone's private trade-off is aligned to one public number, and nobody needs to know anyone else's preferences.

Voting fails to do this because a ranking carries no rate of exchange. Arrow's independence axiom says society's verdict on a versus b may depend only on who prefers a to b, not on *how much*. Prices express intensity, and ballots by construction don't. Both theorems are about how much information an aggregation rule is allowed to use.

96.3 The mathematics

Preferences and utility

> **Preference relation**
>
> A **preference** on a set X of bundles is a relation $\succsim$ ("at least as good as") that is **complete** (for all x, y: $x \succsim y$ or $y \succsim x$) and **transitive**. A function $u : X \to \mathbb{R}$ **represents** it if $x \succsim y \iff u(x) \geq u(y)$.

On a finite set every preference has a utility (rank the bundles and number them). On $\mathbb{R}^2$ the natural-looking **lexicographic** order, "more apples is better, and bread only breaks ties", has none.

Proof. Suppose u represents it. For each apple quantity $x \in \mathbb{R}$, $(x, 1) \succ (x, 0)$, so the interval $I_x = (u(x,0), u(x,1))$ is non-empty and contains a rational q_x. If $x < x'$ then $(x, 1) \prec (x', 0)$, so I_x lies entirely below $I_{x'}$ and $q_x \neq q_{x'}$. That gives an injection from $\mathbb{R}$ into $\mathbb{Q}$, which is impossible because $\mathbb{R}$ is uncountable (Ch. 64). ∎

Debreu proved in 1954 that **continuity** (strict-preference sets are open) is enough to guarantee a continuous utility, which is what licenses calculus in economics.

Exchange, efficiency and equilibrium

Let consumers $i = 1, \dots, I$ have endowments $\boldsymbol{\omega}_i \in \mathbb{R}^L_{\geq 0}$ of L goods. An **allocation** $(\mathbf{x}_i)$ is **feasible** if $\sum_i \mathbf{x}_i = \sum_i \boldsymbol{\omega}_i$. It is **Pareto efficient** if no feasible allocation makes everyone weakly better off and someone strictly better off, the multi-objective optimality of §23.9.

Walrasian (competitive) equilibrium

A price vector $\mathbf{p}$ and a feasible allocation $(\mathbf{x}_i^*)$ such that each $\mathbf{x}_i^*$ is a best bundle for i in the budget set $\{\mathbf{x} \geq 0 : \mathbf{p}\cdot\mathbf{x} \leq \mathbf{p}\cdot\boldsymbol{\omega}_i\}$.

Ann and Bob

Ten apples and ten loaves in total. Ann starts with $(8,2)$ and has $u_A = x^{0.6}y^{0.4}$; Bob starts with $(2,8)$ and has $u_B = x^{0.4}y^{0.6}$. Fix the bread price at 1 and the apple price at p. Maximising $x^a y^{1-a}$ on a budget I by a Lagrange multiplier (§6.11) gives the Cobb–Douglas rule "spend the fraction a on apples": $x = aI/p$. Ann's income is $8p+2$ and Bob's is $2p+8$. Apples clear when

$$\frac{0.6(8p+2)+0.4(2p+8)}{p} = 10 \iff 5.6p + 4.4 = 10p \iff p = 1.$$

So Ann ends with $(6,4)$ and Bob with $(4,6)$. Equal rates of substitution, $\frac{0.6}{0.4}\frac{y}{x} = \frac{0.4}{0.6}\frac{10-y}{10-x}$, give the contract curve $y = 8x/(18-x)$, and $(6,4)$ lies on it: $48/12 = 4$.

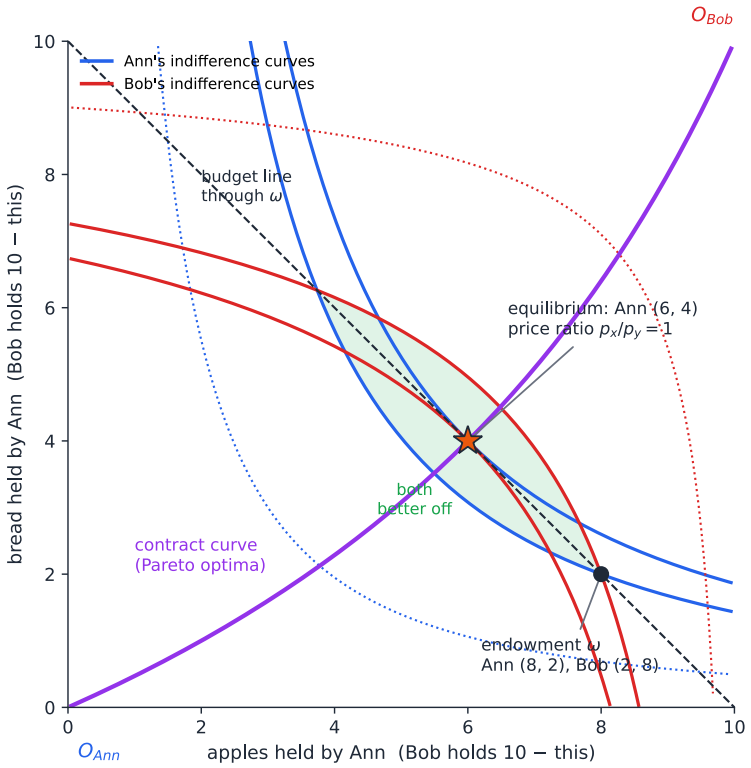

Figure 96.1 — The Edgeworth box. Trades in the green lens help both. The price line through the endowment meets the contract curve exactly where both indifference curves are tangent to it.

First fundamental theorem of welfare economics

If preferences are **locally non-satiated** (near any bundle there is a strictly better one), every Walrasian equilibrium allocation is Pareto efficient.

Proof. Let $(\mathbf{p}, \mathbf{x}^*)$ be an equilibrium and suppose a feasible $(\mathbf{y}_i)$ Pareto-dominates it. If $\mathbf{y}_j \succ_j \mathbf{x}_j^*$, then $\mathbf{y}_j$ was unaffordable, so $\mathbf{p}\cdot\mathbf{y}_j > \mathbf{p}\cdot\boldsymbol{\omega}_j$. If $\mathbf{y}_i \succsim_i \mathbf{x}_i^*$, then $\mathbf{p}\cdot\mathbf{y}_i \geq \mathbf{p}\cdot\boldsymbol{\omega}_i$. Otherwise $\mathbf{y}_i$ would cost strictly less than the budget, a slightly better bundle nearby would still be affordable, and it would beat $\mathbf{x}_i^*$, contradicting optimality. Summing over all consumers, with at least one strict inequality,

$$\mathbf{p}\cdot\sum_i \mathbf{y}_i > \mathbf{p}\cdot\sum_i \boldsymbol{\omega}_i,$$

which contradicts feasibility $\sum_i \mathbf{y}_i = \sum_i \boldsymbol{\omega}_i$. ∎

Notice what the proof did *not* use: convexity, differentiability, or anyone knowing anyone else's tastes. Prices did all the coordinating. Two companions complete the picture. The **second welfare theorem** says that with convex preferences *every* Pareto optimum is an equilibrium after suitable lump-sum transfers. Its proof is a separating hyperplane, whose normal vector *is* the price (Ch. 47, Ch. 48). **Existence** of an equilibrium (Arrow and Debreu, 1954) is a fixed-point theorem: the map "raise prices of over-demanded goods" sends the price simplex continuously into itself, the same kind of fixed-point argument (Brouwer's theorem, or Kakutani's extension of it) that gives Nash equilibria (Ch. 39).

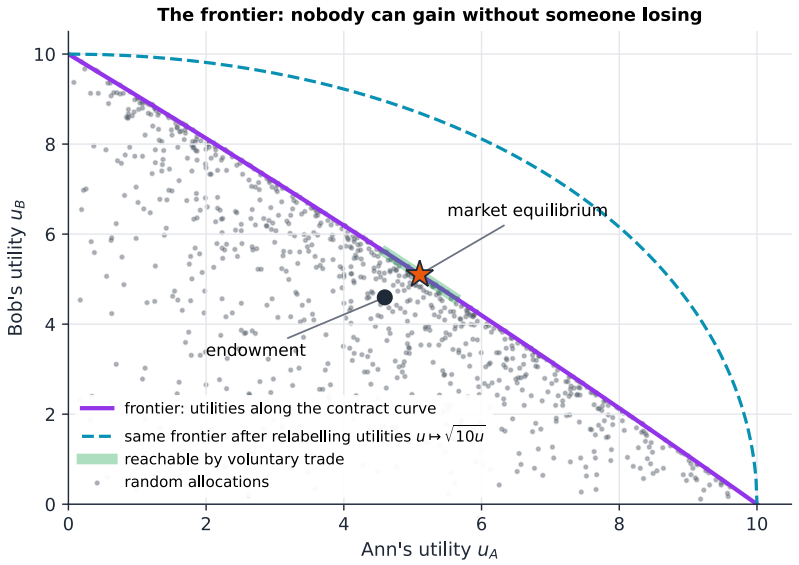

Figure 96.2 — The utility-possibility frontier. The market lands on it, but only somewhere in the short green segment the endowment allows. Its shape is not even meaningful: relabelling utilities (same preferences) bends a straight line into a circle.

Figure 96.2 already hints at the hook's answer. Efficiency is a very weak demand. Every point of the frontier is efficient, including "Ann gets everything". Choosing *among* efficient points is a question of justice, and it requires comparing Ann's welfare with Bob's, a comparison that ordinal utility forbids.

Arrow's theorem, proved

Let A be a set of at least three alternatives and $N = \{1, \dots, n\}$ the voters. A **social welfare function** F maps each profile of strict individual rankings to a strict social ranking. The axioms (stated in §42.3) are **unanimity** (if all rank a above b, so does society) and **independence of irrelevant alternatives** (IIA: society's a-versus-b verdict depends only on each voter's a-versus-b verdict).

Arrow (1951)

If $|A| \geq 3$ and F satisfies unanimity and IIA, some voter n^* is a dictator: society ranks a above c whenever n^* does.

Proof (following Geanakoplos, 2005).

Step 1: extremes stay extreme. Suppose every voter puts alternative b at the very top or very bottom of their ranking. We claim society does too. If not, there are a, c with $a \succ b \succ c$ socially. Change every voter's ranking by moving c just above a. No voter's a-versus-b or b-versus-c comparison changes, because b is extreme. By IIA society still has $a \succ b$ and $b \succ c$, so $a \succ c$ by transitivity. But now every voter has c above a, and unanimity demands $c \succ a$. Contradiction.

Step 2: find the pivot. Start with a profile where everyone ranks b last, so society does (unanimity). Move b to the top of voter 1's ranking, then voter 2's, and so on. At the end everyone ranks b first and so does society. Let n^* be the first voter whose move changes society's ranking of b. By Step 1 it jumps from bottom to top. Call the profiles just before and just after this move I and II.

Step 3: n^* dictates every pair not involving b. Take $a, c \neq b$ and any profile in which n^* ranks a above c. Rearrange it, without changing anyone's a-versus-c order, so that n^* ranks $a \succ b \succ c$, voters before n^* put b first and voters after put b last. On the pair $\{a, b\}$ every voter now agrees with profile I, where b was socially last, so by IIA society has $a \succ b$. On $\{b, c\}$ every voter agrees with profile II, where b was socially first, so $b \succ c$. Hence society has $a \succ c$. Everyone except n^* ranked a and c arbitrarily, so by IIA society follows n^* on $\{a, c\}$.

Step 4: n^* dictates pairs involving b too. Repeat Steps 2–3 with a third alternative c in the role of b. This produces a voter who dictates every pair not involving c, including $\{a, b\}$. But going from profile I to profile II, only n^* changed her ranking, and society's verdict on a versus b flipped. So nobody other than n^* can dictate $\{a, b\}$, and the new dictator is n^* again. ∎

Kinship with Gibbard–Satterthwaite. Given a strategy-proof voting rule f that picks a winner and can elect anyone, define a social ranking by "a above b if f elects a when every voter lifts a and b (in their own order) to the top of their ballot". Strategy-proofness implies that this ranking satisfies IIA and is transitive, and ontoness gives unanimity. Arrow then supplies a dictator, and that dictator's favourite always wins under f. The pivotal voter of Step 2 is the "voter whose ranking flips society's choice" that Ch. 42 promised.

Why markets escape: an exchange economy isn't a social welfare function on arbitrary rankings. Preferences are restricted (more is better, convexity), the outcome is an allocation rather than a ranking, and prices use the *marginal rates* that IIA throws away. Restrict preferences for voting too, for example to **single-peaked** ones (each voter has an ideal point on a left–right line), and majority rule becomes transitive again (Black, 1948).

? How often can a voter cheat?

Gibbard–Satterthwaite says every non-dictatorial rule is manipulable at *some* profile. Is manipulation common or vanishingly rare? Friedgut, Kalai and Nisan (2008), and then Mossel and Rácz (2015) for any number of alternatives, proved that for any rule far from every dictatorship, a random profile is manipulable with probability at least an inverse polynomial in n and the number of alternatives. The proofs use Fourier analysis on the group $\{0,1\}^n$, which is the representation theory of Ch. 95. What the *sharp* bound is remains open.

Bargaining as a game: Rubinstein

Two players split a pie of size 1. Player 1 offers a split, and player 2 accepts or rejects. After a rejection, one period passes and player 2 makes an offer, and so on forever. A payoff received t periods from now is worth δ^t of its face value, with $0 < \delta < 1$.

> **Rubinstein (1982)**
>
> The game has a unique subgame-perfect equilibrium. The first proposer gets $\dfrac{1}{1+\delta}$, the responder accepts at once, and nothing is wasted.

Proof (Shaked and Sutton). Every subgame where a given player proposes is the same game. Let M and m be the supremum and infimum of the proposer's payoff over all subgame-perfect equilibria. A responder who rejects becomes the proposer next period, worth at most δM today. So any offer giving her more than δM is accepted, and the proposer can secure nearly $1-\delta M$: $m \ge 1-\delta M$. Rejecting is worth at least δm to the responder, so she never accepts less, and the proposer gets at most $1-\delta m$ (a rejected offer gives the proposer at most $\delta(1-m) \le 1-\delta m$): $M \le 1-\delta m$. Combining,

$$M \le 1-\delta m \le 1-\delta(1-\delta M) \implies M(1-\delta^2) \le 1-\delta \implies M \le \frac{1}{1+\delta},$$

and then $m \ge 1-\delta M \ge \frac{1}{1+\delta}$. So $M = m = \frac{1}{1+\delta}$. ∎

The first-mover advantage $\frac{1}{1+\delta} - \frac{\delta}{1+\delta}$ vanishes as offers come faster. With different patience rates, $\delta_i = e^{-r_i\Delta}$ for a period of length Δ, the stationary equations $x_1 = 1-\delta_2 x_2$, $x_2 = 1-\delta_1 x_1$ give

$$x_1 = \frac{1-\delta_2}{1-\delta_1\delta_2} = \frac{1-e^{-r_2\Delta}}{1-e^{-(r_1+r_2)\Delta}} \longrightarrow \frac{r_2}{r_1+r_2} \quad (\Delta \to 0).$$

That is precisely the maximiser of the weighted Nash product $x^{1/r_1}(1-x)^{1/r_2}$. With equal patience it is the symmetric Nash solution $\frac{1}{2}$ of Ch. 44. Nash's axioms are what impatience looks like in the limit, and patience is bargaining power.

Two more debts: Shapley and Myerson–Satterthwaite

Why Shapley's axioms leave no freedom. Every game v on N is uniquely a combination $v = \sum_{T \ne \varnothing} c_T\, u_T$ of **unanimity games** $u_T(S) = 1$ if $T \subseteq S$, else 0 (solve for the "dividends" c_T by inclusion–exclusion). In $c\,u_T$, players outside T are null and those inside are symmetric, so efficiency forces $c/|T|$ each. Additivity then fixes the value of every game: $\phi_i(v) = \sum_{T \ni i} c_T/|T|$. For the microgrid of Ch. 44 the dividends are $c_A = 10$, $c_B = 20$, $c_C = 0$, $c_{AB} = 10$, $c_{AC} = c_{BC} = 40$, $c_{ABC} = -30$, and A gets $10 + 5 + 20 - 10 = 25$, as before. Drop additivity and you get the nucleolus, the Banzhaf index and other values, each defensible and each different.

Why efficient trade can't balance its budget. A seller with cost c and a buyer with value v, both independent and uniform on $[0,1]$, want to trade whenever $v > c$. For any incentive-compatible mechanism that both agree to join, the payment identity of Ch. 42 (Myerson's lemma, applied to each side) shows that an exactly balanced budget requires expected **virtual surplus**

$$E\Big[\big(\underbrace{2v-1}_{\text{buyer's virtual value}} - \underbrace{2c}_{\text{seller's virtual cost}}\big)\, q(v,c)\Big] \;\ge\; 0,$$

where q is the probability of trade. For efficient trade, $q = \mathbf{1}\{v > c\}$, and the left side is $\int_0^1 \int_0^v (2v-1-2c)\,dc\,dv = \int_0^1 (v^2 - v)\,dv = -\frac{1}{6} < 0$. So no such mechanism exists (Myerson and Satterthwaite, 1983). The best achievable rule trades only when $v - c \ge \frac{1}{4}$. It makes the integral exactly 0 and captures $\frac{9}{64}$ of the $\frac{1}{6}$ available gains, about 84%.

96.4 The algorithm

Arrow's theorem is small enough to check by brute force. With two voters and three alternatives, IIA means a rule is just one function per pair from "(voter 1 prefers x?, voter 2 prefers x?)" to "society prefers x?". Unanimity fixes two of the four inputs, so each pair has two free bits and there are $2^6 = 64$ candidate rules. Keep those that never produce a cycle on any of the $6^2 = 36$ profiles:

```
from itertools import permutations, product, combinations

alts = "abc"
rankings = list(permutations(alts))                 # 6 strict rankings
pairs = list(combinations(alts, 2))                 # (a,b), (a,c), (b,c)
prefers = lambda r, x, y: r.index(x) < r.index(y)

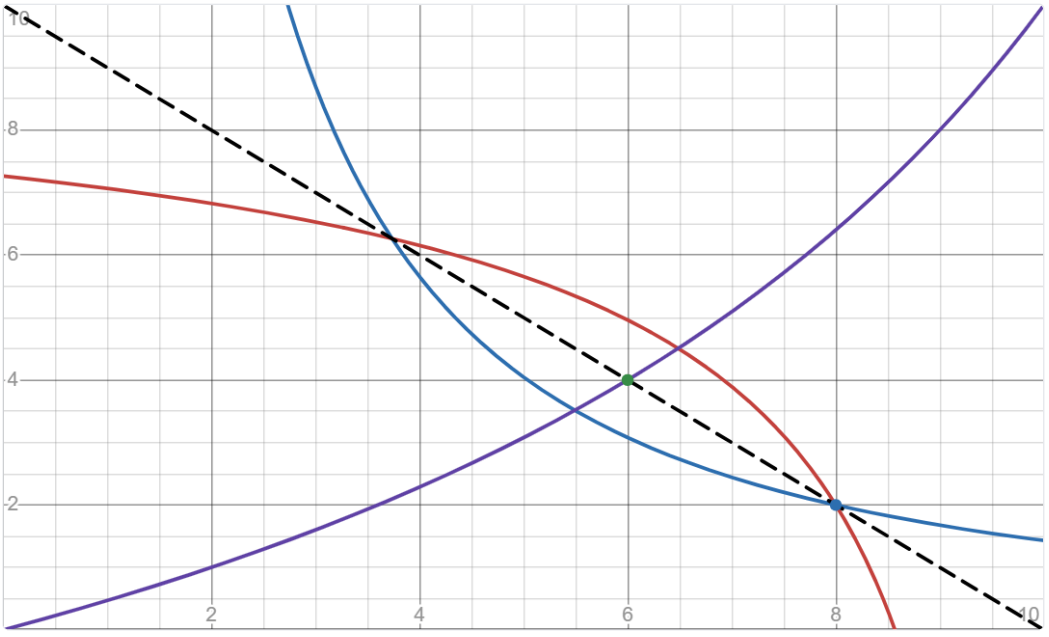
survivors = []
for bits in product([False, True], repeat=6):
    rule = {p: {(True, True): True, (False, False): False,
                (True, False): bits[2 * i], (False, True): bits[2 * i + 1]} for i, p in enumerate(pairs)}
    def social(profile, x, y):                      # does society rank x above y?
        if (x, y) in rule:
            return rule[(x, y)][tuple(prefers(r, x, y) for r in profile)]
        return not rule[(y, x)][tuple(prefers(r, y, x) for r in profile)]
    ok = all(not (social(P, x, y) and social(P, y, z) and social(P, z, x))
             for P in product(rankings, repeat=2) for x, y, z in permutations(alts))
    if ok:
        survivors.append(bits)
print(len(survivors), "transitive rules out of 64:", survivors)
```

Exactly two rules survive: "voter 1 decides every pair" and "voter 2 decides every pair". For three voters the same search has 2^{18} candidates, and it is still instant. Brute force grows doubly exponentially, though: n voters give $2^n - 2$ free bits per pair. Computer proofs of impossibility theorems (Tang and Lin, 2009, using a SAT solver) work by reducing to such a small base case and proving an induction step by hand.

Computing a market equilibrium is harder than checking one. The natural algorithm is **tâtonnement** ("groping"), Walras' own idea: raise the price of every good in excess demand, lower it for goods in excess supply, and repeat. Each step costs one evaluation of the excess-demand function $\mathbf{z}(\mathbf{p}) = \sum_i \big(\mathbf{x}_i(\mathbf{p}) - \boldsymbol{\omega}_i\big)$. For economies where goods are **gross substitutes** (raising one price raises demand for every other good), tâtonnement converges. In general it need not, and Scarf's algorithm (1967), which follows a path through a triangulated price simplex, was the first method guaranteed to find an approximate fixed point.

96.5 The experiment

First, drag the Edgeworth box. Ann's weight on apples is 0.6 and Bob's is 0.4; the endowment is $(8, 2)$.



Ann's (blue) and Bob's (red) indifference curves through the endowment, the contract curve (purple) and the budget line at price ratio 1.

Change the endowment $(8, 2)$ to $(9, 5)$ (replace both $8^{0.6} \cdot 2^{0.4}$ and $2^{0.4} \cdot 8^{0.6}$ by the new holdings, Ann's in the first line and Bob's $(1, 5)$ in the second). The lens moves, but the contract curve does not, because it depends only on preferences. Then change the weights 0.6 and 0.4 to equal values 0.5 and watch the contract curve straighten into the diagonal.

Then run tâtonnement, first on the box economy and then on Herbert Scarf's 1960 economy. In Scarf's economy three consumers each own one good and want two goods in fixed proportions.

```
import numpy as np

# Tatonnement: raise the price of whatever is over-demanded, lower it if under-demanded.
a, b = 0.6, 0.4                 # Cobb-Douglas weights on apples for Ann and Bob
wA = np.array([8.0, 2.0])       # Ann's endowment (apples, bread); Bob has the rest
wB = np.array([10.0, 10.0]) - wA

def excess_box(p):              # p = (p_apple, p_bread)
    IA, IB = p @ wA, p @ wB
    xA = np.array([a * IA / p[0], (1 - a) * IA / p[1]])
    xB = np.array([b * IB / p[0], (1 - b) * IB / p[1]])
    return xA + xB - wA - wB

def excess_scarf(p):            # Scarf (1960): consumer i owns good i, wants goods i and i+1 in fixed 1:1 ratio
    z = -np.ones(3)
    for i in range(3):
        k = (i + 1) % 3
        q = p[i] / (p[i] + p[k])          # consumer i's income buys q units of each of goods i and k
        z[i] += q; z[k] += q
    return z

def tatonnement(excess, p, h=0.05, steps=4000):
    path = [p.copy()]
    for _ in range(steps):
        p = np.maximum(p + h * excess(p), 1e-9)
        p = p / p.sum()                   # only relative prices matter
        path.append(p.copy())
    return np.array(path)

box = tatonnement(excess_box, np.array([0.8, 0.2]))
print("box economy: final prices", box[-1].round(4), " excess demand", excess_box(box[-1]).round(6))

scarf = tatonnement(excess_scarf, np.array([0.5, 0.3, 0.2]))
dist = np.linalg.norm(scarf - 1 / 3, axis=1)
print("Scarf economy: distance from equilibrium (1/3,1/3,1/3) at steps 0, 1000, 2000, 4000:",
      dist[[0, 1000, 2000, 4000]].round(4))
```

The box economy settles at equal prices $(0.5, 0.5)$, our $p = 1$. Scarf's economy has a unique equilibrium at equal prices, yet the distance from it *grows* from 0.22 to about 0.5, and prices circle the equilibrium without ever approaching it. Things to try: shrink the step `h` to 0.005 (does the spiral stop growing?), start Scarf's prices at exactly $(1/3, 1/3, 1/3)$ plus a tiny nudge, and plot `scarf[:, 0]` against `scarf[:, 1]` to see the orbit.

? The market that never settles

In continuous time Scarf's prices move on closed orbits around the equilibrium forever. His economy is perfectly well behaved (unique equilibrium, continuous demand), yet the invisible hand never finds it. Whether an equilibrium is *stable* is a question about a dynamical system $\dot{\mathbf{p}} = \mathbf{z}(\mathbf{p})$, and centres, spirals and limit cycles are classified in Ch. 83.

96.6 The challenge

1. **Intuition.** In the Edgeworth box, why must the contract curve pass through both corners? Is the equilibrium's position on the contract curve determined by preferences, by endowments, or by both?
2. **Derivation.** Borda count (Ch. 44) satisfies unanimity and isn't a dictatorship, so by Arrow it violates IIA. Construct an explicit three-voter, three-candidate pair of profiles in which no voter changes her a-versus-b order but Borda's social a-versus-b order flips.
3. **Implementation.** Extend the brute-force Arrow search to three voters (2^{18} rules). Then drop unanimity (all 4 inputs free per pair, 2^{24} rules for three voters) and list the transitive IIA rules that survive. Wilson's theorem (1972) predicts what they are: describe them.
4. **Open investigation.** Run tâtonnement on random exchange economies with three goods and Cobb–Douglas, Leontief or CES consumers. Estimate how often it fails to converge as preferences move from substitutes towards complements. No general characterisation of the economies on which simple price dynamics converge is known.

96.7 Loose threads

The hook asked how markets can aggregate preferences perfectly while votes cannot aggregate them at all. Now we can say. The first welfare theorem asks for very little (efficiency only, which even "Ann gets everything" satisfies), and it gets to use prices, which encode marginal rates of substitution. Arrow asks for much more, a full social ranking that works on every possible profile, while IIA forbids it to use intensity. Prices carry information that ballots throw away, and markets promise something that ballots are asked to exceed. Rubinstein added that even raw haggling, given impatience, ends at Nash's axiomatic split. Myerson–Satterthwaite added a limit on what any market can do when people hold private information.

What we didn't tell you:

- **Common values and the winner's curse.** In the auctions of Ch. 43, when an item is worth the same unknown amount to everyone, winning means you were the most optimistic. Milgrom and Weber (1982) made "affiliated" signals precise: high signals make other high signals more likely. They proved the **linkage principle**, which says that formats tying the price more closely to other bidders' information raise expected revenue. So the English auction beats the second-price auction, which beats the first-price. The 2020 Nobel prize was awarded for the spectrum auctions built on this.
- **Which equilibrium is reasonable?** The Intuitive Criterion of Ch. 41 kills implausible beliefs in signalling games, but stronger refinements (divinity, stability in the sense of Kohlberg and Mertens) can disagree with it, and experiments find people often play the "unreasonable" pooling equilibria. Whether refinement theory describes behaviour or only consistency is still argued.
- **Large markets.** Debreu and Scarf (1963) proved that as an economy is replicated, the **core** (allocations no coalition can block) shrinks to the set of Walrasian equilibria. With many traders, competitive prices are the only allocations that survive coalitional bargaining.

? Anything can happen, and finding it is hard

Individual demand functions have strong structure, but the Sonnenschein–Mantel–Debreu theorem (1972–74) says aggregate excess demand can be essentially *any* continuous function satisfying Walras' law. So economic theory alone predicts almost nothing about the number, location or stability of equilibria. And finding one is, in general, as hard as finding a Brouwer fixed point: computing equilibria of exchange economies is PPAD-complete. What PPAD is, and why guaranteed existence doesn't make search easy, is in Ch. 30.

Each of these is a doorway into the economics research literature. The proofs you have just seen, an inequality summed over consumers, a pivot hunted down by moving one voter at a time, a sup and an inf squeezed together, are typical of how that literature works: short arguments around a clever choice of what to compare. How such arguments are found is the subject of Ch. 98.

Chapter 97 — Measure Theory and Modern Probability

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 5, Ch. 19, Ch. 31, Ch. 36, Ch. 60 · **Leads to:** Ch. 98, Ch. 89 · **Related:** Ch. 35, Ch. 55, Ch. 61, Ch. 73, Ch. 80 **Reading time:** ~30 min

97.1 The hook

Throw an ideal dart at the interval $[0, 1]$, so that every point is equally likely. What is the probability that it lands *exactly* on 0.5?

It must be zero. If it were some $\varepsilon > 0$, the same would be true for every point, and a million points would already carry total probability $10^6\varepsilon$, which exceeds 1 once $\varepsilon > 10^{-6}$. So every single point has probability 0, and yet the dart lands *somewhere*, with probability 1. Zero plus zero plus zero, uncountably many times, makes one.

Fine, you say: probabilities add for countably many disjoint events, not uncountably many. Then the rationals in $[0, 1]$, which are countable, have total probability $0 + 0 + \cdots = 0$. The dart almost surely misses every rational, even though rationals are dense and lie between any two points it could hit.

Now two harder questions.

Can every set of points be given a probability? Not "every set you can describe", but *every* subset of $[0, 1]$. Surely the dart either lands in a set or it doesn't, so "the probability it lands in S" should mean something for every S.

Can a fair game be beaten? Bet 1 on a fair coin. If you lose, double the stake; stop at the first win. You stop with probability 1, and when you stop you are up exactly 1. Your fortune is a fair game (a martingale, Ch. 36), so its expectation should stay 0. Yet it ends at 1 with certainty.

The first question has the answer **no**, and the proof is half a page. The second has the answer "only if you have infinite credit", but saying precisely *why* requires rebuilding probability. In 1933 Andrei Kolmogorov did exactly that, by declaring that probability *is* a measure: a rule that assigns sizes to a carefully chosen family of sets. This chapter shows why the family has to be chosen, and what the rebuilding buys: a strong law of large numbers that needs only a mean, a precise version of "you can't beat a fair game", distributions with no density and no jumps, and a notion of dimension for wild sets.

97.2 The big idea

The Riemann integral of Ch. 5 slices the *domain* into thin strips and adds height × width. Lebesgue sliced the *range* instead (§60.3). For each height y, ask "how big is the set of x where $f(x) > y$?", and add up those sizes over all heights:

$$\int f\,dm = \int_0^\infty m\{x : f(x) > y\}\,dy \qquad (f \geq 0).$$

A banker counting a pile of coins does the same: rather than going through the coins in the order they lie (Riemann), she sorts them by denomination and multiplies each value by how many coins have it (Lebesgue). The order of the coins no longer matters, only the *size* of each set $\{f > y\}$. That is why the Lebesgue integral copes with functions that jump about wildly.

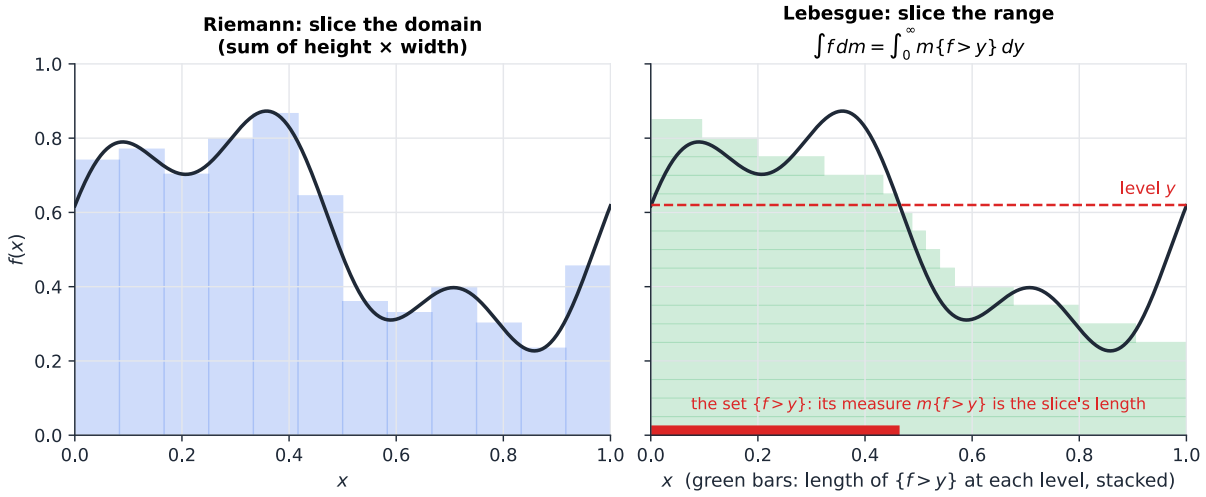

Figure 97.1 — Riemann versus Lebesgue. The Lebesgue integral needs only one thing, the size $m\{f > y\}$ of each "level set", however scattered that set is.

So everything rests on measuring sets. A **measure** is a size function that adds up correctly over countably many disjoint pieces. A **probability** is a measure with total size 1. A **random variable** is a function whose level sets can be measured, and its **expectation** is its Lebesgue integral. The family of sets we are allowed to measure, a **σ-algebra**, turns out to be more than a technicality: in probability it represents *information*. "The sets I can decide after seeing the first n coin tosses" is a σ-algebra, and a gambler's strategy may only use that one. This is how measure theory solves the doubling puzzle.

97.3 The mathematics

σ-algebra, measure, probability space

A **σ-algebra** on a set Ω is a family $\mathcal{F}$ of subsets that contains Ω and is closed under complements and countable unions. A **measure** is a map $\mu : \mathcal{F} \to [0,\infty]$ with $\mu(\varnothing) = 0$ and **countable additivity**: $\mu\big(\bigcup_k A_k\big) = \sum_k \mu(A_k)$ for disjoint $A_1, A_2, \ldots \in \mathcal{F}$. A **probability space** $(\Omega, \mathcal{F}, P)$ is a measure space with $P(\Omega) = 1$ (Kolmogorov, 1933). A **random variable** is a function $X : \Omega \to \mathbb{R}$ with $\{X \le t\} \in \mathcal{F}$ for every t, and $E[X] = \int_\Omega X \, dP$.

Countable additivity gives continuity for free. If $A_1 \subseteq A_2 \subseteq \cdots$, then writing $\bigcup A_n$ as the disjoint union of the rings $A_n \setminus A_{n-1}$ gives $\mu(\bigcup A_n) = \lim \mu(A_n)$. Almost every limit theorem in probability starts from this one line.

Result 1: you cannot measure every set

Vitali (1905)

There is no function μ defined on *all* subsets of the circle $[0,1)$ (with addition mod 1) that is countably additive, invariant under rotation, and has $\mu([0,1)) = 1$.

Proof. Call $x \sim y$ if $x - y$ is rational. This splits $[0,1)$ into equivalence classes, each a rotated copy of $\mathbb{Q} \cap [0,1)$. Using the axiom of choice, pick exactly one point from each class, and call the resulting set V. For each rational $q \in [0,1)$ let $V_q = V + q \pmod 1$.

The sets V_q are disjoint: if $v + q \equiv v' + q'$ with $v, v' \in V$, then $v \sim v'$, so $v = v'$ (one point per class) and $q = q'$. They cover $[0,1)$: any x is equivalent to some $v \in V$, and $x - v \equiv q$ for a rational q. So $[0,1)$ is the disjoint union of countably many rotated copies of V. If μ existed, rotation invariance would make all $\mu(V_q)$ equal to $\mu(V)$, and countable additivity would give

$$1 = \mu([0,1)) = \sum_{q} \mu(V_q) = \sum_{q} \mu(V) \in \{0, \infty\}.$$

Contradiction. ■

This is why probability needs σ-algebras: we must give up measuring *some* sets. The good news (Carathéodory's extension theorem) is that we lose nothing we care about. Length on intervals extends uniquely to a countably additive measure on the **Borel** σ-algebra, the smallest one containing all intervals, which includes every set you can build from intervals by countably many unions, intersections and complements. Vitali's set needed the axiom of choice to exist at all, which answers the question Ch. 60 left open. Solovay showed in 1970 that, if one gives up full choice (and assumes a large cardinal is consistent), it is consistent that *every* set of reals is Lebesgue measurable.

The same extension builds infinite coin-tossing. Write the dart's position in binary, $x = 0.b_1 b_2 b_3 \ldots$. Under Lebesgue measure the digits b_k are independent fair coin flips. So "an infinite sequence of fair tosses" and "a uniform point of $[0,1]$" are the same probability space. The strong law of large numbers for coins becomes **Borel's normal number theorem** (1909): Lebesgue-almost every real number has, in its binary expansion, half its digits equal to 1. Kolmogorov's **extension theorem** generalises this. Any consistent family of finite-dimensional distributions comes from one probability measure on the space of whole paths, and that is how Brownian motion is constructed. The Gaussian finite-dimensional distributions of Ch. 36 define a measure on paths, and a further argument (Kolmogorov's continuity criterion, or Lévy's explicit series of tent functions) shows that the paths can be taken continuous. The resulting **Wiener measure** puts probability 1 on paths that are differentiable nowhere.

? One ball becomes two

Vitali's set is a mild warning. In 1924 Banach and Tarski cut a solid ball into five pieces and, using only rotations and translations, reassembled them into *two* balls each identical to the original. The pieces are non-measurable, so no volume is violated, because none is assigned. In one or two dimensions this is impossible: a finitely additive, motion-invariant "area" exists on every subset of the plane. The difference is that the rotation group of space contains a free group, and the plane's doesn't. Why that algebraic fact breaks geometry, and what it says about the axiom of choice, is in Ch. 68.

Result 2: big sets of size zero, and the dimension between

Build the **Cantor set** C: from $[0,1]$ remove the open middle third $(\tfrac13, \tfrac23)$, then the middle third of each remaining piece, and so on forever. After n steps 2^n intervals of length 3^{-n} remain.

The Cantor set is uncountable and has measure zero

$m(C) = 0$, yet C has as many points as $[0,1]$. Its Hausdorff dimension is at most $\log 2 / \log 3 \approx 0.6309$ (in fact exactly this).

Proof. C is contained in the n-th stage, which has length $(2/3)^n \to 0$, so $m(C) = 0$. A point lies in C exactly when it has a ternary expansion $0.t_1 t_2 t_3 \ldots$ using only the digits 0 and 2. Mapping $t_k \mapsto t_k/2$ turns that into a binary expansion, a surjection from C onto $[0,1]$. So C is uncountable.

For dimension, define the s-dimensional **Hausdorff measure** $\mathcal{H}^s(A) = \lim_{\delta \to 0} \inf \sum_i (\operatorname{diam} U_i)^s$, the infimum taken over countable covers of A by sets U_i of diameter at most δ. The **Hausdorff dimension** is the value of s at which $\mathcal{H}^s$ drops from ∞ to 0. Cover C by its 2^n stage-n intervals:

$$\mathcal{H}^s_{3^{-n}}(C) \le 2^n \, (3^{-n})^s = \left(\frac{2}{3^s}\right)^n.$$

For $s > \log 2 / \log 3$ the base is below 1 and the bound tends to 0, so $\mathcal{H}^s(C) = 0$. Hence $\dim_H C \le \log 2 / \log 3$. The matching lower bound spreads mass evenly over C and shows that no cover can do much better. ■

So Hausdorff measure interpolates between counting ($s=0$), length ($s=1$) and area ($s=2$). It also answers Ch. 73. A set can have zero area and still have $\mathcal{H}^s > 0$ for every $s < 2$, so dimension 2 does not require area. Shishikura proved that the boundary of the Mandelbrot set has Hausdorff dimension 2. Whether it has positive area as well is still an open problem. Box counting uses covers by equal-sized boxes. Hausdorff dimension lets the sizes vary, so it can be smaller, for instance 0 for the countable set $\{0, 1, \frac{1}{2}, \frac{1}{3}, \dots\}$, whose box dimension is $\frac{1}{2}$.

Now spread probability evenly over C. Choose fair bits b_k and set $X = \sum_k 2b_k/3^k$. Its CDF F is the **Cantor function** (Figure 97.2). It is continuous, so X has no atoms: $P(X = x) = 0$ for every x. But F is flat on every removed interval, so $F' = 0$ almost everywhere and X has no density either, since $\int F' = 0 \neq 1$. Discrete or continuous with a density, the dichotomy of §19.7, is not the whole story.

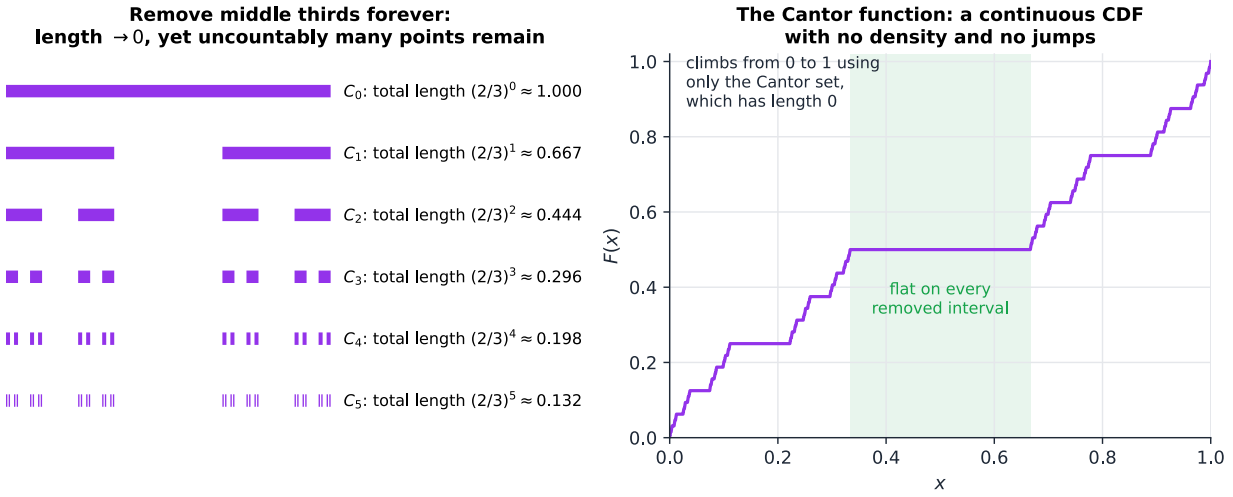

Figure 97.2 — The Cantor set and its distribution function. All the probability lives on a set of length zero, but no single point carries any of it.

The **Lebesgue decomposition theorem** says this is the only other possibility. Every probability distribution on $\mathbb{R}$ is uniquely a mixture of a discrete part, an absolutely continuous part (one with a density), and a **singular continuous** part like the Cantor distribution. The **Radon–Nikodym theorem** says when a density exists: μ has a density $d\mu/dm$ exactly when $m(A) = 0$ forces $\mu(A) = 0$. Likelihood ratios in statistics, change of measure in finance and the Wasserstein couplings of Ch. 55 are all Radon–Nikodym derivatives.

Convergence, made precise

The monotone and dominated convergence theorems were stated in §60.3. Measure theory adds an important distinction between kinds of convergence of random variables:

- **almost surely:** $P(X_n \to X) = 1$;
- **in probability:** $P(|X_n - X| > \varepsilon) \to 0$ for every ε;
- **in L^1:** $E|X_n - X| \to 0$;
- **in distribution:** CDFs converge at continuity points (the central limit theorem's kind).

Almost-sure convergence implies convergence in probability, but not conversely. Sweep an indicator of width $1/k$ repeatedly across $[0,1]$ (widths $1, \frac{1}{2}, \frac{1}{2}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \dots$). The probability of being hit tends to 0, yet every point is hit infinitely often, so the sequence converges at *no* point.

Kolmogorov's strong law. Let $X_1, X_2, \dots$ be independent with the same distribution. Then $\bar{X}_n \to \mu$ almost surely **if and only if** $E|X_1| < \infty$ and $\mu = E[X_1]$. If $E|X_1| = \infty$, then $\limsup |\bar{X}_n| = \infty$ almost surely. Ch. 31 proved the law with four moments. The proof with one moment **truncates**: let $Y_k = X_k \mathbf{1}\{|X_k| \le k\}$. Then

$$\sum_k P(X_k \neq Y_k) = \sum_k P(|X_1| > k) \le E|X_1| < \infty,$$

so by Borel–Cantelli only finitely many X_k differ from Y_k, and it suffices to study the Y_k. These are bounded, with $\sum_k \operatorname{Var}(Y_k)/k^2 < \infty$ (a short computation), and a maximal inequality then gives convergence of $\sum (Y_k - EY_k)/k$, which turns into convergence of averages by Kronecker's lemma. Etemadi (1981) found a proof that needs only pairwise independence. Everything happens on the single probability space of infinite sequences, which is why the measure-theoretic setting is not optional.

Result 3: you cannot beat a fair game, unless you can

Information enters through σ-algebras. A **filtration** $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \cdots$ lists what is known at each time. For coin tossing, $\mathcal{F}_n$ consists of the events decided by the first n tosses.

> **Conditional expectation, martingale, stopping time**
>
> Given X with $E|X| < \infty$ and a sub-σ-algebra $\mathcal{G}$, the **conditional expectation** $E[X \mid \mathcal{G}]$ is the (almost surely unique) $\mathcal{G}$-measurable Y with $E[Y\mathbf{1}_A] = E[X\mathbf{1}_A]$ for every $A \in \mathcal{G}$. It exists by Radon–Nikodym. When $E[X^2] < \infty$ it is the orthogonal projection of X onto the $\mathcal{G}$-measurable variables (§9.9), the best guess of X from the information in $\mathcal{G}$. A **martingale** is a sequence M_n, each $\mathcal{F}_n$-measurable and integrable, with $E[M_{n+1} \mid \mathcal{F}_n] = M_n$. A **stopping time** is a random time τ with $\{\tau \le n\} \in \mathcal{F}_n$: you decide to stop using only the past.

Optional stopping (bounded version)

If M is a martingale and $\tau \le N$ is a bounded stopping time, then $E[M_\tau] = E[M_0]$.

Proof. Write the stopped value as a sum of the increments you were present for:

$$M_\tau = M_0 + \sum_{k=1}^{N} \mathbf{1}\{\tau \ge k\}\,(M_k - M_{k-1}).$$

The event $\{\tau \ge k\}$ is the complement of $\{\tau \le k-1\}$, so it lies in $\mathcal{F}_{k-1}$. Conditioning on $\mathcal{F}_{k-1}$, the indicator is known and comes outside:

$$E\big[\mathbf{1}\{\tau \ge k\}(M_k - M_{k-1})\big] = E\big[\mathbf{1}\{\tau \ge k\}\,E[M_k - M_{k-1} \mid \mathcal{F}_{k-1}]\big] = 0.$$

Sum the finitely many terms. ■

The doubling strategy has an **unbounded** stopping time, and that is the only place it slips through. Its stopped fortune $M_{n\wedge\tau}$ is 1 with probability $1 - 2^{-n}$ and $-(2^n - 1)$ with probability 2^{-n}. That has mean exactly 0 for every n, by the theorem. As $n \to \infty$ it converges almost surely to 1, yet its mean stays 0. This is precisely the escaping-mass spike of §60.3: a loss of about 2^n on an event of probability 2^{-n}, which no integrable function dominates. The general theorem says $E[M_\tau] = E[M_0]$ whenever $\tau < \infty$ almost surely and the stopped process $\{M_{n\wedge\tau}\}$ is **uniformly integrable** (for example, dominated by one integrable variable). A sufficient condition is $E[\tau] < \infty$ together with bounded increments. Doubling has $E[\tau] = 2$, but its increments are unbounded. With any finite credit line, the strategy is a bounded stopping time and the game is fair again.

Martingale convergence (Doob)

If a martingale satisfies $\sup_n E|M_n| < \infty$, then M_n converges almost surely to a finite limit M_∞. If the martingale is uniformly integrable (for instance, bounded), then $M_n \to M_\infty$ in L^1 as well, and $M_n = E[M_\infty \mid \mathcal{F}_n]$.

The idea of Doob's proof is that a martingale which oscillated forever would have to cross some band $[a, b]$ infinitely often. Buying at a and selling at b would then be a winning strategy against a fair game, and an "upcrossing inequality" bounds the expected number of crossings by $\sup E|M_n|/(b-a)$. The doubling fortune is a warning here too: $E|M_{n\wedge\tau}| < 2$, so it converges almost surely (to 1), but not in L^1.

Martingale convergence is how polar codes (Ch. 80) are proved to work. Follow a random path down Arıkan's recursion, choosing the "better" or "worse" synthetic channel by a fair coin at each level. The capacity $I_n \in [0,1]$ of the channel you reach is a bounded martingale, because each split preserves average capacity. So I_n converges almost surely, and in particular $I_{n+1} - I_n \to 0$. But a split changes the capacity by an amount that is zero *only* when the capacity is already 0 or 1. (For the erasure channel this is exact: the split sends I to I^2 or $2I - I^2$.) So the limit is 0 or 1 almost surely: almost every channel polarises to useless or perfect, and by the martingale property the fraction that become perfect is the original capacity.

Bernstein–von Mises, stated properly. For a smooth, identifiable model with finitely many parameters, true parameter θ_0 and a prior with continuous positive density near θ_0,

$$\big\| \Pi(\cdot \mid X_1, \dots, X_n) - \mathcal{N}\big(\hat\theta_n,\, (nI(\theta_0))^{-1}\big) \big\|_{\mathrm{TV}} \;\to\; 0 \quad \text{in } P_{\theta_0}\text{-probability},$$

where $\hat\theta_n$ is the maximum-likelihood estimate and TV is total variation distance between measures. Every word in it ("in probability", "total variation", the conditional law Π) is measure-theoretic. Under misspecification, which was the question of Ch. 35, Kleijn and van der Vaart (2012) showed that the posterior still becomes Gaussian, centred at the KL-closest parameter θ^*. But its covariance is the inverse Hessian of the KL divergence, not the "sandwich" covariance of $\hat\theta_n$, so credible sets have the wrong frequentist coverage.

Carleson's theorem, finally, now has its precise form. If $\int_0^{2\pi} |f|^2 < \infty$, the Fourier partial sums $S_N f(x)$ converge to $f(x)$ for all x outside a Lebesgue-null set (Carleson, 1966; Hunt extended it to L^p, $p > 1$). For L^1 it fails badly: Kolmogorov built an integrable function whose Fourier series diverges almost everywhere (1923), and then one where it diverges everywhere (1926).

? Carleson in two dimensions

For a function on the torus $[0, 2\pi)^2$ there is no single "partial sum": you must choose which frequencies (k_1, k_2) to keep. Keep a growing square, $\max(|k_1|, |k_2|) \le N$, and Carleson's theorem extends (Fefferman, Sjölin, 1971). Keep a growing disc, $k_1^2 + k_2^2 \le R^2$, the most natural choice, and nobody knows whether the partial sums of every square-integrable function converge almost everywhere. Fefferman's 1971 theorem that the disc is a bad Fourier multiplier on L^p for $p \neq 2$ shows how strange discs are, but the L^2 question is **open**.

97.4 The algorithm

A computer never sees a non-measurable set, so measure theory's algorithms are about integrals, and the Lebesgue view gives a practical one. To integrate $f \ge 0$ against a measure μ that you can sample from, draw $X_1, \dots, X_n \sim \mu$, sort the values $f(X_i)$, and integrate the layer-cake formula $\int_0^\infty \mu\{f > y\}\,dy$ using the empirical fractions. Sorting and summing collapses this to the ordinary Monte Carlo average:

```
layer_cake(f, sample, n):
    v = sort([f(sample()) for _ in range(n)])            # O(n log n)
    # mu{f > y} is estimated by the fraction of v above y; integrate over y
    total = 0; prev = 0
    for i, y in enumerate(v):                            # between consecutive values
        total += (y - prev) * (n - i) / n                # height of slice * measure of level set
        prev = y
    return total                                         # equals mean(v) exactly
```

The telescoping identity "slice integral = sample mean" is why Monte Carlo (Ch. 38) is Lebesgue integration in disguise. It never needs f to be continuous, only measurable, and its error is $\sigma/\sqrt{n}$ whatever the dimension, whereas a Riemann grid's error degrades with dimension.

Two more computational facts:

- **Sampling singular distributions.** The Cantor variable is generated digit by digit, $X = \sum_k 2b_k/3^k$. With k digits the error is at most 3^{-k}, so 40 digits already reach the limit of double precision. Its CDF, the Cantor function, is computed the same way: read ternary digits until the first 1, then convert the 2s before it to binary 1s.
- **Computing Hausdorff dimension.** There is no general algorithm. For self-similar sets satisfying a separation condition, Moran's equation $\sum_i r_i^s = 1$ gives the dimension (for C: $2 \cdot 3^{-s} = 1$). For sets like the Mandelbrot boundary, numerical box counting gives only an estimate, and here it estimates a different quantity. Rigorous computer-assisted bounds on Hausdorff dimensions, for example of Julia sets, are an active research area.

97.5 The experiment

The script below tests three claims of this chapter: doubling with a credit limit is a fair game, the Cantor variable has no density and no atoms, and a bounded stopping time cannot beat a random walk.

```
import numpy as np
rng = np.random.default_rng(0)

# 1. The doubling gambler with a credit limit: at most K losses in a row can be covered.
K, trials = 10, 200_000                  # try K = 3, 10, 20
flips = rng.random((trials, K)) < 0.5    # True = win
first_win = np.where(flips.any(axis=1), flips.argmax(axis=1), K)
# stake 2^t at round t; win at round t nets +1, losing all K rounds nets -(2^K - 1)
gain = np.where(first_win < K, 1.0, -(2.0 ** K - 1))
print(f"K={K}: P(ruin) = {np.mean(gain < 0):.5f}, mean gain = {gain.mean():+.4f} "
      f"(+-{gain.std() / np.sqrt(trials):.4f})")

# 2. A random variable with no density and no atoms: X = sum 2*b_k / 3^k, b_k fair bits.
depth, n = 40, 200_000
bits = rng.integers(0, 2, size=(n, depth))
X = (2 * bits / 3.0 ** np.arange(1, depth + 1)).sum(axis=1)
print("mean, variance:", X.mean().round(4), X.var().round(4), " (theory 1/2 and 1/8)")
print("fraction landing in the removed middle third (1/3, 2/3):", np.mean((X > 1/3) & (X < 2/3)))
for L in [1, 3, 6]:                      # cover the support by 2^L intervals of length 3^-L
    cells = np.unique(np.floor(X * 3 ** L))
    print(f"level {L}: occupied cells {len(cells)} = 2^{L}, total length {len(cells) / 3 ** L:.4f}")

# 3. Optional stopping: a bounded stopping time cannot beat a fair game.
walk = np.cumsum(rng.choice([-1, 1], size=(trials, 50)), axis=1)
hit = np.argmax(walk >= 3, axis=1)                      # first time the walk reaches +3 ...
tau = np.where((walk >= 3).any(axis=1), hit, 49)        # ... or step 50, whichever comes first
print("E[M_tau] with tau <= 50:", walk[np.arange(trials), tau].mean().round(3))
```

With the seed above, $K = 10$ gives a ruin frequency near $2^{-10} \approx 0.00098$ and a mean gain of -0.08 ± 0.07, consistent with 0. The Cantor variable has mean 0.5004 and variance 0.1254 (theory $\frac{1}{2}$ and $\frac{1}{8}$), never lands in the removed middle third, and occupies exactly 2^L of the 3^L cells at level L. The stopped walk averages -0.011, again consistent with 0. Things to change:

- **Raise K to 20.** Ruin becomes a one-in-a-million event. Run it several times: most runs show a mean gain of nearly $+1$, and the rare run that contains a ruin shows a huge loss. The expectation is 0, but the *typical* outcome is $+1$. That gap is exactly the failure of uniform integrability.
- **Remove the cap of 50 steps** in part 3 (let the walk run 5000 steps). The proportion of walks that reach $+3$ climbs towards 1, the mean of M_τ climbs towards 3, and optional stopping stops applying.
- **Change the Cantor rule** to digits from $\{0, 1, 2\}$ chosen with probabilities $(p, 0, 1-p)$, or to base 5 keeping two digits. Predict the dimension of the support from Moran's equation, and estimate it from the cell counts as $\log(\text{cells})/(L \log 3)$.

97.6 The challenge

1. **Intuition.** A friend says: "Probability zero means impossible." Using the dart, the rationals and the Cantor set, explain why measure theory distinguishes "probability zero" from "impossible", and why it has to.
2. **Derivation.** Show that the Cantor distribution has mean $\frac{1}{2}$ and variance $\frac{1}{8}$, using only its self-similarity: $X \overset{d}{=} \frac{2b}{3} + \frac{X'}{3}$, where b is a fair bit independent of the copy X'.
3. **Implementation.** Simulate the "sweeping indicator" sequence of §97.3 on a grid of 10^4 points. Show numerically that $P(|X_n| > 0) \to 0$ while every grid point is hit infinitely often. Then find a subsequence that converges almost surely, as a theorem of Riesz guarantees.
4. **Open investigation.** Take a random fractal: start with $[0, 1]$, split every interval into thirds, and keep each third independently with probability p. For which p does the limit set survive, and what is its dimension when it does? Then repeat in 2-D with squares (Mandelbrot's percolation), and explore numerically for which p the surviving set contains a path crossing the square. The exact critical p for crossing is not known.

97.7 Loose threads

The hook asked whether every set can be given a probability, and whether a fair game can be beaten. Measure theory says no to the first, because Vitali's set breaks any countably additive, translation-invariant size. So probability lives on a σ-algebra, and that sacrifice costs nothing we can describe. To the second it says "not with finite credit". A fair game stays fair at every bounded stopping time. The doubling strategy wins only by putting a loss of 2^n on an event of

probability 2^{-n}, the same escaping mass that breaks $\lim \int = \int \lim$. Along the way the σ-algebra turned into information, the Cantor set gave a distribution with neither density nor atoms, and Hausdorff measure gave dimensions between the integers.

What we did not tell you:

- **Stochastic integrals.** Brownian paths have infinite length on every interval, so $\int H_t \, dB_t$ cannot be a Riemann–Stieltjes integral. Itô defined it as an L^2 limit, and its isometry $E[(\int H \, dB)^2] = E \int H^2 \, dt$ is a statement about measures on path space. The resulting calculus, and its link between diffusions and PDEs, is taken up in Ch. 89.
- **L^p spaces.** Identify functions that agree almost everywhere, and the integrable functions form a complete normed space L^1, the square-integrable ones a Hilbert space L^2. This is the quotient promised in Ch. 99, and the setting of Ch. 61.
- **Weak convergence.** The central limit theorem and the Wasserstein distances of Ch. 55 are about convergence of *measures*, not of random variables. Prokhorov's theorem says when a family of measures has convergent subsequences.

? When the parameter is a whole function

Bernstein–von Mises makes Bayesians and frequentists agree, but only for finitely many parameters. In 1999 David Freedman showed that in a simple infinite-dimensional model (estimating a whole function observed in white noise), the posterior can be asymptotically Gaussian yet give credible sets with frequentist coverage tending to zero. Castillo and Nickl (2013–14) recovered versions of the theorem in carefully chosen weaker norms. Which nonparametric questions a posterior answers honestly, and how to choose priors so that it does, is a current research frontier, of exactly the kind Ch. 98 is about.

Chapter 98 — Mathematical Research: How New Mathematics Is Created

> **Level 3 · Track J — Mathematics at the Frontier Builds on:** Ch. 63, Ch. 28, Ch. 26, Ch. 57 · **Leads to:** every open thread in this book (Figure 98.3), and the ones nobody has written down yet · **Related:** Ch. 27, Ch. 30, Ch. 32, Ch. 67, Ch. 68, Ch. 73 **Reading time:** ~30 min

98.1 The hook

Line up the odd primes and split them into two teams. Team Three takes the primes that leave remainder 3 when divided by 4: $3, 7, 11, 19, 23, 31, \ldots$ Team One takes those that leave remainder 1: $5, 13, 17, 29, 37, 41, \ldots$ Now run a race. At each x, count how many primes up to x each team has. Call the counts $\pi(x; 4, 3)$ and $\pi(x; 4, 1)$.

Team Three is ahead at $x = 3$, and still ahead or level at $x = 100$, 1000, 10,000. Chebyshev noticed this in 1853. An experimental scientist would be entitled, by $x = 20{,}000$, to announce a law of nature: *the $4k + 3$ primes always lead.*

The law fails at $x = 26{,}861$, a prime of the form $4k + 1$, where Team One goes ahead by a single prime, for two integers. Then Team Three is back in front until $x = 616{,}841$. In the first ten million integers, Team One is in the lead at only 3,406 values of x. And yet in 1914 J. E. Littlewood proved that the lead changes hands **infinitely often**.

A second race is even crueller. The prime-counting function $\pi(x)$ is approximated by the logarithmic integral $\mathrm{li}(x) = \int_0^x dt/\ln t$, and in every table anyone has ever computed, $\pi(x) < \mathrm{li}(x)$. At $x = 10^7$ the gap is 339 primes. The inequality has been checked by computer for every x up to 10^{19}. Littlewood's same 1914 paper proved that it is false: $\pi(x) - \mathrm{li}(x)$ also changes sign infinitely often. Nobody has ever seen a single crossing. The first one is known to lie somewhere between 10^{19} and about 1.4×10^{316}.

So here is the question this last chapter is about. If a pattern can survive ten quintillion checks and still be false, **how does anyone ever come to know anything new in mathematics?** Where do conjectures come from, how do you decide which ones to believe, how do you hunt for the counterexample that would kill one, and what does it take to turn one into a theorem?

Chapter after chapter of this book ended with a `[!mystery]` pointing here: the exponent ω of Ch. 26, $R(5, 5)$ in Ch. 28 and Ch. 32, the four-colour proof of Ch. 27, the Mandelbrot set of Ch. 73, the zeta zeros of Ch. 57. Nobody can resolve them. This chapter shows how each is being attacked, with methods you could use yourself.

98.2 The big idea

Research is a loop, not a ladder. Textbooks, this one included, present mathematics as a ladder of definitions, theorems and proofs, each rung resting on the last. That is the shape of finished mathematics. Mathematics in the making has the shape of Figure 98.1.

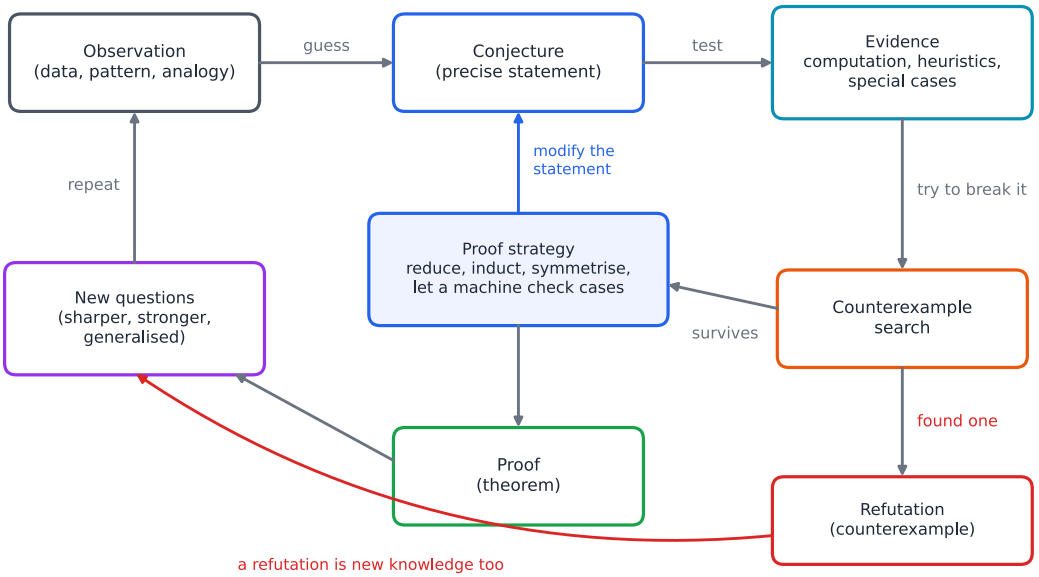

Figure 98.1 — The conjecture lifecycle. Both exits, proof and refutation, lead back to new questions; the loop has no final state.

1. **Observation.** A pattern in a table, a simulation, an analogy between fields, or a proof that works "too well".
2. **Conjecture.** The pattern stated precisely enough to be false. "Primes like remainder 3" is a mood; "$\pi(x; 4, 3) \geq \pi(x; 4, 1)$ for all x" is a conjecture.
3. **Evidence.** Computation, special cases, heuristic models, consistency with other conjectures.
4. **Counterexample search.** You try hard to break it. Most conjectures die here, and that is a success: a counterexample is a theorem too.
5. **Proof strategy.** If it survives, look for a reason: reduce, strengthen for induction, exploit symmetry, or cut it to finitely many cases for a machine.
6. **New questions.** A proof shows what else is true; a refutation asks what the *right* statement was.

Evidence is not uniform. Think like a detective. Ten thousand witnesses who all saw the suspect in the same café prove less than one fingerprint, because the witnesses are correlated. The checks of $\pi(x) < \mathrm{li}(x)$ up to 10^{19} are ten quintillion correlated witnesses, all dominated by the same slowly varying terms. A **heuristic model**, which explains *why* a pattern should hold and how large the deviations should be, is worth more than any number of checks; Result 3 shows one predicting a counterexample nobody has seen.

The frontier is a literature. Before you spend a month on a pattern, you find out whether it is known (OEIS), who has worked on it (MathSciNet, zbMATH) and what the latest attempt looks like (arXiv); when you have a proof, you may ask a machine to check it (Lean, Coq, Isabelle). Section 98.4 makes this a procedure.

In this chapter the `[!mystery]` callouts change meaning. Elsewhere they pointed to a chapter holding the answer. Here the honest answer is: **nobody knows yet.**

98.3 The mathematics

Four kinds of statement

The vocabulary of research

- A **conjecture** is a precise, falsifiable statement believed but not proved.
- A **counterexample** to $\forall n\, P(n)$ is a single n with $\neg P(n)$. One settles the matter forever.
- A **heuristic** is an argument that would be a proof if an unproved modelling assumption held, typically "these quantities behave like independent random variables".
- A **certificate** is a finite object, cheap to check, that implies the claim: a colouring, a factorization, a proof file. Finding it may be hard; checking it is easy (the NP idea of Ch. 30, as a research method).

Research is largely the art of converting one kind of statement into another. Each result below shows one conversion, on a problem the book left open.

Result 1: symmetry turns a search into a proof

Ch. 28 introduced Ramsey numbers: $R(s,t)$ is the smallest N such that every red/blue colouring of the edges of the complete graph K_N contains a red K_s or a blue K_t. It stated $R(4,4) = 18$. To prove $R(4,4) > 17$ you must exhibit a colouring of K_{17} with no monochromatic K_4: a certificate. A blind search is hopeless, since there are 2^{136} colourings. But the right colouring can be found by thinking instead of searching, and then *checked* by thinking too.

The Paley graph P_{17}

The **quadratic residues** modulo 17 are the non-zero squares: $Q = \{1, 2, 4, 8, 9, 13, 15, 16\}$, exactly half of the 16 non-zero residues. Join $u, v \in \{0, 1, \ldots, 16\}$ by a red edge if $u - v \in Q$, and by a blue edge otherwise.

The colouring is well defined because $-1 \equiv 16 = 4^2$ is a square, so $u - v \in Q$ if and only if $v - u \in Q$.

Theorem 98.1 (Greenwood–Gleason, 1955)

P_{17} contains no red K_4 and no blue K_4. Hence $R(4,4) \geq 18$.

Proof. We use three facts about Q, all checkable from the list: Q is closed under multiplication; the product of two non-residues is a residue; and $3 \notin Q$. (The non-zero residues mod 17 form a cyclic group of order 16, and Q is its subgroup of index 2, which gives the first two facts.)

Step 1: the graph looks the same from every red edge. For $a \in Q$ and any b, the map $f(x) = ax + b$ sends a red edge to a red edge, because $f(u) - f(v) = a(u - v)$ and Q is closed under multiplication. Now take any red edge $\{u, v\}$. Since $v - u \in Q$, so is its inverse, and $g(x) = (x - u)/(v - u)$ is such a map, with $g(u) = 0$ and $g(v) = 1$. So if a red K_4 exists, there is one containing the vertices 0 and 1.

Step 2: the two other vertices of that K_4 are red neighbours of both 0 and 1. Those are the x with $x \in Q$ and $x - 1 \in Q$. Running through Q: $x = 2, 9, 16$ qualify (as $1, 8, 15 \in Q$), while $1, 4, 8, 13, 15$ do not (as $0, 3, 7, 12, 14 \notin Q$). So the candidates are $\{2, 9, 16\}$.

Step 3: no two candidates are joined in red. Their differences are $9 - 2 = 7$, $16 - 9 = 7$ and $16 - 2 = 14$, none of which lies in Q. So there is no red K_4.

Step 4: the blue graph is a copy of the red one. Multiply every vertex by the non-residue 3. A blue edge has $u - v \notin Q$, so $3(u - v)$ is a product of two non-residues, hence in Q: blue edges become red. A blue K_4 would become a red K_4, which Step 3 excluded. ■

A brute-force check of all $\binom{17}{4} = 2380$ four-vertex subsets agrees. But the proof never examined 2380 cases: symmetry collapsed them to *one* ("cliques through 0 and 1"), then to a three-element set. Combined with the recursive bound $R(4,4) \leq R(3,4) + R(4,3) = 9 + 9 = 18$, the value $R(4,4) = 18$ is settled.

Why the same idea stalls at $R(5,5)$. The best known colouring for the next case, found by Exoo in 1989, is a colouring of K_{42} with no monochromatic K_5, so $R(5,5) \geq 43$. No Paley graph does as well, and no one has found structure that gives K_{43}. On the other side, proving $R(5,5) \leq N$ means showing that *every* one of the $2^{\binom{N}{2}}$ colourings fails; for $N = 43$ that is 2^{903}, a 272-digit number. The upper bound came down from 49 (1995) to 48 (2018) to 46 (Angeltveit and McKay, 2024), each step mixing linear-programming bounds with huge, carefully organised computer searches. McKay and Radziszowski found 656 colourings of K_{42} with no monochromatic K_5, found no more, and *conjectured* that $R(5,5) = 43$: a conjecture built on a search that came up empty, exactly the kind of evidence the hook warned about.

Paul Erdős liked to say that if hostile aliens demanded $R(5,5)$ on pain of destroying the Earth, we should marshal every computer and mathematician and try to find it. If they demanded $R(6,6)$ (known only to lie between 102 and the 160s), we should try to destroy the aliens.

? Is $R(5,5)=43$?

Everyone expects it; nobody can prove it. Asymptotically, $(\sqrt{2})^k < R(k,k)$ by Ch. 32's random colourings, and $R(k,k) < (4-\varepsilon)^k$ only since 2023 (Campos, Griffiths, Morris and Sahasrabudhe), later about 3.8^k. Whether the true base is $\sqrt{2}$, near 4, or between is an **open problem**. No chapter of any book contains the answer.

Result 2: one finite gadget, an asymptotic theorem

Ch. 26 left a number hanging: the exponent ω of matrix multiplication, defined as the infimum of all τ such that two $n\times n$ matrices can be multiplied in $O(n^{\tau})$ arithmetic operations. Reading the input forces $\omega \ge 2$; the schoolbook method gives $\omega \le 3$. The key to every improvement since 1969 is the following conversion of a *finite* fact into an *asymptotic* bound.

Bilinear algorithm

A **bilinear algorithm** for $k\times k$ matrices with r multiplications computes r products

$$m_\ell = \Big(\sum_{i,j} \alpha_{ij}^{(\ell)} a_{ij}\Big)\Big(\sum_{i,j} \beta_{ij}^{(\ell)} b_{ij}\Big), \qquad \ell = 1,\dots,r,$$

and then each entry c_{ij} of $\mathbf{C}=\mathbf{AB}$ as a fixed linear combination of $m_1,\dots,m_r$, with constant coefficients α,β,γ. It must never use $a_{ij}b_{kl}=b_{kl}a_{ij}$.

Strassen's 1969 algorithm is a bilinear algorithm with $k=2$, $r=7$.

Theorem 98.2

If there is a bilinear algorithm for $k\times k$ matrices with r multiplications, then $\omega \le \log_k r$.

Proof. Because the algorithm never commutes a factor of $\mathbf{A}$ past a factor of $\mathbf{B}$, it is an identity in any ring, in particular in the ring of $m\times m$ matrices. So an $n\times n$ product with $n=k^t$ can be computed by splitting each matrix into a $k\times k$ grid of blocks of size n/k, forming the r block products recursively, and combining them with a fixed number c of block additions, each costing $(n/k)^2$ operations. The operation count satisfies

$$T(n) = r\,T(n/k) + c\,(n/k)^2, \qquad T(1)=1.$$

Unrolling it, as in the recursion tree of Ch. 26:

$$T(k^t) = r^t + c\sum_{i=1}^{t} r^{\,i-1}\,k^{2(t-i)} = r^t + \frac{c}{r}\,k^{2t}\sum_{i=1}^{t}\Big(\frac{r}{k^2}\Big)^{i}.$$

If $r > k^2$ the geometric sum is at most $\frac{r/k^2}{r/k^2-1}(r/k^2)^t$, so $T(k^t) \le C\,r^t = C\,n^{\log_k r}$ for a constant C. (If $r \le k^2$ the bound is $O(n^2\log n)$, which is even better; in fact $r<k^2$ is impossible.) For general n, pad the matrices with zeros up to the next power k^t with $n \le k^t < kn$; this multiplies the cost by at most $k^{\log_k r}=r$, a constant. Hence $T(n)=O(n^{\log_k r})$, and $\omega \le \log_k r$. $\blacksquare$

With $k=2$, $r=7$ this gives $\omega \le \log_2 7 \approx 2.807$. The theorem turns an asymptotic question into *finite* puzzles: for each k, what is the smallest r? For $k=3$ the record is Laderman's $r=23$ (1976), giving only $\log_3 23 \approx 2.854$; beating Strassen needs $r \le 21$, since $3^{2.807}\approx 21.85$. The best lower bound is 19, and nobody knows whether 20, 21 or 22 are possible. In 2022 a reinforcement-learning search (AlphaTensor) found a 4×4 algorithm with 47 multiplications, valid in arithmetic modulo 2: $\log_4 47 \approx 2.777$, a certificate humans had missed for fifty years.

The records come from elsewhere: since Coppersmith and Winograd (1990, $\omega < 2.376$), from approximate ("border rank") versions of Theorem 98.2 applied to large, cleverly chosen tensors. The 2024 record is $\omega < 2.3714$, improvements now arriving in the fourth decimal place.

? Is $\omega = 2$?

Many experts believe so, partly because the group-theoretic approach of Cohn and Umans (2003) would give $\omega=2$ if certain combinatorial objects exist. But the method behind every record since 1990, applied to the tensors used so far, provably cannot go below about 2.3. Reaching 2 needs an idea nobody has had: an **open problem**, answered in no chapter.

Result 3: a heuristic that predicted a counterexample nobody has seen

Return to the hook. Why should anyone believe Littlewood rather than the tables? The cleanest illustration is a third race, from Ch. 63: the **Mertens function**

$$M(x) = \sum_{n\le x} \mu(n),$$

where the Möbius function $\mu(n)$ is 0 if n has a repeated prime factor, and $(-1)^k$ if n is a product of k distinct primes. So $\mu(6)=1$, $\mu(30)=-1$, $\mu(12)=0$. In 1897 Mertens conjectured $|M(x)| < \sqrt{x}$ for all $x>1$. Figure 98.2 shows why: our computation gives $\max |M(x)|/\sqrt{x} = 0.472$ over $1000 \le x \le 10^7$, and the inequality has been verified up to 10^{16}.

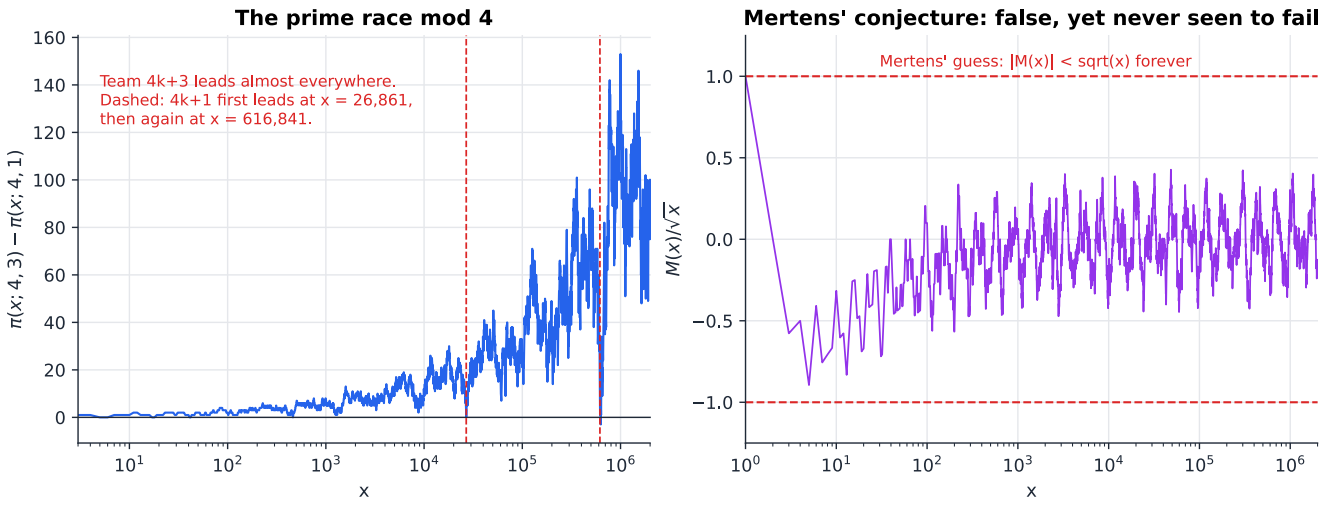

Figure 98.2 — Two patterns that survive every table and are still false. Left: $\pi(x;4,3)-\pi(x;4,1)$, first negative at $x = 26{,}861$. Right: $M(x)/\sqrt{x}$, which never comes near the dashed lines below 10^{16}, yet must cross them eventually.

Here is the heuristic. Pretend that, on the squarefree integers, the signs $\mu(n) = \pm 1$ are independent fair coin flips. Then $M(x)$ is a random walk (Ch. 34) with one step for each squarefree $n \le x$. About $6/\pi^2 \approx 0.608$ of all integers are squarefree, so

$$E\big[M(x)\big] = 0, \qquad \operatorname{Var}\big[M(x)\big] \approx \frac{6}{\pi^2}\,x, \qquad \text{so} \qquad \frac{M(x)}{\sqrt{x}} \text{ is typically of size } \sqrt{6/\pi^2} \approx 0.78.$$

So far the model agrees with Mertens: deviations of order $\sqrt{x}$. But a random walk does more than fluctuate at scale $\sqrt{n}$. The **law of the iterated logarithm** says that a walk S_n of fair ± 1 steps satisfies, with probability one,

$$\limsup_{n\to\infty} \frac{S_n}{\sqrt{2n \ln\ln n}} = 1.$$

Since $\sqrt{\ln\ln n} \to \infty$, the ratio $S_n/\sqrt{n}$ is unbounded. In the model, $|M(x)|/\sqrt{x}$ eventually exceeds 1, and 10, and any bound you name. The heuristic predicts that Mertens is wrong, and why the tables cannot see it: $\sqrt{\ln\ln x}$ is 1.90 at $x = 10^{16}$ and only 2.28 at $x = 10^{80}$.

The heuristic is not a proof (μ is not random), but it pointed the right way. In 1985 Odlyzko and te Riele proved $\limsup M(x)/\sqrt{x} > 1.06$ without finding any x: they computed 2000 zeros of the zeta function to about 100 digits and showed, through an explicit formula, that $M(x)/\sqrt{x}$ must swing beyond ± 1 somewhere. The first counterexample is known only to be smaller than roughly $e^{10^{33}}$.

The same random model gives a sharper statement that *is* believed, and that is equivalent to the biggest open problem in the book:

Theorem 98.3 (von Koch, 1901; Littlewood, 1912; stated without proof)

The Riemann hypothesis is true if and only if $M(x) = O\big(x^{1/2+\varepsilon}\big)$ for every $\varepsilon > 0$. Equivalently, if and only if $|\pi(x) - \operatorname{li}(x)| = O\big(\sqrt{x}\ln x\big)$.

So the Riemann hypothesis, a statement about complex zeros (Ch. 57, Ch. 18), says the Möbius signs cancel like coin flips, up to a factor x^{ε}. Mertens asked for too much (no x^{ε}, constant exactly 1) and died; the coin-flip version survives. The prime race is governed by similar zeros: Rubinstein and Sarnak (1994) showed, assuming a generalised Riemann hypothesis and a hypothesis on the zeros, that Team Three leads on a set of logarithmic density 0.9959. So strong a bias is why the counterexample came late; a bias short of 1 is why it came at all.

? Where is the first crossing of $\pi(x)$ and $\operatorname{li}(x)$?

Littlewood proved it exists. Skewes (1933) gave the first explicit bound, about $10^{10^{10^{34}}}$, assuming the Riemann hypothesis. Modern work has located a region of crossings below about 1.4×10^{316}, but whether an earlier one exists between 10^{19} and there is **unknown**. So is the Riemann hypothesis itself: more than ten trillion zeros lie on the line $\operatorname{Re}\{s\} = \frac{1}{2}$, and no proof is in sight.

Proofs no human reads

Results 1 and 2 used symmetry and recursion to *avoid* computation. When it cannot be avoided, a new question arises: what does it mean to trust a proof?

- **The four-colour theorem** (Ch. 27), Appel and Haken, 1976, has the shape *unavoidability plus reducibility*: every planar map contains one of a finite list of configurations, and each one on the list can be removed and its colouring restored. The list had nearly two thousand entries, and checking them took about 1200 hours of computer time. Robertson, Sanders, Seymour and Thomas cut it to 633 in 1996; Gonthier checked the entire proof in the Coq proof assistant in 2005.
- **The Kepler conjecture** on sphere packing (Hales, 1998) left its referees "99% certain"; Hales's Flyspeck project answered with a formal proof in 2014.
- **Boolean Pythagorean triples.** Heule, Kullmann and Marek (2016) showed by a SAT solver (Ch. 30) that $\{1,\dots,7824\}$ can be 2-coloured with no monochromatic $a^2 + b^2 = c^2$ and $\{1,\dots,7825\}$ cannot. The impossibility certificate was 200 terabytes, checked by a formally verified checker.

The trusted part shrinks: nobody trusts a 200-terabyte search, but people trust a small checker, which trusts a small set of logical rules (Ch. 65, Ch. 66). In 2022 the Lean community completed Peter Scholze's *Liquid Tensor Experiment*, formalising a cutting-edge theorem; in 2023 the proof of the polynomial Freiman–Ruzsa conjecture was formalised about three weeks after it appeared. Formal verification (Ch. 67) now checks new theorems, not just old ones.

98.4 The algorithm

A counterexample hunter

Most of research is not proof. It is disciplined searching. Here is the skeleton every serious conjecture-tester shares.

```
HUNT(P, N):                      # test "P(n) holds for all n <= N"
    build the data incrementally   # sieve, recurrence, running sum: never recompute from scratch
    for n = 1 .. N:
        update the running quantity Q(n)
        if not P(n):
            output certificate (n and the data that refutes P); stop
        if Q(n) sets a record (max, min, closest approach):
            log (n, Q(n))          # the records are the real result
    report: "no counterexample below N"; plus the record table
```

The record table matters more than the verdict. "No counterexample below 10^7" is weak; "the closest approach was 0.472 at $x = 2803$, and records grow like $\sqrt{\ln \ln x}$" is a measurement you can compare with a heuristic.

Complexity. The sieve of Eratosthenes (and the Möbius sieve below) costs $O(N \ln \ln N)$ time and $O(N)$ memory, and memory runs out first. A **segmented sieve** works in blocks of about $\sqrt{N}$, cutting memory to $O(\sqrt{N})$. The great records ($\pi(x) < \mathrm{li}(x)$ to 10^{19}, Goldbach to 4×10^{18}) add distributed computing and analytic methods that count primes without listing them.

Failure cases.

- *Floating point.* $\mathrm{li}(10^{19}) \approx 2.3 \times 10^{17}$ carries an absolute rounding error of tens in double precision. Harmless while $\mathrm{li}(x) - \pi(x) \approx 10^8$, fatal near a crossing, where rounding decides the sign. Use exact integers, or interval arithmetic.
- *Unrepresentative ranges.* Biases like the prime race's live on a logarithmic scale: going from 10^4 to 10^5 is one more decade, not "ten times the evidence".
- *The law of small numbers* (Richard Guy): there are not enough small numbers for the demands made of them. Chords joining n points on a circle cut it into $1, 2, 4, 8, 16$ regions for $n = 1, \ldots, 5$, and then 31.

Exploring the literature

A procedure, in the order a working mathematician uses it:

1. **OEIS** (oeis.org). If your problem produces integers, paste in the first ten. The On-Line Encyclopedia of Integer Sequences holds more than 370,000 sequences with formulas, references and code. Type $1, 2, 4, 8, 16, 31$ and you get A000127, its closed form $\binom{n}{4} + \binom{n}{2} + 1$, and a century of references. Many "new" patterns turn out to be known within a minute.
2. **Name the objects.** Search with the field's names, not yours: "Paley graph", "tensor rank", "Chebyshev bias". Surveys give them to you.
3. **MathSciNet** (Mathematical Reviews, from 1940) and **zbMATH Open** (free since 2021) review nearly every research paper, classified by subject (MSC 05 combinatorics, 11 number theory, 37 dynamics). Their real power is the *citation graph*: find one good paper, read who cited it, and walk forward in time to the current state of the problem.
4. **arXiv** (arxiv.org), since 1991, holds preprints, often years before publication: `math.CO`, `math.NT`, `math.DS`, `cs.CC`. Every record in this chapter since 2018 appeared there first. Preprints are not refereed: strong evidence, not theorems.
5. **Proof assistants.** Lean's `mathlib`, Coq and Isabelle hold hundreds of thousands of formalised results: what is truly established, in exact form, ready to build on.
6. **Ask people.** MathOverflow, a seminar, an email to the author of the closest paper. A precise, well-prepared question usually gets an answer.

98.5 The experiment

The script below runs the hook's prime race and the Mertens test side by side, with the record-keeping of the hunter. It reproduces the numbers quoted in this chapter in a few seconds.

```
import numpy as np
import matplotlib.pyplot as plt

N = 10**7           # how far to look (try 10**6, then 10**8 if you have the memory)
q, a, b = 4, 3, 1   # race between primes = a (mod q) and primes = b (mod q); try (3,2,1), (8,3,1)

sieve = np.ones(N + 1, dtype=bool); sieve[:2] = False
for i in range(2, int(N**0.5) + 1):
    if sieve[i]:
        sieve[i*i::i] = False
p = np.nonzero(sieve)[0]

step = np.zeros(N + 1, dtype=np.int64)
step[p[p % q == a]] += 1
step[p[p % q == b]] -= 1
lead = np.cumsum(step)                      # pi(x;q,a) - pi(x;q,b)
losing = np.nonzero(lead < 0)[0]
print(f"team {a} (mod {q}) ahead or level at {N + 1 - len(losing):,} of {N + 1:,} values of x")
print("first x where team", b, "leads:", losing[0] if len(losing) else "none below N")

mu = np.ones(N + 1, dtype=np.int64); mu[0] = 0   # Moebius function by a sieve
for r in p:
    mu[r::r] *= -1
    if r * r <= N:
        mu[r*r::r*r] = 0
M = np.cumsum(mu)
x = np.arange(1, N + 1)
ratio = M[1:] / np.sqrt(x)
big = np.abs(ratio[999:]).argmax() + 1000
print(f"max |M(x)|/sqrt(x) for 1000 <= x <= N: {abs(ratio[big - 1]):.3f} at x = {big:,}")

xs = np.unique(np.geomspace(10, N, 5000).astype(int))
fig, ax = plt.subplots(1, 2, figsize=(11, 4))
ax[0].semilogx(xs, lead[xs]); ax[0].axhline(0, color="k", lw=0.8)
ax[0].set_title(f"pi(x;{q},{a}) - pi(x;{q},{b})")
ax[1].semilogx(xs, M[xs] / np.sqrt(xs)); ax[1].axhline(1, ls="--", color="r"); ax[1].axhline(-1, ls="--", color="r")
ax[1].set_title("M(x)/sqrt(x)")
plt.show()
```

With the default knobs it prints that Team Three is ahead or level at 9,996,595 of the 10,000,001 values $0 \le x \le 10^7$, that Team One first leads at 26,861, and that $\max |M(x)|/\sqrt{x} = 0.472$ at $x = 2803$. Things to change:

1. **Set `q, a, b = 3, 2, 1`.** No lead change below 10^7. Conclude nothing: the first one (Bays and Hudson, 1978) is at $x = 608{,}981{,}813{,}029$, beyond any array your laptop can hold.
2. **Set `q, a, b = 8, 3, 1`**, then `(8, 5, 1)` and `(8, 7, 1)`. Chebyshev's bias says the non-squares $3, 5, 7$ should beat the square 1. By how much?
3. **Change `N`** between 10^6 and 10^8 (the last needs about 6 GB). The Mertens record barely moves; compare it with $\sqrt{\ln \ln N}$.
4. **Replace the Möbius signs by coin flips**: put `mu[mu != 0] = np.random.choice([-1, 1], size=np.count_nonzero(mu))` just before `M = np.cumsum(mu)`. Over twenty seeds, how often does the walk cross ± 1 below 10^7? That is Result 3's heuristic, made empirical.

98.6 The challenge

1. **Intuition.** $\pi(x) < \mathrm{li}(x)$ holds up to 10^{19} and is false; ten trillion zeta zeros lie on the critical line, and most mathematicians believe the Riemann hypothesis. Explain, without formulas, why the second body of evidence counts for more. What would make you stop believing it?
2. **Derivation.** (a) Show that the Paley graph P_{13}, built from the quadratic residues modulo 13, has no red K_4 and no blue K_4, by adapting Steps 1 to 4 of Theorem 98.1. What does that prove about $R(4,4)$, and why is it weaker than Theorem 98.1? (b) In Theorem 98.2, take $k = 3$. Show that a bilinear algorithm with r multiplications improves on Strassen's exponent if and only if $r \le 21$.
3. **Implementation.** Write a colouring hunter: start from a random red/blue colouring of K_n and repeatedly flip an edge lying in the most monochromatic K_4s, with occasional random flips to escape local minima. For $n = 17$, is what it finds a relabelling of P_{17}? Then hunt for colourings with no monochromatic K_5. How far below 42 do you get stuck?
4. **Open investigation.** Pick one problem from Figure 98.3. Find its OEIS entry (if any), its latest arXiv preprint, and the zbMATH or MathSciNet review of the paper that posed it. Design a computation that *could* find a counterexample below a bound you can afford, run it with a record table, and write one paragraph on what your negative result does and does not tell you.

98.7 Loose threads

In the last chapter, the loose threads point to no other chapter. They are the edge of what anyone knows.

Open problems this book has pointed at, by track

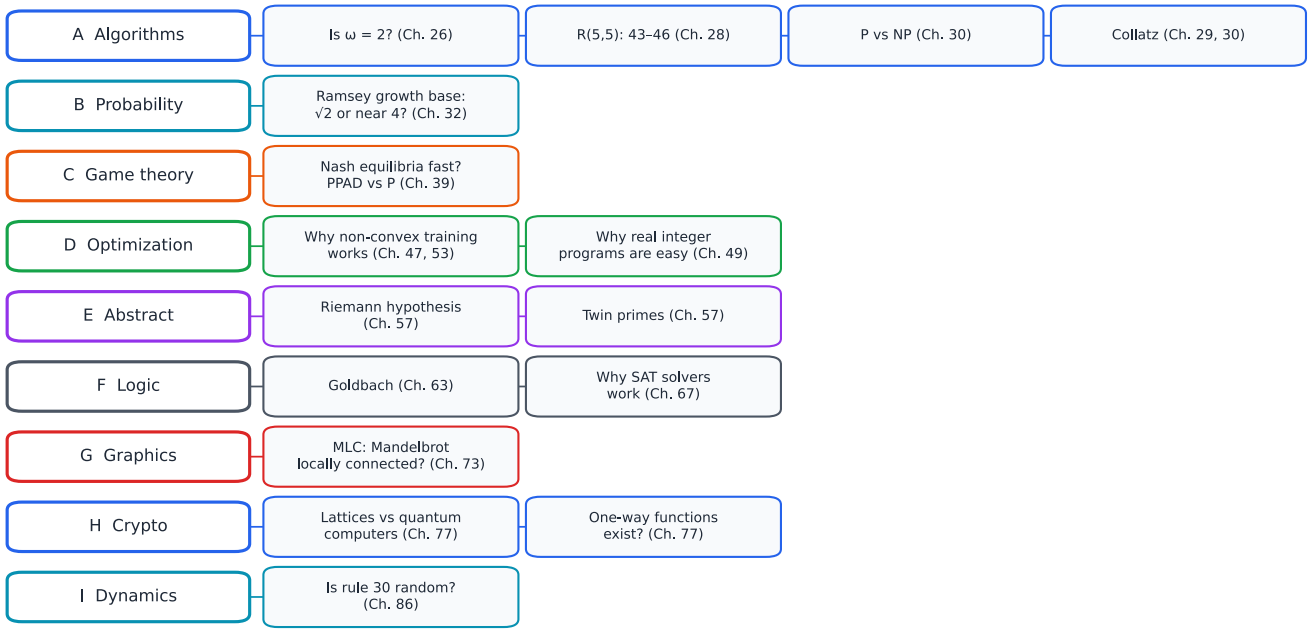

Figure 98.3 — The open problems this book has pointed at, by track. Every box is a question that nobody, anywhere, can currently answer.

- **Is $\omega = 2$?** Unknown. The best bound is $\omega < 2.3714$ (Ch. 26). Even the smallest finite version, whether 3×3 matrices can be multiplied with 22 or fewer multiplications, is open.
- **What is $R(5,5)$?** Somewhere in $\{43, 44, 45, 46\}$ (Ch. 28); the asymptotic base of $R(k,k)$ is somewhere between $\sqrt{2}$ and about 3.8 (Ch. 32).
- **The four-colour theorem** is closed: true, and formally verified. What remains open is softer: is there a proof a human can read in an afternoon? (Ch. 27)
- **Is the Mandelbrot set locally connected?** Open (Ch. 73). Yoccoz proved it at a large class of parameters in the 1990s; the "infinitely renormalizable" ones are where the difficulty lives. MLC would imply that hyperbolic components are dense, also open.
- **The Riemann hypothesis** (Ch. 57) is open, and with it the size of the prime races' deviations and the place where $\pi(x)$ first passes $\mathrm{li}(x)$.
- **P versus NP** (Ch. 30), one-way functions (Ch. 77), why SAT and integer-programming solvers work so well (Ch. 67, Ch. 49), why gradient descent trains non-convex networks (Ch. 47): all open, and probably connected in ways nobody yet sees.
- **Goldbach, twin primes, Collatz, rule 30** (Ch. 63, Ch. 57, Ch. 30, Ch. 86): checked to enormous bounds, explained by heuristics, unproved. Ch. 65 and Ch. 68 explain why some such statement might have no proof at all.

> **The thread you pick**
>
> Most of this book's unanswered questions have answers in other chapters. The ones in Figure 98.3 do not. They are waiting for someone to notice a pattern, to find the symmetry that collapses a search, the gadget that implies an asymptotic bound, or the heuristic that predicts where the counterexample hides. The methods are in this chapter, and the tools (a sieve, a SAT solver, the OEIS, arXiv, a proof assistant) are free. **Which thread will you pull?**

This book has given you a map, incomplete on purpose, because the real one is too. Pick a thread, run the hunter, read the last three papers on it, and write down a conjecture precise enough to be wrong. That is how all of this mathematics was made, and how the next chapter, the one nobody has written yet, will be.

Appendix — Derivations and Proofs

Appendix A — Calculus and Complex Numbers

This appendix gives complete proofs of the single-variable calculus results, the complex-exponential results and the two multivariable results that the chapters of Parts I and II state with only a sketch. The results are proved in logical order, not in the order the chapters use them: the mean value theorem comes first because almost everything else rests on it, and Euler's formula comes after Taylor's theorem because one of its proofs needs the Taylor series of cos and sin.

What is assumed. The real numbers are complete (every non-empty set bounded above has a least upper bound). From completeness we take, without proof, three standard facts: the **extreme value theorem** (a continuous function on a closed bounded interval $[a,b]$ attains a maximum and a minimum), the **intermediate value theorem** (a continuous function on $[a,b]$ takes every value between $f(a)$ and $f(b)$), and the **Riemann integrability of continuous functions** on $[a,b]$, together with the elementary properties of the integral (linearity, additivity over intervals, and monotonicity: $f \le g \Rightarrow \int f \le \int g$). We also use the differentiation rules (sum, product, quotient, chain) of Ch. 4 §4.2–4.3, the derivatives $\sin' = \cos$, $\cos' = -\sin$, and the identity $\cos^2\theta + \sin^2\theta = 1$. The implicit function theorem is stated precisely and used, but not proved.

Level of rigour. Every hypothesis is stated; every step of every proof is justified from the assumptions above or from an earlier result of this appendix. Where a hypothesis cannot be dropped, a counterexample is given. Proofs end with ■.

Complex-valued functions. Several results are applied to functions $F : [a,b] \to \mathbb{C}$ of a real variable, such as $e^{j\omega t}$. For these, $F = U + jV$ with $U = \mathrm{Re}\{F\}$, $V = \mathrm{Im}\{F\}$ real, and limits, continuity, derivatives and integrals are taken component by component: $F' = U' + jV'$, $\int F = \int U + j\int V$. Because complex addition and multiplication obey the same algebraic laws as real ones and $|z|$ obeys the triangle inequality, the sum, product, quotient and chain rules (for a real inner function) carry over word for word.

A.1 Rolle's theorem, the mean value theorem and Cauchy's mean value theorem

The mean value theorem (MVT) is the bridge between local information (a derivative at a point) and global information (a change over an interval). It is the tool used to prove the FTC, Taylor's theorem, L'Hôpital's rule, the uniqueness half of Euler's formula and Clairaut's theorem below.

We first need the fact that a derivative vanishes at an interior extremum.

Lemma A.1 (Fermat)

Let f be defined on an open interval I, let $c \in I$, and suppose $f(c) \ge f(x)$ for all $x \in I$ (or $f(c) \le f(x)$ for all $x \in I$). If $f'(c)$ exists, then $f'(c) = 0$.

Proof. Take the maximum case; the minimum case follows by applying it to $-f$. For $h > 0$ small enough that $c + h \in I$, $f(c+h) - f(c) \le 0$, so

$$\frac{f(c+h)-f(c)}{h} \le 0 \quad (h>0), \qquad \frac{f(c+h)-f(c)}{h} \ge 0 \quad (h<0).$$

The derivative is the limit of these quotients as $h \to 0$; the limit of the right-hand quotients ($h \to 0^+$) is ≤ 0 and that of the left-hand ones ($h \to 0^-$) is ≥ 0 (limits preserve non-strict inequalities). Both one-sided limits equal $f'(c)$, so $0 \le f'(c) \le 0$. ■

Theorem A.1 (Rolle, MVT, Cauchy MVT)

Let f and g be real-valued, continuous on $[a,b]$ and differentiable on (a,b), with $a < b$.

1. **(Rolle)** If $f(a) = f(b)$, there is $c \in (a,b)$ with $f'(c) = 0$.
2. **(Mean value theorem)** There is $c \in (a,b)$ with
$$f'(c) = \frac{f(b)-f(a)}{b-a}.$$
3. **(Cauchy's mean value theorem)** There is $c \in (a,b)$ with
$$\big[f(b)-f(a)\big]\,g'(c) = \big[g(b)-g(a)\big]\,f'(c).$$

If in addition $g'(x) \neq 0$ on (a,b), then $g(b) \neq g(a)$ and $\dfrac{f(b)-f(a)}{g(b)-g(a)} = \dfrac{f'(c)}{g'(c)}$.

Proof.

Rolle. By the extreme value theorem, f attains a maximum value M and a minimum value m on $[a,b]$.

- If $M = m$, f is constant on $[a,b]$, so $f'(c) = 0$ for every $c \in (a,b)$.
- If $M > m$, at least one of M, m differs from the common endpoint value $f(a) = f(b)$. Say $M \neq f(a)$ (the other case is symmetric). Then the maximum is attained at some c with $c \neq a$, $c \neq b$, i.e. $c \in (a,b)$. On the open interval (a,b), $f(c) \ge f(x)$ for all x, and $f'(c)$ exists, so $f'(c) = 0$ by Lemma A.1.

MVT. Let $s = \dfrac{f(b)-f(a)}{b-a}$ (the slope of the chord) and define

$$\varphi(x) = f(x) - f(a) - s\,(x-a).$$

φ is continuous on $[a,b]$ and differentiable on (a,b) (a difference of such functions), with $\varphi(a) = 0$ and $\varphi(b) = f(b) - f(a) - s(b-a) = 0$. Rolle gives $c \in (a,b)$ with $0 = \varphi'(c) = f'(c) - s$.

Cauchy MVT. Define

$$h(x) = \big[f(b) - f(a)\big]g(x) - \big[g(b) - g(a)\big]f(x).$$

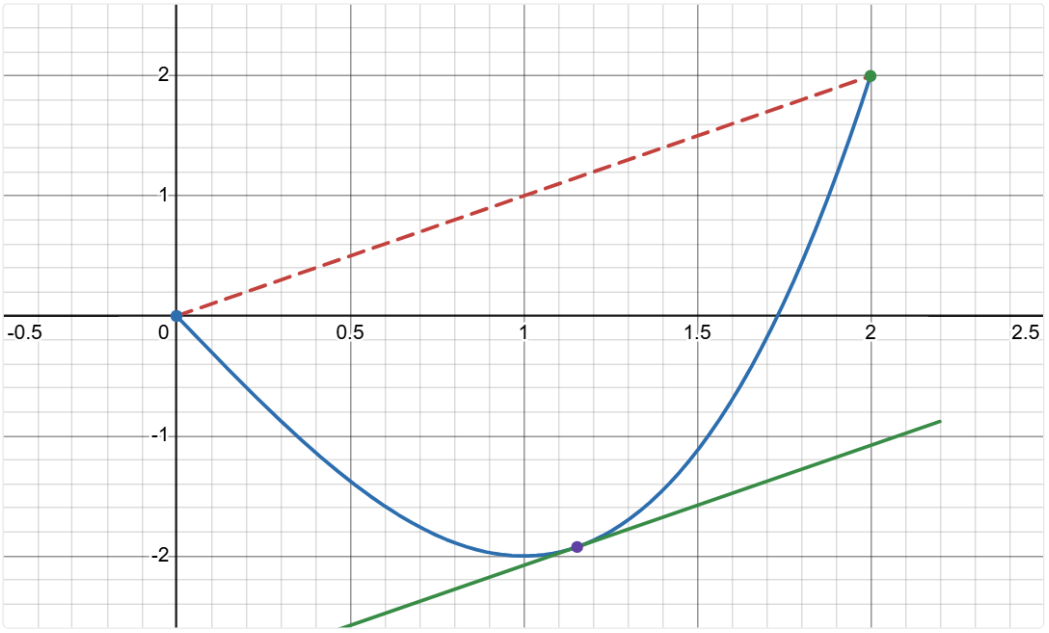
h is continuous on $[a, b]$, differentiable on (a, b), and

$$h(a) = f(b)g(a) - f(a)g(a) - g(b)f(a) + g(a)f(a) = f(b)g(a) - g(b)f(a),$$

$$h(b) = f(b)g(b) - f(a)g(b) - g(b)f(b) + g(a)f(b) = f(b)g(a) - g(b)f(a).$$

So $h(a) = h(b)$, and Rolle gives c with $h'(c) = [f(b) - f(a)]g'(c) - [g(b) - g(a)]f'(c) = 0$, which is the claim. Finally, if $g' \neq 0$ on (a, b) then $g(b) \neq g(a)$, for otherwise Rolle applied to g would produce a zero of g'; dividing by $[g(b) - g(a)]g'(c) \neq 0$ gives the quotient form. ■

The MVT is the special case $g(x) = x$ of Cauchy's theorem. Geometrically, Cauchy's theorem says that a parametric curve $t \mapsto (g(t), f(t))$ has, somewhere, a tangent parallel to the chord joining its ends.



Mean value theorem for $f(x) = x^3 - 3x$ on $[0, 2]$: the chord (red, dashed) has slope 1, and the tangent at $c = 2/\sqrt{3} \approx 1.1547$ (green) is parallel to it, since $f'(c) = 3c^2 - 3 = 1$.

Corollary A.1 (consequences of the MVT)

Let I be an interval and f differentiable on I.

1. If $f'(x) = 0$ for all $x \in I$, then f is constant on I. This holds also for complex-valued f.
2. If $f' = g'$ on I, then $f - g$ is constant on I.
3. If $f' > 0$ on I then f is strictly increasing on I; if $f' \geq 0$, non-decreasing. (Similarly for $<$, $\leq$.)
4. If $|f'(x)| \leq M$ on I, then $|f(x_2) - f(x_1)| \leq M|x_2 - x_1|$ for all $x_1, x_2 \in I$.

Proof. For $x_1 < x_2$ in I, f is continuous on $[x_1, x_2]$ (differentiable implies continuous) and differentiable on (x_1, x_2), so $f(x_2) - f(x_1) = f'(c)(x_2 - x_1)$ for some $c \in (x_1, x_2)$. Items 1, 3 and 4 for real f read off directly from this formula. For complex $f = U + jV$, $f' = 0$ means $U' = V' = 0$, so U and V are each constant, hence so is f. Item 2 is item 1 applied to $f - g$. ■

Remarks.

- *Differentiability in the interior is essential.* $f(x) = |x|$ on $[-1, 1]$ is continuous with $f(-1) = f(1)$, yet $f'(x) = \pm 1$ wherever it exists: there is no c with $f'(c) = 0$. The failure is the single point $x = 0$ where f' does not exist.
- *Continuity at the endpoints is essential.* $f(x) = x$ on $[0, 1)$ with $f(1) = 0$ is differentiable on $(0, 1)$ and has $f(0) = f(1)$, but $f' \equiv 1$.
- *The MVT itself fails for complex-valued functions.* $F(t) = e^{jt}$ on $[0, 2\pi]$ has $F(2\pi) - F(0) = 0$, but $F'(t) = je^{jt}$ has modulus 1 everywhere, so no c gives $F'(c) \cdot 2\pi = 0$. (Euler's formula, used here only as an illustration, is proved in §A.6 without this example.) What survives for complex functions is Corollary A.1(1), proved through real and imaginary parts, and the inequality form (4), which can be proved from the FTC (§A.2) as $|F(x_2) - F(x_1)| = \left|\int_{x_1}^{x_2} F'\right| \leq M|x_2 - x_1|$ when F' is continuous. This is why the proof of Euler's formula in §A.6 is arranged around "zero derivative implies constant".
- *Where it is used.* The MVT and its corollaries are stated in Ch. 4 §4.2; Corollary A.1(2) is the justification of the "$+C$" of indefinite integration in Ch. 5 §5.1.4, and item 4 is the Lipschitz estimate behind the existence–uniqueness theory of Ch. 11 §11.7 and the error analysis of fixed-point and Newton iterations in Ch. 22.

A.2 The Fundamental Theorem of Calculus

The FTC connects the two halves of calculus: the integral, defined as a limit of Riemann sums (Ch. 5 §5.1.2), and the derivative. We recall the definition so that the proof of Part 2 can refer to it.

Riemann integral

A **partition** P of $[a,b]$ is a finite set of points $a = x_0 < x_1 < \cdots < x_n = b$, with mesh $\|P\| = \max_i (x_i - x_{i-1})$. A **Riemann sum** for f is $\sum_{i=1}^{n} f(c_i)\,\Delta x_i$ with $\Delta x_i = x_i - x_{i-1}$ and any tags $c_i \in [x_{i-1}, x_i]$. A bounded function f is **Riemann integrable** on $[a,b]$, with integral $\int_a^b f$, if for every $\varepsilon > 0$ there is $\delta > 0$ such that every Riemann sum with $\|P\| < \delta$ (and any choice of tags) lies within ε of $\int_a^b f$. We set $\int_b^a f = -\int_a^b f$ and $\int_a^a f = 0$.

We first need the mean value theorem for integrals.

Lemma A.2 (Mean value theorem for integrals)

If f is continuous on the closed interval with end-points $p \neq q$, there is c between p and q (inclusive) with

$$\frac{1}{q-p}\int_p^q f(t)\,dt = f(c).$$

Proof. Suppose $p < q$ (otherwise swap them; both sides of the formula are unchanged). By the extreme value theorem f has a minimum $m = f(t_1)$ and a maximum $M = f(t_2)$ on $[p,q]$. Monotonicity of the integral applied to $m \le f \le M$ gives $m(q-p) \le \int_p^q f \le M(q-p)$, so the average $\mu = \frac{1}{q-p}\int_p^q f$ satisfies $m \le \mu \le M$. By the intermediate value theorem applied to f on the closed interval between t_1 and t_2, there is c in that interval, hence in $[p,q]$, with $f(c) = \mu$. ∎

Theorem A.2 (Fundamental Theorem of Calculus)

Part 1. Let f be Riemann integrable on $[a,b]$ and define $A(x) = \displaystyle\int_a^x f(t)\,dt$ for $x \in [a,b]$. Then A is continuous on $[a,b]$. If moreover f is continuous at a point $x_0 \in [a,b]$, then A is differentiable at x_0 (one-sidedly if x_0 is an end-point) and $A'(x_0) = f(x_0)$. In particular, if f is continuous on $[a,b]$, then $A' = f$ on $[a,b]$: every continuous function has an antiderivative.

Part 2. Let F be continuous on $[a,b]$ and differentiable on (a,b), and suppose $F' = f$ on (a,b), where f is Riemann integrable on $[a,b]$. Then

$$\int_a^b f(x)\,dx = F(b) - F(a).$$

Proof of Part 1. Since f is integrable it is bounded, say $|f| \le K$. For $x, x+h \in [a,b]$, additivity of the integral gives

$$A(x+h) - A(x) = \int_x^{x+h} f(t)\,dt,$$

and monotonicity gives $|A(x+h) - A(x)| \le K|h|$, so A is (Lipschitz) continuous.

Now let f be continuous at x_0 and let $\varepsilon > 0$. Choose $\delta > 0$ with $|f(t) - f(x_0)| < \varepsilon$ whenever $|t - x_0| < \delta$, $t \in [a,b]$. For $0 < |h| < \delta$ with $x_0 + h \in [a,b]$, write $f(x_0) = \frac{1}{h}\int_{x_0}^{x_0+h} f(x_0)\,dt$; then

$$\left| \frac{A(x_0+h) - A(x_0)}{h} - f(x_0) \right| = \left| \frac{1}{h}\int_{x_0}^{x_0+h} \big[f(t) - f(x_0)\big]\,dt \right| \le \frac{1}{|h|}\cdot |h|\,\varepsilon = \varepsilon,$$

because every t between x_0 and $x_0 + h$ satisfies $|t - x_0| < \delta$. Hence the difference quotient tends to $f(x_0)$. (When f is continuous on the whole interval one can instead quote Lemma A.2: the difference quotient equals $f(c_h)$ with c_h between x_0 and $x_0 + h$, and $f(c_h) \to f(x_0)$ — this is the version in Ch. 5.) ∎

Proof of Part 2. Let $\varepsilon > 0$ and choose δ as in the definition of $\int_a^b f$. Take any partition $a = x_0 < \cdots < x_n = b$ with mesh $< \delta$. On each sub-interval $[x_{i-1}, x_i]$, F is continuous, and differentiable in the interior, so by the MVT (Theorem A.1) there is $c_i \in (x_{i-1}, x_i)$ with $F(x_i) - F(x_{i-1}) = F'(c_i)\Delta x_i = f(c_i)\Delta x_i$. Summing, the left side telescopes:

$$F(b) - F(a) = \sum_{i=1}^{n} \big[F(x_i) - F(x_{i-1})\big] = \sum_{i=1}^{n} f(c_i)\,\Delta x_i.$$

The right side is a Riemann sum with mesh $< \delta$, so it is within ε of $\int_a^b f$. Thus $|F(b) - F(a) - \int_a^b f| < \varepsilon$ for every $\varepsilon > 0$, i.e. the two are equal. ∎

The proof of Part 2 does not use Part 1. For continuous f there is also the two-line proof of Ch. 5: A and F both have derivative f on (a,b), so $F = A + C$ by Corollary A.1(2); both are continuous on $[a,b]$, so the identity extends to the end-points, and $F(b) - F(a) = A(b) - A(a) = \int_a^b f$. The version above is stronger: it needs only integrability of F', not continuity.

Remarks.

- *Part 1 needs continuity at the point.* With $f(t) = -1$ for $t < 0$ and $f(t) = +1$ for $t \ge 0$ on $[-1,1]$, $A(x) = \int_{-1}^{x} f = |x| - 1$, which is continuous (as Part 1 promises for any integrable f) but not differentiable at 0, the jump of f. In circuit language: the charge $q(t) = \int i\,dt$ on a capacitor is continuous even when the current switches abruptly, but dq/dt fails to exist at the switching instant.
- *Part 2 needs $F' = f$ on the whole interval.* The formal computation $\int_{-1}^{1} \frac{dx}{x^2} = \big[-\frac{1}{x}\big]_{-1}^{1} = -2$ is absurd for a positive integrand. Here $F = -1/x$ is not continuous (not even defined) on $[-1,1]$, and $1/x^2$ is unbounded, hence not Riemann integrable; the integral is improper and divergent (Ch. 5 §5.3).
- *Part 2 needs F' to be integrable.* $F(x) = x^2 \sin(1/x^2)$, $F(0) = 0$, is differentiable at every point of $[0,1]$, but $F'(x) = 2x\sin(1/x^2) - \frac{2}{x}\cos(1/x^2)$ for $x \neq 0$ is unbounded near 0, so the Riemann integral of F' over $[0,1]$ does not exist even though $F(1) - F(0) = \sin 1$ is perfectly finite.
- *Complex-valued integrands.* Applying both parts to the real and imaginary parts shows that they hold verbatim for $f : [a,b] \to \mathbb{C}$; for example $\int_0^T e^{j\omega t}\,dt = \big[e^{j\omega t}/(j\omega)\big]_0^T$ for $\omega \neq 0$, because $\frac{d}{dt}e^{j\omega t} = j\omega e^{j\omega t}$ (§A.6).
- *Where it is used.* The FTC is stated in Ch. 5 §5.1.5. Part 1 underlies every "accumulated quantity" of Ch. 5 §5.8 (charge from current, energy from power) and the integrating-factor method of Ch. 11 §11.3; Part 2 is the evaluation rule used in every chapter.

A.3 Integration by parts and integration by substitution

Each of the two main integration techniques is a differentiation rule read backwards through FTC Part 2: parts reverses the product rule, substitution reverses the chain rule. The proofs are short, but the hypotheses are where students (and computer algebra systems) go wrong.

Theorem A.3 (Integration by parts)

Let u and v be continuously differentiable (C^1) on $[a, b]$, real- or complex-valued. Then

$$\int_a^b u(x)\, v'(x)\, dx = \Big[u(x)\, v(x)\Big]_a^b - \int_a^b u'(x)\, v(x)\, dx.$$

On any interval where u, v are C^1, the indefinite form $\int u\, v'\, dx = uv - \int u'v\, dx$ holds (each side an antiderivative of uv', up to an additive constant).

Proof. By the product rule, $(uv)' = u'v + uv'$ on $[a, b]$ (one-sided at the end-points), and the right-hand side is continuous because u, v, u', v' are. Continuous functions are integrable, so FTC Part 2 applied to $F = uv$ gives

$$\Big[uv\Big]_a^b = \int_a^b (uv)'\, dx = \int_a^b u'v\, dx + \int_a^b uv'\, dx,$$

using linearity of the integral. Rearranging gives the formula. For the indefinite form: if G is an antiderivative of $u'v$ (it exists by FTC Part 1), then $(uv - G)' = u'v + uv' - u'v = uv'$, so $uv - G$ is an antiderivative of uv'. For complex-valued u, v the product rule holds by the same algebra, and FTC applies componentwise. ∎

Theorem A.4 (Integration by substitution)

Let $g : [\alpha, \beta] \to \mathbb{R}$ be C^1, and let f be continuous on an interval I that contains $g([\alpha, \beta])$. Then

$$\int_\alpha^\beta f\big(g(t)\big)\, g'(t)\, dt = \int_{g(\alpha)}^{g(\beta)} f(x)\, dx.$$

g need **not** be one-to-one.

Inverse form. If in addition g is strictly monotonic on $[\alpha, \beta]$, then for $a = g(\alpha)$, $b = g(\beta)$ every integral $\int_a^b f(x)\, dx$ may be computed as $\int_{g^{-1}(a)}^{g^{-1}(b)} f(g(t))\, g'(t)\, dt$, i.e. by putting $x = g(t)$, $dx = g'(t)\, dt$ and transforming the limits with g^{-1}.

Proof. Fix $x_0 \in I$ and let $F(x) = \int_{x_0}^x f(s)\, ds$ for $x \in I$. Since f is continuous on the interval I, FTC Part 1 gives $F' = f$ on I. The composite $F \circ g$ is defined on $[\alpha, \beta]$ because g takes values in I, and by the chain rule

$$\frac{d}{dt} F\big(g(t)\big) = F'\big(g(t)\big)\, g'(t) = f\big(g(t)\big)\, g'(t),$$

which is continuous on $[\alpha, \beta]$ (composition and product of continuous functions). FTC Part 2, applied twice, gives

$$\int_\alpha^\beta f\big(g(t)\big) g'(t)\, dt = F\big(g(\beta)\big) - F\big(g(\alpha)\big) = \int_{g(\alpha)}^{g(\beta)} f(x)\, dx.$$

The inverse form is the same identity read from right to left; monotonicity is needed only so that $t = g^{-1}(x)$ is a well-defined function and the new limits $g^{-1}(a) = \alpha$, $g^{-1}(b) = \beta$ are determined uniquely. ∎

Remarks.

- *Non-injective substitutions are fine in the forward direction.* With $g(t) = t^2$ on $[-1, 2]$ (which is not one-to-one: it folds $[-1, 0]$ back over $[0, 1]$),

$$\int_{-1}^{2} 2t \cos(t^2)\, dt = \int_1^4 \cos x\, dx = \sin 4 - \sin 1 \approx -1.59827,$$

which agrees with direct numerical quadrature to all printed digits. The folded part is traversed twice in opposite directions and cancels — the theorem accounts for orientation automatically, which is why no absolute value $|g'|$ appears (contrast the multivariable change of variables of Ch. 6 §6.8, which uses $|\det \mathbf{J}|$ and does require injectivity).

- *The hypothesis that g is C^1 on the whole interval is essential.* The tangent half-angle substitution $x = \tan(t/2)$ of Ch. 5 §5.6.5 turns $\int \frac{dt}{2+\cos t}$ into $\int \frac{2\,dx}{3+x^2}$. Applied blindly to $\int_0^{2\pi}$, it maps both limits to $x = \tan 0 = \tan \pi = 0$ and gives 0, which is impossible for a positive integrand. The true value is $2\pi/\sqrt{3} \approx 3.62760$ (checked by numerical quadrature). The error: $\tan(t/2)$ is not even defined at $t = \pi$, so the hypotheses fail. The correct procedure is to split at $t = \pi$; each half maps onto a half-line of x and gives an improper integral equal to $\pi/\sqrt{3}$.
- *The hypothesis on f concerns the whole range of g.* f must be continuous on an interval containing all values $g(t)$, not merely on the interval between $g(\alpha)$ and $g(\beta)$. If g wanders outside that interval into a region where f is singular, the left side may diverge while the right side is finite.
- *Integration by parts with a jump.* If u or v has a jump discontinuity inside $[a, b]$, split the interval at the jump; the boundary terms then contribute the jump values. This is the "jump method" for Fourier coefficients in Ch. 15 §15.7.
- *Where they are used.* The rules are stated in Ch. 5 §5.5–5.6. Parts gives the Laplace-transform derivative rule $\mathcal{L}\{x'\} = sX(s) - x(0^-)$ (Ch. 14), the decay of Fourier coefficients with smoothness (Ch. 15), the symmetry of Sturm–Liouville operators (Ch. 11 §11.8) and the integral form of Taylor's remainder (§A.4). Linear substitution $x = at + b$ gives the time-shift and time-scaling theorems of every transform in Part V.

A.4 Taylor's theorem with Lagrange and integral remainders

Taylor's theorem quantifies how well the Taylor polynomial

$$p_n(x) = \sum_{k=0}^{n} \frac{f^{(k)}(a)}{k!}(x-a)^k = f(a) + f'(a)(x-a) + \cdots + \frac{f^{(n)}(a)}{n!}(x-a)^n$$

approximates f near a (Ch. 4 §4.7). The **remainder** is $R_n(x) = f(x) - p_n(x)$. Two exact formulas for it are proved here: Lagrange's, which needs the weakest hypotheses and gives the familiar error bound, and the integral form, which is exact without an unknown intermediate point.

Theorem A.5 (Taylor's theorem)

Let I be an open interval, $a, x \in I$, and $n \geq 0$ an integer.

(a) Lagrange remainder. If f is $n+1$ times differentiable on I, then there is a point c strictly between a and x (take $c = a$ if $x = a$) such that

$$R_n(x) = \frac{f^{(n+1)}(c)}{(n+1)!}(x-a)^{n+1}.$$

Consequently, if $|f^{(n+1)}| \leq M$ on the interval between a and x, then $|R_n(x)| \leq \dfrac{M\,|x-a|^{n+1}}{(n+1)!}$.

(b) Integral remainder. If f is C^{n+1} on I (that is, $f^{(n+1)}$ exists and is continuous), then

$$R_n(x) = \frac{1}{n!}\int_a^x f^{(n+1)}(t)\,(x-t)^n\,dt.$$

Proof of (a). The case $x = a$ is trivial ($R_n(a) = 0$), so fix $x \neq a$. Define the constant K by

$$f(x) = p_n(x) + \frac{K}{(n+1)!}(x-a)^{n+1},$$

which is possible because $(x-a)^{n+1} \neq 0$. We must show $K = f^{(n+1)}(c)$ for some c between a and x. The trick is to treat the expansion point as the variable: for $t \in I$ define

$$G(t) = f(x) - \sum_{k=0}^{n} \frac{f^{(k)}(t)}{k!}(x-t)^k - \frac{K}{(n+1)!}(x-t)^{n+1}.$$

Values at the ends. At $t = x$ every term with $k \geq 1$ and the last term vanish, and the $k = 0$ term is $f(x)$, so $G(x) = 0$. At $t = a$, the sum is $p_n(x)$, so $G(a) = f(x) - p_n(x) - \frac{K}{(n+1)!}(x-a)^{n+1} = 0$ by the choice of K.

Derivative. Each $f^{(k)}$ with $k \leq n$ is differentiable on I, so G is differentiable on I (hence continuous). By the product rule, for $k \geq 1$,

$$\frac{d}{dt}\left[\frac{f^{(k)}(t)}{k!}(x-t)^k\right] = \frac{f^{(k+1)}(t)}{k!}(x-t)^k - \frac{f^{(k)}(t)}{(k-1)!}(x-t)^{k-1},$$

and for $k = 0$ the derivative is $f'(t)$, which is the first term of the same formula with no second term. Summing over $k = 0, \dots, n$, the second part of term k cancels the first part of term $k-1$; the sum telescopes to its last surviving piece, $\frac{f^{(n+1)}(t)}{n!}(x-t)^n$. Therefore

$$G'(t) = -\frac{f^{(n+1)}(t)}{n!}(x-t)^n + \frac{K}{n!}(x-t)^n = \frac{(x-t)^n}{n!}\Big[K - f^{(n+1)}(t)\Big].$$

Rolle. G is continuous on the closed interval between a and x, differentiable inside it, and vanishes at both ends. By Rolle's theorem (Theorem A.1) there is c strictly between a and x with $G'(c) = 0$. Since $c \neq x$, $(x-c)^n \neq 0$, so $K = f^{(n+1)}(c)$. The bound follows by taking absolute values. ∎

Proof of (b). Induction on n.

Base case $n = 0$. The claim is $f(x) - f(a) = \int_a^x f'(t)\,dt$, which is FTC Part 2 (Theorem A.2) applied to the continuous function f'.

Inductive step. Suppose the formula holds for $n-1$ (with $n \geq 1$) and that f is C^{n+1}; then in particular f is C^n and

$$R_{n-1}(x) = \frac{1}{(n-1)!}\int_a^x f^{(n)}(t)(x-t)^{n-1}\,dt.$$

Integrate by parts (Theorem A.3) with $u(t) = f^{(n)}(t)$ and $v(t) = -\dfrac{(x-t)^n}{n!}$, so that $v'(t) = \dfrac{(x-t)^{n-1}}{(n-1)!}$; both u and v are C^1 because f is C^{n+1}. Then

$$R_{n-1}(x) = \left[-f^{(n)}(t)\frac{(x-t)^n}{n!}\right]_{t=a}^{t=x} + \int_a^x f^{(n+1)}(t)\frac{(x-t)^n}{n!}\,dt = \frac{f^{(n)}(a)}{n!}(x-a)^n + \frac{1}{n!}\int_a^x f^{(n+1)}(t)(x-t)^n\,dt.$$

Since $R_n(x) = R_{n-1}(x) - \frac{f^{(n)}(a)}{n!}(x-a)^n$ (the degree-n polynomial has one more term), this is exactly the formula for R_n. ∎

From (b) back to (a). Under the stronger hypothesis $f \in C^{n+1}$, (a) also follows from (b) via the weighted mean value theorem for integrals: $(x-t)^n$ does not change sign between a and x, so $\int_a^x f^{(n+1)}(t)(x-t)^n\,dt = f^{(n+1)}(c)\int_a^x (x-t)^n\,dt = f^{(n+1)}(c)\frac{(x-a)^{n+1}}{n+1}$ for some c (the proof is that of Lemma A.2, with $m \leq f^{(n+1)} \leq M$ multiplied by the one-signed weight). Dividing by $n!$ gives Lagrange's form.

Corollary A.5 (The exponential, sine and cosine series)

For every real x,

$$e^x = \sum_{k=0}^{\infty} \frac{x^k}{k!}, \qquad \cos x = \sum_{m=0}^{\infty} \frac{(-1)^m x^{2m}}{(2m)!}, \qquad \sin x = \sum_{m=0}^{\infty} \frac{(-1)^m x^{2m+1}}{(2m+1)!}.$$

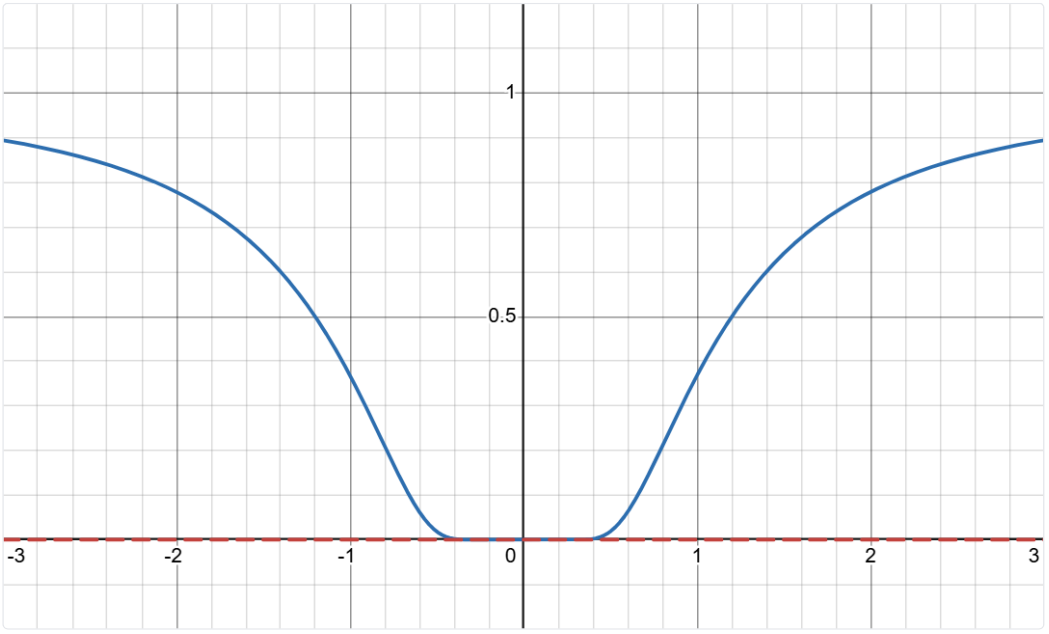
Proof. First, $r^n/n! \to 0$ for every fixed $r \geq 0$: choose an integer $N \geq 2r$; for $n > N$, each factor r/k with $k > N$ is at most $\tfrac{1}{2}$, so $\frac{r^n}{n!} = \frac{r^N}{N!}\prod_{k=N+1}^{n}\frac{r}{k} \leq \frac{r^N}{N!}2^{-(n-N)} \to 0$.

For cos and sin, every derivative is one of $\pm\sin, \pm\cos$, so $|f^{(n+1)}| \leq 1$ everywhere; by Theorem A.5(a) with $a = 0$, $|R_n(x)| \leq |x|^{n+1}/(n+1)! \to 0$. The Taylor coefficients at 0 follow from the cycle $\cos,\ -\sin,\ -\cos,\ \sin$ evaluated at 0: $1, 0, -1, 0, \ldots$ for cos and $0, 1, 0, -1, \ldots$ for sin. For e^x every derivative is e^x, so on the interval between 0 and x, $|f^{(n+1)}| \leq e^{|x|}$ and $|R_n(x)| \leq e^{|x|}|x|^{n+1}/(n+1)! \to 0$. In each case $p_n(x) \to f(x)$, which is what convergence of the series to f means. ∎

Numerical check. For $e^{0.5}$ with $n = 3$: $p_3(0.5) = 1 + 0.5 + 0.125 + 0.020\overline{83} = 1.645\overline{83}$, and $e^{0.5} = 1.6487213$, so the actual error is 0.0028879. Lagrange's bound with $M = e^{0.5}$ is $1.6487 \times 0.5^4/24 = 0.0042935$, which is indeed larger. For $\cos\pi$ with the degree-6 polynomial (which equals p_7, since the x^7 coefficient is zero), $p_6(\pi) = -1.21135$, error 0.21135, and the bound $\pi^8/8! = 0.23533$ holds.

Remarks.

- *A smooth function need not equal its Taylor series.* Let $\varphi(x) = e^{-1/x^2}$ for $x \neq 0$ and $\varphi(0) = 0$. By induction, for $x \neq 0$, $\varphi^{(k)}(x) = P_k(1/x)\,e^{-1/x^2}$ with P_k a polynomial (differentiate and use the chain rule). Since $u^m e^{-u^2} \to 0$ as $|u| \to \infty$ for every m, the difference quotient $\varphi^{(k)}(h)/h = \frac{1}{h}P_k(\frac{1}{h})e^{-1/h^2} \to 0$, so $\varphi^{(k+1)}(0) = 0$ for every k. The Taylor series of φ at 0 is identically zero, yet $\varphi(x) > 0$ for $x \neq 0$: here $R_n(x) = \varphi(x)$ for every n, and Theorem A.5 is not contradicted — the derivatives of φ near 0 grow so fast that the bound does not tend to 0. Functions equal to their Taylor series near every point are called **analytic**; in complex analysis (Ch. 18) differentiability in the complex sense forces analyticity, which is one reason that theory is so rigid.
- *Lagrange's form does not hold for complex-valued functions* (it is a mean value statement; see the remark in §A.1). The integral form (b) does hold for complex-valued f, by applying it to real and imaginary parts, and gives the bound $|R_n(x)| \leq M|x-a|^{n+1}/(n+1)!$ with $M = \max|f^{(n+1)}|$, since $|\int F| \leq \int|F|$.
- *Peano form.* If f is C^{n+1} near a, part (a) gives $R_n(x) = O(|x-a|^{n+1})$: halving the step reduces the error of a degree-n approximation by about 2^{n+1}. This is the source of the error orders of the finite-difference formulas in Ch. 4 §4.7, of the trapezoidal and Simpson rules in Ch. 5 §5.7, and of Runge–Kutta methods in Ch. 22.
- *Where it is used.* Linearization and small-signal models (Ch. 4 §4.8), the second-derivative test and Newton's method in optimization (Ch. 23 §23.4–23.6) and the two-variable Taylor theorem of Ch. 6 §6.3 (obtained by applying Theorem A.5 to $t \mapsto f(\mathbf{a} + t\mathbf{h})$).



The function e^{-1/x^2} (blue) is infinitely differentiable, and every derivative vanishes at 0, so its Maclaurin series is the zero function (red, dashed) — which agrees with it only at the origin.

A.5 L'Hôpital's rule (the $0/0$ case)

Theorem A.6 (L'Hôpital's rule, $0/0$ form)

Let $-\infty \leq a < b \leq \infty$ and let f, g be differentiable on (a, b) with $g'(x) \neq 0$ for all $x \in (a, b)$. Suppose

$$\lim_{x \to a^+} f(x) = \lim_{x \to a^+} g(x) = 0 \qquad \text{and} \qquad \lim_{x \to a^+} \frac{f'(x)}{g'(x)} = L,$$

where L is a real number, $+\infty$ or $-\infty$. Then $g(x) \neq 0$ on (a, b) and

$$\lim_{x \to a^+} \frac{f(x)}{g(x)} = L.$$

The same holds for left-hand limits $x \to b^-$ (including $b = +\infty$), and hence, by combining the two sides, for two-sided limits $x \to a$ when the hypotheses hold on a punctured neighbourhood of a.

Proof for finite a. Extend f and g to $[a, b)$ by setting $f(a) = g(a) = 0$. Because the limits at a^+ are 0, the extended functions are continuous on $[a, x]$ for every $x \in (a, b)$, and they are differentiable on (a, x).

Step 1: g does not vanish. If $g(x) = 0$ for some $x \in (a, b)$, then $g(a) = g(x) = 0$ and Rolle's theorem would give a point of (a, x) where $g' = 0$, contrary to hypothesis.

Step 2: Cauchy's MVT. Fix $x \in (a, b)$. By Theorem A.1(3) on $[a, x]$ (where $g' \neq 0$ on (a, x)), there is $\xi_x \in (a, x)$ with

$$\frac{f(x)}{g(x)} = \frac{f(x) - f(a)}{g(x) - g(a)} = \frac{f'(\xi_x)}{g'(\xi_x)}.$$

Step 3: pass to the limit. Let V be any neighbourhood of L (an interval $(L - \varepsilon, L + \varepsilon)$ if L is finite, or (K, ∞) if $L = +\infty$, or $(-\infty, -K)$ if $L = -\infty$). By hypothesis there is $\eta > 0$ with $f'(s)/g'(s) \in V$ for all $s \in (a, a + \eta)$. If $x \in (a, a + \eta)$, then $\xi_x \in (a, x) \subset (a, a + \eta)$, so $f(x)/g(x) = f'(\xi_x)/g'(\xi_x) \in V$. Since V was arbitrary, $f(x)/g(x) \to L$. ∎

Proof for $a = -\infty$ (and, symmetrically, for $b = +\infty$). Take $b = +\infty$ for definiteness, with the hypotheses holding on (M, ∞), $M > 0$, as $x \to +\infty$. Put $F(t) = f(1/t)$ and $G(t) = g(1/t)$ for $t \in (0, 1/M)$. By the chain rule $F'(t) = -f'(1/t)/t^2$ and $G'(t) = -g'(1/t)/t^2 \neq 0$, and

$$\lim_{t \to 0^+} F(t) = \lim_{x \to \infty} f(x) = 0, \quad \lim_{t \to 0^+} G(t) = 0, \quad \frac{F'(t)}{G'(t)} = \frac{f'(1/t)}{g'(1/t)} \xrightarrow[t \to 0^+]{} L.$$

The finite case at 0^+ gives $F(t)/G(t) \to L$, i.e. $f(x)/g(x) \to L$ as $x = 1/t \to \infty$. ∎

Example. $\lim_{x \to 0} \dfrac{1 - \cos x}{x^2}$: numerator and denominator tend to 0, and $g'(x) = 2x \neq 0$ for $x \neq 0$. The ratio of derivatives $\frac{\sin x}{2x}$ is again $0/0$ with $(2x)' = 2 \neq 0$, and $\frac{\cos x}{2} \to \frac{1}{2}$. Applying Theorem A.6 twice (inner limit first) gives $\frac{1}{2}$. The Taylor series give the same answer at once: $1 - \cos x = \frac{x^2}{2} - \frac{x^4}{24} + \dots$. Similarly $\lim_{x \to 0} \frac{\sin x - x}{x^3} = -\frac{1}{6}$.

Remarks.

- *The Ch. 4 sketch versus this proof.* The sketch in Ch. 4 §4.2 assumes f, g are differentiable *at* a with $g'(a) \neq 0$. The proof above assumes nothing at a itself, which is what is needed when the rule must be applied repeatedly (after one application, f' and g' are typically $0/0$ at a again) and for limits at infinity.
- *The rule is one-directional.* $f(x) = x^2 \sin(1/x)$, $g(x) = x$ at $a = 0$: $f/g = x \sin(1/x) \to 0$ by the squeeze theorem, but $f'/g' = 2x \sin(1/x) - \cos(1/x)$ has no limit. If $\lim f'/g'$ does not exist, the rule says nothing.
- *The hypothesis $g' \neq 0$ is not a formality.* It is needed in Step 1 and in Cauchy's theorem. The classical example of Stolz, in the ∞/∞ form, shows what goes wrong: $f(x) = x + \sin x \cos x$, $g(x) = e^{\sin x} f(x)$ as $x \to \infty$. Here $f' = 2\cos^2 x$ and $g' = e^{\sin x} \cos x \, (f + 2\cos x)$, so after cancelling the common factor $\cos x$, $\frac{f'}{g'} = \frac{2e^{-\sin x} \cos x}{f + 2\cos x} \to 0$; but $f/g = e^{-\sin x}$ oscillates between e^{-1} and e. The culprit: g' vanishes at every zero of $\cos x$, arbitrarily far out, and the "cancellation" divided by zero.
- *The ∞/∞ form.* If instead $|g(x)| \to \infty$ as $x \to a^+$ (no condition on f), the conclusion again holds. The proof applies Cauchy's MVT on $[x, y]$ with y fixed close to a and $x \to a^+$, writing $\frac{f(x)}{g(x)} = \frac{f(x) - f(y)}{g(x) - g(y)} \cdot \frac{g(x) - g(y)}{g(x)} + \frac{f(y)}{g(x)}$ and noting that the last two factors tend to 1 and 0; see Rudin's *Principles*, Thm 5.13.
- *Where it is used.* Limits in Ch. 4 §4.1–4.2 (exponentials dominate powers), initial and final value theorems and the residue at a simple pole $\lim_{s \to p}(s - p)N(s)/D(s) = N(p)/D'(p)$ (Ch. 14, Ch. 18), and the value $\operatorname{sinc}(0) = 1$ used throughout Ch. 16.

A.6 Euler's formula

Ch. 2 §2.4 derives $e^{j\theta} = \cos\theta + j\sin\theta$ in three ways. Here we make two of them rigorous. The first question is what $e^{j\theta}$ *means*: the real exponential is not defined for imaginary arguments, so we must choose a definition and then prove the formula from it.

The complex exponential

For $z \in \mathbb{C}$,

$$e^z = \exp(z) = \sum_{n=0}^{\infty} \frac{z^n}{n!} = \lim_{N \to \infty} \sum_{n=0}^{N} \frac{z^n}{n!}.$$

The series converges for every z: its real and imaginary parts are real series whose terms are bounded in modulus by $|z|^n/n!$, and $\sum |z|^n/n! = e^{|z|}$ converges (Corollary A.5), so both are absolutely convergent and hence convergent. For real z this agrees with the real exponential, by Corollary A.5.

Throughout this section write

$$c(\theta) = \cos\theta + j\sin\theta, \qquad \bar{c}(\theta) = \cos\theta - j\sin\theta \qquad (\theta \in \mathbb{R}),$$

so that $c'(\theta) = -\sin\theta + j\cos\theta = j\,c(\theta)$, $\bar{c}'(\theta) = -\sin\theta - j\cos\theta = -j\,\bar{c}(\theta)$, and $c(\theta)\,\bar{c}(\theta) = \cos^2\theta + \sin^2\theta = 1$.

Theorem A.7 (Euler's formula)

For every real θ,

$$e^{j\theta} = \cos\theta + j\sin\theta.$$

Moreover $\dfrac{d}{d\theta} e^{j\theta} = j\,e^{j\theta}$, and $e^{j\theta}$ is the **only** differentiable function $y : \mathbb{R} \to \mathbb{C}$ with $y' = jy$ and $y(0) = 1$.

We give two independent proofs. The first uses the Taylor series of cos and sin; the second uses only their derivatives.

Proof 1 — power series

Let $S_N(\theta) = \sum_{n=0}^{N} \frac{(j\theta)^n}{n!}$. The powers of j cycle with period 4: $j^{2m} = (j^2)^m = (-1)^m$ and $j^{2m+1} = j\,(-1)^m$. Split the partial sum with an odd number of terms, S_{2N+1}, into even and odd n:

$$S_{2N+1}(\theta) = \sum_{m=0}^{N} \frac{(-1)^m \theta^{2m}}{(2m)!} + j \sum_{m=0}^{N} \frac{(-1)^m \theta^{2m+1}}{(2m+1)!}.$$

No rearrangement of an infinite series is involved: this is a regrouping of finitely many terms. The real part is the N-th partial sum of the cosine series and the imaginary part is the N-th partial sum of the sine series, so by Corollary A.5,

$$\operatorname{Re}\{S_{2N+1}(\theta)\} \to \cos\theta, \qquad \operatorname{Im}\{S_{2N+1}(\theta)\} \to \sin\theta \qquad (N \to \infty).$$

A sequence of complex numbers converges if and only if its real and imaginary parts converge, so $S_{2N+1}(\theta) \to \cos\theta + j\sin\theta$. But the whole sequence $S_N(\theta)$ converges to $e^{j\theta}$ by definition, and every subsequence of a convergent sequence has the same limit. Hence $e^{j\theta} = \cos\theta + j\sin\theta$. ■

Proof 2 — the differential equation and uniqueness

This proof has two steps: the series satisfies the initial-value problem $y' = jy$, $y(0) = 1$, and that problem has only one solution.

> **Lemma A.7a (Uniqueness)**
>
> Let I be an interval containing 0 and $y : I \to \mathbb{C}$ differentiable with $y'(\theta) = j\,y(\theta)$ on I. Then $y(\theta) = y(0)\,c(\theta)$ for all $\theta \in I$.

Proof. Let $w(\theta) = y(\theta)\,\bar{c}(\theta)$. By the product rule (valid for complex-valued functions),

$$w' = y'\,\bar{c} + y\,\bar{c}' = (jy)\,\bar{c} + y\,(-j\bar{c}) = 0.$$

By Corollary A.1(1) for complex-valued functions, w is constant on I, equal to $w(0) = y(0)\bar{c}(0) = y(0)$. Multiplying $y\bar{c} = y(0)$ by c and using $c\bar{c} = 1$ gives $y = y(0)\,c$. ■

> **Lemma A.7b (Derivative of the series)**
>
> $E(\theta) = \sum_{n=0}^{\infty} \frac{(j\theta)^n}{n!}$ is differentiable on $\mathbb{R}$ with $E'(\theta) = j\,E(\theta)$.

Proof. Fix θ and let $0 < |h| \le 1$. For each $n \ge 2$, Theorem A.5(a) applied to $t \mapsto t^n$ at $a = \theta$ with $n = 1$ gives

$$(\theta + h)^n - \theta^n - n\theta^{n-1}h = \frac{n(n-1)\gamma^{n-2}}{2}h^2$$

for some γ between θ and $\theta + h$, so that $|\gamma| \le |\theta| + 1 =: r$. For $n = 0, 1$ the left side is 0. The series $\sum_n \frac{j^n n\theta^{n-1}}{n!} = j\sum_{n\ge1}\frac{(j\theta)^{n-1}}{(n-1)!} = jE(\theta)$ converges, so we may combine three convergent series term by term:

$$E(\theta+h) - E(\theta) - h\,jE(\theta) = \sum_{n=2}^{\infty} \frac{j^n}{n!}\Big[(\theta+h)^n - \theta^n - n\theta^{n-1}h\Big].$$

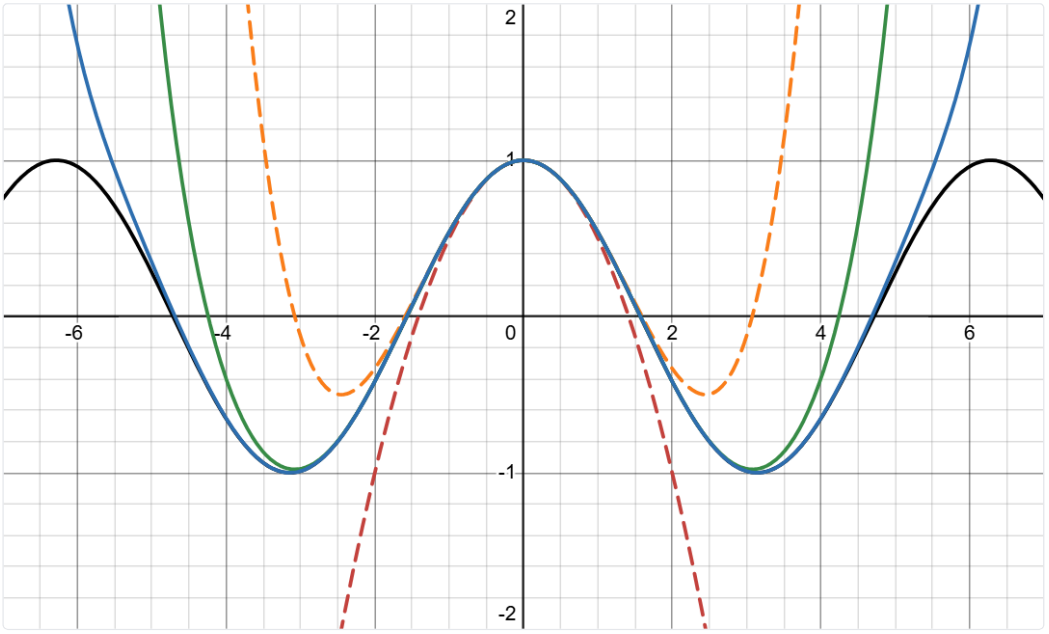
Taking moduli and using $|j^n| = 1$,

$$\Big|E(\theta+h) - E(\theta) - h\,jE(\theta)\Big| \le \frac{h^2}{2}\sum_{n=2}^{\infty}\frac{n(n-1)}{n!}r^{n-2} = \frac{h^2}{2}\sum_{m=0}^{\infty}\frac{r^m}{m!} = \frac{h^2}{2}e^r.$$

Dividing by $|h|$: $\left|\frac{E(\theta+h)-E(\theta)}{h} - jE(\theta)\right| \le \frac{|h|}{2}e^{|\theta|+1} \to 0$ as $h \to 0$. ■

(The identity $\sum_{n\ge2}\frac{n(n-1)}{n!}r^{n-2} = e^r$ used in the last step was also checked numerically, e.g. both sides equal 9.97418 at $r = 2.3$.)

Conclusion of Proof 2. By Lemma A.7b, $y = E$ satisfies $y' = jy$ on $\mathbb{R}$ with $y(0) = 1$. By Lemma A.7a, $E(\theta) = c(\theta) = \cos\theta + j\sin\theta$. The uniqueness statement of the theorem is Lemma A.7a with $y(0) = 1$. ■



The real part of the partial sums of $e^{j\theta}$ (degrees 2, 4, 8, 12) against $\cos\theta$ (black). Each polynomial hugs the cosine over a wider interval; by Corollary A.5 the agreement extends to any bounded interval as the degree grows.

Corollary A.7 (Consequences of Euler's formula)

For all real α, β, θ:

1. $|e^{j\theta}| = 1$ and $\overline{e^{j\theta}} = e^{-j\theta} = 1/e^{j\theta}$.
2. $e^{j(\alpha+\beta)} = e^{j\alpha}e^{j\beta}$; taking real and imaginary parts gives $\cos(\alpha+\beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta$ and $\sin(\alpha+\beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta$.
3. $\cos\theta = \dfrac{e^{j\theta} + e^{-j\theta}}{2}$ and $\sin\theta = \dfrac{e^{j\theta} - e^{-j\theta}}{2j}$.
4. $e^{j\theta} = 1$ if and only if $\theta = 2\pi m$ for some integer m; hence $e^{j\theta}$ is periodic with fundamental period 2π.
5. For real ω, $\dfrac{d}{dt}e^{j\omega t} = j\omega\, e^{j\omega t}$.

Proof. (1) $|e^{j\theta}|^2 = \cos^2\theta + \sin^2\theta = 1$; $\overline{c(\theta)} = \cos\theta - j\sin\theta = \cos(-\theta) + j\sin(-\theta) = c(-\theta)$ because cos is even and sin odd; and $c(\theta)c(-\theta) = c(\theta)\bar{c}(\theta) = 1$. (2) Fix α and let $y(\theta) = e^{j(\alpha+\theta)} = c(\alpha+\theta)$. By the chain rule $y'(\theta) = c'(\alpha+\theta) = j\,y(\theta)$, and $y(0) = e^{j\alpha}$. Lemma A.7a gives $y(\theta) = e^{j\alpha}e^{j\theta}$. Expanding $c(\alpha)c(\beta)$ and comparing real and imaginary parts gives the compound-angle formulas — so these formulas are a *consequence* of Euler's formula, not an input to it (Proof 2 used only $\sin' = \cos$, $\cos' = -\sin$ and $\cos^2 + \sin^2 = 1$). (3) Add and subtract $e^{j\theta} = \cos\theta + j\sin\theta$ and $e^{-j\theta} = \cos\theta - j\sin\theta$. (4) $e^{j\theta} = 1$ means $\cos\theta = 1$ and $\sin\theta = 0$; and $\cos\theta = 1$ exactly when $\theta \in 2\pi\mathbb{Z}$, which is the statement that the point at arc length θ on the unit circle returns to $(1,0)$ only after whole turns (the unit-circle definition of cos, Ch. 3 §3.1); conversely $\theta = 2\pi m$ gives $\cos\theta = 1$, $\sin\theta = 0$. Then $e^{j(\theta+T)} = e^{j\theta}$ for all θ iff $e^{jT} = 1$ (by (2)) iff $T \in 2\pi\mathbb{Z}$. (5) Chain rule with Theorem A.7: $\frac{d}{dt}c(\omega t) = \omega\, c'(\omega t) = j\omega\, c(\omega t)$. ∎

Remarks.

- *Why two proofs.* Proof 1 explains where the formula "comes from" — the even and odd parts of the exponential series are the cosine and sine series — but it leans on Taylor's theorem for cos and sin. Proof 2 is the more robust argument: it shows that *any* reasonable definition of $e^{j\theta}$ — anything differentiable that satisfies $y' = jy$, $y(0) = 1$ — is forced to equal $\cos\theta + j\sin\theta$. It is the simplest instance of the uniqueness theorem for linear ODEs (Ch. 11 §11.7), and the same "multiply by the inverse solution and show the derivative vanishes" trick proves that $e^{\mathbf{A}t}$ is the unique solution of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ (Ch. 11 §11.9).
- *Radians are essential.* The proofs use $\sin' = \cos$, which holds only when angles are measured in radians (Ch. 3 §3.1). In degrees, $\frac{d}{d\theta}\sin\theta^\circ = \frac{\pi}{180}\cos\theta^\circ$, and $e^{j\theta}$ would have to be replaced by $e^{j\pi\theta/180}$.
- *The general exponential.* For $z = \sigma + j\omega$, the identity $e^z = e^\sigma e^{j\omega} = e^\sigma(\cos\omega + j\sin\omega)$ requires the addition law $e^{z+w} = e^z e^w$ for complex z, w, which follows from the Cauchy product of two absolutely convergent series (or from the uniqueness argument in the complex-variable setting of Ch. 18). It is the basis of the s-plane picture of e^{st}: σ sets growth or decay and ω sets oscillation.
- *Where it is used.* Phasors and impedance (Ch. 2 §2.8–2.9); all trigonometric identities by the "master method" (Ch. 3 §3.6); complex Fourier series and transforms (Ch. 15, Ch. 16); characteristic-root solutions of linear ODEs (Ch. 12).

A.7 De Moivre's theorem and the n-th roots of unity

We use the polar form of Ch. 2 §2.1: every $z \neq 0$ can be written $z = r\,e^{j\varphi}$ with $r = |z| > 0$ and φ real (an argument of z), and φ is determined up to an additive multiple of 2π (Corollary A.7(4)).

Theorem A.8 (De Moivre)

For every integer n (positive, zero or negative) and every real θ,

$$(\cos\theta + j\sin\theta)^n = \cos n\theta + j\sin n\theta, \qquad \text{i.e.} \qquad \left(e^{j\theta}\right)^n = e^{jn\theta},$$

and for $r > 0$, $(re^{j\theta})^n = r^n e^{jn\theta}$.

Proof. *$n \geq 0$, by induction.* For $n = 0$ both sides equal 1. If $(e^{j\theta})^n = e^{jn\theta}$, then by Corollary A.7(2),

$$\left(e^{j\theta}\right)^{n+1} = e^{jn\theta}\,e^{j\theta} = e^{j(n\theta+\theta)} = e^{j(n+1)\theta}.$$

$n = -m < 0$. By Corollary A.7(1), $(e^{j\theta})^{-1} = e^{-j\theta}$, so $(e^{j\theta})^{-m} = \left((e^{j\theta})^{-1}\right)^m = (e^{j(-\theta)})^m = e^{-jm\theta}$ by the case already proved. The last statement follows because real and complex powers of a product factor: $(r\,e^{j\theta})^n = r^n(e^{j\theta})^n$ for integer n (commutativity of multiplication). ∎

n-th roots and roots of unity

For an integer $n \geq 1$ and $z \in \mathbb{C}$, an **n-th root** of z is any $w \in \mathbb{C}$ with $w^n = z$. The n-th roots of 1 are the **n-th roots of unity**. Write $W = W_n = e^{j2\pi/n}$.

Theorem A.9 (n-th roots)

Let $n \geq 1$ and $z = re^{j\varphi} \neq 0$. Then $w^n = z$ has **exactly** n solutions,

$$w_k = r^{1/n}\, e^{j(\varphi + 2\pi k)/n}, \qquad k = 0, 1, \dots, n-1,$$

where $r^{1/n}$ is the positive real n-th root. They are $w_k = w_0 W^k$, equally spaced on the circle of radius $r^{1/n}$. In particular the n-th roots of unity are $1, W, W^2, \dots, W^{n-1}$, and:

1. $w^n - 1 = \prod_{k=0}^{n-1} \left(w - W^k\right)$ for all $w \in \mathbb{C}$;
2. for every integer m,

$$\sum_{k=0}^{n-1} W^{mk} = \begin{cases} n, & n \mid m, \\ 0, & \text{otherwise.} \end{cases}$$

Proof. *Each w_k is a root.* By Theorem A.8, $w_k^n = r\, e^{j(\varphi+2\pi k)} = r\, e^{j\varphi} e^{j2\pi k} = z$, using Corollary A.7(2) and $e^{j2\pi k} = 1$.

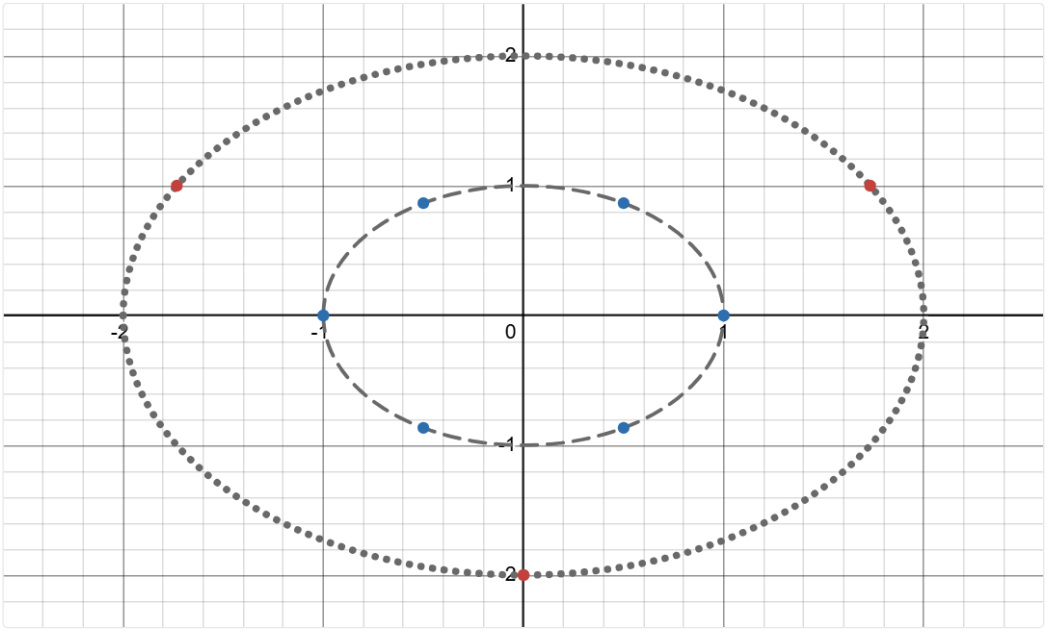
Every root is some w_k. Let $w^n = z$. Then $w \neq 0$ (else $z = 0$), so $w = \rho e^{j\psi}$ with $\rho > 0$. By Theorem A.8, $\rho^n e^{jn\psi} = re^{j\varphi}$. Taking moduli (Corollary A.7(1)) gives $\rho^n = r$; since $t \mapsto t^n$ is strictly increasing on $(0, \infty)$ (its derivative nt^{n-1} is positive, Corollary A.1(3)), $\rho = r^{1/n}$. Dividing out, $e^{j(n\psi - \varphi)} = 1$, so by Corollary A.7(4), $n\psi - \varphi = 2\pi m$ for some integer m, i.e. $\psi = (\varphi + 2\pi m)/n$. By the division algorithm $m = qn + k$ with $q \in \mathbb{Z}$ and $0 \leq k \leq n-1$; then $e^{j\psi} = e^{j(\varphi+2\pi k)/n}\, e^{j2\pi q} = e^{j(\varphi+2\pi k)/n}$, so $w = w_k$.

The w_k are distinct. If $w_k = w_l$ with $0 \leq l < k \leq n-1$, dividing gives $e^{j2\pi(k-l)/n} = 1$, so $(k-l)/n$ is an integer by Corollary A.7(4). But $0 < k - l < n$, a contradiction. Hence there are exactly n roots. The form $w_k = w_0 W^k$ is Corollary A.7(2).

(1) Factorisation. Let $p(w) = w^n - 1$. If $p(\alpha) = 0$, polynomial division gives $p(w) = (w - \alpha)q(w)$ with q monic of degree $n-1$ (the factor theorem). Apply this with $\alpha = W^0 = 1$; each remaining W^k, $k \geq 1$, satisfies $0 = p(W^k) = (W^k - 1)q(W^k)$ with $W^k - 1 \neq 0$ (distinctness), so W^k is a root of q. Repeating n times leaves a monic polynomial of degree 0, i.e. the constant 1.

(2) Sums. If $n \mid m$, then $W^m = e^{j2\pi(m/n)} = 1$ and every term is 1: the sum is n. Otherwise $\rho = W^m \neq 1$ (Corollary A.7(4)) and $\rho^n = (W^n)^m = 1$. The finite geometric sum gives $\sum_{k=0}^{n-1} \rho^k = \frac{1-\rho^n}{1-\rho} = 0$. ∎

Example. The cube roots of $z = 8j$: $r = 8$, $\varphi = \pi/2$, so $w_k = 2e^{j(\pi/6 + 2\pi k/3)}$, i.e. $w_0 = \sqrt{3} + j$, $w_1 = -\sqrt{3} + j$, $w_2 = -2j$. Each cubes to $8j$ (checked numerically), and their sum is 0, as part 2 with $m = 1$ predicts for $w_0(1 + W + W^2)$.



The sixth roots of unity (blue) form a regular hexagon on the unit circle; the cube roots of $8j$ (red) form an equilateral triangle on the circle of radius $8^{1/3} = 2$, rotated to angle $\varphi/n = 30°$.

Remarks.

- *Why exactly n and not infinitely many.* The infinitely many arguments $\varphi + 2\pi m$ of z give infinitely many candidate angles $(\varphi + 2\pi m)/n$, but they repeat with period n in m. This is the precise sense in which $z^{1/n}$ is "multi-valued" (Ch. 2 §2.6, Ch. 18).
- *De Moivre is for integer exponents.* Applied naively to $n = \frac{1}{2}$ it would give a contradiction: $e^{j0} = e^{j2\pi} = 1$, yet "$\left(e^{j2\pi}\right)^{1/2} = e^{j\pi} = -1$" while $\left(e^{j0}\right)^{1/2} = 1$. Likewise $(z^a)^b = z^{ab}$ fails for non-integer exponents: $\left((-1)^2\right)^{1/2} = 1$ but $\left((-1)^{1/2}\right)^2 = -1$ for either choice of $(-1)^{1/2} = \pm j$.
- *The hypothesis $z \neq 0$.* For $z = 0$ the only root is $w = 0$, with multiplicity n; the polar argument is undefined.
- *Where it is used.* Part 2 is the orthogonality relation of the DFT, $\sum_{k=0}^{N-1} e^{j2\pi(m-l)k/N} = N\delta_{ml}$ for $0 \leq m, l < N$ (Ch. 15 §15.7, Ch. 24), and with $n = 3$ it is the identity $1 + a + a^2 = 0$, $a = e^{j2\pi/3}$, which makes the phasors of a balanced three-phase set sum to zero (Ch. 3 §3.3). Part 1 underlies root-finding and factoring in Ch. 2 §2.6, the poles of Butterworth filters (equally spaced on a circle in the s-plane), and the N-point FFT's recursive splitting of W_N into $W_{N/2}$.

A.8 RMS of a sinusoid and of a sum of sinusoids of different frequencies

The statement "powers of components at different frequencies add" is used constantly — for harmonic distortion, for noise, for Parseval's theorem. Here it is proved in two settings: exactly over a common period when the frequencies are harmonics of one fundamental, and as a long-time average when they are not (for example $\cos t + \cos \sqrt{2}\,t$, which is not periodic at all).

Mean, mean-square and RMS

For x continuous on $[t_0, t_0+T]$, $T>0$, the **mean** and **RMS value over the window** are

$$\bar{x}_{[t_0,T]} = \frac{1}{T}\int_{t_0}^{t_0+T} x(t)\,dt, \qquad X_{\mathrm{rms},[t_0,T]} = \sqrt{\frac{1}{T}\int_{t_0}^{t_0+T} x(t)^2\,dt}.$$

For a T-periodic x the window is one period. For an arbitrary bounded x, the **long-time mean-square value** (average power in $1\ \Omega$) is $\langle x^2\rangle = \lim_{T\to\infty}\frac{1}{T}\int_{t_0}^{t_0+T} x^2\,dt$, when the limit exists.

Lemma A.8 (Averages over a period do not depend on the starting point; averages of sinusoids)

1. If x is continuous and T-periodic, then $\int_{t_0}^{t_0+T} x\,dt$ is the same for every t_0.
2. For $\Omega \neq 0$ and any real ψ, t_0, $T>0$,

$$\left|\int_{t_0}^{t_0+T} \cos(\Omega t+\psi)\,dt\right| \le \frac{2}{|\Omega|},$$

and the integral is exactly 0 when T is an integer multiple of $2\pi/|\Omega|$.

Proof. (1) Let $I(t_0) = \int_{t_0}^{t_0+T} x\,dt = \int_0^{t_0+T} x\,dt - \int_0^{t_0} x\,dt$. By FTC Part 1 (Theorem A.2) and the chain rule, $I'(t_0) = x(t_0+T) - x(t_0) = 0$, so I is constant by Corollary A.1(1). (2) An antiderivative of $\cos(\Omega t+\psi)$ is $\sin(\Omega t+\psi)/\Omega$, so by FTC Part 2 the integral equals $\big[\sin(\Omega(t_0+T)+\psi) - \sin(\Omega t_0+\psi)\big]/\Omega$, whose modulus is at most $2/|\Omega|$. If $T = 2\pi q/|\Omega|$ with q an integer, the two sines are equal because sin has period 2π. ∎

Theorem A.10 (RMS of sinusoids)

(a) Single sinusoid. Let $x(t) = C + A\cos(\omega t+\phi)$ with $\omega>0$ and A, C, ϕ real, and $T = 2\pi/\omega$. Over any window of length T,

$$\bar{x} = C, \qquad X_{\mathrm{rms}} = \sqrt{C^2 + \tfrac{1}{2}A^2}; \qquad \text{for } C=0:\ X_{\mathrm{rms}} = \frac{|A|}{\sqrt{2}}.$$

(b) Different frequencies, long-time average. Let

$$x(t) = A_0 + \sum_{k=1}^{N} A_k\cos(\omega_k t+\phi_k),$$

with real A_k, ϕ_k and **distinct** positive frequencies $\omega_1,\dots,\omega_N$ (no commensurability assumed). Then, uniformly in t_0,

$$\left|\frac{1}{T}\int_{t_0}^{t_0+T} x^2\,dt - P\right| \le \frac{B}{T}, \qquad P = A_0^2 + \sum_{k=1}^{N}\frac{A_k^2}{2},$$

with the constant

$$B = \sum_{k=1}^{N}\left(\frac{4|A_0A_k|}{\omega_k} + \frac{A_k^2}{2\omega_k}\right) + \sum_{1\le k<l\le N} 2|A_kA_l|\left(\frac{1}{|\omega_k-\omega_l|} + \frac{1}{\omega_k+\omega_l}\right).$$

Hence $\langle x^2\rangle = P$ and the long-time RMS value is $\sqrt{A_0^2 + \sum_k A_k^2/2}$, independent of the phases ϕ_k.

(c) Harmonics. If $\omega_k = n_k\omega_0$ for distinct positive integers n_k, then x is periodic with period $T_0 = 2\pi/\omega_0$, and the mean-square value over **any** window of length T_0 equals P exactly.

Proof. Write $\theta_k = \omega_k t + \phi_k$. Expanding the square of a finite sum,

$$x^2 = A_0^2 + 2A_0\sum_k A_k\cos\theta_k + \sum_k A_k^2\cos^2\theta_k + 2\sum_{k<l} A_kA_l\cos\theta_k\cos\theta_l.$$

Use the power-reduction and product-to-sum identities (both follow from Corollary A.7(2)–(3)):

$$\cos^2\theta_k = \tfrac{1}{2} + \tfrac{1}{2}\cos 2\theta_k, \qquad 2\cos\theta_k\cos\theta_l = \cos(\theta_k-\theta_l) + \cos(\theta_k+\theta_l).$$

So

$$x^2 = \underbrace{A_0^2 + \sum_k \frac{A_k^2}{2}}_{P} + 2A_0\sum_k A_k\cos\theta_k + \sum_k \frac{A_k^2}{2}\cos 2\theta_k + \sum_{k<l} A_kA_l\Big[\cos(\theta_k-\theta_l) + \cos(\theta_k+\theta_l)\Big].$$

Every term after P is a constant times $\cos(\Omega t+\psi)$ with angular frequency Ω equal to one of ω_k, $2\omega_k$, $\omega_k-\omega_l$ or $\omega_k+\omega_l$ ($k<l$). **None of these is zero**: the ω_k are positive, and $\omega_k-\omega_l\neq 0$ because the frequencies are distinct. This is the only place the hypothesis is used.

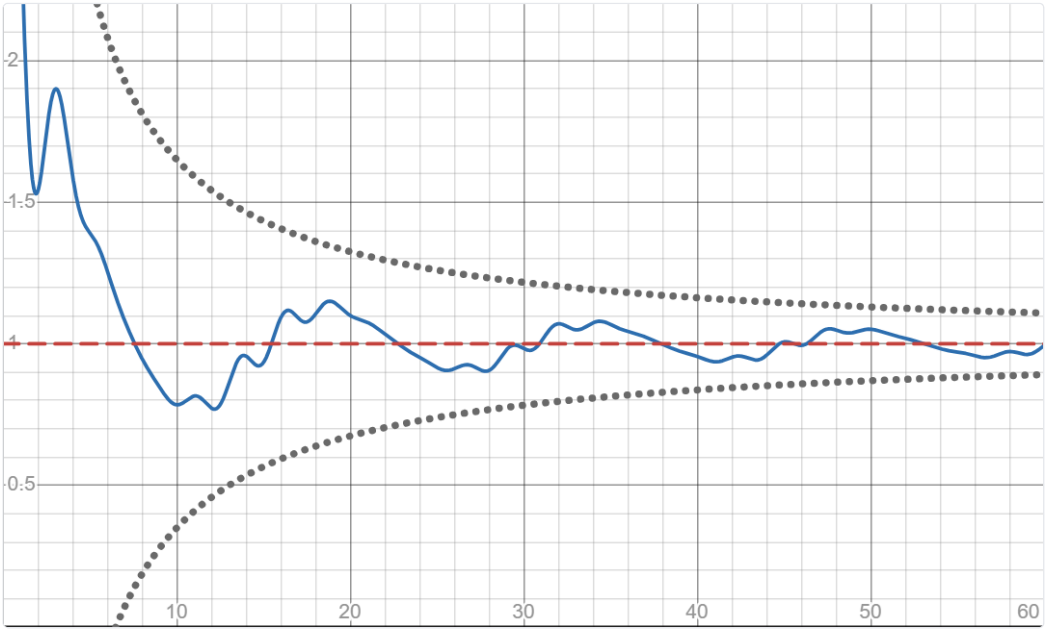
(b) Integrate over $[t_0, t_0+T]$, divide by T and apply Lemma A.8(2) term by term with the triangle inequality: the terms contribute at most $\frac{1}{T}\cdot 2|A_0A_k|\frac{2}{\omega_k}$, $\frac{1}{T}\cdot\frac{A_k^2}{2}\cdot\frac{2}{2\omega_k}$, and $\frac{1}{T}|A_kA_l|\big(\frac{2}{|\omega_k-\omega_l|}+\frac{2}{\omega_k+\omega_l}\big)$. Their sum is B/T. Letting $T\to\infty$ gives $\langle x^2\rangle = P$.

(a) is the case $N=1$, $\omega_1=\omega$, $A_0=C$ of the expansion: the oscillating terms have frequencies ω and 2ω, and $T=2\pi/\omega$ is a multiple of both $2\pi/\omega$ and $2\pi/(2\omega)$, so by Lemma A.8(2) their integrals over the window vanish exactly; the mean-square is $C^2+A^2/2$. The mean is C by the same lemma applied to x itself.

(c) Each Ω above is now a non-zero integer multiple of ω_0: $n_k\omega_0$, $2n_k\omega_0$, $(n_k-n_l)\omega_0$ or $(n_k+n_l)\omega_0$. So T_0 is an integer multiple of every $2\pi/|\Omega|$, every oscillating term integrates to exactly 0 over any window of length T_0 (Lemma A.8(2)), and the mean-square is exactly P. ■

Numerical checks.

- Ch. 3 Worked Example 3.29: $v = 10 + 8\cos\omega t + 6\cos(3\omega t + 40^\circ)$ gives $P = 100 + 32 + 18 = 150\ \mathrm{V}^2$, $V_{\mathrm{rms}} = 12.2474\ \mathrm{V}$; averaging v^2 over one period at 200 000 points gives 12.247449 V.
- The non-periodic signal $x = \cos t + \cos\sqrt{2}\,t$ has $P = 1$ and, from the formula, $B = \frac{1}{2}+\frac{1}{2\sqrt{2}}+2\big(\frac{1}{\sqrt{2}-1}+\frac{1}{\sqrt{2}+1}\big) = 6.51$. Numerical integration gives windowed mean-squares over $[0,T]$ of $0.7848,\ 0.98667,\ 0.99969,\ 1.00028$ for $T = 10, 100, 1000, 10\,000$; the deviations $0.215,\ 0.0133,\ 0.0003,\ 0.0003$ respect the bound $B/T = 0.65,\ 0.065,\ 0.0065,\ 0.00065$.



Running mean-square of $\cos t + \cos\sqrt{2}\,t$ (blue). It never settles over a "period" (there is none) but converges to $P = \frac{1}{2}+\frac{1}{2} = 1$ (red), staying inside the envelope $1 \pm B/T$ of Theorem A.10(b) (grey).

Remarks.

- *Distinct frequencies are essential.* For $x = \cos\omega t + \cos(\omega t + \pi) \equiv 0$ the formula would predict $\langle x^2\rangle = \frac{1}{2}+\frac{1}{2} = 1$, but the true value is 0; for $\cos\omega t + \cos\omega t$ it would predict 1 against the true 2. The cross term $\cos(\theta_k - \theta_l)$ then has frequency 0 and does not average out. Components at the *same* frequency must first be combined with phasors: $A\cos(\omega t+\alpha) + B\cos(\omega t+\beta) = \mathrm{Re}\{(Ae^{j\alpha}+Be^{j\beta})e^{j\omega t}\}$ has mean-square $\frac{1}{2}|Ae^{j\alpha}+Be^{j\beta}|^2$ (Ch. 3 §3.3).
- *The $1/T$ convergence rate matters for instruments.* A true-RMS meter averaging over a window T has a reading error of order B/T; the constant B is dominated by the closest pair of frequencies, $1/|\omega_k-\omega_l|$. Two tones 1 Hz apart need an averaging time of many seconds — the beat period (Ch. 3 §3.7) — before their powers can be read as adding.
- *Power adds, amplitude does not.* The peak value of x depends strongly on the phases; only the mean-square value is phase-independent.
- *Extension.* The same proof with $N\to\infty$ (under $\sum A_k^2 < \infty$ and an argument for exchanging limit and sum) gives Parseval's theorem for Fourier series (Ch. 15 §15.8); the statistical analogue — the variances of uncorrelated random signals add — is in Ch. 21.
- *Where it is used.* Ch. 3 §3.2 and §3.7, Ch. 5 §5.9 (the DC-plus-AC rule $V_{\mathrm{rms}}^2 = V_{\mathrm{dc}}^2 + V_{\mathrm{ac,rms}}^2$ is the case of a constant plus a zero-mean periodic part) and total harmonic distortion (Ch. 15 §15.8).

A.9 Equality of mixed partial derivatives (Clairaut–Schwarz)

Notation follows Ch. 6 §6.2: $f_{xy} = \dfrac{\partial}{\partial y}\Big(\dfrac{\partial f}{\partial x}\Big)$ (first x, then y) and $f_{yx} = \dfrac{\partial}{\partial x}\Big(\dfrac{\partial f}{\partial y}\Big)$.

Theorem A.11 (Clairaut, Schwarz)

Let $U \subset \mathbb{R}^2$ be open, $(a,b)\in U$, and $f: U\to\mathbb{R}$.

(a) Clairaut. If f_x, f_y, f_{xy} and f_{yx} exist on U and f_{xy}, f_{yx} are continuous at (a,b), then $f_{xy}(a,b) = f_{yx}(a,b)$.

(b) Schwarz (sharper form). If f_x, f_y and f_{xy} exist on U and f_{xy} is continuous at (a,b), then $f_{yx}(a,b)$ exists and equals $f_{xy}(a,b)$.

In particular, if $f\in C^2(U)$, then $f_{xy} = f_{yx}$ throughout U.

Proof. Choose $\delta > 0$ such that the closed square $|x-a|\le\delta$, $|y-b|\le\delta$ lies in U. For $0<|h|,|k|<\delta$ form the **second difference**

$$\Delta(h,k) = f(a+h,b+k) - f(a+h,b) - f(a,b+k) + f(a,b),$$

the alternating sum of f over the corners of a small rectangle.

Step 1: Δ via f_{xy}. Let $\varphi(x) = f(x,b+k) - f(x,b)$ for x between a and $a+h$. Then $\Delta = \varphi(a+h) - \varphi(a)$. Since f_x exists on U, φ is differentiable with $\varphi'(x) = f_x(x,b+k) - f_x(x,b)$ (and therefore continuous). By the MVT there is $\theta_1 \in (0,1)$ with

$$\Delta = h\,\varphi'(a+\theta_1 h) = h\Big[f_x(a+\theta_1 h,\, b+k) - f_x(a+\theta_1 h,\, b)\Big].$$

Now fix $x_1 = a+\theta_1 h$ and consider $y \mapsto f_x(x_1, y)$; it is differentiable with derivative $f_{xy}(x_1,y)$ because f_{xy} exists on U. By the MVT again, there is $\theta_2 \in (0,1)$ with

$$\Delta(h,k) = hk\, f_{xy}(a+\theta_1 h,\; b+\theta_2 k).$$

Step 2 (for (a)): Δ via f_{yx}. Grouping the same four terms the other way, $\Delta = \psi(b+k) - \psi(b)$ with $\psi(y) = f(a+h,y) - f(a,y)$. The same two applications of the MVT, first in y (using f_y) and then in x (using f_{yx}), give $\theta_3, \theta_4 \in (0,1)$ with

$$\Delta(h,k) = hk\, f_{yx}(a+\theta_4 h,\; b+\theta_3 k).$$

Conclusion of (a). Comparing, $f_{xy}(a+\theta_1 h, b+\theta_2 k) = f_{yx}(a+\theta_4 h, b+\theta_3 k)$ for all small non-zero h,k. Put $k = h$ and let $h \to 0$: both points tend to (a,b), and continuity of f_{xy} and f_{yx} at (a,b) gives $f_{xy}(a,b) = f_{yx}(a,b)$. ∎

Proof of (b). Only Step 1 is used. Let $\varepsilon > 0$. By continuity of f_{xy} at (a,b) choose $\delta' \in (0,\delta]$ with $|f_{xy}(p,q) - f_{xy}(a,b)| < \varepsilon$ whenever $|p-a| < \delta'$, $|q-b| < \delta'$. The point in Step 1 satisfies this, so

$$\left|\frac{\Delta(h,k)}{hk} - f_{xy}(a,b)\right| < \varepsilon \qquad \text{for all } 0 < |h|, |k| < \delta'.$$

Fix h and let $k \to 0$. Since f_y exists at $(a+h,b)$ and at (a,b),

$$\frac{\Delta(h,k)}{k} = \frac{f(a+h,b+k) - f(a+h,b)}{k} - \frac{f(a,b+k) - f(a,b)}{k} \;\longrightarrow\; f_y(a+h,b) - f_y(a,b).$$

A non-strict inequality survives the limit, so

$$\left|\frac{f_y(a+h,b) - f_y(a,b)}{h} - f_{xy}(a,b)\right| \le \varepsilon \qquad \text{for all } 0 < |h| < \delta'.$$

This says precisely that the difference quotient defining $f_{yx}(a,b) = \frac{\partial}{\partial x} f_y\big|_{(a,b)}$ converges to $f_{xy}(a,b)$. ∎

The counterexample. Let

$$f(x,y) = \begin{cases} \dfrac{xy\,(x^2 - y^2)}{x^2 + y^2}, & (x,y) \neq (0,0), \\[2mm] 0, & (x,y) = (0,0). \end{cases}$$

In polar coordinates $f = \tfrac{1}{4} r^2 \sin 4\phi$, so f is continuous and small near the origin. For $(x,y) \neq (0,0)$ the quotient rule gives (checked with a computer algebra system)

$$f_x = \frac{y\,(x^4 + 4x^2y^2 - y^4)}{(x^2+y^2)^2}, \qquad f_y = \frac{x\,(x^4 - 4x^2y^2 - y^4)}{(x^2+y^2)^2}.$$

At the origin, $f(x,0) = 0$ and $f(0,y) = 0$ give $f_x(0,0) = f_y(0,0) = 0$. Since $|x^4 \pm 4x^2y^2 - y^4| \le 2(x^2+y^2)^2$, we have $|f_x| \le 2|y|$ and $|f_y| \le 2|x|$, so f_x, f_y are continuous everywhere: f is C^1. On the axes, $f_x(0,y) = -y$ and $f_y(x,0) = x$ (including at 0). Therefore

$$f_{xy}(0,0) = \lim_{k\to 0} \frac{f_x(0,k) - f_x(0,0)}{k} = -1, \qquad f_{yx}(0,0) = \lim_{h\to 0} \frac{f_y(h,0) - f_y(0,0)}{h} = +1.$$

The mixed partials exist everywhere but differ at the origin. Away from the origin both equal

$$f_{xy} = f_{yx} = \frac{(x^2-y^2)(x^4 + 10x^2y^2 + y^4)}{(x^2+y^2)^3} = \cos 2\phi\,\big(1 + 2\sin^2 2\phi\big),$$

which depends only on the direction ϕ: it is $+1$ along the x-axis and -1 along the y-axis, so it has no limit at the origin. The continuity hypothesis of Theorem A.11 fails exactly there, and the conclusion fails with it.

Remarks.

- *Higher order.* If $f \in C^k$ on an open set in $\mathbb{R}^n$, any two k-th order partial derivatives that differentiate the same number of times in each variable are equal. Proof: any ordering can be turned into any other by swapping adjacent differentiations, and each swap is Theorem A.11 applied to a $(k-2)$-th order partial (which is C^2) as a function of the two variables being swapped, the others held fixed.
- *Why engineers may swap orders freely — and when not.* Potentials and fields from smooth physical models are C^2 away from sources. At a point charge or on a conductor edge they are not, and statements such as $\nabla \times \nabla\varphi = \mathbf{0}$ must be checked separately (or interpreted in the sense of distributions).
- *Where it is used.* Symmetry of the Hessian (Ch. 6 §6.2, §6.10; Ch. 23 §23.4); the exactness test $M_y = N_x$ for $M\,dx + N\,dy$ (Ch. 6 §6.3, Ch. 11 §11.1); $\nabla \times \nabla\varphi = \mathbf{0}$ and $\nabla \cdot (\nabla \times \mathbf{F}) = 0$ (Ch. 7); the Cauchy–Riemann equations and harmonicity of $\operatorname{Re}\{f\}$ (Ch. 18).

A.10 The Lagrange multiplier condition

The method of Lagrange multipliers (Ch. 6 §6.11) rests on one geometric fact: at a constrained extremum, ∇f is perpendicular to the constraint surface. To make "surface" precise we need the implicit function theorem, which says that near a regular point the constraint set is the graph of a smooth function. Write points of $\mathbb{R}^n$ as $\mathbf{x} = (\mathbf{u}, \mathbf{v})$ with $\mathbf{u} \in \mathbb{R}^{n-m}$, $\mathbf{v} \in \mathbb{R}^m$, and Jacobian blocks $D_{\mathbf{u}}$, $D_{\mathbf{v}}$; gradients are column vectors and $Df = \nabla f^{\mathsf{T}}$ is a row.

Implicit function theorem (used without proof)

Let $\Omega \subset \mathbb{R}^{n-m} \times \mathbb{R}^m$ be open, $\mathbf{G} : \Omega \to \mathbb{R}^m$ of class C^1, and $(\mathbf{u}^*, \mathbf{v}^*) \in \Omega$ with $\mathbf{G}(\mathbf{u}^*, \mathbf{v}^*) = \mathbf{0}$ and the $m \times m$ matrix $D_{\mathbf{v}}\mathbf{G}(\mathbf{u}^*, \mathbf{v}^*)$ invertible. Then there are open sets $\mathcal{U} \ni \mathbf{u}^*$ and $\mathcal{V} \ni \mathbf{v}^*$ with $\mathcal{U} \times \mathcal{V} \subset \Omega$, and a C^1 function $\boldsymbol{\varphi} : \mathcal{U} \to \mathcal{V}$ with $\boldsymbol{\varphi}(\mathbf{u}^*) = \mathbf{v}^*$, such that

$$\{(\mathbf{u}, \mathbf{v}) \in \mathcal{U} \times \mathcal{V} : \ \mathbf{G}(\mathbf{u}, \mathbf{v}) = \mathbf{0}\} = \{(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u})) : \ \mathbf{u} \in \mathcal{U}\}.$$

(Proof: Rudin, *Principles*, Thm 9.28, via the contraction mapping principle. The derivative formula $D\boldsymbol{\varphi} = -(D_{\mathbf{v}}\mathbf{G})^{-1} D_{\mathbf{u}}\mathbf{G}$ quoted in Ch. 6 §6.6 is re-derived in Step 3 below.)

Theorem A.12 (Lagrange multiplier condition)

Let $U \subset \mathbb{R}^n$ be open, $1 \le m < n$, and $f, g_1, \dots, g_m : U \to \mathbb{R}$ of class C^1. Let $S = \{\mathbf{x} \in U : \ g_i(\mathbf{x}) = c_i, \ i = 1, \dots, m\}$ and suppose $\mathbf{x}^* \in S$ is a **local extremum of f on S**: there is $\rho > 0$ with $f(\mathbf{x}) \le f(\mathbf{x}^*)$ for all $\mathbf{x} \in S$ with $\|\mathbf{x} - \mathbf{x}^*\| < \rho$ (or $\ge$ for all such $\mathbf{x}$). Suppose the **regularity condition** holds: $\nabla g_1(\mathbf{x}^*), \dots, \nabla g_m(\mathbf{x}^*)$ are linearly independent. Then there are unique scalars $\lambda_1, \dots, \lambda_m$ with

$$\nabla f(\mathbf{x}^*) = \lambda_1 \nabla g_1(\mathbf{x}^*) + \cdots + \lambda_m \nabla g_m(\mathbf{x}^*).$$

For a single constraint ($m = 1$) the condition reads $\nabla f(\mathbf{x}^*) = \lambda \nabla g(\mathbf{x}^*)$ with $\nabla g(\mathbf{x}^*) \neq \mathbf{0}$.

Proof. Treat the maximum case (for a minimum replace f by $-f$, which replaces $\boldsymbol{\lambda}$ by $-\boldsymbol{\lambda}$). Let $\mathbf{g} = (g_1, \dots, g_m)^{\mathsf{T}}$ and $\mathbf{c} = (c_1, \dots, c_m)^{\mathsf{T}}$.

Step 0: choose coordinates. The $m \times n$ Jacobian $D\mathbf{g}(\mathbf{x}^*)$ has linearly independent rows, so its rank is m and it has m linearly independent columns. Renumber the coordinates (which permutes the components of every gradient in the same way and does not affect the conclusion) so that these are the last m columns. Writing $\mathbf{x} = (\mathbf{u}, \mathbf{v})$ and $\mathbf{x}^* = (\mathbf{u}^*, \mathbf{v}^*)$,

$$D\mathbf{g}(\mathbf{x}^*) = \begin{bmatrix} \mathbf{A} & \mathbf{B} \end{bmatrix}, \qquad \mathbf{A} = D_{\mathbf{u}}\mathbf{g}(\mathbf{x}^*) \ (m \times (n-m)), \quad \mathbf{B} = D_{\mathbf{v}}\mathbf{g}(\mathbf{x}^*) \ (m \times m, \ \text{invertible}).$$

Step 1: the constraint set is a graph. Apply the implicit function theorem to $\mathbf{G} = \mathbf{g} - \mathbf{c}$ on $\Omega = U$. We get open $\mathcal{U} \ni \mathbf{u}^*$, $\mathcal{V} \ni \mathbf{v}^*$ and a C^1 map $\boldsymbol{\varphi} : \mathcal{U} \to \mathcal{V}$ with $\boldsymbol{\varphi}(\mathbf{u}^*) = \mathbf{v}^*$ such that the points of S in $\mathcal{U} \times \mathcal{V}$ are exactly the points $(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u}))$.

Step 2: an unconstrained problem. Define $F(\mathbf{u}) = f(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u}))$ on $\mathcal{U}$; it is C^1 by the chain rule. Because $\boldsymbol{\varphi}$ is continuous, there is a neighbourhood $\mathcal{U}' \subset \mathcal{U}$ of $\mathbf{u}^*$ on which $\|(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u})) - \mathbf{x}^*\| < \rho$. For $\mathbf{u} \in \mathcal{U}'$ the point $(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u}))$ lies in S and within ρ of $\mathbf{x}^*$, so $F(\mathbf{u}) \le f(\mathbf{x}^*) = F(\mathbf{u}^*)$: F has an unconstrained local maximum at $\mathbf{u}^*$. For each $i = 1, \dots, n-m$, the one-variable function $t \mapsto F(\mathbf{u}^* + t\mathbf{e}_i)$ is defined on an open interval around 0, has a maximum at $t = 0$ and is differentiable there, so by Fermat's lemma (Lemma A.1) $\partial F / \partial u_i(\mathbf{u}^*) = 0$. By the chain rule,

$$\mathbf{0}^{\mathsf{T}} = DF(\mathbf{u}^*) = D_{\mathbf{u}}f(\mathbf{x}^*) + D_{\mathbf{v}}f(\mathbf{x}^*)\, D\boldsymbol{\varphi}(\mathbf{u}^*).$$

Step 3: the slope of the constraint set. Differentiating the identity $\mathbf{g}(\mathbf{u}, \boldsymbol{\varphi}(\mathbf{u})) = \mathbf{c}$ on $\mathcal{U}$ at $\mathbf{u}^*$ (chain rule),

$$\mathbf{A} + \mathbf{B}\, D\boldsymbol{\varphi}(\mathbf{u}^*) = \mathbf{0} \qquad \Longrightarrow \qquad D\boldsymbol{\varphi}(\mathbf{u}^*) = -\mathbf{B}^{-1}\mathbf{A}.$$

Step 4: define the multipliers. Let $\boldsymbol{\lambda}^{\mathsf{T}} = D_{\mathbf{v}}f(\mathbf{x}^*)\, \mathbf{B}^{-1}$, a $1 \times m$ row vector. Then $\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{B} = D_{\mathbf{v}}f(\mathbf{x}^*)$ by construction, and by Steps 2 and 3,

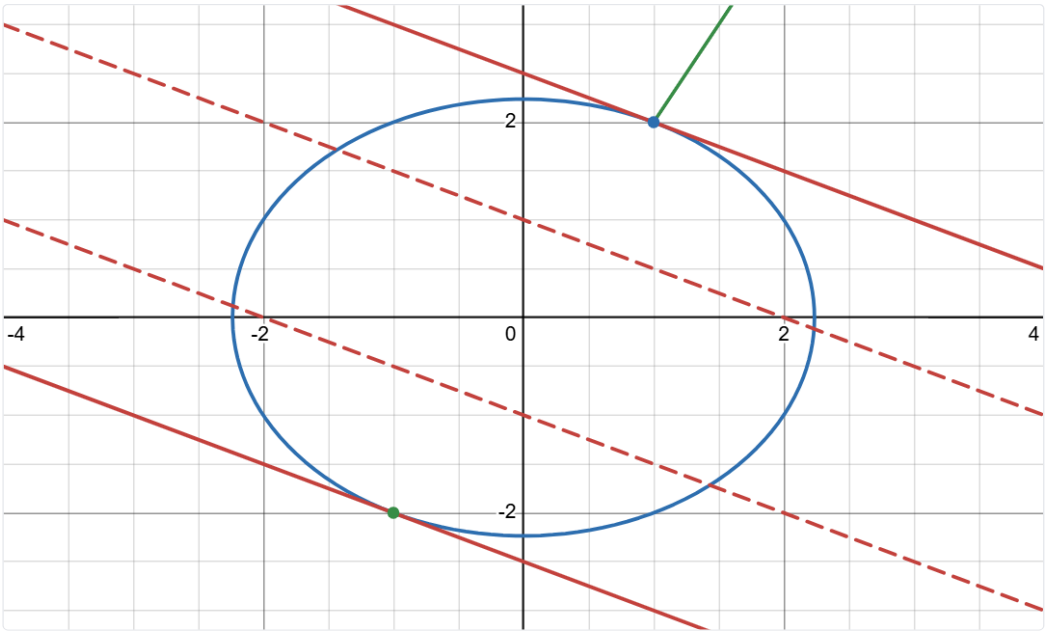
$$\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{A} = D_{\mathbf{v}}f\, \mathbf{B}^{-1}\mathbf{A} = -D_{\mathbf{v}}f\, D\boldsymbol{\varphi}(\mathbf{u}^*) = D_{\mathbf{u}}f(\mathbf{x}^*).$$

Putting the two blocks side by side, $\boldsymbol{\lambda}^{\mathsf{T}}\begin{bmatrix} \mathbf{A} & \mathbf{B} \end{bmatrix} = \begin{bmatrix} D_{\mathbf{u}}f & D_{\mathbf{v}}f \end{bmatrix}$, i.e. $Df(\mathbf{x}^*) = \boldsymbol{\lambda}^{\mathsf{T}} D\mathbf{g}(\mathbf{x}^*)$. Transposing, $\nabla f(\mathbf{x}^*) = D\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}\boldsymbol{\lambda} = \sum_i \lambda_i \nabla g_i(\mathbf{x}^*)$.

Uniqueness. If also $\nabla f = \sum_i \mu_i \nabla g_i$, then $\sum_i (\lambda_i - \mu_i) \nabla g_i(\mathbf{x}^*) = \mathbf{0}$, and linear independence forces $\lambda_i = \mu_i$. $\blacksquare$

For one constraint ($m = 1$), after renumbering so that $g_{x_n}(\mathbf{x}^*) \neq 0$, the proof gives the explicit multiplier $\lambda = f_{x_n}(\mathbf{x}^*) / g_{x_n}(\mathbf{x}^*)$, and Step 3 is the familiar implicit-differentiation formula $\partial x_n / \partial x_i = -g_{x_i} / g_{x_n}$ of Ch. 4 §4.4.

Geometric reading. The columns of $\begin{bmatrix} \mathbf{I} \\ D\boldsymbol{\varphi}(\mathbf{u}^*) \end{bmatrix}$ span the tangent space $T = \ker D\mathbf{g}(\mathbf{x}^*)$ of S at $\mathbf{x}^*$ (an $(n-m)$-dimensional subspace, by Step 3 and the rank–nullity theorem of Ch. 9). Step 2 says $Df(\mathbf{x}^*)$ annihilates T: $\nabla f \perp T$. The orthogonal complement of $\ker D\mathbf{g}$ is the row space of $D\mathbf{g}$, spanned by the ∇g_i — which is Step 4.



Extremising $f = x + 2y$ on the circle $x^2 + y^2 = 5$ (Ch. 6, Worked Example 1). Level lines of f (red) cross the circle where f can still increase along it; at the extremes $(\pm 1, \pm 2)$ they are tangent, so $\nabla f = (1, 2)$ (green, at the maximum) is parallel to $\nabla g = (2x, 2y)$, with $\lambda = \frac{1}{2}$ at $(1, 2)$.

Remarks.

- *Regularity cannot be dropped.* Minimise $f(x, y) = x$ on $S: \; y^2 - x^3 = 0$. On S, $x^3 = y^2 \geq 0$, so $x \geq 0$ and the minimum is 0, at the origin. But $\nabla g = (-3x^2, \; 2y)$ vanishes there, while $\nabla f = (1, 0)$; no λ satisfies $(1, 0) = \lambda(0, 0)$. The cusp of S at the origin is not the graph of a C^1 function in either variable, so Step 1 fails. (The weaker **Fritz John** condition $\lambda_0 \nabla f = \lambda \nabla g$ with $(\lambda_0, \lambda) \neq (0, 0)$ survives, with $\lambda_0 = 0$; it carries no information about f.)
- *The condition is necessary, not sufficient.* $f = x^3 + y$ on $g = y = 0$: at the origin $\nabla f = (0, 1) = 1 \cdot \nabla g$, yet on the constraint $f = x^3$ has no extremum at 0 . Candidates must be compared, or tested with the bordered Hessian (Ch. 6 §6.11).
- *The meaning of λ.* Suppose the constrained optimum $\mathbf{x}^*(c)$ and its multiplier $\lambda(c)$ depend differentiably on the level c of a single constraint, and let $f^*(c) = f(\mathbf{x}^*(c))$. Then, by the chain rule and the theorem,

$$\frac{df^*}{dc} = \nabla f \cdot \frac{d\mathbf{x}^*}{dc} = \lambda \, \nabla g \cdot \frac{d\mathbf{x}^*}{dc} = \lambda \frac{d}{dc} g\big(\mathbf{x}^*(c)\big) = \lambda \cdot \frac{d}{dc} c = \lambda.$$

The multiplier is the sensitivity of the optimal value to the constraint level — a "shadow price". Check: on $x^2 + y^2 = c$, $\max(x + 2y) = \sqrt{5c}$, whose derivative $\sqrt{5}/(2\sqrt{c})$ equals $\frac{1}{2} = \lambda$ at $c = 5$.

- *Where it is used.* Ch. 6 §6.11 (the method), Ch. 23 §23.4 (Lagrange and KKT conditions — KKT is this theorem plus sign conditions for active inequality constraints, under an analogous regularity hypothesis), equality-constrained least squares and economic dispatch (equal incremental cost $= \lambda$) in Ch. 23 §23.8, §23.10, and the variational characterisation of eigenvalues: maximising $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}$ for symmetric $\mathbf{A}$ subject to $\mathbf{x}^{\mathsf{T}}\mathbf{x} = 1$ gives $2\mathbf{A}\mathbf{x} = \lambda \, 2\mathbf{x}$, the eigenvalue equation, with the multiplier equal to the maximum value (Ch. 10).

Appendix B — Vector Calculus and Field Theorems

What is proved here. The results that make vector calculus usable in field theory: the change-of-variables formula and the Jacobian as an area scale factor; the gradient as the direction of steepest ascent; the theorems of Green, Gauss (divergence) and Stokes; the equivalence "curl-free ⇔ conservative" on simply connected domains, with its failure on the punctured plane; the standard vector identities by index notation; grad, div, curl and Laplacian in cylindrical and spherical coordinates via scale factors; and the passage from Maxwell's integral laws to their differential form, the continuity equation and the vacuum wave equation.

Prerequisites. Partial derivatives, the multivariable chain rule, Clairaut's theorem on mixed partials and Fubini's theorem (Ch. 6); determinants (Ch. 8); line, surface and volume integrals as defined in Ch. 7.

Level of rigour. Every theorem is stated with explicit hypotheses. The proofs are complete for the "elementary" regions on which the integral theorems are really proved (regions bounded by graphs). The step from elementary regions to general regions — cutting a region into finitely many elementary pieces — is carried out as an argument about cancelling boundary contributions, and the topological facts it uses (that such a decomposition exists for the piecewise-smooth regions met in engineering) are stated, not proved. In the change-of-variables theorem the linear-algebra step is proved in full and the passage to nonlinear maps is a careful sketch. Throughout, "smooth" means C^1 (continuous first partial derivatives) unless C^2 is stated; regions are bounded and their boundaries piecewise smooth.

Notation follows the book (Notation and Conventions): cylindrical coordinates are (r, ϕ, z), spherical coordinates are (R, θ, ϕ) with θ the polar angle from $+z$; ∂_i abbreviates $\partial/\partial x_i$ with $(x_1, x_2, x_3) = (x, y, z)$.

B.1 Change of variables and the Jacobian as area scale factor

The change-of-variables formula is used every time the book writes $dA = r\,dr\,d\phi$ or $dV = R^2 \sin\theta\, dR\, d\theta\, d\phi$ (§6.8, §6.9), and every time a probability density is transformed (Ch. 19). Its heart is a statement about linear maps, which we prove exactly; the nonlinear statement then follows because a differentiable map is, on a small enough square, almost linear.

Jacobian matrix and determinant

For a map $\mathbf{T}(u, v) = \big(x(u, v),\ y(u, v)\big)$ with continuous first partials, the **Jacobian matrix** and **Jacobian determinant** at (u, v) are

$$D\mathbf{T} = \begin{bmatrix} x_u & x_v \\ y_u & y_v \end{bmatrix}, \qquad \frac{\partial(x, y)}{\partial(u, v)} = \det D\mathbf{T} = x_u y_v - x_v y_u.$$

Theorem B.1a — Linear maps scale area by $|\det|$

Let $\mathbf{A}$ be a real 2×2 matrix and $S \subset \mathbb{R}^2$ a bounded region with an area (for instance a finite union of rectangles, or any region bounded by finitely many smooth curves). Then $\mathbf{A}(S) = \{\mathbf{A}\mathbf{s} : \mathbf{s} \in S\}$ has an area and

$$\operatorname{area}\big(\mathbf{A}(S)\big) = |\det \mathbf{A}|\ \operatorname{area}(S).$$

Theorem B.1b — Change of variables in a double integral

Let $U \subset \mathbb{R}^2$ be open, $\mathbf{T} : U \to \mathbb{R}^2$ one-to-one with continuous first partial derivatives, and $\det D\mathbf{T} \neq 0$ on U. Let S be a closed bounded region in U with piecewise-smooth boundary, and $R = \mathbf{T}(S)$. If f is continuous on R, then

$$\iint_R f(x, y)\, dx\, dy = \iint_S f\big(\mathbf{T}(u, v)\big) \left|\frac{\partial(x, y)}{\partial(u, v)}\right| du\, dv.$$

The same holds in $\mathbb{R}^3$ with $|\partial(x, y, z)/\partial(u, v, w)|$, and the hypothesis $\det D\mathbf{T} \neq 0$ may fail on a set of zero area (such as the origin in polar coordinates) without changing the conclusion.

Proof of B.1a.

Step 1 — reduction to rectangles. If the formula holds for every axis-parallel rectangle, it holds for finite unions of non-overlapping rectangles (areas add, and the images of non-overlapping rectangles under an invertible linear map are non-overlapping). A region with an area is, by definition of area (the Riemann/Jordan construction behind the double integral in §6.7), squeezed between an inner union of grid rectangles S_- and an outer union S_+ with $\operatorname{area}(S_+) - \operatorname{area}(S_-) < \varepsilon$. Then $\mathbf{A}(S_-) \subset \mathbf{A}(S) \subset \mathbf{A}(S_+)$ and the two outer sets have areas $|\det \mathbf{A}|\operatorname{area}(S_\pm)$ differing by at most $|\det \mathbf{A}|\varepsilon$. Letting $\varepsilon \to 0$ gives the formula for S. If $\det \mathbf{A} = 0$, $\mathbf{A}$ maps the plane into a line (or a point), and any bounded subset of a line has zero area, which is what the formula says. So assume $\det \mathbf{A} \neq 0$ and S a rectangle $[a, b] \times [c, d]$.

Step 2 — factor $\mathbf{A}$ into elementary matrices. Gaussian elimination (§8.7) reduces any invertible matrix to the identity by row operations, each of which is left-multiplication by an elementary matrix. Hence $\mathbf{A} = \mathbf{E}_1 \mathbf{E}_2 \cdots \mathbf{E}_k$ with each $\mathbf{E}_i$ of one of three types:

$$\text{scaling } \begin{bmatrix} \lambda & 0 \\ 0 & 1 \end{bmatrix} \text{ or } \begin{bmatrix} 1 & 0 \\ 0 & \lambda \end{bmatrix}\ (\lambda \neq 0), \qquad \text{swap } \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \qquad \text{shear } \begin{bmatrix} 1 & c \\ 0 & 1 \end{bmatrix} \text{ or } \begin{bmatrix} 1 & 0 \\ c & 1 \end{bmatrix}.$$

Since $\det(\mathbf{A}) = \prod \det \mathbf{E}_i$ and $\mathbf{A}(S) = \mathbf{E}_1(\mathbf{E}_2(\cdots \mathbf{E}_k(S)))$, it suffices to prove $\operatorname{area}(\mathbf{E}(S)) = |\det \mathbf{E}|\operatorname{area}(S)$ for each elementary $\mathbf{E}$ and every region S with an area — not just rectangles, because the intermediate images $\mathbf{E}_k(S)$, $\mathbf{E}_{k-1}\mathbf{E}_k(S)$, … are parallelograms. By Step 1 (applied to the single matrix $\mathbf{E}$) the general case follows from the case of rectangles, so it is enough to check rectangles for each type.

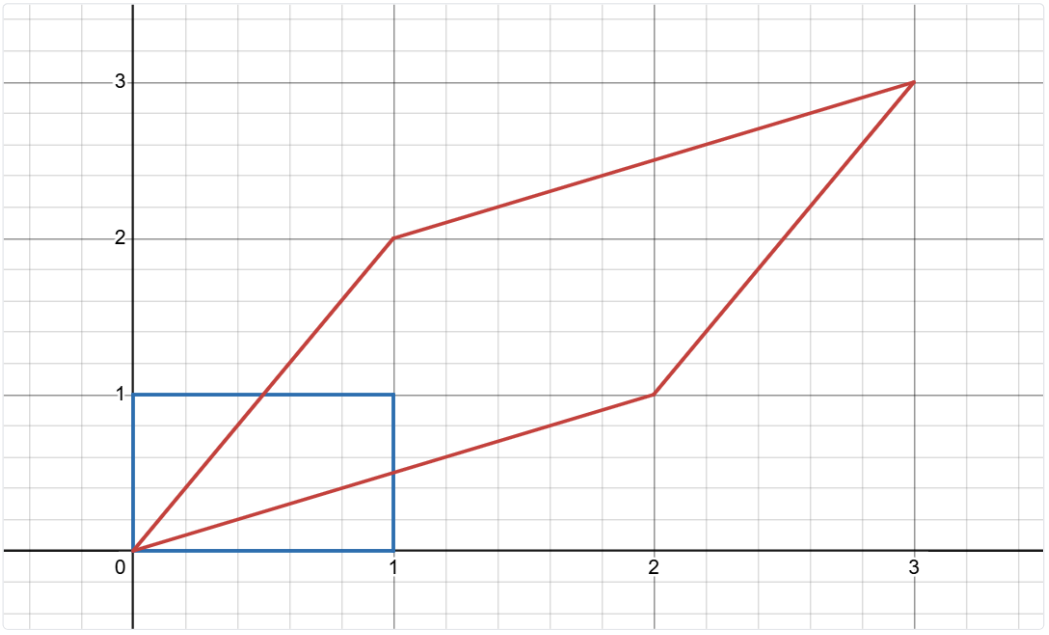
Step 3 — the three types.

- *Scaling* $(u, v) \mapsto (\lambda u, v)$ sends $[a, b] \times [c, d]$ to a rectangle with side lengths $|\lambda|(b - a)$ and $d - c$: area multiplied by $|\lambda| = |\det \mathbf{E}|$.
- *Swap* $(u, v) \mapsto (v, u)$ sends a rectangle to a congruent rectangle: area unchanged, and $|\det \mathbf{E}| = |-1| = 1$.
- *Shear* $(u, v) \mapsto (u + cv,\ v)$ sends $[a, b] \times [c_1, d_1]$ to the parallelogram $P = \{(x, y) : c_1 \le y \le d_1,\ a + cy \le x \le b + cy\}$. By Fubini, slicing horizontally,

$$\operatorname{area}(P) = \int_{c_1}^{d_1} \big[(b + cy) - (a + cy)\big]\, dy = (b - a)(d_1 - c_1),$$

so the area is unchanged, and $\det \mathbf{E} = 1$. (This is Cavalieri's principle: every horizontal slice keeps its length.) The lower shear is the same with the roles of x and y exchanged.

Multiplying the factors gives $\operatorname{area}(\mathbf{A}(S)) = \prod_i |\det \mathbf{E}_i| \operatorname{area}(S) = |\det \mathbf{A}| \operatorname{area}(S)$. ■



The unit square (blue) and its image under $\mathbf{A} = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$ (red): a parallelogram spanned by $(2, 1)$ and $(1, 2)$, of area $|\det \mathbf{A}| = 3$.

Proof sketch of B.1b.

Step 1 — local linearity, uniformly. Fix a compact set $K \subset U$ containing S in its interior. Because the partial derivatives of $\mathbf{T}$ are continuous on K they are uniformly continuous there, so for every $\varepsilon > 0$ there is $h_0 > 0$ such that for every square $Q \subset K$ of side $h < h_0$ with centre $\mathbf{q}$ and every $\mathbf{u} \in Q$,

$$\big\|\mathbf{T}(\mathbf{u}) - \mathbf{T}(\mathbf{q}) - D\mathbf{T}(\mathbf{q})(\mathbf{u} - \mathbf{q})\big\| \le \varepsilon h.$$

(Apply the mean value theorem to each component along the segment from $\mathbf{q}$ to $\mathbf{u}$.) So $\mathbf{T}(Q)$ lies within distance εh of the parallelogram $\mathbf{T}(\mathbf{q}) + D\mathbf{T}(\mathbf{q})(Q - \mathbf{q})$, whose area by Theorem B.1a is $|\det D\mathbf{T}(\mathbf{q})| h^2$.

Step 2 — area of the image of a small square. The εh-neighbourhood of that parallelogram's boundary has area at most (perimeter)$\times 2\varepsilon h + \pi(\varepsilon h)^2 \le C\varepsilon h^2$, where C depends only on a bound for $\|D\mathbf{T}\|$ on K. Since $\mathbf{T}$ is one-to-one with invertible derivative, it maps the boundary of Q onto the boundary of $\mathbf{T}(Q)$ (invariance of domain, here a consequence of the inverse function theorem, §6.6), and therefore $\mathbf{T}(Q)$ differs from the parallelogram only inside that thin neighbourhood. Hence

$$\Big|\operatorname{area}\big(\mathbf{T}(Q)\big) - |\det D\mathbf{T}(\mathbf{q})|\, h^2\Big| \le C\varepsilon h^2.$$

Step 3 — Riemann sums. Cover S by a grid of squares Q_k of side h with centres $\mathbf{q}_k$. The squares meeting ∂S have total area $\to 0$ as $h \to 0$ (a piecewise-smooth curve has zero area), and so do their images (Step 2 bounds image areas by a constant times h^2). For the interior squares, the images $\mathbf{T}(Q_k)$ tile R up to a set of small area, and

$$\sum_k f\big(\mathbf{T}(\mathbf{q}_k)\big) \operatorname{area}\big(\mathbf{T}(Q_k)\big) = \sum_k f\big(\mathbf{T}(\mathbf{q}_k)\big) |\det D\mathbf{T}(\mathbf{q}_k)| h^2 + O\big(\varepsilon \max|f| \operatorname{area}(S)\big)\,.$$

The left side is a Riemann sum for $\iint_R f\, dA$ (over a partition of R into the curvilinear pieces $\mathbf{T}(Q_k)$, whose diameters $\to 0$ uniformly), and the first sum on the right is a Riemann sum for $\iint_S f(\mathbf{T}) |\det D\mathbf{T}|\, du\, dv$. Let $h \to 0$ and then $\varepsilon \to 0$. If $\det D\mathbf{T} = 0$ or injectivity fails only on a set Z of zero area, apply the result on S minus a small neighbourhood of Z and let the neighbourhood shrink; both integrals change by arbitrarily little. In three dimensions the same argument runs with cubes and parallelepipeds, using the 3×3 elementary-matrix factorisation. ■

Remarks.

- *Why the absolute value.* An integral of a positive function is positive, but $\det D\mathbf{T}$ is negative for orientation-reversing maps (e.g. the swap). The absolute value is the price of measuring unsigned area. In the integral theorems (B.3–B.5) orientation matters and the sign of the Jacobian reappears as the rule for orienting boundaries.
- *Why injectivity.* If $\mathbf{T}$ covers part of R twice the right side counts that part twice. Example: $\mathbf{T}(r, \phi) = (r\cos\phi, r\sin\phi)$ on $0 \le r \le 1$, $0 \le \phi \le 4\pi$ gives $\iint r\, dr\, d\phi = 2\pi$, twice the area of the unit disc.

- *Scale factors.* For an orthogonal coordinate system the columns of $D\mathbf{T}$ are perpendicular with lengths h_1, h_2, h_3, so $|\det D\mathbf{T}| = h_1 h_2 h_3$: this gives r (cylindrical) and $R^2 \sin\theta$ (spherical) without expanding a determinant, as used in §6.9 and again in B.8 below.
- *Used in:* polar, cylindrical and spherical integrals (§6.8–6.9); the volume elements of §7.8; the transformation of densities $f_Y(\mathbf{y}) = f_X(\mathbf{x})/|\det D\mathbf{T}|$ in Ch. 19.

B.2 The gradient as the direction of steepest ascent

§6.4–6.5 define the gradient by its components and state that it points uphill. The proof rests on one fact — that for a differentiable function every directional derivative is a dot product with ∇f — and on the Cauchy–Schwarz inequality. The point of stating the hypotheses carefully is that the existence of partial derivatives alone is **not** enough.

Differentiability and directional derivative

$f : U \to \mathbb{R}$ ($U \subset \mathbb{R}^n$ open) is **differentiable** at $\mathbf{a}$ if there is a vector $\mathbf{g}$ with

$$f(\mathbf{a}+\mathbf{h}) = f(\mathbf{a}) + \mathbf{g}\cdot\mathbf{h} + o(\|\mathbf{h}\|) \quad (\mathbf{h}\to\mathbf{0}).$$

Then necessarily $\mathbf{g} = \nabla f(\mathbf{a}) = (\partial_1 f, \dots, \partial_n f)(\mathbf{a})$. For a unit vector $\hat{\mathbf{u}}$ the **directional derivative** is $D_{\hat{\mathbf{u}}} f(\mathbf{a}) = \lim_{s\to 0^+} \big[f(\mathbf{a}+s\hat{\mathbf{u}}) - f(\mathbf{a})\big]/s$.

Theorem B.2 — Steepest ascent and normality to level sets

Let f be differentiable at $\mathbf{a}$.

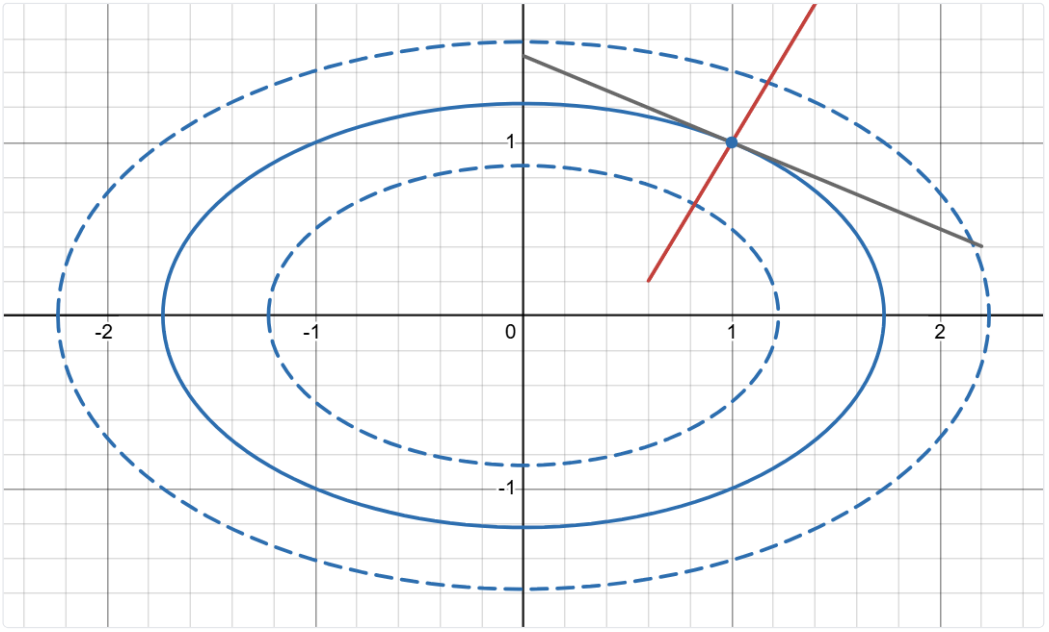
1. For every unit vector $\hat{\mathbf{u}}$, $D_{\hat{\mathbf{u}}} f(\mathbf{a}) = \nabla f(\mathbf{a})\cdot\hat{\mathbf{u}}$.
2. If $\nabla f(\mathbf{a}) \neq \mathbf{0}$, then $\max_{\|\hat{\mathbf{u}}\|=1} D_{\hat{\mathbf{u}}} f(\mathbf{a}) = \|\nabla f(\mathbf{a})\|$, attained **only** at $\hat{\mathbf{u}} = \nabla f(\mathbf{a})/\|\nabla f(\mathbf{a})\|$; the minimum $-\|\nabla f(\mathbf{a})\|$ is attained only in the opposite direction; and $D_{\hat{\mathbf{u}}} f(\mathbf{a}) = 0$ exactly for $\hat{\mathbf{u}} \perp \nabla f(\mathbf{a})$.
3. If $\mathbf{r}(t)$ is a curve, differentiable at $t = 0$, lying in the level set $\{f = f(\mathbf{a})\}$ with $\mathbf{r}(0) = \mathbf{a}$, then $\nabla f(\mathbf{a})\cdot\mathbf{r}'(0) = 0$.

Proof.

Part 1. Put $\mathbf{h} = s\hat{\mathbf{u}}$ in the definition: $f(\mathbf{a}+s\hat{\mathbf{u}}) - f(\mathbf{a}) = s\,\nabla f(\mathbf{a})\cdot\hat{\mathbf{u}} + o(s)$. Divide by $s > 0$ and let $s \to 0^+$; the remainder tends to 0 because $o(\|\mathbf{h}\|)/\|\mathbf{h}\| \to 0$ and $\|\mathbf{h}\| = s$.

Part 2. By Cauchy–Schwarz, $|\nabla f\cdot\hat{\mathbf{u}}| \le \|\nabla f\|\,\|\hat{\mathbf{u}}\| = \|\nabla f\|$, so $-\|\nabla f\| \le D_{\hat{\mathbf{u}}} f \le \|\nabla f\|$. Equality in Cauchy–Schwarz holds if and only if $\hat{\mathbf{u}}$ is a scalar multiple of ∇f; with $\|\hat{\mathbf{u}}\| = 1$ the only multiples are $\pm\nabla f/\|\nabla f\|$, which give $\pm\|\nabla f\|$ respectively. Writing $\nabla f\cdot\hat{\mathbf{u}} = \|\nabla f\|\cos\alpha$ shows the whole picture: the rate of increase is the projection of the gradient onto the direction of travel, and it is zero exactly when $\alpha = 90^\circ$.

Part 3. The function $g(t) = f(\mathbf{r}(t))$ is constant, so $g'(0) = 0$. By the chain rule (valid because f is differentiable at $\mathbf{a}$ and $\mathbf{r}$ at 0), $g'(0) = \nabla f(\mathbf{a})\cdot\mathbf{r}'(0)$. ∎



Level curves of $f = x^2 + 2y^2$. At $\mathbf{a} = (1,1)$ the gradient direction $(2,4)$ (red) is normal to the level curve $f = 3$ and to its tangent line $x + 2y = 3$ (grey): it crosses the contours by the shortest route.

Remarks.

- *Differentiability is essential.* Let $f(x,y) = x^2 y/(x^2+y^2)$ for $(x,y) \neq \mathbf{0}$ and $f(\mathbf{0}) = 0$. Both partials at the origin are 0 (the function vanishes on both axes), so the would-be gradient is $\mathbf{0}$; yet along $\hat{\mathbf{u}} = (1,1)/\sqrt{2}$, $f(s/\sqrt{2}, s/\sqrt{2})/s = 1/(2\sqrt{2}) \neq 0$. The formula $D_{\hat{\mathbf{u}}} f = \nabla f\cdot\hat{\mathbf{u}}$ fails: this f is continuous but not differentiable at $\mathbf{0}$. A convenient sufficient condition for differentiability is that the partials exist near $\mathbf{a}$ and are continuous at $\mathbf{a}$ (§6.3).
- *Units.* $\|\nabla f\|$ has units of f per metre, which is why $\|\nabla V\|$ is a field strength in V/m. The relation $\mathbf{E} = -\nabla V$ says that $\mathbf{E}$ points in the direction of steepest **descent** of potential and is normal to the equipotentials (Part 3).

- *"Steepest" depends on the metric.* Steepest means per unit Euclidean distance. If distance is measured with a weighted norm $\|\mathbf{h}\|_{\mathbf{M}} = \sqrt{\mathbf{h}^{\mathsf{T}}\mathbf{M}\mathbf{h}}$ ($\mathbf{M}$ symmetric positive definite), the same Cauchy–Schwarz argument in the $\mathbf{M}$-inner product shows that the steepest direction is $\mathbf{M}^{-1}\nabla f$ — the idea behind preconditioned and Newton-type methods in Ch. 23.
- *Used in:* gradient descent and the stationarity condition $\nabla f = \mathbf{0}$ (§6.4, Ch. 23); Lagrange multipliers, where $\nabla f \parallel \nabla g$ follows from Part 3 applied to the constraint surface (§6.11); field lines orthogonal to equipotentials (§7.5).

B.3 Green's theorem

Green's theorem is the two-dimensional prototype of all the integral theorems (§7.9). We prove it completely for regions that are simultaneously of "type I" and "type II", then extend it by cutting.

Elementary plane regions and positive orientation

A closed bounded region D is **type I** (vertically simple) if $D = \{(x,y) : a \le x \le b,\ g_1(x) \le y \le g_2(x)\}$ with $g_1 \le g_2$ continuous and piecewise C^1 on $[a,b]$; it is **type II** (horizontally simple) if $D = \{(x,y) : c \le y \le d,\ h_1(y) \le x \le h_2(y)\}$ with the analogous conditions. The boundary ∂D is **positively oriented** if D lies to the left as one traverses it: counter-clockwise on an outer boundary, clockwise on the boundary of a hole.

Theorem B.3 — Green's theorem

Let D be a closed bounded region whose boundary ∂D consists of finitely many piecewise-smooth simple closed curves, positively oriented. Let P, Q have continuous first partial derivatives on an open set containing D. Then

$$\oint_{\partial D} (P\,dx + Q\,dy) = \iint_D \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right) dA.$$

Proof. Both sides are linear in (P, Q), so it suffices to prove separately

$$\oint_{\partial D} P\,dx = -\iint_D \frac{\partial P}{\partial y}\,dA \qquad \text{and} \qquad \oint_{\partial D} Q\,dy = \iint_D \frac{\partial Q}{\partial x}\,dA.$$

Step 1 — the P identity on a type I region. Since $\partial P/\partial y$ is continuous, Fubini's theorem and the fundamental theorem of calculus in y give

$$-\iint_D \frac{\partial P}{\partial y}\,dA = -\int_a^b \left[\int_{g_1(x)}^{g_2(x)} \frac{\partial P}{\partial y}(x,y)\,dy\right] dx = \int_a^b \Big[P\big(x, g_1(x)\big) - P\big(x, g_2(x)\big)\Big]\,dx.$$

The positively oriented boundary of a type I region consists of (at most) four arcs:

- C_1, the bottom graph, $\mathbf{r}(t) = (t, g_1(t))$, $a \le t \le b$, traversed left to right. Here $dx = dt$, so $\int_{C_1} P\,dx = \int_a^b P(t, g_1(t))\,dt$.
- C_2, the right side $x = b$, $g_1(b) \le y \le g_2(b)$ (possibly a single point). Here x is constant, so $dx = 0$ and $\int_{C_2} P\,dx = 0$.
- C_3, the top graph, traversed right to left. Parametrising by $(t, g_2(t))$ and reversing direction, $\int_{C_3} P\,dx = -\int_a^b P(t, g_2(t))\,dt$.
- C_4, the left side $x = a$; again $\int_{C_4} P\,dx = 0$.

Adding, $\oint_{\partial D} P\,dx = \int_a^b \big[P(t, g_1(t)) - P(t, g_2(t))\big]\,dt$, which is the expression above.

Step 2 — the Q identity on a type II region. With $D = \{c \le y \le d,\ h_1(y) \le x \le h_2(y)\}$,

$$\iint_D \frac{\partial Q}{\partial x}\,dA = \int_c^d \Big[Q\big(h_2(y), y\big) - Q\big(h_1(y), y\big)\Big]\,dy.$$

On the positively oriented boundary the right graph $x = h_2(y)$ is traversed upward, contributing $+\int_c^d Q(h_2(y), y)\,dy$; the left graph $x = h_1(y)$ is traversed downward, contributing $-\int_c^d Q(h_1(y), y)\,dy$; the horizontal top and bottom segments contribute nothing because $dy = 0$ on them. The asymmetry between Steps 1 and 2 is the origin of the minus sign in $Q_x - P_y$: going counter-clockwise, the *bottom* is traversed in the $+x$ direction but the *right* side in the $+y$ direction.

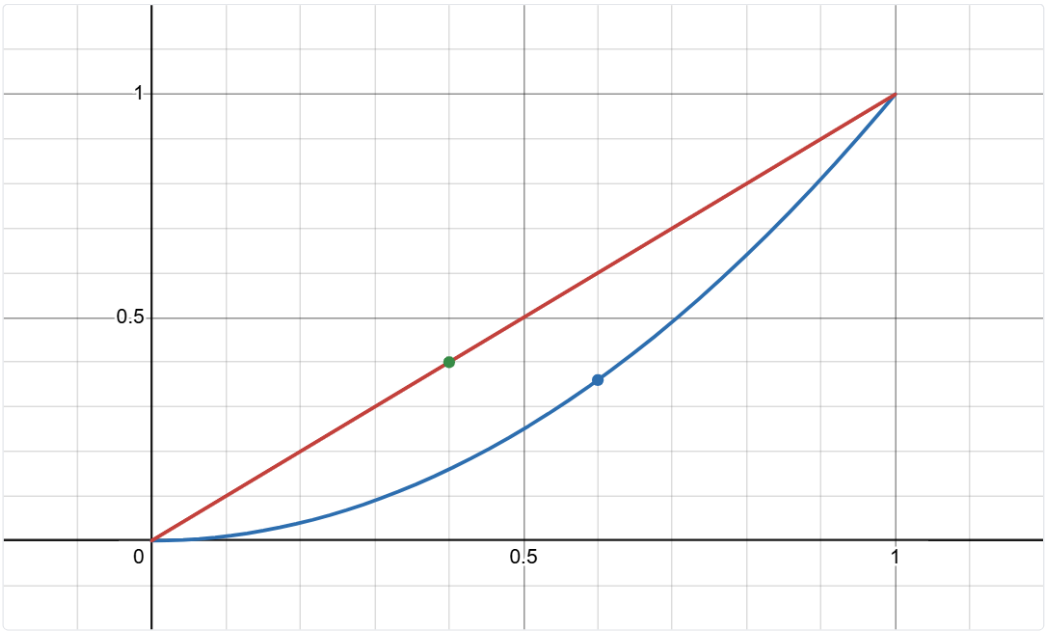
Step 3 — regions of both types. If D is both type I and type II (a disc, a rectangle, a triangle, any convex region), Steps 1 and 2 apply to the same oriented boundary, and adding them proves the theorem for D.

Step 4 — general regions by decomposition. Suppose D can be cut by finitely many piecewise-smooth arcs into regions $D_1, \dots, D_m$, each of both types, overlapping only along the cuts. (For regions bounded by finitely many piecewise-smooth curves such a decomposition exists; in practice one draws a few vertical and horizontal cuts.) Apply Step 3 to each D_k with its own positive orientation and add:

$$\sum_{k=1}^{m} \oint_{\partial D_k} (P\,dx + Q\,dy) = \sum_{k=1}^{m} \iint_{D_k} (Q_x - P_y)\,dA = \iint_D (Q_x - P_y)\,dA,$$

the last equality because the cuts have zero area. On the left, each cut arc is a boundary arc of exactly two pieces, which lie on opposite sides of it. "Keep the region on your left" therefore traverses the arc in opposite directions for the two pieces, and since reversing a curve negates a line integral, the two contributions cancel. What remains are the arcs of ∂D, each traversed with D on its left — that is, ∂D with positive orientation. This proves the theorem for D.

Step 5 — holes. A region with holes, such as the annulus $1 \le x^2 + y^2 \le 4$, is handled by the same cutting: two radial cuts split the annulus into two pieces, each a finite union of elementary regions. After cancellation the outer circle is traversed counter-clockwise and the inner circle clockwise — exactly the positive orientation of the definition. ∎



The region $x^2 \le y \le x$, $0 \le x \le 1$, which is both type I and type II. For $P = x - y^2$, $Q = xy$ both sides of Green's theorem equal $\iint_D 3y\,dA = \frac{1}{5}$ (checked symbolically): the bottom arc C_1 (blue, left to right) contributes $\frac{7}{10}$, the top arc C_3 (red, right to left) contributes $-\frac{1}{2}$.

Remarks.

- *The C^1 hypothesis cannot fail even at one point.* For $P = -y/(x^2+y^2)$, $Q = x/(x^2+y^2)$ on the closed unit disc, $Q_x - P_y = 0$ wherever defined, yet $\oint_{|\mathbf{r}|=1}(P\,dx + Q\,dy) = 2\pi$. Green's theorem is not violated: P and Q are not defined at the origin, which lies in D. Applied instead to the annulus $\varepsilon \le |\mathbf{r}| \le 1$ it gives the correct statement — the counter-clockwise circulations around the two circles are equal. This example is the subject of B.6.
- *Area formula.* $P = -y/2$, $Q = x/2$ gives $\operatorname{area}(D) = \frac{1}{2}\oint_{\partial D}(x\,dy - y\,dx)$, the principle of the planimeter and of the "shoelace" polygon-area formula (§7.9).
- *Flux form.* Replacing (P, Q) by $(-F_y, F_x)$ gives $\oint_{\partial D}\mathbf{F}\cdot\hat{\mathbf{n}}\,ds = \iint_D \nabla\cdot\mathbf{F}\,dA$ with $\hat{\mathbf{n}}$ the outward normal: the 2-D divergence theorem, which B.4 lifts to three dimensions.
- *Used in:* the proof of Stokes' theorem (B.5); Cauchy's integral theorem in Ch. 18, where Green applied to $f = u + jv$ together with the Cauchy–Riemann equations gives $\oint f\,dz = 0$ (under the extra hypothesis that f' is continuous, which Goursat's proof removes).

B.4 The divergence theorem

The divergence theorem (Gauss's theorem) converts the flux through a closed surface into a volume integral of the divergence (§7.11). The proof has exactly the structure of B.3: one Cartesian component at a time, the fundamental theorem of calculus along one axis, and a cut-and-cancel argument for general regions.

Flux and outward normal

For a piecewise-smooth surface S with a chosen continuous unit normal $\hat{\mathbf{n}}$, the **flux** of $\mathbf{F}$ is $\iint_S \mathbf{F}\cdot d\mathbf{S} = \iint_S \mathbf{F}\cdot\hat{\mathbf{n}}\,dS$. If $S = \mathbf{r}(D)$ with $\mathbf{r}_u \times \mathbf{r}_v$ pointing along $\hat{\mathbf{n}}$, then $\iint_S \mathbf{F}\cdot d\mathbf{S} = \iint_D \mathbf{F}(\mathbf{r}(u,v))\cdot(\mathbf{r}_u\times\mathbf{r}_v)\,du\,dv$ (§7.7). For the boundary ∂V of a solid V, $\hat{\mathbf{n}}$ is always the **outward** normal.

Elementary solids

A closed bounded solid V is **z-simple** if $V = \{(x,y,z) : (x,y)\in D_{xy},\ g_1(x,y) \le z \le g_2(x,y)\}$ for a plane region D_{xy} with piecewise-smooth boundary and $g_1 \le g_2$ continuous on D_{xy} and C^1 on its interior; **x-simple** and **y-simple** are defined in the same way with the roles of the coordinates permuted. V is **elementary** if it is simple in all three directions (balls, boxes, tetrahedra, any convex solid with piecewise-smooth boundary).

Theorem B.4 — Divergence theorem

Let V be a closed bounded solid that can be cut into finitely many elementary solids, with piecewise-smooth boundary ∂V oriented by the outward normal. Let $\mathbf{F} = (F_1, F_2, F_3)$ have continuous first partial derivatives on an open set containing V. Then

$$\oint_{\partial V}\mathbf{F}\cdot d\mathbf{S} = \iiint_V \nabla\cdot\mathbf{F}\,dV, \qquad \nabla\cdot\mathbf{F} = \partial_1 F_1 + \partial_2 F_2 + \partial_3 F_3.$$

Proof.

Step 1 — a box. Let $V = [a_1,b_1]\times[a_2,b_2]\times[a_3,b_3]$. Take the third term first. By Fubini and the fundamental theorem of calculus in z,

$$\iiint_V \frac{\partial F_3}{\partial z}\,dV = \int_{a_1}^{b_1}\int_{a_2}^{b_2}\Big[F_3(x,y,b_3) - F_3(x,y,a_3)\Big]\,dy\,dx.$$

Now compute the flux of the single component $F_3\hat{\mathbf{z}}$ out of the six faces. On the top face $z = b_3$ the outward normal is $+\hat{\mathbf{z}}$ and $dS = dx\,dy$, giving $\iint F_3(x,y,b_3)\,dx\,dy$; on the bottom face $z = a_3$ it is $-\hat{\mathbf{z}}$, giving $-\iint F_3(x,y,a_3)\,dx\,dy$; on the four side faces the normal is $\pm\hat{\mathbf{x}}$ or $\pm\hat{\mathbf{y}}$, perpendicular to $\hat{\mathbf{z}}$, so they contribute nothing. The two expressions agree. The same computation in x and in y gives the corresponding identities for $F_1\hat{\mathbf{x}}$ and $F_2\hat{\mathbf{y}}$; adding the three proves

the theorem for the box. This case already contains the physics: the net outflow in the z direction is the difference between what leaves through the top and what enters through the bottom, and $\partial_z F_3$ is that difference per unit volume.

Step 2 — the F_3 term on a z-simple solid. Let $V = \{(x,y) \in D_{xy},\ g_1 \le z \le g_2\}$. As in Step 1,

$$\iiint_V \frac{\partial F_3}{\partial z}\, dV = \iint_{D_{xy}} \Big[F_3\big(x,y,g_2(x,y)\big) - F_3\big(x,y,g_1(x,y)\big)\Big]\, dA.$$

The boundary ∂V has three parts.

- *Top S_2*: parametrise by $\mathbf{r}(x,y) = (x,y,g_2(x,y))$, $(x,y) \in D_{xy}$. Then $\mathbf{r}_x \times \mathbf{r}_y = (1,0,g_{2,x}) \times (0,1,g_{2,y}) = (-g_{2,x},\ -g_{2,y},\ 1)$, whose z-component is positive, so it points upward — out of V. Hence $\iint_{S_2} F_3\hat{\mathbf{z}} \cdot d\mathbf{S} = \iint_{D_{xy}} F_3(x,y,g_2)\,(\hat{\mathbf{z}} \cdot (-g_{2,x}, -g_{2,y}, 1))\, dA = \iint_{D_{xy}} F_3(x,y,g_2)\, dA$.
- *Bottom S_1*: the same parametrisation with g_1 gives an upward normal, but outward is now downward, so the sign flips: $\iint_{S_1} F_3\hat{\mathbf{z}} \cdot d\mathbf{S} = -\iint_{D_{xy}} F_3(x,y,g_1)\, dA$.
- *Lateral wall S_3* (the vertical surface over ∂D_{xy}, possibly empty): it is made of vertical lines, so its normal is horizontal and $F_3\hat{\mathbf{z}} \cdot \hat{\mathbf{n}} = 0$.

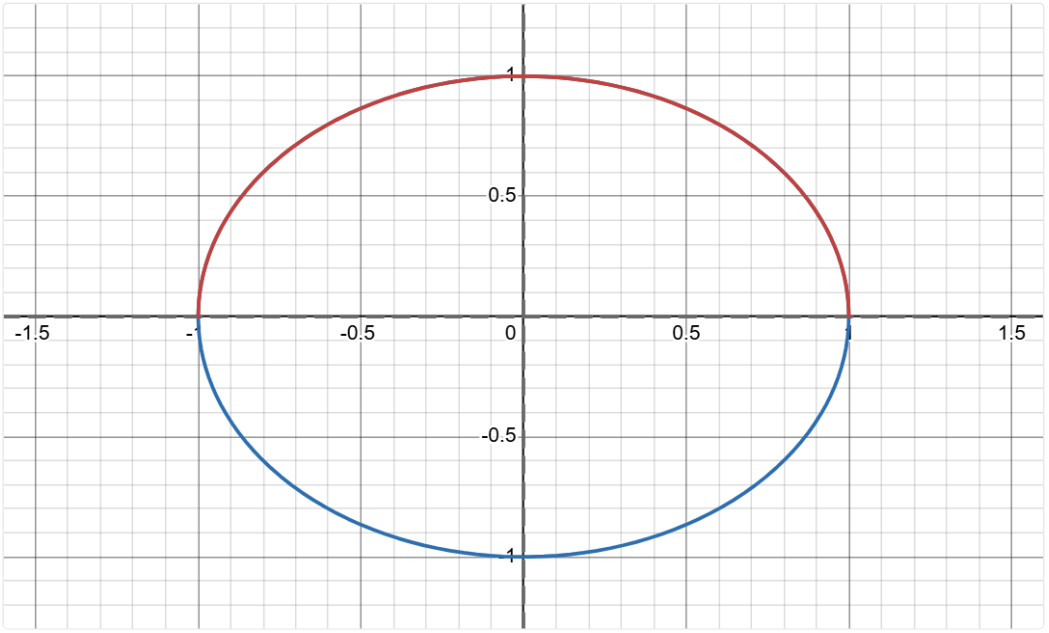
Adding the three parts reproduces the volume integral: $\oint_{\partial V} F_3\hat{\mathbf{z}} \cdot d\mathbf{S} = \iiint_V \partial_z F_3\, dV$. Note how cleanly the tilt of the top surface disappears: the factor $\sqrt{1+g_x^2+g_y^2}$ in dS is exactly cancelled by the factor $1/\sqrt{1+g_x^2+g_y^2}$ in $\hat{\mathbf{n}} \cdot \hat{\mathbf{z}}$ — the flux through a tilted patch equals the flux through its shadow on the xy-plane.

Step 3 — elementary solids. If V is x-, y- and z-simple, Step 2 and its two permuted versions give

$$\oint_{\partial V} F_1\hat{\mathbf{x}} \cdot d\mathbf{S} = \iiint_V \partial_x F_1\, dV, \quad \oint_{\partial V} F_2\hat{\mathbf{y}} \cdot d\mathbf{S} = \iiint_V \partial_y F_2\, dV, \quad \oint_{\partial V} F_3\hat{\mathbf{z}} \cdot d\mathbf{S} = \iiint_V \partial_z F_3\, dV,$$

and adding the three proves the theorem for V.

Step 4 — cutting. If $V = V_1 \cup \cdots \cup V_m$ with elementary pieces meeting only along (piecewise-smooth) faces, add the theorem for each piece. The volume integrals add to $\iiint_V \nabla \cdot \mathbf{F}\, dV$ since the faces have zero volume. Each internal face belongs to exactly two pieces, and the outward normal of one is the inward normal of the other, so its two flux contributions are equal and opposite and cancel. The remaining faces make up ∂V, each with the outward normal of V. ■



Cross-section of the unit ball, an elementary solid: it is z-simple with $g_{1,2} = \mp\sqrt{1-x^2-y^2}$ (top hemisphere red). Cuts along coordinate planes (grey) split non-elementary solids, such as a hollow shell, into elementary pieces; the flux through each cut cancels in pairs. For $\mathbf{F} = (x^3, y^3, z^3)$ both sides of the theorem on the unit ball equal $12\pi/5$ (checked symbolically).

Remarks.

- *Why C^1 on all of V.* For the point-charge field $\mathbf{F} = \hat{\mathbf{R}}/R^2$, $\nabla \cdot \mathbf{F} = \frac{1}{R^2}\partial_R(R^2 \cdot R^{-2}) = 0$ for $R > 0$, yet the flux through any sphere centred at the origin is $\frac{1}{a^2} \cdot 4\pi a^2 = 4\pi$. The theorem does not apply to a ball containing the origin, where $\mathbf{F}$ is singular. Applied to the shell $\varepsilon \le R \le a$, whose boundary includes the inner sphere with **inward-pointing** normal (outward from the shell), it correctly gives $4\pi - 4\pi = 0$. The physicist's repair, $\nabla \cdot (\hat{\mathbf{R}}/R^2) = 4\pi\delta^3(\mathbf{R})$, is discussed in §7.11.
- *Coordinate-free divergence.* Applying the theorem to a small ball $B_\varepsilon(\mathbf{a})$ and using continuity of $\nabla \cdot \mathbf{F}$ (mean value theorem for integrals) gives $\nabla \cdot \mathbf{F}(\mathbf{a}) = \lim_{\varepsilon \to 0} \frac{1}{\mathrm{vol}(B_\varepsilon)} \oint_{\partial B_\varepsilon} \mathbf{F} \cdot d\mathbf{S}$: the divergence is outward flux per unit volume, independent of coordinates. This is the starting point of B.8.
- *Green's identities.* Applying the theorem to $\mathbf{F} = u\nabla w$ and using the product rule $\nabla \cdot (u\nabla w) = \nabla u \cdot \nabla w + u\nabla^2 w$ (B.7) gives Green's first identity $\oint_{\partial V} u\, \partial_n w\, dS = \iiint_V (\nabla u \cdot \nabla w + u\nabla^2 w)\, dV$, from which the uniqueness of solutions of Laplace's and Poisson's equations follows (§7.11, §13.6).
- *Used in:* Gauss's law in differential form and the continuity equation (B.9); the energy method for the heat equation (§13.4); finite-volume discretisations (Ch. 22).

B.5 Stokes' theorem

Stokes' theorem lifts Green's theorem from a flat region to a curved surface in space (§7.10). The cleanest proof does not tile the surface at all: it pulls the whole problem back to the parameter domain, applies Green's theorem there, and recognises the integrand. All the geometry is concentrated in one algebraic lemma.

Parametrised surface and induced orientation

A **smooth parametrised surface** is $S = \mathbf{r}(D)$ where D is a plane region to which Green's theorem applies (B.3), $\mathbf{r}$ is one-to-one on D and of class C^2 on an open set containing D, and $\mathbf{r}_u \times \mathbf{r}_v \neq \mathbf{0}$ on D. It is oriented by $\hat{\mathbf{n}} = \mathbf{r}_u \times \mathbf{r}_v / \|\mathbf{r}_u \times \mathbf{r}_v\|$. Its boundary curve $C = \partial S$ is $\mathbf{r}(\partial D)$, traversed in the direction inherited from the positive orientation of ∂D; this is the **right-hand rule**: with the thumb along $\hat{\mathbf{n}}$, the fingers curl along C.

Lemma B.5 — The antisymmetric part of the Jacobian is a cross product

Let $\mathbf{F}$ be C^1, $\mathbf{J} = D\mathbf{F}$ its Jacobian matrix ($J_{ij} = \partial_j F_i$), and $\boldsymbol{\omega} = \nabla \times \mathbf{F}$. Then for all vectors $\mathbf{a}, \mathbf{b}$

$$(\mathbf{J} - \mathbf{J}^{\mathsf{T}})\,\mathbf{a} = \boldsymbol{\omega} \times \mathbf{a}, \qquad \text{hence} \qquad \mathbf{b} \cdot (\mathbf{J}\mathbf{a}) - \mathbf{a} \cdot (\mathbf{J}\mathbf{b}) = \boldsymbol{\omega} \cdot (\mathbf{a} \times \mathbf{b}).$$

Proof of the lemma. The first component of $(\mathbf{J} - \mathbf{J}^{\mathsf{T}})\mathbf{a}$ is $(\partial_2 F_1 - \partial_1 F_2)a_2 + (\partial_3 F_1 - \partial_1 F_3)a_3 = -\omega_3 a_2 + \omega_2 a_3$, which is the first component of $\boldsymbol{\omega} \times \mathbf{a} = (\omega_2 a_3 - \omega_3 a_2, \dots)$. The other two components follow by cyclic permutation $1 \to 2 \to 3 \to 1$. For the second identity, $\mathbf{a} \cdot (\mathbf{J}\mathbf{b}) = \mathbf{b} \cdot (\mathbf{J}^{\mathsf{T}}\mathbf{a})$, so the left side is $\mathbf{b} \cdot \big((\mathbf{J} - \mathbf{J}^{\mathsf{T}})\mathbf{a}\big) = \mathbf{b} \cdot (\boldsymbol{\omega} \times \mathbf{a}) = \boldsymbol{\omega} \cdot (\mathbf{a} \times \mathbf{b})$ by the cyclic property of the scalar triple product (§7.2). ∎

Theorem B.5 — Stokes' theorem

Let $S = \mathbf{r}(D)$ be a smooth parametrised surface with boundary C oriented by the right-hand rule, or a finite union of such surfaces glued along boundary arcs with compatible orientations. If $\mathbf{F}$ has continuous first partial derivatives on an open set containing S, then

$$\oint_C \mathbf{F} \cdot d\mathbf{r} = \iint_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S}.$$

Proof.

Step 1 — pull the line integral back to D. Let $(u(t), v(t))$ trace ∂D positively. Then $\mathbf{r}(u(t), v(t))$ traces C, and by the chain rule $\frac{d}{dt}\mathbf{r} = \mathbf{r}_u \dot{u} + \mathbf{r}_v \dot{v}$. Hence

$$\oint_C \mathbf{F} \cdot d\mathbf{r} = \oint_{\partial D} \big(\tilde{P}\,du + \tilde{Q}\,dv\big), \qquad \tilde{P}(u,v) = \mathbf{F}(\mathbf{r}) \cdot \mathbf{r}_u, \quad \tilde{Q}(u,v) = \mathbf{F}(\mathbf{r}) \cdot \mathbf{r}_v.$$

Because $\mathbf{F}$ is C^1 and $\mathbf{r}$ is C^2, $\tilde{P}$ and $\tilde{Q}$ are C^1, so Green's theorem applies.

Step 2 — Green's theorem in the (u,v)-plane.

$$\oint_{\partial D} \big(\tilde{P}\,du + \tilde{Q}\,dv\big) = \iint_D \left(\frac{\partial \tilde{Q}}{\partial u} - \frac{\partial \tilde{P}}{\partial v}\right) du\,dv.$$

Step 3 — differentiate. By the chain rule $\partial_u\big[\mathbf{F}(\mathbf{r}(u,v))\big] = \mathbf{J}\mathbf{r}_u$ and $\partial_v\big[\mathbf{F}(\mathbf{r}(u,v))\big] = \mathbf{J}\mathbf{r}_v$, with $\mathbf{J}$ evaluated at $\mathbf{r}(u,v)$. The product rule gives

$$\frac{\partial \tilde{Q}}{\partial u} = (\mathbf{J}\mathbf{r}_u) \cdot \mathbf{r}_v + \mathbf{F} \cdot \mathbf{r}_{vu}, \qquad \frac{\partial \tilde{P}}{\partial v} = (\mathbf{J}\mathbf{r}_v) \cdot \mathbf{r}_u + \mathbf{F} \cdot \mathbf{r}_{uv}.$$

Since $\mathbf{r}$ is C^2, Clairaut's theorem gives $\mathbf{r}_{uv} = \mathbf{r}_{vu}$, so the second-derivative terms cancel on subtraction. This is the only place C^2 is used.

Step 4 — recognise the curl. By Lemma B.5 with $\mathbf{a} = \mathbf{r}_u$, $\mathbf{b} = \mathbf{r}_v$,

$$\frac{\partial \tilde{Q}}{\partial u} - \frac{\partial \tilde{P}}{\partial v} = \mathbf{r}_v \cdot (\mathbf{J}\mathbf{r}_u) - \mathbf{r}_u \cdot (\mathbf{J}\mathbf{r}_v) = (\nabla \times \mathbf{F})\big(\mathbf{r}(u,v)\big) \cdot \big(\mathbf{r}_u \times \mathbf{r}_v\big).$$

Step 5 — identify the flux. Combining Steps 1–4,

$$\oint_C \mathbf{F} \cdot d\mathbf{r} = \iint_D (\nabla \times \mathbf{F})(\mathbf{r}) \cdot (\mathbf{r}_u \times \mathbf{r}_v)\,du\,dv = \iint_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S},$$

the last equality being the definition of flux with the orientation $\hat{\mathbf{n}} \parallel \mathbf{r}_u \times \mathbf{r}_v$.

Step 6 — glued surfaces. If $S = S_1 \cup \cdots \cup S_m$ with each S_k a smooth parametrised surface and the orientations agreeing across shared edges, add the theorem for each piece. The flux integrals add. A shared edge is traversed in opposite directions by the induced orientations of its two neighbours (compatibility of orientation means precisely this), so its line integrals cancel, leaving the outer boundary C. This covers closed-up shapes such as a hemisphere parametrised in two patches, a cylinder with a lid, or a polyhedral surface. ∎

Check. For $\mathbf{F} = (z, x, y)$, $\nabla \times \mathbf{F} = (1,1,1)$. On the upper unit hemisphere with outward normal, the boundary is the unit circle in the xy-plane, counter-clockwise; there $\mathbf{F} = (0, \cos t, \sin t)$, $d\mathbf{r} = (-\sin t, \cos t, 0)\,dt$, and $\oint \mathbf{F} \cdot d\mathbf{r} = \int_0^{2\pi} \cos^2 t\,dt = \pi$. The flux of the constant vector $(1,1,1)$ through the hemisphere equals its flux through the flat unit disc (both surfaces share the boundary — see the remark below), which is $1 \cdot \pi = \pi$. ✓

Remarks.

- *Green is the special case.* With $\mathbf{r}(u,v) = (u, v, 0)$ we get $\mathbf{r}_u \times \mathbf{r}_v = \hat{\mathbf{z}}$ and $(\nabla \times \mathbf{F}) \cdot \hat{\mathbf{z}} = \partial_x F_y - \partial_y F_x$: Theorem B.3. The graph case $z = g(x,y)$ sketched in §7.10 is $\mathbf{r}(x,y) = (x, y, g(x,y))$, $\mathbf{r}_x \times \mathbf{r}_y = (-g_x, -g_y, 1)$.
- *Orientation is a hypothesis.* On a non-orientable surface such as the Möbius strip no continuous $\hat{\mathbf{n}}$ exists and the theorem has no meaning; on an orientable one, reversing $\hat{\mathbf{n}}$ reverses C and both sides change sign together.

- *Independence of the surface.* If S and S' have the same boundary C with the same induced orientation, the theorem gives the same flux of $\nabla\times\mathbf{F}$ through both. This is consistent with B.4: $S\cup(-S')$ is a closed surface, and the outward flux of a curl through a closed surface is $\iiint \nabla\cdot(\nabla\times\mathbf{F})\,dV = 0$ by B.7. It is exactly the consistency requirement that forced Maxwell's displacement current (B.9).
- *Coordinate-free curl.* For a small flat disc of radius ε centred at $\mathbf{a}$ with normal $\hat{\mathbf{n}}$, continuity of $\nabla\times\mathbf{F}$ gives $(\nabla\times\mathbf{F})(\mathbf{a})\cdot\hat{\mathbf{n}} = \lim_{\varepsilon\to 0}\frac{1}{\pi\varepsilon^2}\oint \mathbf{F}\cdot d\mathbf{r}$: curl is circulation per unit area, as in §7.5.
- *Used in:* Faraday's and Ampère's laws in differential form (B.9); the curl test for conservative fields (B.6); EMF in moving and stationary loops (§7.12).

B.6 Curl-free versus conservative fields

§7.6 states that a field with zero curl is the gradient of a potential *if the domain is simply connected*. This section proves the equivalence of the three characterisations of a conservative field, proves the curl test on star-shaped and then simply connected domains, and shows by the standard counterexample that the topological hypothesis cannot be removed.

Conservative, star-shaped, simply connected

Let $D\subset\mathbb{R}^n$ ($n=2$ or 3) be open and connected. A continuous field $\mathbf{F}$ on D is **conservative** if $\mathbf{F}=\nabla f$ for some C^1 function f on D (a **potential**; in electrostatics the potential is $V=-f$). D is **star-shaped** about $\mathbf{a}\in D$ if the segment from $\mathbf{a}$ to every $\mathbf{x}\in D$ lies in D (convex sets, all of $\mathbb{R}^3$, a half-space). D is **simply connected** if every closed curve in D can be continuously shrunk to a point without leaving D: there is a continuous $\mathbf{H}:[0,1]\times[0,1]\to D$ with $\mathbf{H}(s,0)=\boldsymbol{\gamma}(s)$, $\mathbf{H}(s,1)=$ a constant point, and $\mathbf{H}(0,t)=\mathbf{H}(1,t)$ for all t.

Theorem B.6 — Conservative fields and the curl test

Let $\mathbf{F}$ be continuous on an open connected set $D\subset\mathbb{R}^3$ (for $D\subset\mathbb{R}^2$ read $\nabla\times\mathbf{F}$ as the scalar $\partial_x F_y-\partial_y F_x$).

1. The following are equivalent: (a) $\mathbf{F}$ is conservative; (b) $\int_C \mathbf{F}\cdot d\mathbf{r}$ depends only on the endpoints of the piecewise-smooth curve $C\subset D$; (c) $\oint_C \mathbf{F}\cdot d\mathbf{r}=0$ for every piecewise-smooth closed curve $C\subset D$.
2. If $\mathbf{F}$ is C^1 and conservative, then $\nabla\times\mathbf{F}=\mathbf{0}$ on D.
3. (**Poincaré lemma**) If D is star-shaped about $\mathbf{a}$, $\mathbf{F}$ is C^1 and $\nabla\times\mathbf{F}=\mathbf{0}$ on D, then $\mathbf{F}=\nabla f$ with
$$f(\mathbf{x}) = \int_0^1 \mathbf{F}\big(\mathbf{a}+t(\mathbf{x}-\mathbf{a})\big)\cdot(\mathbf{x}-\mathbf{a})\,dt.$$
4. If D is simply connected, $\mathbf{F}$ is C^1 and $\nabla\times\mathbf{F}=\mathbf{0}$ on D, then $\mathbf{F}$ is conservative.

Proof.

Part 1, (a)⇒(b). If $\mathbf{F}=\nabla f$ and C is parametrised by $\mathbf{r}(t)$, $\alpha\le t\le\beta$, then by the chain rule $\frac{d}{dt}f(\mathbf{r}(t)) = \nabla f\cdot\mathbf{r}'(t)$ on each smooth piece, and the fundamental theorem of calculus (summed over the pieces, the intermediate values telescoping) gives $\int_C \mathbf{F}\cdot d\mathbf{r} = f(\mathbf{r}(\beta))-f(\mathbf{r}(\alpha))$.

(b)⇒(c). A closed curve starts and ends at the same point, so it has the same endpoints as the constant path, whose integral is 0.

(c)⇒(b). If C_1, C_2 run from $\mathbf{p}$ to $\mathbf{q}$, then C_1 followed by C_2 reversed is closed, so $0=\int_{C_1}-\int_{C_2}$.

(b)⇒(a). Fix $\mathbf{p}_0\in D$ and define $f(\mathbf{x})=\int_{\mathbf{p}_0}^{\mathbf{x}}\mathbf{F}\cdot d\mathbf{r}$ along any piecewise-smooth path in D; one exists because an open connected set is path-connected by polygonal paths, and the value is path-independent by (b). For $\mathbf{x}\in D$ choose $\delta>0$ with the ball $B_\delta(\mathbf{x})\subset D$. For $0<|h|<\delta$, reach $\mathbf{x}+h\hat{\mathbf{x}}$ by going first to $\mathbf{x}$ and then along the straight segment $\mathbf{x}+s\hat{\mathbf{x}}$, $0\le s\le h$:
$$\frac{f(\mathbf{x}+h\hat{\mathbf{x}})-f(\mathbf{x})}{h} = \frac{1}{h}\int_0^h F_1(\mathbf{x}+s\hat{\mathbf{x}})\,ds \xrightarrow{\;h\to 0\;} F_1(\mathbf{x})$$
by continuity of F_1. So $\partial_x f = F_1$, and likewise $\partial_y f = F_2$, $\partial_z f = F_3$. The partials are continuous, so f is C^1 and $\nabla f=\mathbf{F}$.

Part 2. If $\mathbf{F}=\nabla f$ with $\mathbf{F}$ of class C^1, then f is C^2 and $(\nabla\times\nabla f)_3 = \partial_x\partial_y f-\partial_y\partial_x f=0$ by Clairaut; similarly for the other components (see also B.7).

Part 3. Take $\mathbf{a}=\mathbf{0}$ (translate). Put $\mathbf{y}=t\mathbf{x}$. Since $\mathbf{F}$ is C^1 and $[0,1]$ is compact, we may differentiate under the integral sign:
$$\partial_i f(\mathbf{x}) = \int_0^1 \Big[F_i(t\mathbf{x}) + \sum_{j} x_j\, t\,(\partial_i F_j)(t\mathbf{x})\Big]dt.$$
The curl condition says $\partial_i F_j=\partial_j F_i$ for all i,j (each such equation is one component of $\nabla\times\mathbf{F}=\mathbf{0}$). Hence $\sum_j x_j\, t\,\partial_i F_j(t\mathbf{x}) = t\sum_j x_j\,\partial_j F_i(t\mathbf{x}) = t\,\frac{d}{dt}\big[F_i(t\mathbf{x})\big]$, by the chain rule. Therefore
$$\partial_i f(\mathbf{x}) = \int_0^1 \frac{d}{dt}\Big[t\,F_i(t\mathbf{x})\Big]dt = 1\cdot F_i(\mathbf{x}) - 0 = F_i(\mathbf{x}),$$
using the product rule $\frac{d}{dt}[tF_i] = F_i + t\frac{d}{dt}F_i$. Star-shapedness was used exactly once: to guarantee $t\mathbf{x}\in D$ for $t\in[0,1]$.

Part 4. By Part 1 it suffices to show $\oint_\gamma \mathbf{F}\cdot d\mathbf{r}=0$ for every closed piecewise-smooth $\boldsymbol{\gamma}$ in D. Let $\mathbf{H}$ be a contraction of $\boldsymbol{\gamma}$ as in the definition. A continuous homotopy inside an open set can be replaced by a C^2 one with the same bottom edge, staying inside D (a standard smoothing fact, which we assume; it is proved by convolving $\mathbf{H}$ with a smooth bump and using that $\mathbf{H}([0,1]^2)$ is a compact subset of the open set D). With $\mathbf{H}$ of class C^2, Steps 1–4 of the proof of B.5 apply verbatim to $\mathbf{r}=\mathbf{H}$ on the square $[0,1]^2$ — they used neither injectivity nor $\mathbf{r}_u\times\mathbf{r}_v\neq\mathbf{0}$ — and give
$$\oint_{\partial[0,1]^2} \mathbf{F}(\mathbf{H})\cdot\big(\mathbf{H}_s\,ds+\mathbf{H}_t\,dt\big) = \iint_{[0,1]^2} (\nabla\times\mathbf{F})(\mathbf{H})\cdot(\mathbf{H}_s\times\mathbf{H}_t)\,ds\,dt = 0.$$

Traverse the boundary of the square counter-clockwise. The bottom edge $t = 0$ gives $\oint_\gamma \mathbf{F} \cdot d\mathbf{r}$. The top edge $t = 1$ is mapped to a single point, so $\mathbf{H}_s = \mathbf{0}$ there and it contributes 0. The right edge $s = 1$ (upward) and the left edge $s = 0$ (downward) are the same path $t \mapsto \mathbf{H}(0, t) = \mathbf{H}(1, t)$ traversed in opposite directions, so they cancel. Hence $\oint_\gamma \mathbf{F} \cdot d\mathbf{r} = 0$. ■

The counterexample on the punctured plane

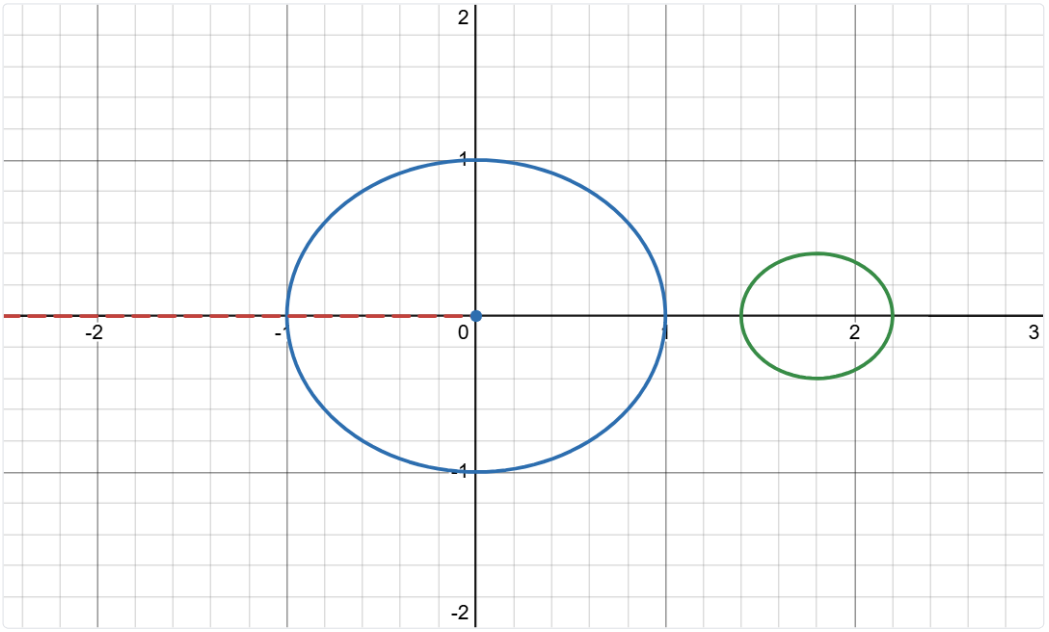
On $D = \mathbb{R}^2 \setminus \{\mathbf{0}\}$ let

$$\mathbf{F}(x, y) = \frac{-y\,\hat{\mathbf{x}} + x\,\hat{\mathbf{y}}}{x^2 + y^2} = \frac{1}{r}\hat{\boldsymbol{\phi}}.$$

Curl. $\partial_x \dfrac{x}{x^2+y^2} = \dfrac{y^2 - x^2}{(x^2+y^2)^2}$ and $\partial_y \dfrac{-y}{x^2+y^2} = \dfrac{y^2 - x^2}{(x^2+y^2)^2}$, so $\partial_x F_y - \partial_y F_x = 0$ everywhere on D; $\mathbf{F}$ is C^∞ there.

Circulation. On the unit circle $\mathbf{r} = (\cos t, \sin t)$, $\mathbf{F} = (-\sin t, \cos t) = \mathbf{r}'(t)$, so $\oint \mathbf{F} \cdot d\mathbf{r} = \int_0^{2\pi} 1\, dt = 2\pi \neq 0$. By Part 1, $\mathbf{F}$ is **not** conservative on D.

What goes wrong. D is not simply connected: the unit circle cannot be shrunk to a point without passing through the origin. Locally $\mathbf{F} = \nabla\phi$ with ϕ the polar angle, and on the slit plane $D \setminus \{(x, 0) : x \leq 0\}$ — which is star-shaped about $(1, 0)$ — $\phi \in (-\pi, \pi)$ is a genuine potential, as Part 3 guarantees. But ϕ cannot be extended continuously across the slit: it jumps by 2π. For any closed curve in D, the circulation is 2π times its winding number about the origin; a loop that does not encircle the origin has zero circulation.



The punctured plane. Circulation of $\hat{\boldsymbol{\phi}}/r$ round the blue circle is 2π; round the green circle, which does not enclose the origin, it is 0. Removing the red slit makes the domain star-shaped and the polar angle a single-valued potential.

Remarks.

- *Electromagnetic meaning.* The field of a long straight wire on the z-axis is $\mathbf{H} = \dfrac{I}{2\pi r}\hat{\boldsymbol{\phi}}$: curl-free in the region $r > 0$ but with circulation I around the wire (Ampère's law). The magnetic scalar potential $\psi = -I\phi/(2\pi)$ with $\mathbf{H} = -\nabla\psi$ is therefore multivalued, a fact exploited in magnetostatics by introducing a "barrier" surface — the slit above.
- *Holes of different dimension.* $\mathbb{R}^3$ minus a line is not simply connected (loops around the line), but $\mathbb{R}^3$ minus a point **is**: every loop can be slid off the point. So a C^1 curl-free field on $\mathbb{R}^3 \setminus \{\mathbf{0}\}$, such as the Coulomb field, is always conservative, which is why the electrostatic potential $q/(4\pi\varepsilon_0 R)$ exists globally. (The analogous statement for divergence-free fields fails there: $\hat{\mathbf{R}}/R^2$ has zero divergence on $\mathbb{R}^3 \setminus \{\mathbf{0}\}$ but is not a curl, since its flux through a sphere is $4\pi \neq 0$ while the flux of a curl through a closed surface vanishes by B.5.)
- *Kirchhoff's voltage law.* KVL is statement (c) for $\mathbf{E}$. Faraday's law (B.9) says $\nabla \times \mathbf{E} = -\partial_t \mathbf{B}$, so KVL holds only where $\partial_t \mathbf{B}$ is negligible — see the engineering note in §7.6.
- *Used in:* finding potentials (§7.6); exact differential equations, where $M\,dx + N\,dy$ is exact if $M_y = N_x$ on a simply connected domain (Ch. 11); the existence of analytic logarithms on simply connected domains and the role of the winding number in the residue theorem (Ch. 18).

B.7 Vector identities by index notation

The identities of §7.5 can each be verified by writing out components, but index notation proves them all with two tools: the Levi-Civita symbol and one contraction identity.

Summation convention, Kronecker delta, Levi-Civita symbol

Indices $i, j, k, \ldots$ run over $1, 2, 3$, and a **repeated index is summed**: $a_i b_i = \sum_{i=1}^{3} a_i b_i$. The **Kronecker delta** is $\delta_{ij} = 1$ if $i = j$ and 0 otherwise. The **Levi-Civita symbol** ε_{ijk} is $+1$ if (i, j, k) is an even permutation of $(1, 2, 3)$, -1 if odd, and 0 if any two indices coincide. Then, in Cartesian components,

$$\mathbf{a} \cdot \mathbf{b} = a_i b_i, \quad (\mathbf{a} \times \mathbf{b})_i = \varepsilon_{ijk} a_j b_k, \quad \nabla \cdot \mathbf{F} = \partial_i F_i, \quad (\nabla \times \mathbf{F})_i = \varepsilon_{ijk} \partial_j F_k, \quad \nabla^2 f = \partial_i \partial_i f.$$

(For instance $(\mathbf{a}\times\mathbf{b})_1 = \varepsilon_{123}a_2b_3 + \varepsilon_{132}a_3b_2 = a_2b_3 - a_3b_2$.) Three properties of ε_{ijk} are used repeatedly: it is **cyclic**, $\varepsilon_{ijk} = \varepsilon_{jki} = \varepsilon_{kij}$; it is **antisymmetric** under swapping any two indices; and it annihilates symmetric objects: if $S_{jk} = S_{kj}$ then $\varepsilon_{ijk}S_{jk} = 0$ (rename $j \leftrightarrow k$ to get $\varepsilon_{ikj}S_{kj} = -\varepsilon_{ijk}S_{jk}$, so the sum equals its own negative).

Lemma B.7 — The ε–δ identity

$$\varepsilon_{kij}\,\varepsilon_{kmn} = \delta_{im}\delta_{jn} - \delta_{in}\delta_{jm}.$$

Proof. Fix i, j, m, n. On the left, a term $\varepsilon_{kij}\varepsilon_{kmn}$ is non-zero only if $i \neq j$, $m \neq n$, and k is the third index different from both i, j and from both m, n; so the left side vanishes unless $i \neq j$ and $\{m, n\} = \{i, j\}$, and then exactly one k contributes. If $(m, n) = (i, j)$ the two symbols are equal and the product is $+1$; if $(m, n) = (j, i)$ they differ by one swap and the product is -1. On the right: if $i \neq j$ and $(m, n) = (i, j)$ we get $1 - 0 = 1$; if $(m, n) = (j, i)$, $0 - 1 = -1$; if $i = j$ the two terms are $\delta_{im}\delta_{in} - \delta_{in}\delta_{im} = 0$; and if $\{m, n\} \neq \{i, j\}$ with $i \neq j$, some index of $\{i, j\}$ is missing from $\{m, n\}$, which kills both terms. The two sides agree in every case. ∎

Contracting once more gives $\varepsilon_{kij}\varepsilon_{kmj} = 3\delta_{im} - \delta_{im} = 2\delta_{im}$; the BAC–CAB rule follows at once: $[\mathbf{a}\times(\mathbf{b}\times\mathbf{c})]_i = \varepsilon_{ijk}a_j\varepsilon_{kmn}b_mc_n = \varepsilon_{kij}\varepsilon_{kmn}a_jb_mc_n = b_i(a_jc_j) - c_i(a_jb_j)$, i.e. $\mathbf{a}\times(\mathbf{b}\times\mathbf{c}) = \mathbf{b}(\mathbf{a}\cdot\mathbf{c}) - \mathbf{c}(\mathbf{a}\cdot\mathbf{b})$.

Theorem B.7 — Vector-calculus identities

Let f, g be scalar and $\mathbf{A}, \mathbf{B}$ vector fields on an open set in $\mathbb{R}^3$. If they are C^1:

1. $\nabla(fg) = f\nabla g + g\nabla f$;
2. $\nabla\cdot(f\mathbf{A}) = f\,\nabla\cdot\mathbf{A} + \mathbf{A}\cdot\nabla f$;
3. $\nabla\times(f\mathbf{A}) = f\,\nabla\times\mathbf{A} + \nabla f\times\mathbf{A}$;
4. $\nabla\cdot(\mathbf{A}\times\mathbf{B}) = \mathbf{B}\cdot(\nabla\times\mathbf{A}) - \mathbf{A}\cdot(\nabla\times\mathbf{B})$;
5. $\nabla\times(\mathbf{A}\times\mathbf{B}) = \mathbf{A}(\nabla\cdot\mathbf{B}) - \mathbf{B}(\nabla\cdot\mathbf{A}) + (\mathbf{B}\cdot\nabla)\mathbf{A} - (\mathbf{A}\cdot\nabla)\mathbf{B}$;
6. $\nabla(\mathbf{A}\cdot\mathbf{B}) = (\mathbf{A}\cdot\nabla)\mathbf{B} + (\mathbf{B}\cdot\nabla)\mathbf{A} + \mathbf{A}\times(\nabla\times\mathbf{B}) + \mathbf{B}\times(\nabla\times\mathbf{A})$.

If they are C^2:

7. $\nabla\times(\nabla f) = \mathbf{0}$;
8. $\nabla\cdot(\nabla\times\mathbf{A}) = 0$;
9. $\nabla\times(\nabla\times\mathbf{A}) = \nabla(\nabla\cdot\mathbf{A}) - \nabla^2\mathbf{A}$, where $\nabla^2\mathbf{A}$ is the vector whose Cartesian components are $\nabla^2 A_i$.

Here $(\mathbf{B}\cdot\nabla)\mathbf{A}$ has components $B_j\partial_j A_i$.

Proof. Every step is the ordinary product rule $\partial_j(uv) = (\partial_j u)v + u\,\partial_j v$ for scalar components, plus the algebra of ε and δ.

1. $\partial_i(fg) = f\,\partial_i g + g\,\partial_i f$.
2. $\partial_i(fA_i) = f\,\partial_i A_i + A_i\,\partial_i f$.
3. $\varepsilon_{ijk}\partial_j(fA_k) = f\,\varepsilon_{ijk}\partial_j A_k + \varepsilon_{ijk}(\partial_j f)A_k$; the second term is $(\nabla f\times\mathbf{A})_i$.
4. $\partial_i(\varepsilon_{ijk}A_jB_k) = \varepsilon_{ijk}(\partial_i A_j)B_k + \varepsilon_{ijk}A_j(\partial_i B_k)$. By cyclicity $\varepsilon_{ijk} = \varepsilon_{kij}$, the first term is $B_k\,\varepsilon_{kij}\partial_i A_j = \mathbf{B}\cdot(\nabla\times\mathbf{A})$. By one swap $\varepsilon_{ijk} = -\varepsilon_{jik}$, the second is $-A_j\,\varepsilon_{jik}\partial_i B_k = -\mathbf{A}\cdot(\nabla\times\mathbf{B})$.
5. $[\nabla\times(\mathbf{A}\times\mathbf{B})]_i = \varepsilon_{ijk}\partial_j(\varepsilon_{kmn}A_mB_n) = \varepsilon_{kij}\varepsilon_{kmn}\partial_j(A_mB_n) = (\delta_{im}\delta_{jn} - \delta_{in}\delta_{jm})\big[(\partial_j A_m)B_n + A_m\partial_j B_n\big]$. The four resulting terms are $B_j\partial_j A_i + A_i\partial_j B_j - B_i\partial_j A_j - A_j\partial_j B_i$, which is the i-th component of the right side.
6. Compute $[\mathbf{A}\times(\nabla\times\mathbf{B})]_i = \varepsilon_{kij}\varepsilon_{kmn}A_j\partial_m B_n = A_j\partial_i B_j - A_j\partial_j B_i$ by Lemma B.7. Hence $A_j\partial_i B_j = [\mathbf{A}\times(\nabla\times\mathbf{B})]_i + [(\mathbf{A}\cdot\nabla)\mathbf{B}]_i$. Add the same identity with $\mathbf{A}\leftrightarrow\mathbf{B}$; the left sides add to $\partial_i(A_jB_j)$.
7. $(\nabla\times\nabla f)_i = \varepsilon_{ijk}\partial_j\partial_k f = 0$, because $\partial_j\partial_k f$ is symmetric in j, k (Clairaut, using C^2) and ε_{ijk} annihilates symmetric objects.
8. $\partial_i(\varepsilon_{ijk}\partial_j A_k) = \varepsilon_{ijk}\,\partial_i\partial_j A_k = 0$, for the same reason with the symmetric pair (i, j).
9. $[\nabla\times(\nabla\times\mathbf{A})]_i = \varepsilon_{ijk}\partial_j(\varepsilon_{kmn}\partial_m A_n) = \varepsilon_{kij}\varepsilon_{kmn}\partial_j\partial_m A_n = (\delta_{im}\delta_{jn} - \delta_{in}\delta_{jm})\partial_j\partial_m A_n = \partial_i(\partial_j A_j) - \partial_j\partial_j A_i$. ∎

All nine were also checked symbolically for arbitrary component functions.

Remarks.

- *Smoothness matters for 7–9.* They rest on Clairaut's theorem. At a singularity they can fail in the distributional sense: the polar angle ϕ of B.6 has $\nabla\phi = \hat{\boldsymbol{\phi}}/r$, whose curl is zero for $r > 0$ but equals $2\pi\delta(x)\delta(y)\hat{\mathbf{z}}$ as a distribution (the circulation 2π concentrated on the axis). Likewise $\nabla^2(1/R) = -4\pi\delta^3(\mathbf{R})$.
- *Identity 9 in curvilinear coordinates.* Only in Cartesian coordinates is $\nabla^2\mathbf{A}$ obtained by applying the scalar Laplacian to each component, because only there are the unit vectors constant. In cylindrical or spherical coordinates the **vector Laplacian is defined** by identity 9, $\nabla^2\mathbf{A} := \nabla(\nabla\cdot\mathbf{A}) - \nabla\times(\nabla\times\mathbf{A})$, evaluated with the formulas of B.8; e.g. $(\nabla^2\mathbf{A})_r = \nabla^2 A_r - A_r/r^2 - (2/r^2)\partial_\phi A_\phi$, not $\nabla^2 A_r$.
- *Identity 5 is not symmetric in appearance* but is antisymmetric under $\mathbf{A}\leftrightarrow\mathbf{B}$, as it must be: a quick check catches sign errors.
- *Used in:* the wave equation (identity 9, B.9); the necessity of the displacement current (identity 8, B.9); Poynting's theorem, $\nabla\cdot(\mathbf{E}\times\mathbf{H}) = \mathbf{H}\cdot(\nabla\times\mathbf{E}) - \mathbf{E}\cdot(\nabla\times\mathbf{H})$ (identity 4, §7.12); Green's identities (identity 2, B.4); potentials $\mathbf{B} = \nabla\times\mathbf{A}$, $\mathbf{E} = -\nabla V - \partial_t\mathbf{A}$ (identities 7–8).

B.8 Gradient, divergence, curl and Laplacian in curvilinear coordinates

The cylindrical and spherical formulas tabulated in §7.5 and used throughout Ch. 13 are often "derived" by drawing a small curved box and estimating fluxes. Here they are derived exactly, for every orthogonal coordinate system at once, using only the chain rule and the identities of B.7. The only geometric input is the set of three scale factors.

Orthogonal curvilinear coordinates and scale factors

Let $\mathbf{x} = \mathbf{x}(u_1, u_2, u_3)$ be a one-to-one C^2 map from an open set of (u_1, u_2, u_3)-space onto an open set $\Omega \subset \mathbb{R}^3$, with non-zero Jacobian determinant. The coordinates are **orthogonal** if the three tangent vectors $\partial \mathbf{x}/\partial u_i$ are mutually perpendicular at every point. The **scale factors** and **unit vectors** are

$$h_i = \left\| \frac{\partial \mathbf{x}}{\partial u_i} \right\|, \qquad \hat{\mathbf{u}}_i = \frac{1}{h_i}\frac{\partial \mathbf{x}}{\partial u_i} \qquad (i = 1, 2, 3, \text{ no sum}),$$

and we assume the system is right-handed: $\hat{\mathbf{u}}_1 \times \hat{\mathbf{u}}_2 = \hat{\mathbf{u}}_3$ (and cyclically). A field is written $\mathbf{F} = F_1\hat{\mathbf{u}}_1 + F_2\hat{\mathbf{u}}_2 + F_3\hat{\mathbf{u}}_3$, and ∂_i now means $\partial/\partial u_i$.

For cylindrical coordinates $(u_1, u_2, u_3) = (r, \phi, z)$, $\mathbf{x} = (r\cos\phi, r\sin\phi, z)$:

$$\frac{\partial \mathbf{x}}{\partial r} = (\cos\phi, \sin\phi, 0), \quad \frac{\partial \mathbf{x}}{\partial \phi} = r(-\sin\phi, \cos\phi, 0), \quad \frac{\partial \mathbf{x}}{\partial z} = (0, 0, 1), \qquad (h_r, h_\phi, h_z) = (1,\ r,\ 1).$$

For spherical coordinates $(u_1, u_2, u_3) = (R, \theta, \phi)$, $\mathbf{x} = (R\sin\theta\cos\phi,\ R\sin\theta\sin\phi,\ R\cos\theta)$:

$$\frac{\partial \mathbf{x}}{\partial R} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta), \quad \frac{\partial \mathbf{x}}{\partial \theta} = R(\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta), \quad \frac{\partial \mathbf{x}}{\partial \phi} = R\sin\theta(-\sin\phi, \cos\phi, 0),$$

so $(h_R, h_\theta, h_\phi) = (1,\ R,\ R\sin\theta)$. Pairwise dot products are zero by inspection, and both systems are right-handed ($\hat{\mathbf{r}} \times \hat{\boldsymbol{\phi}} = \hat{\mathbf{z}}$, $\hat{\mathbf{R}} \times \hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\phi}}$). The maps are one-to-one with non-zero Jacobian away from the z-axis ($r = 0$, respectively $\sin\theta = 0$); the formulas below hold there.

Lemma B.8 — Gradients of the coordinate functions

Regard u_i as functions of $\mathbf{x}$ (via the inverse map, which is C^2 by the inverse function theorem). Then

$$\nabla u_i = \frac{\hat{\mathbf{u}}_i}{h_i}, \qquad \text{and consequently} \qquad \hat{\mathbf{u}}_1 = h_2 h_3\, \nabla u_2 \times \nabla u_3, \quad \hat{\mathbf{u}}_1 = h_1 \nabla u_1 \quad \text{(and cyclically)}.$$

Proof. The Jacobian matrix of $\mathbf{x}(\mathbf{u})$ has columns $h_i\hat{\mathbf{u}}_i$, so it factors as $\mathbf{Q}\,\mathrm{diag}(h_1, h_2, h_3)$ with $\mathbf{Q} = [\hat{\mathbf{u}}_1\ \hat{\mathbf{u}}_2\ \hat{\mathbf{u}}_3]$ orthogonal. The Jacobian of the inverse map $\mathbf{u}(\mathbf{x})$ is the inverse matrix, $\mathrm{diag}(1/h_1, 1/h_2, 1/h_3)\,\mathbf{Q}^{\mathsf{T}}$, whose i-th row is $\hat{\mathbf{u}}_i^{\mathsf{T}}/h_i$. But the i-th row of the Jacobian of $\mathbf{u}(\mathbf{x})$ is $(\nabla u_i)^{\mathsf{T}}$. The consequences follow from $\nabla u_2 \times \nabla u_3 = \hat{\mathbf{u}}_2 \times \hat{\mathbf{u}}_3/(h_2h_3) = \hat{\mathbf{u}}_1/(h_2h_3)$. ∎

Theorem B.8 — Differential operators in orthogonal coordinates

For a C^1 scalar f and C^1 field $\mathbf{F} = \sum F_i\hat{\mathbf{u}}_i$ (and C^2 f for the Laplacian), with $h = h_1h_2h_3$:

$$\begin{aligned}
\nabla f &= \frac{1}{h_1}\frac{\partial f}{\partial u_1}\hat{\mathbf{u}}_1 + \frac{1}{h_2}\frac{\partial f}{\partial u_2}\hat{\mathbf{u}}_2 + \frac{1}{h_3}\frac{\partial f}{\partial u_3}\hat{\mathbf{u}}_3, \\
\nabla \cdot \mathbf{F} &= \frac{1}{h}\left[\frac{\partial}{\partial u_1}(h_2h_3F_1) + \frac{\partial}{\partial u_2}(h_3h_1F_2) + \frac{\partial}{\partial u_3}(h_1h_2F_3)\right], \\
\nabla \times \mathbf{F} &= \frac{1}{h}\det\begin{bmatrix} h_1\hat{\mathbf{u}}_1 & h_2\hat{\mathbf{u}}_2 & h_3\hat{\mathbf{u}}_3 \\ \partial_1 & \partial_2 & \partial_3 \\ h_1F_1 & h_2F_2 & h_3F_3 \end{bmatrix}, \\
\nabla^2 f &= \frac{1}{h}\left[\frac{\partial}{\partial u_1}\left(\frac{h_2h_3}{h_1}\frac{\partial f}{\partial u_1}\right) + \frac{\partial}{\partial u_2}\left(\frac{h_3h_1}{h_2}\frac{\partial f}{\partial u_2}\right) + \frac{\partial}{\partial u_3}\left(\frac{h_1h_2}{h_3}\frac{\partial f}{\partial u_3}\right)\right].
\end{aligned}$$

Proof.

Gradient. By the chain rule, $\partial f/\partial x_j = \sum_i (\partial f/\partial u_i)(\partial u_i/\partial x_j)$, i.e. $\nabla f = \sum_i \partial_i f\, \nabla u_i$. Insert Lemma B.8.

Divergence. It suffices (by linearity) to treat $F_1\hat{\mathbf{u}}_1$. Write it as $(h_2h_3F_1)\,(\nabla u_2 \times \nabla u_3)$ using Lemma B.8. By identity 4 of B.7 and identity 7 (the u_i are C^2),

$$\nabla \cdot (\nabla u_2 \times \nabla u_3) = \nabla u_3 \cdot (\nabla \times \nabla u_2) - \nabla u_2 \cdot (\nabla \times \nabla u_3) = 0.$$

Then identity 2 of B.7 gives

$$\nabla \cdot (F_1\hat{\mathbf{u}}_1) = \nabla(h_2h_3F_1) \cdot (\nabla u_2 \times \nabla u_3) = \nabla(h_2h_3F_1) \cdot \frac{\hat{\mathbf{u}}_1}{h_2h_3} = \frac{1}{h_1h_2h_3}\frac{\partial}{\partial u_1}(h_2h_3F_1),$$

the last step by the gradient formula (only the $\hat{\mathbf{u}}_1$-component survives the dot product). The other two terms follow cyclically.

Curl. Again treat $F_1\hat{\mathbf{u}}_1 = (h_1F_1)\nabla u_1$. By identity 3 of B.7 and identity 7,

$$\nabla \times \big((h_1F_1)\nabla u_1\big) = \nabla(h_1F_1) \times \nabla u_1 = \left[\sum_k \frac{1}{h_k}\partial_k(h_1F_1)\hat{\mathbf{u}}_k\right] \times \frac{\hat{\mathbf{u}}_1}{h_1} = \frac{1}{h_3h_1}\partial_3(h_1F_1)\,\hat{\mathbf{u}}_2 - \frac{1}{h_1h_2}\partial_2(h_1F_1)\,\hat{\mathbf{u}}_3,$$

using $\hat{\mathbf{u}}_3 \times \hat{\mathbf{u}}_1 = \hat{\mathbf{u}}_2$ and $\hat{\mathbf{u}}_2 \times \hat{\mathbf{u}}_1 = -\hat{\mathbf{u}}_3$. Adding the cyclic analogues for $F_2\hat{\mathbf{u}}_2$ and $F_3\hat{\mathbf{u}}_3$ and collecting the coefficient of each unit vector gives, for example,

$$(\nabla \times \mathbf{F})_1 = \frac{1}{h_2h_3}\Big[\partial_2(h_3F_3) - \partial_3(h_2F_2)\Big],$$

which is exactly the expansion of the stated determinant along its first row.

Laplacian. $\nabla^2 f = \nabla \cdot (\nabla f)$; apply the divergence formula to $F_i = \frac{1}{h_i}\partial_i f$. ∎

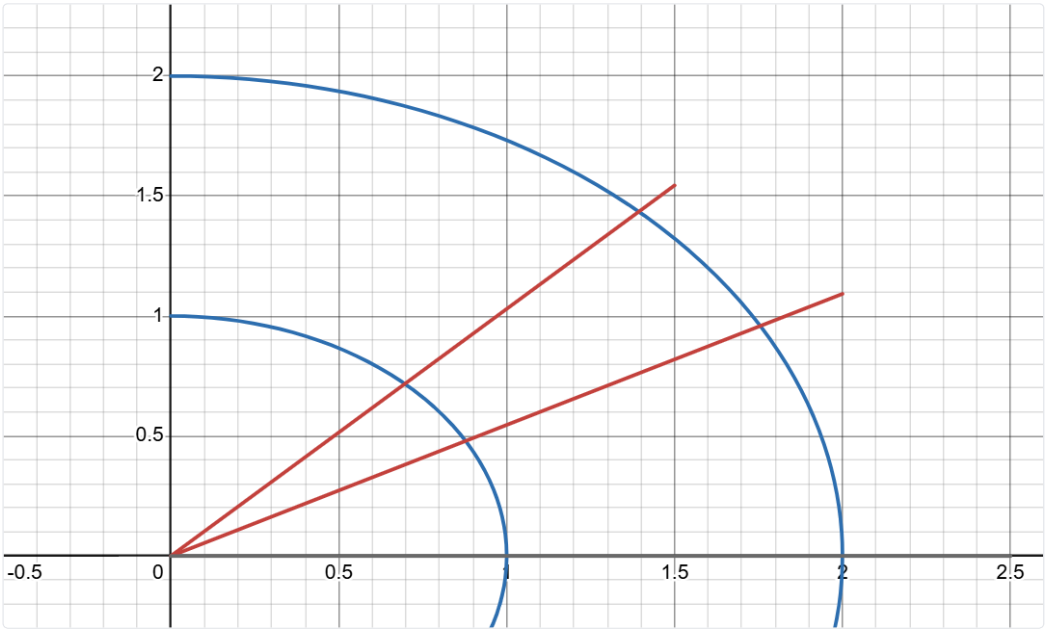
Specialising (all formulas were verified symbolically against the Cartesian operators on test fields):

Cylindrical coordinates (r,ϕ,z), $h=(1,r,1)$

$$\nabla f=\frac{\partial f}{\partial r}\hat{\mathbf{r}}+\frac{1}{r}\frac{\partial f}{\partial \phi}\hat{\boldsymbol{\phi}}+\frac{\partial f}{\partial z}\hat{\mathbf{z}},\qquad \nabla\cdot\mathbf{F}=\frac{1}{r}\frac{\partial}{\partial r}(rF_r)+\frac{1}{r}\frac{\partial F_\phi}{\partial \phi}+\frac{\partial F_z}{\partial z},$$
$$\nabla\times\mathbf{F}=\left(\frac{1}{r}\frac{\partial F_z}{\partial \phi}-\frac{\partial F_\phi}{\partial z}\right)\hat{\mathbf{r}}+\left(\frac{\partial F_r}{\partial z}-\frac{\partial F_z}{\partial r}\right)\hat{\boldsymbol{\phi}}+\frac{1}{r}\left(\frac{\partial}{\partial r}(rF_\phi)-\frac{\partial F_r}{\partial \phi}\right)\hat{\mathbf{z}},$$
$$\nabla^2 f=\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial f}{\partial r}\right)+\frac{1}{r^2}\frac{\partial^2 f}{\partial \phi^2}+\frac{\partial^2 f}{\partial z^2}.$$

Spherical coordinates (R,θ,ϕ), $h=(1,R,R\sin\theta)$

$$\nabla f=\frac{\partial f}{\partial R}\hat{\mathbf{R}}+\frac{1}{R}\frac{\partial f}{\partial \theta}\hat{\boldsymbol{\theta}}+\frac{1}{R\sin\theta}\frac{\partial f}{\partial \phi}\hat{\boldsymbol{\phi}},$$
$$\nabla\cdot\mathbf{F}=\frac{1}{R^2}\frac{\partial}{\partial R}(R^2F_R)+\frac{1}{R\sin\theta}\frac{\partial}{\partial \theta}(\sin\theta\,F_\theta)+\frac{1}{R\sin\theta}\frac{\partial F_\phi}{\partial \phi},$$
$$\nabla\times\mathbf{F}=\frac{1}{R\sin\theta}\left(\frac{\partial}{\partial \theta}(\sin\theta\,F_\phi)-\frac{\partial F_\theta}{\partial \phi}\right)\hat{\mathbf{R}}+\frac{1}{R}\left(\frac{1}{\sin\theta}\frac{\partial F_R}{\partial \phi}-\frac{\partial}{\partial R}(RF_\phi)\right)\hat{\boldsymbol{\theta}}+\frac{1}{R}\left(\frac{\partial}{\partial R}(RF_\theta)-\frac{\partial F_R}{\partial \theta}\right)\hat{\boldsymbol{\phi}},$$
$$\nabla^2 f=\frac{1}{R^2}\frac{\partial}{\partial R}\left(R^2\frac{\partial f}{\partial R}\right)+\frac{1}{R^2\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial f}{\partial \theta}\right)+\frac{1}{R^2\sin^2\theta}\frac{\partial^2 f}{\partial \phi^2}.$$



Cylindrical (polar) coordinate curves. The patch between $r=1,2$ and $\phi=0.5,0.8$ has radial sides of length Δr but arcs of length $r\,\Delta\phi$ — longer on the outer circle. That growth is the scale factor $h_\phi=r$, and it is why $\partial_r(rF_r)$, not $\partial_r F_r$, appears in the divergence.

Remarks.

- *Orthogonality is essential.* For non-orthogonal coordinates ∇u_i is no longer parallel to $\partial\mathbf{x}/\partial u_i$ and the formulas need the full metric tensor $g_{ij}=\partial_i\mathbf{x}\cdot\partial_j\mathbf{x}$; e.g. $\nabla\cdot\mathbf{F}=\frac{1}{\sqrt{g}}\partial_i(\sqrt{g}\,F^i)$ with contravariant components. All coordinate systems in this book are orthogonal.
- *Check by a known field.* For the Coulomb field $F_R=1/R^2$: $\nabla\cdot\mathbf{F}=\frac{1}{R^2}\partial_R(1)=0$ for $R>0$, consistent with B.4. For $f=1/R$: $\nabla^2 f=\frac{1}{R^2}\partial_R(R^2\cdot(-R^{-2}))=0$. For the wire field $F_\phi=1/r$: $(\nabla\times\mathbf{F})_z=\frac{1}{r}\partial_r(r\cdot\frac{1}{r})=0$, consistent with B.6.
- *A pitfall.* Do not differentiate unit vectors as if constant: $\nabla\cdot\hat{\mathbf{r}}=\frac{1}{r}\partial_r(r)=\frac{1}{r}\neq 0$, even though "$F_r=1$ is constant". The scale factors encode exactly the variation of $\hat{\mathbf{u}}_i$ that a naive componentwise derivative misses.
- *Axis singularities.* On $r=0$ (or $\sin\theta=0$) the coordinates fail to be a valid chart; smooth Cartesian fields still have finite operators there, and the apparently singular terms such as $\frac{1}{r^2}\partial_\phi^2 f$ combine into finite limits.
- *Used in:* separation of variables for Laplace's equation in cylinders and spheres (Bessel and Legendre equations, §13.6); radiation and waveguide fields (§7.12); the gradient in polar coordinates (§6.4).

B.9 Maxwell's equations: from integral to differential form, continuity, and waves

§7.12 derives the differential form of Maxwell's equations in a few lines. This section supplies the two analytical facts those lines rely on — localisation of an integral identity, and differentiation of a flux under the integral sign — and states the smoothness hypotheses under which the differential form, the continuity equation and the wave equation follow.

Lemma B.9a — Localisation

Let $\Omega \subset \mathbb{R}^3$ be open.

1. If g is continuous on Ω and $\iiint_B g\,dV = 0$ for every closed ball $B \subset \Omega$, then $g \equiv 0$ on Ω.
2. If $\mathbf{G}$ is continuous on Ω and $\iint_S \mathbf{G}\cdot d\mathbf{S} = 0$ for every flat disc $S \subset \Omega$ (of every orientation), then $\mathbf{G} \equiv \mathbf{0}$ on Ω.

Proof. (1) Suppose $g(\mathbf{a}) > 0$ for some $\mathbf{a}$ (the case < 0 is symmetric). By continuity there is $\delta > 0$ with $g > g(\mathbf{a})/2$ on the ball $B_\delta(\mathbf{a}) \subset \Omega$, so $\iiint_{B_\delta} g\,dV \geq \frac{g(\mathbf{a})}{2}\cdot\frac{4}{3}\pi\delta^3 > 0$, a contradiction. (2) Suppose $\mathbf{G}(\mathbf{a}) \neq \mathbf{0}$ and put $\hat{\mathbf{n}} = \mathbf{G}(\mathbf{a})/\|\mathbf{G}(\mathbf{a})\|$. The continuous function $\mathbf{G}\cdot\hat{\mathbf{n}}$ equals $\|\mathbf{G}(\mathbf{a})\| > 0$ at $\mathbf{a}$, so it exceeds half that on a ball around $\mathbf{a}$; the flat disc through $\mathbf{a}$ with normal $\hat{\mathbf{n}}$ and small radius δ lies in that ball and has flux at least $\tfrac12\|\mathbf{G}(\mathbf{a})\|\pi\delta^2 > 0$, a contradiction. ∎

Lemma B.9b — Differentiating a flux through a fixed surface

Let $S = \mathbf{r}(D)$ be a fixed (time-independent) smooth parametrised surface and $\mathbf{B}(\mathbf{x},t)$ a field such that $\mathbf{B}$ and $\partial\mathbf{B}/\partial t$ are continuous on $S \times I$ for an open time interval I. Then

$$\frac{d}{dt}\iint_S \mathbf{B}\cdot d\mathbf{S} = \iint_S \frac{\partial \mathbf{B}}{\partial t}\cdot d\mathbf{S}.$$

The same holds for volume integrals $\frac{d}{dt}\iiint_V \rho\,dV = \iiint_V \partial_t\rho\,dV$ over a fixed V.

Proof. In parameters the flux is $\Phi(t) = \iint_D \mathbf{B}(\mathbf{r}(u,v),t)\cdot\mathbf{n}(u,v)\,du\,dv$ with $\mathbf{n} = \mathbf{r}_u \times \mathbf{r}_v$ independent of t. The integrand and its t-derivative $\partial_t\mathbf{B}(\mathbf{r},t)\cdot\mathbf{n}$ are continuous on the compact set $D \times [t_0-\eta, t_0+\eta]$, hence uniformly continuous. By the mean value theorem, $\big[\Phi(t_0+\tau)-\Phi(t_0)\big]/\tau = \iint_D \partial_t\mathbf{B}(\mathbf{r},t_0+\vartheta\tau)\cdot\mathbf{n}\,du\,dv$ for some $\vartheta = \vartheta(u,v) \in (0,1)$, and uniform continuity makes this converge to $\iint_D \partial_t\mathbf{B}(\mathbf{r},t_0)\cdot\mathbf{n}\,du\,dv$ as $\tau \to 0$. The volume case is identical. ∎

Theorem B.9 — Differential form of Maxwell's equations

Let $\Omega \subset \mathbb{R}^3$ be open and I an open time interval. Suppose $\mathbf{D},\mathbf{B},\mathbf{E},\mathbf{H}$ are C^1 in $(\mathbf{x},t)$ on $\Omega \times I$ and $\rho, \mathbf{J}$ are continuous. Then the integral laws

$$\oint_{\partial V}\mathbf{D}\cdot d\mathbf{S} = \iiint_V \rho\,dV, \qquad \oint_{\partial V}\mathbf{B}\cdot d\mathbf{S} = 0,$$
$$\oint_{\partial S}\mathbf{E}\cdot d\mathbf{l} = -\frac{d}{dt}\iint_S \mathbf{B}\cdot d\mathbf{S}, \qquad \oint_{\partial S}\mathbf{H}\cdot d\mathbf{l} = \iint_S \mathbf{J}\cdot d\mathbf{S} + \frac{d}{dt}\iint_S \mathbf{D}\cdot d\mathbf{S},$$

holding for every solid $V \subset \Omega$ to which B.4 applies and every fixed oriented surface $S \subset \Omega$ to which B.5 applies, at every $t \in I$, are **equivalent** to the differential laws

$$\nabla\cdot\mathbf{D} = \rho, \qquad \nabla\cdot\mathbf{B} = 0, \qquad \nabla\times\mathbf{E} = -\frac{\partial\mathbf{B}}{\partial t}, \qquad \nabla\times\mathbf{H} = \mathbf{J} + \frac{\partial\mathbf{D}}{\partial t} \qquad \text{on } \Omega\times I.$$

Proof.

Integral ⇒ differential. (Gauss.) By B.4, $\oint_{\partial V}\mathbf{D}\cdot d\mathbf{S} = \iiint_V \nabla\cdot\mathbf{D}\,dV$, so $\iiint_V(\nabla\cdot\mathbf{D}-\rho)\,dV = 0$ for every ball $V \subset \Omega$. The integrand is continuous ($\mathbf{D}$ is C^1, ρ continuous), so Lemma B.9a(1) gives $\nabla\cdot\mathbf{D} = \rho$. The same argument with $\rho = 0$ gives $\nabla\cdot\mathbf{B} = 0$.

(Faraday.) For a fixed surface, Lemma B.9b moves the time derivative inside, and B.5 converts the circulation:

$$\iint_S\left(\nabla\times\mathbf{E} + \frac{\partial\mathbf{B}}{\partial t}\right)\cdot d\mathbf{S} = 0 \qquad \text{for every flat disc } S \subset \Omega.$$

The bracket is continuous, so Lemma B.9a(2) gives $\nabla\times\mathbf{E} = -\partial_t\mathbf{B}$. (Ampère–Maxwell.) Identically, $\iint_S(\nabla\times\mathbf{H} - \mathbf{J} - \partial_t\mathbf{D})\cdot d\mathbf{S} = 0$ for every disc, whence $\nabla\times\mathbf{H} = \mathbf{J} + \partial_t\mathbf{D}$.

Differential ⇒ integral. Integrate each differential law over V or S and apply B.4, B.5 and Lemma B.9b in the reverse direction. ∎

Corollary B.9c — The continuity equation

(a) If charge is conserved in the integral sense, $\frac{d}{dt}\iiint_V \rho\,dV = -\oint_{\partial V}\mathbf{J}\cdot d\mathbf{S}$ for every fixed $V \subset \Omega$, with ρ of class C^1 and $\mathbf{J}$ of class C^1, then

$$\frac{\partial\rho}{\partial t} + \nabla\cdot\mathbf{J} = 0.$$

(b) Conversely, the continuity equation is a **consequence** of Maxwell's equations whenever $\mathbf{H}$ and $\mathbf{D}$ are C^2 and $\mathbf{J}$ is C^1.

Proof. (a) Lemma B.9b and B.4 give $\iiint_V(\partial_t\rho + \nabla\cdot\mathbf{J})\,dV = 0$ for every ball; apply Lemma B.9a(1). (b) Take the divergence of the Ampère–Maxwell law. By identity 8 of B.7, $\nabla\cdot(\nabla\times\mathbf{H}) = 0$, so $0 = \nabla\cdot\mathbf{J} + \nabla\cdot\partial_t\mathbf{D}$. Because $\mathbf{D}$ is C^2, the space and time derivatives commute (Clairaut), $\nabla\cdot\partial_t\mathbf{D} = \partial_t(\nabla\cdot\mathbf{D}) = \partial_t\rho$ by Gauss's law. ∎

Part (b) is the precise form of Maxwell's argument for the displacement current (§7.12): without the term $\partial_t\mathbf{D}$ the same computation would force $\nabla\cdot\mathbf{J} = 0$, contradicting charge accumulation on a capacitor plate. In the same way the divergence of Faraday's law gives $\partial_t(\nabla\cdot\mathbf{B}) = 0$, so $\nabla\cdot\mathbf{B} = 0$ is preserved in time once it holds initially: the two divergence equations are constraints compatible with the two curl equations.

Corollary B.9d — The wave equation in vacuum

In a region with $\rho = 0$, $\mathbf{J} = \mathbf{0}$, $\mathbf{D} = \varepsilon_0 \mathbf{E}$, $\mathbf{B} = \mu_0 \mathbf{H}$, and fields of class C^2,

$$\nabla^2 \mathbf{E} = \mu_0 \varepsilon_0 \frac{\partial^2 \mathbf{E}}{\partial t^2}, \qquad \nabla^2 \mathbf{B} = \mu_0 \varepsilon_0 \frac{\partial^2 \mathbf{B}}{\partial t^2}, \qquad c = \frac{1}{\sqrt{\mu_0 \varepsilon_0}}.$$

Proof. Take the curl of Faraday's law. Since $\mathbf{B}$ is C^2, $\nabla \times \partial_t \mathbf{B} = \partial_t (\nabla \times \mathbf{B})$, and by Ampère–Maxwell $\nabla \times \mathbf{B} = \mu_0 \nabla \times \mathbf{H} = \mu_0 \varepsilon_0 \, \partial_t \mathbf{E}$. Hence

$$\nabla \times (\nabla \times \mathbf{E}) = -\partial_t (\nabla \times \mathbf{B}) = -\mu_0 \varepsilon_0 \frac{\partial^2 \mathbf{E}}{\partial t^2}.$$

By identity 9 of B.7 (in Cartesian components), $\nabla \times (\nabla \times \mathbf{E}) = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E} = -\nabla^2 \mathbf{E}$, since $\nabla \cdot \mathbf{E} = \rho / \varepsilon_0 = 0$. This is the first equation. For $\mathbf{B}$, take the curl of Ampère–Maxwell: $\nabla \times (\nabla \times \mathbf{B}) = \mu_0 \varepsilon_0 \partial_t (\nabla \times \mathbf{E}) = -\mu_0 \varepsilon_0 \partial_t^2 \mathbf{B}$, and $\nabla \cdot \mathbf{B} = 0$. $\blacksquare$

Numbers and a check. With $\mu_0 = 4\pi \times 10^{-7}$ H/m and $\varepsilon_0 = 8.8541878 \times 10^{-12}$ F/m, $1/\sqrt{\mu_0 \varepsilon_0} = 2.99792458 \times 10^8$ m/s (computed), the measured speed of light. Dimensionally, $[\mu_0 \varepsilon_0] = (\mathrm{H/m})(\mathrm{F/m}) = \mathrm{s}^2/\mathrm{m}^2$ because $[LC] = \mathrm{s}^2$, so $1/\sqrt{\mu_0 \varepsilon_0}$ is a speed. The plane wave $\mathbf{E} = E_0 \cos(\omega t - kz)\, \hat{\mathbf{x}}$ satisfies the equation exactly when $k^2 = \mu_0 \varepsilon_0 \omega^2$, i.e. $\omega / k = c$; it also satisfies $\nabla \cdot \mathbf{E} = \partial_x E_x = 0$, and Faraday's law then gives $\mathbf{B} = (E_0 / c) \cos(\omega t - kz)\, \hat{\mathbf{y}}$ — transverse and in phase, as solved in §13.5.

Remarks.

- *Why the integral form is more fundamental.* The integral laws make sense for fields that are discontinuous across material interfaces, sheets of charge or surface currents, where the differential form fails (the derivatives do not exist). Applied to thin pillboxes and loops straddling an interface they give the boundary conditions $\hat{\mathbf{n}} \cdot (\mathbf{D}_1 - \mathbf{D}_2) = \rho_s$, $\hat{\mathbf{n}} \times (\mathbf{E}_1 - \mathbf{E}_2) = \mathbf{0}$ (§7.12). The equivalence in Theorem B.9 holds precisely in regions where the C^1 hypothesis is met.
- *Fixed versus moving surfaces.* Lemma B.9b requires S to be stationary. For a moving loop, $\frac{d}{dt} \iint_{S(t)} \mathbf{B} \cdot d\mathbf{S}$ picks up an extra term $-\oint_{\partial S} (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}$ (using $\nabla \cdot \mathbf{B} = 0$); this is the motional EMF of generators. The differential law $\nabla \times \mathbf{E} = -\partial_t \mathbf{B}$ is unaffected.
- *Is the wave equation all of Maxwell?* No. Every solution of Maxwell's equations in vacuum solves the wave equation, but not conversely: a solution of $\nabla^2 \mathbf{E} = c^{-2} \partial_t^2 \mathbf{E}$ must also satisfy $\nabla \cdot \mathbf{E} = 0$ (transversality), and $\mathbf{B}$ is then determined by Faraday's law up to a static field. Longitudinal solutions such as $\cos(\omega t - kz) \hat{\mathbf{z}}$ satisfy the wave equation but are excluded by Gauss's law.
- *Used in:* the wave equation and Helmholtz equation (§7.12, §13.5); Poisson's equation $\nabla^2 V = -\rho/\varepsilon$ from $\mathbf{E} = -\nabla V$, $\nabla \cdot \mathbf{D} = \rho$ (§13.6, §13.8); the phasor form $\partial_t \to j\omega$ used with the Fourier transform (Ch. 16).

Appendix C — Linear Algebra

This appendix gives complete proofs of the central theorems of Part III (Ch. 8, Ch. 9, Ch. 10), which the chapters state with only sketches, together with the two results from numerical analysis and dynamics that lean on them most heavily: the condition-number error bound (§8.10, Ch. 22) and the eigenvalue test for stability of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ (§10.9, §12.7).

Prerequisites. Matrix algebra, row reduction and echelon form (Ch. 8); vector spaces, span, independence, basis and dimension (Ch. 9), in particular the facts that every independent set in a finite-dimensional space can be extended to a basis and that any n independent vectors in an n-dimensional space form a basis. The fundamental theorem of algebra (every non-constant complex polynomial has a complex root) is used without proof.

Rigor. Hypotheses are stated exactly and every step is justified. Scalars are $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$. Where a result holds for complex matrices with T replaced by H, we say so; proofs are written in whichever setting is the more natural. The sections are ordered so that each proof uses only earlier ones.

C.1 Determinants: the product rule and invertibility

Chapter 8 defines $\det \mathbf{A}$ by cofactor expansion and notes that it equals the Leibniz sum. Here we take the Leibniz sum as the working definition, because the proofs are cleanest from it.

Permutations and their sign

A **permutation** of $\{1, \dots, n\}$ is a bijection σ of that set to itself; the set of all $n!$ of them is S_n. A **transposition** swaps two elements and fixes the rest. Every permutation is a product of transpositions, and although the factorisation is not unique, the **parity** of the number of transpositions is; $\operatorname{sgn}\sigma = +1$ for an even number, -1 for an odd number. Hence $\operatorname{sgn}(\sigma\tau) = \operatorname{sgn}\sigma \, \operatorname{sgn}\tau$ and $\operatorname{sgn}\sigma^{-1} = \operatorname{sgn}\sigma$.

Determinant (Leibniz form)

For $\mathbf{A} = [a_{ij}] \in \mathbb{F}^{n\times n}$,

$$\det \mathbf{A} = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma)\, a_{1\sigma(1)} a_{2\sigma(2)} \cdots a_{n\sigma(n)}.$$

We regard det as a function $D(\mathbf{r}_1, \dots, \mathbf{r}_n)$ of the rows $\mathbf{r}_i$ of $\mathbf{A}$.

Multilinear, alternating

A function f of n row vectors in $\mathbb{F}^n$ is **multilinear** if it is linear in each row when the others are held fixed, and **alternating** if $f = 0$ whenever two rows are equal.

Theorem C.1 — Product rule and invertibility

Let $\mathbf{A}, \mathbf{B} \in \mathbb{F}^{n\times n}$. Then

1. $\det(\mathbf{AB}) = \det \mathbf{A} \, \det \mathbf{B}$;
2. $\det \mathbf{A}^{\mathsf{T}} = \det \mathbf{A}$;
3. $\mathbf{A}$ is invertible (there is $\mathbf{X}$ with $\mathbf{AX} = \mathbf{XA} = \mathbf{I}$) if and only if $\det \mathbf{A} \neq 0$, and then $\det \mathbf{A}^{-1} = 1/\det \mathbf{A}$.

Proof

Step 1: det is multilinear, alternating, and $\det \mathbf{I} = 1$. Each Leibniz term contains exactly one factor $a_{i\sigma(i)}$ from row i, so each term — and hence the sum — is linear in row i. For $\mathbf{I}$, the only non-zero term is $\sigma = \mathrm{id}$, giving 1. For the alternating property, suppose rows $p \neq q$ are equal and let τ be the transposition swapping p and q. The map $\sigma \mapsto \sigma\tau$ pairs the permutations into pairs $\{\sigma, \sigma\tau\}$ (it is its own inverse and has no fixed points). In the pair, the terms are

$$\operatorname{sgn}(\sigma) \prod_i a_{i\sigma(i)} \quad \text{and} \quad \operatorname{sgn}(\sigma\tau) \prod_i a_{i\sigma\tau(i)} = -\operatorname{sgn}(\sigma) \prod_i a_{i\sigma\tau(i)}.$$

The two products differ only in the factors for $i = p, q$: the first has $a_{p\sigma(p)} a_{q\sigma(q)}$, the second $a_{p\sigma(q)} a_{q\sigma(p)}$. Since rows p and q are equal, $a_{pk} = a_{qk}$ for all k, so the products are equal and the pair cancels. Hence $\det \mathbf{A} = 0$.

Step 2: alternating implies antisymmetric. If f is multilinear and alternating, swapping two rows negates f. Indeed, put $\mathbf{u} + \mathbf{v}$ in both positions p and q (other rows fixed) and expand by multilinearity:

$$0 = f(\dots, \mathbf{u}+\mathbf{v}, \dots, \mathbf{u}+\mathbf{v}, \dots) = f(\dots,\mathbf{u},\dots,\mathbf{u},\dots) + f(\dots,\mathbf{u},\dots,\mathbf{v},\dots) + f(\dots,\mathbf{v},\dots,\mathbf{u},\dots) + f(\dots,\mathbf{v},\dots,\mathbf{v},\dots).$$

The first and last terms vanish (equal rows), so $f(\dots,\mathbf{u},\dots,\mathbf{v},\dots) = -f(\dots,\mathbf{v},\dots,\mathbf{u},\dots)$.

Step 3: uniqueness lemma. *If f is multilinear and alternating in the rows of an $n \times n$ matrix, then $f(\mathbf{A}) = f(\mathbf{I}) \det \mathbf{A}$ for every $\mathbf{A}$.* Write row i as $\mathbf{r}_i = \sum_k a_{ik}\mathbf{e}_k^{\mathsf{T}}$ and expand f by multilinearity in all n rows:

$$f(\mathbf{A}) = \sum_{k_1=1}^{n} \cdots \sum_{k_n=1}^{n} a_{1k_1} \cdots a_{nk_n}\, f(\mathbf{e}_{k_1}^{\mathsf{T}}, \dots, \mathbf{e}_{k_n}^{\mathsf{T}}).$$

If two indices $k_p = k_q$ coincide, the corresponding f value has two equal rows and vanishes. The surviving index tuples are exactly those with $k_i = \sigma(i)$ for a permutation σ. For such a tuple, the rows $\mathbf{e}_{\sigma(1)}^{\mathsf{T}}, \dots, \mathbf{e}_{\sigma(n)}^{\mathsf{T}}$ can be sorted into $\mathbf{I}$ by a sequence of row swaps whose number has the parity of σ; by Step 2 each swap flips the sign, so $f(\mathbf{e}_{\sigma(1)}^{\mathsf{T}}, \dots, \mathbf{e}_{\sigma(n)}^{\mathsf{T}}) = \operatorname{sgn}(\sigma) f(\mathbf{I})$. Therefore

$$f(\mathbf{A}) = f(\mathbf{I}) \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) a_{1\sigma(1)} \cdots a_{n\sigma(n)} = f(\mathbf{I}) \det \mathbf{A}.$$

Step 4: product rule. Fix $\mathbf{B}$ and define $f(\mathbf{A}) = \det(\mathbf{AB})$. Row i of $\mathbf{AB}$ is $\mathbf{r}_i\mathbf{B}$, a linear function of $\mathbf{r}_i$ alone. Hence f is multilinear in the rows of $\mathbf{A}$ (composition of the linear map $\mathbf{r}_i \mapsto \mathbf{r}_i\mathbf{B}$ with the multilinear det), and alternating (equal rows of $\mathbf{A}$ give equal rows of $\mathbf{AB}$). By Step 3, $\det(\mathbf{AB}) = f(\mathbf{I}) \det \mathbf{A} = \det \mathbf{B} \det \mathbf{A}$. This proves (1).

Step 5: transpose. $\det \mathbf{A}^{\mathsf{T}} = \sum_\sigma \operatorname{sgn}\sigma \prod_i a_{\sigma(i)i}$. Re-index each product by $k = \sigma(i)$, i.e. $i = \sigma^{-1}(k)$: $\prod_i a_{\sigma(i)i} = \prod_k a_{k\sigma^{-1}(k)}$. As σ runs over S_n so does $\pi = \sigma^{-1}$, with $\operatorname{sgn}\pi = \operatorname{sgn}\sigma$. So $\det \mathbf{A}^{\mathsf{T}} = \sum_\pi \operatorname{sgn}\pi \prod_k a_{k\pi(k)} = \det \mathbf{A}$. This proves (2). In particular det is also multilinear and alternating in the **columns**.

Step 6: invertible $\Rightarrow \det \neq 0$. If $\mathbf{AX} = \mathbf{I}$ then by (1), $\det \mathbf{A} \det \mathbf{X} = \det \mathbf{I} = 1$, so $\det \mathbf{A} \neq 0$ and $\det \mathbf{A}^{-1} = 1/\det \mathbf{A}$.

Step 7: $\det \neq 0 \Rightarrow$ invertible. First, *if the columns $\mathbf{a}_1, \dots, \mathbf{a}_n$ of $\mathbf{A}$ are dependent, then* $\det \mathbf{A} = 0$. Some column is a combination of the others, say $\mathbf{a}_k = \sum_{j \neq k} c_j \mathbf{a}_j$. By column multilinearity,

$$\det \mathbf{A} = \sum_{j \neq k} c_j \det[\mathbf{a}_1, \dots, \underbrace{\mathbf{a}_j}_{\text{position } k}, \dots, \mathbf{a}_n],$$

and each determinant on the right has column $\mathbf{a}_j$ in two positions, so vanishes. Contrapositively, $\det \mathbf{A} \neq 0$ implies the n columns are independent, hence a basis of $\mathbb{F}^n$ (Ch. 9). So each $\mathbf{e}_i$ is a combination $\mathbf{A}\mathbf{x}_i$, and $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$ satisfies $\mathbf{AX} = \mathbf{I}$. By Step 6, $\det \mathbf{X} = 1/\det \mathbf{A} \neq 0$, so by the same argument $\mathbf{X}$ has a right inverse $\mathbf{Y}$, $\mathbf{XY} = \mathbf{I}$. Then

$$\mathbf{A} = \mathbf{A}(\mathbf{XY}) = (\mathbf{AX})\mathbf{Y} = \mathbf{Y},$$

so $\mathbf{XA} = \mathbf{XY} = \mathbf{I}$ as well: $\mathbf{X}$ is a two-sided inverse. This proves (3). ■

Remarks

- **What the proof really shows.** Step 3 says the determinant is the *only* multilinear alternating function with $f(\mathbf{I}) = 1$. That characterisation, not the $n!$-term formula, is what makes the determinant useful: it is why row replacement leaves det unchanged, row swaps negate it, and $\det \mathbf{A} = (-1)^s u_{11} \cdots u_{nn}$ from elimination (§8.3). Cofactor expansion along row 1 is also multilinear, alternating and equals 1 at $\mathbf{I}$, which is the cleanest proof that the two definitions in Ch. 8 agree.
- **Square matrices only.** For rectangular $\mathbf{A}$ ($m \times n$) and $\mathbf{B}$ ($n \times m$) with $m < n$, $\mathbf{AB}$ can be invertible though neither factor has a determinant; the replacement is the Cauchy–Binet formula. For $m > n$, $\det(\mathbf{AB}) = 0$ always, since $\operatorname{rank}(\mathbf{AB}) \leq n < m$.
- **Sum rule fails.** $\det(\mathbf{A} + \mathbf{B}) \neq \det \mathbf{A} + \det \mathbf{B}$ in general: $\mathbf{A} = \mathbf{B} = \mathbf{I}_2$ gives $4 \neq 2$.
- **Step 7 is the theoretical half of the invertible matrix theorem** (§8.4): it also shows that a one-sided inverse of a square matrix is automatically two-sided. Numerically, though, $\det \mathbf{A}$ is a poor measure of "nearly singular" — $\det(10^{-1}\mathbf{I}_{30}) = 10^{-30}$ for a perfectly conditioned matrix — which is why §C.11 uses the condition number instead.
- **Uses.** The characteristic polynomial $\det(\lambda\mathbf{I} - \mathbf{A})$ and the fact that λ is an eigenvalue iff $\mathbf{A} - \lambda\mathbf{I}$ is singular (§10.1) rest on part 3; similarity invariance $\det(\mathbf{S}^{-1}\mathbf{AS}) = \det \mathbf{A}$ and $\det \mathbf{A} = \prod \lambda_i$ rest on part 1; Cramer's rule and the Jacobian change of variables (Ch. 6) use both.

C.2 The rank–nullity theorem

Kernel, range, rank, nullity

For a linear map $T : V \to W$, the **kernel** (null space) is $\ker T = \{\mathbf{v} \in V : T\mathbf{v} = \mathbf{0}\}$ and the **range** is $\operatorname{range} T = \{T\mathbf{v} : \mathbf{v} \in V\}$. Both are subspaces. Their dimensions are the **nullity** and the **rank**. For a matrix $\mathbf{A} \in \mathbb{F}^{m \times n}$ acting by $\mathbf{x} \mapsto \mathbf{Ax}$, the kernel is $\operatorname{null}(\mathbf{A})$ and the range is the column space $\operatorname{col}(\mathbf{A})$.

Theorem C.2 — Rank–nullity

Let V be finite-dimensional and $T : V \to W$ linear. Then

$$\dim \operatorname{range} T + \dim \ker T = \dim V.$$

For $\mathbf{A} \in \mathbb{F}^{m \times n}$: $\operatorname{rank} \mathbf{A} + \dim \operatorname{null} \mathbf{A} = n$. Moreover the row rank equals the column rank, $\dim \operatorname{row} \mathbf{A} = \dim \operatorname{col} \mathbf{A}$, and consequently $\dim \operatorname{null} \mathbf{A}^{\mathsf{T}} = m - \operatorname{rank} \mathbf{A}$.

Proof

Rank–nullity. Let $n = \dim V$. The kernel is a subspace of V, hence finite-dimensional; choose a basis $\mathbf{k}_1, \dots, \mathbf{k}_q$ of it ($q = 0$ if $\ker T = \{\mathbf{0}\}$). An independent set extends to a basis of V, so there are $\mathbf{v}_1, \dots, \mathbf{v}_s$ with $\mathbf{k}_1, \dots, \mathbf{k}_q, \mathbf{v}_1, \dots, \mathbf{v}_s$ a basis of V; thus $q + s = n$. We claim that $T\mathbf{v}_1, \dots, T\mathbf{v}_s$ is a basis of $\operatorname{range} T$, which gives $\dim \operatorname{range} T = s = n - q$.

Spanning. Any $\mathbf{w} \in \operatorname{range} T$ is $T\mathbf{v}$ for some $\mathbf{v} = \sum_i a_i \mathbf{k}_i + \sum_j b_j \mathbf{v}_j$. By linearity and $T\mathbf{k}_i = \mathbf{0}$, $\mathbf{w} = \sum_j b_j T\mathbf{v}_j$.

Independence. Suppose $\sum_j c_j T\mathbf{v}_j = \mathbf{0}$. Then $T\big(\sum_j c_j \mathbf{v}_j\big) = \mathbf{0}$, so $\sum_j c_j \mathbf{v}_j \in \ker T$ and equals some $\sum_i d_i \mathbf{k}_i$. The relation $\sum_j c_j \mathbf{v}_j - \sum_i d_i \mathbf{k}_i = \mathbf{0}$ among basis vectors of V forces all $c_j = 0$ (and all $d_i = 0$).

Row rank equals column rank. Let $r = \dim \operatorname{col} \mathbf{A}$ and let $\mathbf{c}_1, \dots, \mathbf{c}_r \in \mathbb{F}^m$ be a basis of $\operatorname{col} \mathbf{A}$; put $\mathbf{C} = [\mathbf{c}_1, \dots, \mathbf{c}_r]$ ($m \times r$). Each column $\mathbf{a}_j$ of $\mathbf{A}$ is a combination $\mathbf{a}_j = \mathbf{C}\mathbf{f}_j$; collecting the coefficient vectors into the $r \times n$ matrix $\mathbf{F} = [\mathbf{f}_1, \dots, \mathbf{f}_n]$ gives the **rank factorisation**

$$\mathbf{A} = \mathbf{C}\mathbf{F}.$$

Read row-wise, row i of $\mathbf{A}$ equals $\sum_{k=1}^{r} c_{ik}$ (row k of $\mathbf{F}$): every row of $\mathbf{A}$ lies in the span of the r rows of $\mathbf{F}$. Hence $\dim \operatorname{row} \mathbf{A} \le r = \dim \operatorname{col} \mathbf{A}$. Applying this inequality to $\mathbf{A}^{\mathsf{T}}$, whose rows are the columns of $\mathbf{A}$, gives the reverse inequality. So the two are equal.

Left null space. Apply the matrix form of rank–nullity to $\mathbf{A}^{\mathsf{T}} \in \mathbb{F}^{n \times m}$, which has m columns and rank $\dim \operatorname{col} \mathbf{A}^{\mathsf{T}} = \dim \operatorname{row} \mathbf{A} = r$: $\dim \operatorname{null} \mathbf{A}^{\mathsf{T}} = m - r$. ∎

Remarks

- **Finite dimension of V is essential; of W it is not.** On the infinite-dimensional space of polynomials, differentiation D has a one-dimensional kernel (the constants) and is onto, so the identity would read $\infty = \infty + 1$ and carries no information. Worse, a map with zero kernel need not be onto there: multiplication by t is one-to-one but misses the constants. For square matrices, by contrast, rank–nullity gives "one-to-one $\iff$ onto", the backbone of the invertible matrix theorem (§8.4).
- **Nothing depends on row reduction.** The chapter proof (§9.6) counts pivot and free columns of the reduced echelon form; the proof above shows the result is a statement about the map, independent of any algorithm or basis.
- **Uses.** Existence and uniqueness for $\mathbf{A}\mathbf{x} = \mathbf{b}$ (§8.6): the solution set is $\mathbf{x}_p + \operatorname{null} \mathbf{A}$, an affine set of dimension $n - r$. In circuit theory, for a connected graph with N nodes and B branches the reduced incidence matrix has rank $N - 1$, so the loop-current space has dimension $B - N + 1$, the number of independent meshes (§8.5). Sections C.6 and C.10 need $\operatorname{rank}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \operatorname{rank} \mathbf{A}$, which follows from rank–nullity once the null spaces are shown equal.

C.3 Existence and uniqueness of the LU factorisation

Leading principal submatrices and minors

For $\mathbf{A} \in \mathbb{F}^{n \times n}$, $\mathbf{A}_k = \mathbf{A}_{1:k,1:k}$ is the **leading principal submatrix** of order k, and $\Delta_k = \det \mathbf{A}_k$ the **leading principal minor**; set $\Delta_0 = 1$. A **unit lower triangular** matrix is lower triangular with ones on the diagonal. A **permutation matrix** is $\mathbf{I}$ with its rows reordered.

Three facts about triangular matrices are used throughout. Products and inverses of (unit) lower triangular matrices are (unit) lower triangular, and likewise for upper. A triangular matrix is invertible iff its diagonal entries are non-zero, its determinant being their product (§8.3). And the **leading-block rule**: if $\mathbf{L}$ is lower and $\mathbf{U}$ upper triangular then

$$(\mathbf{L}\mathbf{U})_k = \mathbf{L}_k \mathbf{U}_k,$$

because $(\mathbf{L}\mathbf{U})_{ij} = \sum_p \ell_{ip} u_{pj}$ and for $i, j \le k$ every non-zero term has $p \le \min(i, j) \le k$.

Theorem C.3 — LU without pivoting

Let $\mathbf{A} \in \mathbb{F}^{n \times n}$.

1. If $\Delta_1, \dots, \Delta_{n-1}$ are all non-zero, then $\mathbf{A} = \mathbf{L}\mathbf{U}$ with $\mathbf{L}$ unit lower triangular and $\mathbf{U}$ upper triangular, and this factorisation is **unique**. The pivots are $u_{kk} = \Delta_k / \Delta_{k-1}$.
2. Conversely, if $\mathbf{A}$ is nonsingular and has such a factorisation, then all $\Delta_k \neq 0$, $k = 1, \dots, n$.

Thus a nonsingular $\mathbf{A}$ has an LU factorisation (Gaussian elimination runs without row interchanges) if and only if every leading principal minor is non-zero.

Theorem C.4 — LU with pivoting

For every nonsingular $\mathbf{A} \in \mathbb{F}^{n \times n}$ there is a permutation matrix $\mathbf{P}$ such that $\mathbf{P}\mathbf{A} = \mathbf{L}\mathbf{U}$, with $\mathbf{L}$ unit lower triangular and $\mathbf{U}$ upper triangular and nonsingular. $\mathbf{P}$ can be chosen (partial pivoting) so that $|\ell_{ik}| \le 1$ for all i, k.

Proof of Theorem C.3

Existence, by induction on n. For $n = 1$, $[a] = [1][a]$. Suppose the result holds for order $n - 1$ and let $\Delta_1, \dots, \Delta_{n-1} \neq 0$. Partition

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{n-1} & \mathbf{b} \\ \mathbf{c}^{\mathsf{T}} & d \end{bmatrix}.$$

The matrix $\mathbf{A}_{n-1}$ has leading minors $\Delta_1, \dots, \Delta_{n-2}$, all non-zero, so by hypothesis $\mathbf{A}_{n-1} = \mathbf{L}'\mathbf{U}'$. Since $\det \mathbf{U}' = \det \mathbf{L}' \det \mathbf{U}' = \Delta_{n-1} \neq 0$, $\mathbf{U}'$ is invertible, and $\mathbf{L}'$ is invertible as a unit triangular matrix. Seek

$$\mathbf{A} = \begin{bmatrix} \mathbf{L}' & \mathbf{0} \\ \boldsymbol{\ell}^{\mathsf{T}} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{U}' & \mathbf{u} \\ \mathbf{0}^{\mathsf{T}} & u_{nn} \end{bmatrix} = \begin{bmatrix} \mathbf{L}'\mathbf{U}' & \mathbf{L}'\mathbf{u} \\ \boldsymbol{\ell}^{\mathsf{T}}\mathbf{U}' & \boldsymbol{\ell}^{\mathsf{T}}\mathbf{u} + u_{nn} \end{bmatrix}.$$

Matching blocks requires

$$\mathbf{L}'\mathbf{u} = \mathbf{b}, \qquad \boldsymbol{\ell}^{\mathsf{T}}\mathbf{U}' = \mathbf{c}^{\mathsf{T}}, \qquad u_{nn} = d - \boldsymbol{\ell}^{\mathsf{T}}\mathbf{u},$$

which have the solutions $\mathbf{u} = \mathbf{L}'^{-1}\mathbf{b}$, $\boldsymbol{\ell}^{\mathsf{T}} = \mathbf{c}^{\mathsf{T}}\mathbf{U}'^{-1}$, $u_{nn} = d - \mathbf{c}^{\mathsf{T}}\mathbf{A}_{n-1}^{-1}\mathbf{b}$. The two factors are unit lower and upper triangular, completing the induction. Note that Δ_n is not needed: u_{nn} may be zero.

Uniqueness, by the same induction. Suppose $\mathbf{A} = \mathbf{L}\mathbf{U}$ is any such factorisation. By the leading-block rule $\mathbf{A}_{n-1} = \mathbf{L}_{n-1}\mathbf{U}_{n-1}$, so by uniqueness at order $n - 1$, $\mathbf{L}_{n-1} = \mathbf{L}'$ and $\mathbf{U}_{n-1} = \mathbf{U}'$. The remaining blocks must then satisfy the three displayed equations, each of which has exactly one solution because $\mathbf{L}'$ and $\mathbf{U}'$ are invertible. So $\mathbf{L}$, $\mathbf{U}$ are determined.

Pivots. By the leading-block rule, $\Delta_k = \det \mathbf{L}_k \det \mathbf{U}_k = u_{11} u_{22} \cdots u_{kk}$ for every k. Dividing consecutive minors gives $u_{kk} = \Delta_k / \Delta_{k-1}$.

Converse. If $\mathbf{A} = \mathbf{L}\mathbf{U}$ is nonsingular then $0 \neq \det \mathbf{A} = \prod_{i=1}^{n} u_{ii}$, so every $u_{ii} \neq 0$ and $\Delta_k = \prod_{i \le k} u_{ii} \neq 0$ for every k. ∎

Proof of Theorem C.4

Induction on n; $n = 1$ is trivial with $\mathbf{P} = [1]$. Let $\mathbf{A}$ be nonsingular of order n. Its first column is non-zero (otherwise $\det \mathbf{A} = 0$ by column linearity), so choose a row p with $|a_{p1}| = \max_i |a_{i1}| > 0$ and let $\mathbf{P}_1$ swap rows 1 and p. Write

$$\mathbf{P}_1 \mathbf{A} = \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{v} & \mathbf{A}' \end{bmatrix} = \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{v}/\alpha & \mathbf{I} \end{bmatrix} \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{S} \end{bmatrix}, \qquad \mathbf{S} = \mathbf{A}' - \frac{\mathbf{v}\mathbf{w}^{\mathsf{T}}}{\alpha},$$

which is verified by multiplying out. The entries of $\mathbf{v}/\alpha$ have modulus at most 1 by the choice of pivot. Taking determinants, $\pm \det \mathbf{A} = \alpha \det \mathbf{S}$, so the **Schur complement** $\mathbf{S}$, of order $n-1$, is nonsingular. By the induction hypothesis $\mathbf{P}_2 \mathbf{S} = \mathbf{L}_2 \mathbf{U}_2$ with multipliers of modulus at most 1. Put

$$\mathbf{P} = \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{P}_2 \end{bmatrix} \mathbf{P}_1, \qquad \mathbf{L} = \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{P}_2 \mathbf{v}/\alpha & \mathbf{L}_2 \end{bmatrix}, \qquad \mathbf{U} = \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{U}_2 \end{bmatrix}.$$

Then

$$\mathbf{P}\mathbf{A} = \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{P}_2 \end{bmatrix} \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{v} & \mathbf{A}' \end{bmatrix} = \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{P}_2 \mathbf{v} & \mathbf{P}_2 \mathbf{A}' \end{bmatrix}, \qquad \mathbf{L}\mathbf{U} = \begin{bmatrix} \alpha & \mathbf{w}^{\mathsf{T}} \\ \mathbf{P}_2 \mathbf{v} & \mathbf{P}_2 \mathbf{v}\mathbf{w}^{\mathsf{T}}/\alpha + \mathbf{L}_2 \mathbf{U}_2 \end{bmatrix},$$

and the bottom-right blocks agree because $\mathbf{L}_2 \mathbf{U}_2 = \mathbf{P}_2 \mathbf{S} = \mathbf{P}_2 \mathbf{A}' - \mathbf{P}_2 \mathbf{v}\mathbf{w}^{\mathsf{T}}/\alpha$. $\mathbf{P}$ is a product of permutation matrices, hence a permutation matrix; $\mathbf{L}$ is unit lower triangular with all multipliers of modulus at most 1 (the permutation $\mathbf{P}_2$ only reorders the entries of $\mathbf{v}/\alpha$); and $\mathbf{U}$ is upper triangular with $\det \mathbf{U} = \alpha \det \mathbf{U}_2 \neq 0$. $\blacksquare$

Remarks

- **The hypothesis cannot be dropped.** $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$ is nonsingular but $\Delta_1 = 0$, and it has no LU factorisation: $u_{11} = a_{11} = 0$ and $\ell_{21} u_{11} = a_{21} = 1$ are incompatible. One row swap fixes it, as Theorem C.4 guarantees.
- **Uniqueness needs $\Delta_1, \dots, \Delta_{n-1} \neq 0$.** $\begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \ell & 1 \end{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$ for every ℓ. Without the unit-diagonal normalisation of $\mathbf{L}$ uniqueness also fails, since $(\mathbf{L}\mathbf{D}^{-1})(\mathbf{D}\mathbf{U})$ is another factorisation for any nonsingular diagonal $\mathbf{D}$.
- **Existence is not stability.** $\mathbf{A} = \begin{bmatrix} \varepsilon & 1 \\ 1 & 1 \end{bmatrix}$ with $0 < |\varepsilon| \ll 1$ has $\Delta_1 = \varepsilon \neq 0$, so LU without pivoting exists, but $\ell_{21} = 1/\varepsilon$ and $u_{22} = 1 - 1/\varepsilon$ are huge and rounding destroys the answer (see the pivoting discussion in §8.7). The bound $|\ell_{ik}| \le 1$ in Theorem C.4 keeps the computed factors representative of $\mathbf{A}$; growth in $\mathbf{U}$ can still occur in contrived cases but is rare in practice (§24.3).
- **A check.** For $\mathbf{A} = \begin{bmatrix} 2 & 1 & 1 \\ 4 & 3 & 3 \\ 8 & 7 & 9 \end{bmatrix}$: $\Delta_1 = 2$, $\Delta_2 = 2$, $\Delta_3 = 4$, so the pivots without pivoting are $2,\ 1,\ 2$ and $\det \mathbf{A} = 4$. Partial pivoting instead brings row 3 to the top and produces pivots $8,\ -0.75,\ -0.\overline{6}$ (product 4, since the row permutation used is a cyclic shift with determinant $+1$) and multipliers $0.25,\ 0.5,\ 0.\overline{6}$, all at most 1.
- **Uses.** Solving nodal equations (§8.9); the pivot formula $u_{kk} = \Delta_k / \Delta_{k-1}$ is the bridge to Sylvester's criterion in §C.9; the Schur complement $\mathbf{S}$ is exactly Kron reduction of a network (§8.4).

C.4 Cauchy–Schwarz and triangle inequalities

We use the book's convention (§9.8): an inner product on a vector space V over $\mathbb{F}$ is linear in its first argument, conjugate-symmetric, $\langle \mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{v}, \mathbf{u} \rangle^*$, and positive, $\langle \mathbf{u}, \mathbf{u} \rangle > 0$ for $\mathbf{u} \neq \mathbf{0}$. It follows that $\langle \mathbf{u}, a\mathbf{v} \rangle = a^* \langle \mathbf{u}, \mathbf{v} \rangle$. The induced norm is $\|\mathbf{u}\| = \sqrt{\langle \mathbf{u}, \mathbf{u} \rangle}$. No finite-dimensionality is assumed in this section: the results hold verbatim for signals with $\langle x, y \rangle = \int x(t) y^*(t)\, dt$.

Theorem C.5 — Cauchy–Schwarz inequality

For all $\mathbf{u}, \mathbf{v}$ in an inner-product space,

$$|\langle \mathbf{u}, \mathbf{v} \rangle| \le \|\mathbf{u}\| \, \|\mathbf{v}\|,$$

with equality if and only if $\mathbf{u}$ and $\mathbf{v}$ are linearly dependent (one is a scalar multiple of the other).

Theorem C.6 — Triangle inequality

For all $\mathbf{u}, \mathbf{v}$, $\|\mathbf{u} + \mathbf{v}\| \le \|\mathbf{u}\| + \|\mathbf{v}\|$, with equality if and only if one vector is a non-negative real multiple of the other. Consequently the induced norm is a norm, and $d(\mathbf{u}, \mathbf{v}) = \|\mathbf{u} - \mathbf{v}\|$ is a distance.

Proof of Theorem C.5

If $\mathbf{v} = \mathbf{0}$ both sides are 0 (since $\langle \mathbf{u}, \mathbf{0} \rangle = \langle \mathbf{u}, 0 \cdot \mathbf{0} \rangle = 0$) and the vectors are dependent, so the claim holds. Assume $\mathbf{v} \neq \mathbf{0}$. For any scalar s, positivity gives

$$0 \le \|\mathbf{u} - s\mathbf{v}\|^2 = \langle \mathbf{u} - s\mathbf{v}, \mathbf{u} - s\mathbf{v} \rangle = \|\mathbf{u}\|^2 - s^* \langle \mathbf{u}, \mathbf{v} \rangle - s \langle \mathbf{v}, \mathbf{u} \rangle + |s|^2 \|\mathbf{v}\|^2,$$

where we expanded using linearity in the first slot and conjugate-linearity in the second. Choose $s = \langle \mathbf{u}, \mathbf{v} \rangle / \|\mathbf{v}\|^2$, the coefficient of the projection of $\mathbf{u}$ onto $\mathbf{v}$. Writing $c = \langle \mathbf{u}, \mathbf{v} \rangle$, so that $\langle \mathbf{v}, \mathbf{u} \rangle = c^*$, the three last terms are

$$s^* c = \frac{c^* c}{\|\mathbf{v}\|^2}, \qquad s\, c^* = \frac{c\, c^*}{\|\mathbf{v}\|^2}, \qquad |s|^2 \|\mathbf{v}\|^2 = \frac{|c|^2}{\|\mathbf{v}\|^2},$$

so

$$0 \le \|\mathbf{u} - s\mathbf{v}\|^2 = \|\mathbf{u}\|^2 - \frac{|\langle \mathbf{u}, \mathbf{v}\rangle|^2}{\|\mathbf{v}\|^2}.$$

Multiplying by $\|\mathbf{v}\|^2 > 0$ and taking square roots gives the inequality.

Equality. With $\mathbf{v} \neq \mathbf{0}$, equality holds iff $\|\mathbf{u} - s\mathbf{v}\| = 0$, i.e. (by positivity) $\mathbf{u} = s\mathbf{v}$. Conversely, if $\mathbf{u} = a\mathbf{v}$ then $|\langle \mathbf{u}, \mathbf{v}\rangle| = |a|\|\mathbf{v}\|^2 = \|\mathbf{u}\|\|\mathbf{v}\|$. ■

Proof of Theorem C.6

Expand:

$$\|\mathbf{u} + \mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \langle \mathbf{u}, \mathbf{v}\rangle + \langle \mathbf{v}, \mathbf{u}\rangle + \|\mathbf{v}\|^2 = \|\mathbf{u}\|^2 + 2\,\mathrm{Re}\{\langle \mathbf{u}, \mathbf{v}\rangle\} + \|\mathbf{v}\|^2,$$

since $z + z^* = 2\,\mathrm{Re}\{z\}$. Now $\mathrm{Re}\{z\} \le |z|$ and Cauchy–Schwarz give

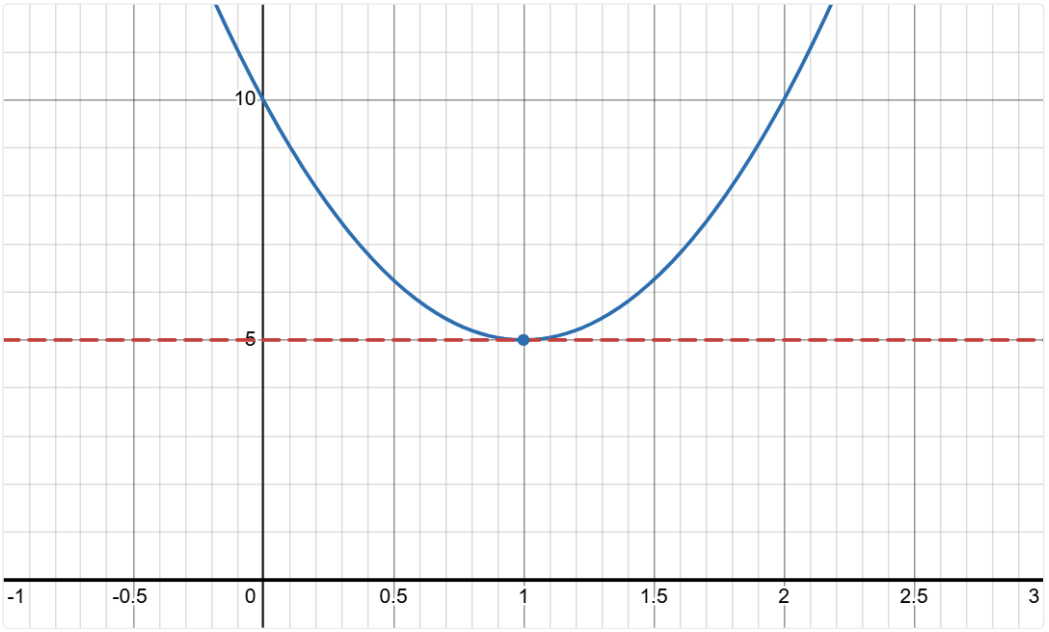
$$\|\mathbf{u} + \mathbf{v}\|^2 \le \|\mathbf{u}\|^2 + 2\|\mathbf{u}\|\|\mathbf{v}\| + \|\mathbf{v}\|^2 = \big(\|\mathbf{u}\| + \|\mathbf{v}\|\big)^2.$$

Take square roots (both sides are non-negative).

Equality requires equality in both steps: $\mathrm{Re}\{\langle \mathbf{u}, \mathbf{v}\rangle\} = |\langle \mathbf{u}, \mathbf{v}\rangle|$, i.e. $\langle \mathbf{u}, \mathbf{v}\rangle$ is real and ≥ 0, and dependence. If $\mathbf{v} \neq \mathbf{0}$ then $\mathbf{u} = a\mathbf{v}$ and $\langle \mathbf{u}, \mathbf{v}\rangle = a\|\mathbf{v}\|^2 \ge 0$ forces $a \ge 0$; the case $\mathbf{v} = \mathbf{0}$ is trivial. Conversely $\mathbf{u} = a\mathbf{v}$, $a \ge 0$, gives $\|(1 + a)\mathbf{v}\| = (1 + a)\|\mathbf{v}\|$.

Norm axioms. $\|\mathbf{u}\| \ge 0$ with equality only at $\mathbf{0}$ is positivity; $\|a\mathbf{u}\| = \sqrt{aa^*\langle \mathbf{u}, \mathbf{u}\rangle} = |a|\|\mathbf{u}\|$; the triangle inequality was just proved. For the distance, symmetry is $\|-\mathbf{w}\| = \|\mathbf{w}\|$ and the triangle inequality for d is Theorem C.6 applied to $(\mathbf{u} - \mathbf{w}) + (\mathbf{w} - \mathbf{v})$. ■

The proof is easiest to see in the real case, where $q(t) = \|\mathbf{u} - t\mathbf{v}\|^2 = \|\mathbf{u}\|^2 - 2t\langle \mathbf{u}, \mathbf{v}\rangle + t^2\|\mathbf{v}\|^2$ is a parabola that never goes below zero, so its discriminant $4\langle \mathbf{u}, \mathbf{v}\rangle^2 - 4\|\mathbf{u}\|^2\|\mathbf{v}\|^2$ is ≤ 0. For $\mathbf{u} = (3, 1)$, $\mathbf{v} = (1, 2)$: $\|\mathbf{u}\|^2 = 10$, $\langle \mathbf{u}, \mathbf{v}\rangle = 5$, $\|\mathbf{v}\|^2 = 5$, so $q(t) = 10 - 10t + 5t^2$ with minimum $q(1) = 5 = 10 - 5^2/5$.



The real Cauchy–Schwarz parabola $q(t) = \|\mathbf{u} - t\mathbf{v}\|^2$ for $\mathbf{u} = (3, 1)$, $\mathbf{v} = (1, 2)$: it stays above the axis, its minimum value is the squared distance from $\mathbf{u}$ to the line through $\mathbf{v}$, and it touches zero only when $\mathbf{u}$ is a multiple of $\mathbf{v}$.

Remarks

- **Positivity is the whole proof.** For an indefinite "inner product" such as the Minkowski form $\langle \mathbf{u}, \mathbf{v}\rangle = u_1v_1 - u_2v_2$ on $\mathbb{R}^2$, Cauchy–Schwarz fails: $\mathbf{u} = (1, 0)$, $\mathbf{v} = (1, 1)$ give $|\langle \mathbf{u}, \mathbf{v}\rangle| = 1$ but $\langle \mathbf{v}, \mathbf{v}\rangle = 0$. Positive *semi*-definiteness is enough for the inequality (the proof goes through after a limiting argument) but not for the equality case.
- **The conjugate is essential in the complex case.** Without it, $\langle (1, j), (1, j)\rangle = 1 + j^2 = 0$ and positivity fails (§9.8).
- **Uses.** Cauchy–Schwarz defines angles, $\cos\theta = \langle \mathbf{u}, \mathbf{v}\rangle/(\|\mathbf{u}\|\|\mathbf{v}\|) \in [-1, 1]$ (§9.7); it proves the **matched filter** is optimal, because the output SNR is proportional to $|\langle s, h\rangle|^2/\|h\|^2 \le \|s\|^2$ with equality iff $h \propto s$ (§9.8, Ch. 21); and it gives $|\rho_{XY}| \le 1$ for the correlation coefficient, with $\langle X, Y\rangle = E[XY]$ on zero-mean random variables (Ch. 19). The triangle inequality is what makes $\|\cdot\|$ usable as an error measure everywhere in Part VII.

C.5 Gram–Schmidt orthonormalisation and the QR factorisation

Theorem C.7 — Gram–Schmidt

Let $\mathbf{a}_1, \dots, \mathbf{a}_n$ be linearly independent vectors in an inner-product space. Define recursively, for $k = 1, \dots, n$,

$$\mathbf{w}_k = \mathbf{a}_k - \sum_{i=1}^{k-1} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \, \mathbf{q}_i, \qquad \mathbf{q}_k = \frac{\mathbf{w}_k}{\|\mathbf{w}_k\|}.$$

Then every $\mathbf{w}_k \neq \mathbf{0}$ (so the division is legitimate), the vectors $\mathbf{q}_1, \dots, \mathbf{q}_n$ are orthonormal, and for every k

$$\operatorname{span}\{\mathbf{q}_1, \dots, \mathbf{q}_k\} = \operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_k\}.$$

In particular every finite-dimensional inner-product space has an orthonormal basis, and every orthonormal set in it extends to an orthonormal basis.

Theorem C.8 — QR factorisation

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ have linearly independent columns ($m \geq n$, $\operatorname{rank} \mathbf{A} = n$). Then $\mathbf{A} = \mathbf{Q}\mathbf{R}$ where $\mathbf{Q} \in \mathbb{R}^{m \times n}$ has orthonormal columns ($\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}_n$) and $\mathbf{R} \in \mathbb{R}^{n \times n}$ is upper triangular with positive diagonal. This factorisation is unique. There is also a **full** QR factorisation $\mathbf{A} = \widetilde{\mathbf{Q}} \begin{bmatrix} \mathbf{R} \\ \mathbf{0} \end{bmatrix}$ with $\widetilde{\mathbf{Q}}$ $m \times m$ orthogonal.

(Complex case: $\mathsf{T} \to \mathsf{H}$, orthogonal $\to$ unitary.)

Proof of Theorem C.7

Induction on k, with the statement S_k: "$\mathbf{w}_1, \dots, \mathbf{w}_k \neq \mathbf{0}$, $\mathbf{q}_1, \dots, \mathbf{q}_k$ are orthonormal, and $\operatorname{span}\{\mathbf{q}_1, \dots, \mathbf{q}_j\} = \operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_j\}$ for $j \leq k$".

Base. $\mathbf{w}_1 = \mathbf{a}_1 \neq \mathbf{0}$, since an independent set contains no zero vector. $\mathbf{q}_1$ is a unit vector and spans the same line as $\mathbf{a}_1$.

Step. Assume S_{k-1}.

1. $\mathbf{w}_k \neq \mathbf{0}$. If $\mathbf{w}_k = \mathbf{0}$, then $\mathbf{a}_k = \sum_{i<k} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \mathbf{q}_i \in \operatorname{span}\{\mathbf{q}_1, \dots, \mathbf{q}_{k-1}\} = \operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_{k-1}\}$, contradicting independence of the $\mathbf{a}$'s.
2. **Orthogonality.** For $l < k$, using linearity in the first slot and $\langle \mathbf{q}_i, \mathbf{q}_l \rangle = \delta_{il}$ for $i, l < k$,

$$\langle \mathbf{w}_k, \mathbf{q}_l \rangle = \langle \mathbf{a}_k, \mathbf{q}_l \rangle - \sum_{i<k} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \langle \mathbf{q}_i, \mathbf{q}_l \rangle = \langle \mathbf{a}_k, \mathbf{q}_l \rangle - \langle \mathbf{a}_k, \mathbf{q}_l \rangle = 0.$$

Dividing by the positive real $\|\mathbf{w}_k\|$ keeps this, and makes $\|\mathbf{q}_k\| = 1$. 3. **Spans.** By the defining formula $\mathbf{q}_k$ is a combination of $\mathbf{a}_k$ and $\mathbf{q}_1, \dots, \mathbf{q}_{k-1}$, which lie in $\operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_{k-1}\}$; so $\operatorname{span}\{\mathbf{q}_1, \dots, \mathbf{q}_k\} \subseteq \operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_k\}$. Conversely $\mathbf{a}_k = \|\mathbf{w}_k\| \mathbf{q}_k + \sum_{i<k} \langle \mathbf{a}_k, \mathbf{q}_i \rangle \mathbf{q}_i$ lies in the left-hand span. Both spans are therefore equal.

This proves S_n. For the final assertions: apply the process to any basis of the space; and to extend an orthonormal set $\mathbf{q}_1, \dots, \mathbf{q}_p$, extend it to a basis $\mathbf{q}_1, \dots, \mathbf{q}_p, \mathbf{a}_{p+1}, \dots, \mathbf{a}_N$ and run the process — it leaves the first p vectors unchanged, because for orthonormal input $\mathbf{w}_k = \mathbf{q}_k$. $\blacksquare$

Proof of Theorem C.8

Existence. Run Gram–Schmidt on the columns $\mathbf{a}_1, \dots, \mathbf{a}_n$ with the standard inner product. Rearranging the definition of $\mathbf{w}_k$,

$$\mathbf{a}_k = \sum_{i=1}^{k-1} r_{ik} \mathbf{q}_i + r_{kk} \mathbf{q}_k, \qquad r_{ik} = \langle \mathbf{a}_k, \mathbf{q}_i \rangle = \mathbf{q}_i^{\mathsf{T}} \mathbf{a}_k \ (i < k), \qquad r_{kk} = \|\mathbf{w}_k\| > 0.$$

Setting $r_{ik} = 0$ for $i > k$, this says column k of $\mathbf{A}$ is column k of $\mathbf{Q}\mathbf{R}$, with $\mathbf{Q} = [\mathbf{q}_1, \dots, \mathbf{q}_n]$ and $\mathbf{R} = [r_{ik}]$ upper triangular with positive diagonal. Orthonormality of the $\mathbf{q}_i$ is $\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}$.

Uniqueness. Suppose $\mathbf{Q}_1\mathbf{R}_1 = \mathbf{Q}_2\mathbf{R}_2$ are two such factorisations. Both $\mathbf{R}_i$ are invertible (positive diagonal). Then $\mathbf{Q}_1 = \mathbf{Q}_2\mathbf{M}$ with $\mathbf{M} = \mathbf{R}_2\mathbf{R}_1^{-1}$ upper triangular with positive diagonal. Also

$$\mathbf{I} = \mathbf{Q}_1^{\mathsf{T}}\mathbf{Q}_1 = \mathbf{M}^{\mathsf{T}}\mathbf{Q}_2^{\mathsf{T}}\mathbf{Q}_2\mathbf{M} = \mathbf{M}^{\mathsf{T}}\mathbf{M},$$

so $\mathbf{M}^{-1} = \mathbf{M}^{\mathsf{T}}$. The left side is upper triangular and the right side lower triangular, so $\mathbf{M}$ is diagonal; then $\mathbf{M}^2 = \mathbf{I}$ with positive diagonal forces $\mathbf{M} = \mathbf{I}$. Hence $\mathbf{R}_1 = \mathbf{R}_2$ and $\mathbf{Q}_1 = \mathbf{Q}_2$.

Full QR. Extend $\mathbf{q}_1, \dots, \mathbf{q}_n$ to an orthonormal basis $\mathbf{q}_1, \dots, \mathbf{q}_m$ of $\mathbb{R}^m$ (Theorem C.7) and put $\widetilde{\mathbf{Q}} = [\mathbf{q}_1, \dots, \mathbf{q}_m]$; the extra columns multiply the zero block. $\blacksquare$

Check. For $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}$: $\mathbf{q}_1 = (1,1,0)/\sqrt{2}$, $r_{11} = \sqrt{2}$; $r_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = 1/\sqrt{2}$; $\mathbf{w}_2 = (1,0,1) - \tfrac{1}{2}(1,1,0) = (\tfrac{1}{2}, -\tfrac{1}{2}, 1)$, $r_{22} = \sqrt{3/2} = 1.2247$. A library QR returns the same $|r_{ik}|$, with signs flipped where it does not enforce a positive diagonal.

Remarks

- **Independence is necessary.** If $\mathbf{a}_k \in \operatorname{span}\{\mathbf{a}_1, \dots, \mathbf{a}_{k-1}\}$ the process produces $\mathbf{w}_k = \mathbf{0}$ and stops. A rank-deficient $\mathbf{A}$ still has a factorisation $\mathbf{A} = \mathbf{Q}\mathbf{R}$ (skip such columns, or use column pivoting, $\mathbf{A}\mathbf{\Pi} = \mathbf{Q}\mathbf{R}$), but $\mathbf{R}$ then has zero diagonal entries and uniqueness is lost.
- **Exact versus floating-point.** The theorem is about exact arithmetic. In floating point, classical Gram–Schmidt loses orthogonality roughly in proportion to $\kappa(\mathbf{A})^2$ times the unit round-off; the modified version (subtract each projection from the running vector) and Householder reflections behave far better (§9.10, §24.3). All three produce the same $\mathbf{Q}$ and $\mathbf{R}$ in exact arithmetic, by the uniqueness just proved.

- **Uses.** Orthogonal polynomials (Legendre, Chebyshev) are Gram–Schmidt applied to $1, t, t^2, \dots$ under an integral inner product (§9.10, §22.6). QR is the stable route to least squares (§C.6) and the engine of the QR eigenvalue algorithm. The extension statement is used in the induction step of the spectral theorem (§C.8) and in building $\mathbf{U}$ in the SVD (§C.10).

C.6 The orthogonal projection theorem and least squares

Orthogonal complement and projection

For a subspace W of an inner-product space V, $W^{\perp} = \{\mathbf{z} \in V : \langle \mathbf{z}, \mathbf{w} \rangle = 0 \text{ for all } \mathbf{w} \in W\}$. A vector $\mathbf{p} \in W$ with $\mathbf{b} - \mathbf{p} \in W^{\perp}$ is called an **orthogonal projection** of $\mathbf{b}$ onto W.

Theorem C.9 — Orthogonal projection theorem

Let W be a **finite-dimensional** subspace of an inner-product space V, and $\mathbf{b} \in V$. Then:

1. $\mathbf{b}$ has exactly one orthogonal projection $\mathbf{p}$ onto W; if $\mathbf{q}_1, \dots, \mathbf{q}_k$ is an orthonormal basis of W,
$$\mathbf{p} = \sum_{i=1}^{k} \langle \mathbf{b}, \mathbf{q}_i \rangle \, \mathbf{q}_i;$$
2. $\mathbf{p}$ is the unique closest point of W to $\mathbf{b}$: for every $\mathbf{w} \in W$,
$$\|\mathbf{b} - \mathbf{w}\|^2 = \|\mathbf{b} - \mathbf{p}\|^2 + \|\mathbf{p} - \mathbf{w}\|^2;$$
3. (Bessel) $\|\mathbf{p}\|^2 = \sum_i |\langle \mathbf{b}, \mathbf{q}_i \rangle|^2 \le \|\mathbf{b}\|^2$.

Theorem C.10 — Normal equations

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^m$. A vector $\hat{\mathbf{x}}$ minimises $J(\mathbf{x}) = \|\mathbf{b} - \mathbf{A}\mathbf{x}\|^2$ if and only if
$$\mathbf{A}^{\mathsf{T}}\mathbf{A}\,\hat{\mathbf{x}} = \mathbf{A}^{\mathsf{T}}\mathbf{b}.$$
The normal equations are always consistent, $\mathbf{A}\hat{\mathbf{x}}$ is the same vector (the projection of $\mathbf{b}$ onto $\operatorname{col}\mathbf{A}$) for every minimiser, and the minimiser is **unique if and only if** $\operatorname{rank}\mathbf{A} = n$ (independent columns), in which case $\hat{\mathbf{x}} = (\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{b} = \mathbf{R}^{-1}\mathbf{Q}^{\mathsf{T}}\mathbf{b}$ with $\mathbf{A} = \mathbf{Q}\mathbf{R}$. (Complex case: $\mathsf{T} \to \mathsf{H}$.)

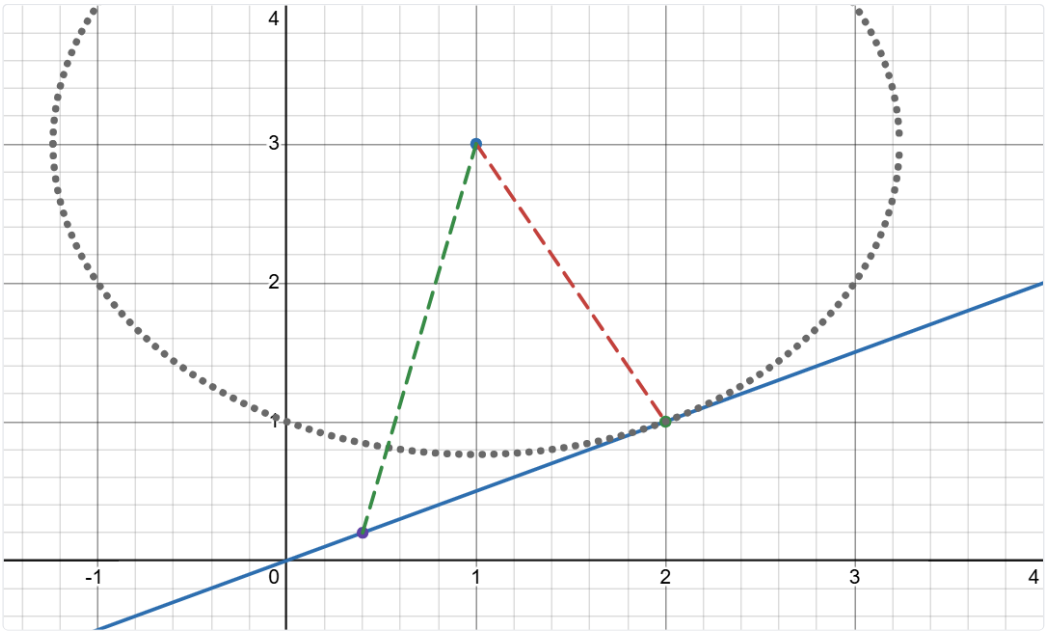
Proof of Theorem C.9

Existence. W has an orthonormal basis $\mathbf{q}_1, \dots, \mathbf{q}_k$ by Theorem C.7. Define $\mathbf{p}$ by the formula. It lies in W, and for each l
$$\langle \mathbf{b} - \mathbf{p}, \mathbf{q}_l \rangle = \langle \mathbf{b}, \mathbf{q}_l \rangle - \sum_i \langle \mathbf{b}, \mathbf{q}_i \rangle \langle \mathbf{q}_i, \mathbf{q}_l \rangle = 0.$$
An arbitrary $\mathbf{w} \in W$ is $\sum_l c_l \mathbf{q}_l$, and $\langle \mathbf{b} - \mathbf{p}, \mathbf{w} \rangle = \sum_l c_l^{*} \langle \mathbf{b} - \mathbf{p}, \mathbf{q}_l \rangle = 0$. So $\mathbf{b} - \mathbf{p} \in W^{\perp}$.

Uniqueness. If $\mathbf{p}, \mathbf{p}'$ are both orthogonal projections, then $\mathbf{p} - \mathbf{p}' = (\mathbf{b} - \mathbf{p}') - (\mathbf{b} - \mathbf{p})$ lies in W (difference of two elements of W) and in $W^{\perp}$ (difference of two elements of the subspace $W^{\perp}$). A vector orthogonal to itself has $\|\mathbf{p} - \mathbf{p}'\|^2 = 0$, so $\mathbf{p} = \mathbf{p}'$.

Best approximation. For $\mathbf{w} \in W$, write $\mathbf{b} - \mathbf{w} = (\mathbf{b} - \mathbf{p}) + (\mathbf{p} - \mathbf{w})$. The first summand is in $W^{\perp}$ and the second in W, so their inner products vanish and the expansion of $\|\mathbf{b} - \mathbf{w}\|^2$ (as in the proof of C.6) reduces to Pythagoras:
$$\|\mathbf{b} - \mathbf{w}\|^2 = \|\mathbf{b} - \mathbf{p}\|^2 + \|\mathbf{p} - \mathbf{w}\|^2 \;\ge\; \|\mathbf{b} - \mathbf{p}\|^2,$$
with equality iff $\|\mathbf{p} - \mathbf{w}\| = 0$, i.e. $\mathbf{w} = \mathbf{p}$.

Bessel. Pythagoras for orthonormal vectors gives $\|\mathbf{p}\|^2 = \sum_i |\langle \mathbf{b}, \mathbf{q}_i \rangle|^2$, and the identity above with $\mathbf{w} = \mathbf{0}$ gives $\|\mathbf{b}\|^2 = \|\mathbf{b} - \mathbf{p}\|^2 + \|\mathbf{p}\|^2 \ge \|\mathbf{p}\|^2$. ∎



Projection of $\mathbf{b} = (1, 3)$ onto the line W spanned by $(2, 1)$: $\mathbf{p} = \frac{5}{5}(2, 1) = (2, 1)$ and the residual $(-1, 2)$ is perpendicular to W. The circle of radius $\|\mathbf{b} - \mathbf{p}\| = \sqrt{5}$ about $\mathbf{b}$ touches W only at $\mathbf{p}$, so any other point $\mathbf{w}$ of W (green segment) is farther away — Pythagoras in picture form.

Proof of Theorem C.10

Let $W = \operatorname{col}\mathbf{A} = \{\mathbf{A}\mathbf{x} : \mathbf{x} \in \mathbb{R}^n\}$, a subspace of $\mathbb{R}^m$ of dimension $\le n$. By Theorem C.9 there is a unique $\mathbf{p} \in W$ minimising $\|\mathbf{b} - \mathbf{w}\|$ over $\mathbf{w} \in W$. Since $J(\mathbf{x}) = \|\mathbf{b} - \mathbf{A}\mathbf{x}\|^2$ and $\mathbf{A}\mathbf{x}$ ranges over exactly W, $\hat{\mathbf{x}}$ minimises J iff $\mathbf{A}\hat{\mathbf{x}} = \mathbf{p}$. By part 1 of C.9 (uniqueness of the orthogonal projection), this holds iff $\mathbf{b} - \mathbf{A}\hat{\mathbf{x}} \perp W$, i.e. iff $\langle \mathbf{b} - \mathbf{A}\hat{\mathbf{x}}, \mathbf{a}_j \rangle = 0$ for each column $\mathbf{a}_j$ (orthogonality to a spanning set suffices, by linearity). Stacking these n conditions,

$$\mathbf{A}^{\mathsf{T}}(\mathbf{b} - \mathbf{A}\hat{\mathbf{x}}) = \mathbf{0} \iff \mathbf{A}^{\mathsf{T}}\mathbf{A}\hat{\mathbf{x}} = \mathbf{A}^{\mathsf{T}}\mathbf{b}.$$

Consistency. $\mathbf{p} \in W$, so $\mathbf{p} = \mathbf{A}\mathbf{x}_0$ for some $\mathbf{x}_0$, which then solves the normal equations. All minimisers share $\mathbf{A}\hat{\mathbf{x}} = \mathbf{p}$.

Uniqueness criterion. First, $\operatorname{null}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \operatorname{null}\mathbf{A}$: clearly $\mathbf{A}\mathbf{x} = \mathbf{0} \Rightarrow \mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{0}$; conversely $\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{0}$ implies $0 = \mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2$, so $\mathbf{A}\mathbf{x} = \mathbf{0}$. The solution set of the consistent system $\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{A}^{\mathsf{T}}\mathbf{b}$ is $\mathbf{x}_0 + \operatorname{null}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \mathbf{x}_0 + \operatorname{null}\mathbf{A}$. It is a single point iff $\operatorname{null}\mathbf{A} = \{\mathbf{0}\}$, i.e. by rank–nullity (C.2) iff $\operatorname{rank}\mathbf{A} = n$. In that case the $n \times n$ matrix $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ has trivial null space, hence is invertible, and $\hat{\mathbf{x}} = (\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{b}$.

QR form. With $\mathbf{A} = \mathbf{Q}\mathbf{R}$ (Theorem C.8), $\mathbf{A}^{\mathsf{T}}\mathbf{A} = \mathbf{R}^{\mathsf{T}}\mathbf{R}$ and $\mathbf{A}^{\mathsf{T}}\mathbf{b} = \mathbf{R}^{\mathsf{T}}\mathbf{Q}^{\mathsf{T}}\mathbf{b}$; cancelling the invertible $\mathbf{R}^{\mathsf{T}}$ gives $\mathbf{R}\hat{\mathbf{x}} = \mathbf{Q}^{\mathsf{T}}\mathbf{b}$. $\blacksquare$

Check. Fitting $y = c_0 + c_1 x$ to $(0,1), (1,2), (2,2), (3,4)$: $\mathbf{A}^{\mathsf{T}}\mathbf{A} = \begin{bmatrix} 4 & 6 \\ 6 & 14 \end{bmatrix}$, $\mathbf{A}^{\mathsf{T}}\mathbf{b} = (9, 18)^{\mathsf{T}}$, so $c_0 = c_1 = 0.9$. The residual $(0.1,\ 0.2,\ -0.7,\ 0.4)$ sums to zero and has zero inner product with $(0, 1, 2, 3)$: it is orthogonal to both columns, exactly as the proof requires.

Remarks

- **Finite dimension of W (or completeness) is needed.** In the space of continuous functions on $[-1, 1]$ with $\langle f, g \rangle = \int fg$, the subspace W of polynomials is infinite-dimensional and dense, so a non-polynomial b such as $|t|$ has no closest polynomial: every $\varepsilon > 0$ is beaten by some polynomial, but 0 is not attained. In Hilbert spaces the theorem holds for every *closed* subspace; that is the setting of Fourier series (Ch. 15), where Bessel's inequality becomes Parseval's identity for a complete orthonormal set.
- **Rank deficiency.** If $\operatorname{rank}\mathbf{A} < n$ the fitted values $\mathbf{A}\hat{\mathbf{x}}$ are still unique but the parameters are not; the conventional choice is the minimum-norm solution $\mathbf{A}^{+}\mathbf{b}$ given by the SVD (§10.7). In parameter estimation this is non-identifiability (§24.7).
- **Normal equations square the condition number.** $\kappa_2(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \kappa_2(\mathbf{A})^2$ (from the SVD, §C.10), which is why QR or SVD is preferred numerically (§23.8, §24.3).
- **The projector.** With full column rank, $\mathbf{P} = \mathbf{A}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}} = \mathbf{Q}\mathbf{Q}^{\mathsf{T}}$ satisfies $\mathbf{P}^2 = \mathbf{P} = \mathbf{P}^{\mathsf{T}}$; conversely any symmetric idempotent matrix is the orthogonal projector onto its column space.
- **Uses.** Least-squares curve fitting and calibration (§9.11, §22.6), linear regression (Ch. 20), the orthogonality principle of Wiener filtering (Ch. 21), and Gauss–Newton steps (§24.7).

C.7 Independence of eigenvectors and diagonalizability

Eigenpairs, multiplicities, diagonalizability

$\lambda \in \mathbb{C}$ is an **eigenvalue** of $\mathbf{A} \in \mathbb{C}^{n \times n}$ with **eigenvector** $\mathbf{v} \neq \mathbf{0}$ if $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$; equivalently (Theorem C.1) $\det(\lambda\mathbf{I} - \mathbf{A}) = 0$. The **algebraic multiplicity** $a(\lambda)$ is the multiplicity of λ as a root of the characteristic polynomial $p(s) = \det(s\mathbf{I} - \mathbf{A})$; the **geometric multiplicity** $g(\lambda) = \dim\operatorname{null}(\mathbf{A} - \lambda\mathbf{I})$. $\mathbf{A}$ is **diagonalizable** if $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$ for some invertible $\mathbf{V}$ and diagonal $\mathbf{\Lambda}$.

Theorem C.11 — Eigenvectors for distinct eigenvalues are independent

If $\mathbf{v}_1, \dots, \mathbf{v}_k$ are eigenvectors of $\mathbf{A}$ for **pairwise distinct** eigenvalues $\lambda_1, \dots, \lambda_k$, then $\mathbf{v}_1, \dots, \mathbf{v}_k$ are linearly independent. More generally, if for each distinct eigenvalue λ_i we take a basis of its eigenspace, the union of these bases is independent.

Theorem C.12 — Diagonalizability

For $\mathbf{A} \in \mathbb{C}^{n\times n}$:

1. $\mathbf{A}$ is diagonalizable if and only if it has n linearly independent eigenvectors; then the columns of $\mathbf{V}$ are such eigenvectors and $\mathbf{\Lambda}$ holds the corresponding eigenvalues.
2. $1 \le g(\lambda) \le a(\lambda)$ for every eigenvalue, and $\mathbf{A}$ is diagonalizable iff $g(\lambda) = a(\lambda)$ for every eigenvalue.
3. In particular, if $\mathbf{A}$ has n distinct eigenvalues, it is diagonalizable.

Proof of Theorem C.11

Suppose not, and among all dependent sets of eigenvectors with distinct eigenvalues choose one with the fewest vectors, $\mathbf{v}_1, \dots, \mathbf{v}_k$; then $k \ge 2$ (a single eigenvector is non-zero, hence independent), and there is a relation

$$c_1\mathbf{v}_1 + \cdots + c_k\mathbf{v}_k = \mathbf{0}$$

in which every $c_i \neq 0$ — if some c_i were zero, the remaining $k-1$ vectors would be a smaller dependent set. Apply $\mathbf{A}$, and separately multiply by λ_k:

$$c_1\lambda_1\mathbf{v}_1 + \cdots + c_k\lambda_k\mathbf{v}_k = \mathbf{0}, \qquad c_1\lambda_k\mathbf{v}_1 + \cdots + c_k\lambda_k\mathbf{v}_k = \mathbf{0}.$$

Subtracting eliminates $\mathbf{v}_k$:

$$c_1(\lambda_1 - \lambda_k)\mathbf{v}_1 + \cdots + c_{k-1}(\lambda_{k-1} - \lambda_k)\mathbf{v}_{k-1} = \mathbf{0}.$$

The coefficients $c_i(\lambda_i - \lambda_k)$ are non-zero because $c_i \neq 0$ and the eigenvalues are distinct. So $\mathbf{v}_1, \dots, \mathbf{v}_{k-1}$ is a smaller dependent set, a contradiction.

General form. Let $\mathcal{B}_i$ be a basis of the eigenspace $E_i = \operatorname{null}(\mathbf{A} - \lambda_i\mathbf{I})$ and suppose a combination of all the vectors in $\bigcup_i \mathcal{B}_i$ vanishes. Grouping terms by eigenvalue, it reads $\mathbf{z}_1 + \cdots + \mathbf{z}_k = \mathbf{0}$ with $\mathbf{z}_i \in E_i$. Those $\mathbf{z}_i$ that are non-zero are eigenvectors for distinct eigenvalues summing to zero, which the first part forbids; so every $\mathbf{z}_i = \mathbf{0}$. Each $\mathbf{z}_i$ is a combination of the independent set $\mathcal{B}_i$, so all its coefficients vanish. ■

Proof of Theorem C.12

Part 1. Write $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_n]$ and $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$. Column j of $\mathbf{AV}$ is $\mathbf{A}\mathbf{v}_j$ and column j of $\mathbf{V\Lambda}$ is $\lambda_j\mathbf{v}_j$, so

$$\mathbf{AV} = \mathbf{V\Lambda} \iff \mathbf{A}\mathbf{v}_j = \lambda_j\mathbf{v}_j \ \text{ for all } j.$$

If the $\mathbf{v}_j$ are n independent eigenvectors, $\mathbf{V}$ is invertible (Theorem C.1, Step 7 and rank–nullity) and $\mathbf{A} = \mathbf{V\Lambda V}^{-1}$. Conversely, if $\mathbf{A} = \mathbf{V\Lambda V}^{-1}$ then $\mathbf{AV} = \mathbf{V\Lambda}$, so the columns of $\mathbf{V}$ — non-zero and independent because $\mathbf{V}$ is invertible — are eigenvectors.

Part 2. $g(\lambda) \ge 1$ because $\mathbf{A} - \lambda\mathbf{I}$ is singular. Let $g = g(\lambda)$, choose a basis $\mathbf{v}_1, \dots, \mathbf{v}_g$ of the eigenspace, extend it to a basis of $\mathbb{C}^n$ and let $\mathbf{S}$ be the invertible matrix with these columns. Since $\mathbf{A}\mathbf{v}_i = \lambda\mathbf{v}_i$ for $i \le g$, the first g columns of $\mathbf{S}^{-1}\mathbf{AS}$ are $\lambda\mathbf{e}_1, \dots, \lambda\mathbf{e}_g$:

$$\mathbf{S}^{-1}\mathbf{AS} = \begin{bmatrix} \lambda\mathbf{I}_g & \mathbf{B} \\ \mathbf{0} & \mathbf{C} \end{bmatrix}.$$

Similar matrices have the same characteristic polynomial, by the product rule: $\det(s\mathbf{I} - \mathbf{S}^{-1}\mathbf{AS}) = \det\left(\mathbf{S}^{-1}(s\mathbf{I} - \mathbf{A})\mathbf{S}\right) = \det(s\mathbf{I} - \mathbf{A})$. The determinant of a block upper-triangular matrix is the product of the determinants of its diagonal blocks (expand down the first g columns, or apply the uniqueness lemma of C.1 to the lower block), so

$$p(s) = (s - \lambda)^g \det(s\mathbf{I} - \mathbf{C}),$$

and $(s-\lambda)^g$ divides p: $a(\lambda) \ge g$.

Now let $\mu_1, \dots, \mu_k$ be the distinct eigenvalues. By the fundamental theorem of algebra $p(s) = \prod_i (s - \mu_i)^{a(\mu_i)}$, so $\sum_i a(\mu_i) = n$. By Theorem C.11 the union of eigenspace bases is an independent set of $\sum_i g(\mu_i)$ eigenvectors, and every eigenvector lies in some eigenspace, so the largest number of independent eigenvectors is exactly $\sum_i g(\mu_i)$. Hence, by Part 1,

$$\mathbf{A} \text{ diagonalizable} \iff \sum_i g(\mu_i) = n = \sum_i a(\mu_i) \iff g(\mu_i) = a(\mu_i) \text{ for all } i,$$

the last step because $g(\mu_i) \le a(\mu_i)$ term by term.

Part 3. With n distinct eigenvalues each has $a = 1$, so $1 \le g \le a = 1$ forces $g = a$. (Directly: one eigenvector per eigenvalue gives n independent eigenvectors by C.11.) ■

Remarks

- **Distinctness is sufficient, not necessary.** $\mathbf{I}$ has a single eigenvalue of multiplicity n and is diagonal. Symmetric matrices are always diagonalizable however their eigenvalues repeat (§C.8).
- **The standard counterexample.** $\mathbf{N} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$ has $a(1) = 2$ but $\operatorname{null}(\mathbf{N} - \mathbf{I}) = \operatorname{span}\{\mathbf{e}_1\}$, so $g(1) = 1 < 2$: it is **defective** and not diagonalizable. Its $\dot{\mathbf{x}} = (\mathbf{N} - 2\mathbf{I})\mathbf{x}$ solutions contain te^{-t} — the critically damped RLC response (§12.2).

- **Generic behaviour.** Matrices with a repeated eigenvalue form a set of measure zero (the discriminant of p vanishes), so almost every matrix met in practice is diagonalizable — but *nearly* defective matrices have ill-conditioned eigenvector matrices $\mathbf{V}$, with consequences in §C.12.
- **Field matters.** The rotation $\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}$ has eigenvalues $\pm j$; it is diagonalizable over $\mathbb{C}$ but not over $\mathbb{R}$. The real block form of §10.3 is the real substitute.
- **Uses.** Diagonalization (§10.3), matrix powers and $e^{\mathbf{A}t}$ (§10.4), modal decomposition of coupled circuits and vibrating systems (§10.8, §12.6), and the stability theorem of §C.12.

C.8 The spectral theorem for real symmetric matrices

Theorem C.13 — Spectral theorem

Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be symmetric, $\mathbf{A}^{\mathsf{T}} = \mathbf{A}$. Then

1. every eigenvalue of $\mathbf{A}$ is real, and to each there corresponds a real eigenvector;
2. eigenvectors belonging to distinct eigenvalues are orthogonal;
3. there is an orthogonal matrix $\mathbf{Q}$ ($\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}$) and a real diagonal $\mathbf{\Lambda}$ with

$$\mathbf{A} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}} = \sum_{i=1}^{n} \lambda_i \, \mathbf{q}_i \mathbf{q}_i^{\mathsf{T}}.$$

Equivalently, $\mathbb{R}^n$ has an orthonormal basis of eigenvectors of $\mathbf{A}$. For complex Hermitian $\mathbf{A} = \mathbf{A}^{\mathsf{H}}$ the same holds with a unitary $\mathbf{U}$: $\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^{\mathsf{H}}$, $\mathbf{\Lambda}$ real.

Proof

Part 1: real eigenvalues. By the fundamental theorem of algebra the characteristic polynomial has a root $\lambda \in \mathbb{C}$, with an eigenvector $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{x} \neq \mathbf{0}$. Consider the scalar $\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x}$. Since $\mathbf{A}$ is real and symmetric, $\mathbf{A}^{\mathsf{H}} = \mathbf{A}$, and the conjugate of this 1×1 matrix is its conjugate transpose:

$$(\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x})^{*} = (\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x})^{\mathsf{H}} = \mathbf{x}^{\mathsf{H}}\mathbf{A}^{\mathsf{H}}\mathbf{x} = \mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x},$$

so $\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x}$ is real. But $\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x} = \lambda\,\mathbf{x}^{\mathsf{H}}\mathbf{x} = \lambda\|\mathbf{x}\|^2$ with $\|\mathbf{x}\|^2 > 0$ real. Hence $\lambda = \mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x}/\|\mathbf{x}\|^2$ is real.

Real eigenvector. $\mathbf{A} - \lambda\mathbf{I}$ is now a real matrix with determinant zero. By Theorem C.1 applied over $\mathbb{R}$, it is not invertible as a real matrix, so (Step 7 of that proof, contrapositive) its columns are dependent over $\mathbb{R}$: there is a real $\mathbf{q} \neq \mathbf{0}$ with $(\mathbf{A} - \lambda\mathbf{I})\mathbf{q} = \mathbf{0}$. (Alternatively, write $\mathbf{x} = \mathbf{y} + j\mathbf{z}$ with $\mathbf{y}, \mathbf{z}$ real; since $\mathbf{A}$ and λ are real, $\mathbf{A}\mathbf{y} = \lambda\mathbf{y}$ and $\mathbf{A}\mathbf{z} = \lambda\mathbf{z}$, and $\mathbf{y}, \mathbf{z}$ are not both zero.)

Part 2: orthogonality. Let $\mathbf{A}\mathbf{u} = \lambda\mathbf{u}$, $\mathbf{A}\mathbf{v} = \mu\mathbf{v}$ with real $\lambda \neq \mu$ and real vectors. Using symmetry,

$$\lambda\,\mathbf{v}^{\mathsf{T}}\mathbf{u} = \mathbf{v}^{\mathsf{T}}\mathbf{A}\mathbf{u} = (\mathbf{A}^{\mathsf{T}}\mathbf{v})^{\mathsf{T}}\mathbf{u} = (\mathbf{A}\mathbf{v})^{\mathsf{T}}\mathbf{u} = \mu\,\mathbf{v}^{\mathsf{T}}\mathbf{u},$$

so $(\lambda - \mu)\mathbf{v}^{\mathsf{T}}\mathbf{u} = 0$ and $\mathbf{v}^{\mathsf{T}}\mathbf{u} = 0$.

Part 3: orthogonal diagonalization, by induction on n. For $n = 1$ take $\mathbf{Q} = [1]$. Assume the statement for symmetric matrices of order $n-1$, and let $\mathbf{A}$ be symmetric of order n.

Step (a): split off one eigenvector. By Part 1 there is a real eigenvalue λ_1 with a real eigenvector, which we normalise to $\|\mathbf{q}_1\| = 1$. By Theorem C.7 extend $\mathbf{q}_1$ to an orthonormal basis $\mathbf{q}_1, \mathbf{p}_2, \dots, \mathbf{p}_n$ of $\mathbb{R}^n$, and set $\mathbf{P} = [\mathbf{p}_2, \dots, \mathbf{p}_n]$ ($n \times (n-1)$) and $\mathbf{Q}_1 = [\mathbf{q}_1\ \mathbf{P}]$, an orthogonal matrix.

Step (b): the similarity is block diagonal. Compute

$$\mathbf{Q}_1^{\mathsf{T}}\mathbf{A}\mathbf{Q}_1 = \begin{bmatrix} \mathbf{q}_1^{\mathsf{T}}\mathbf{A}\mathbf{q}_1 & \mathbf{q}_1^{\mathsf{T}}\mathbf{A}\mathbf{P} \\ \mathbf{P}^{\mathsf{T}}\mathbf{A}\mathbf{q}_1 & \mathbf{P}^{\mathsf{T}}\mathbf{A}\mathbf{P} \end{bmatrix}.$$

Here $\mathbf{q}_1^{\mathsf{T}}\mathbf{A}\mathbf{q}_1 = \lambda_1\mathbf{q}_1^{\mathsf{T}}\mathbf{q}_1 = \lambda_1$; $\mathbf{P}^{\mathsf{T}}\mathbf{A}\mathbf{q}_1 = \lambda_1\mathbf{P}^{\mathsf{T}}\mathbf{q}_1 = \mathbf{0}$ because each $\mathbf{p}_i \perp \mathbf{q}_1$; and $\mathbf{q}_1^{\mathsf{T}}\mathbf{A}\mathbf{P} = (\mathbf{P}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{q}_1)^{\mathsf{T}} = (\mathbf{P}^{\mathsf{T}}\mathbf{A}\mathbf{q}_1)^{\mathsf{T}} = \mathbf{0}^{\mathsf{T}}$ — **this is where symmetry is used a second time.** So

$$\mathbf{Q}_1^{\mathsf{T}}\mathbf{A}\mathbf{Q}_1 = \begin{bmatrix} \lambda_1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{B} \end{bmatrix}, \qquad \mathbf{B} = \mathbf{P}^{\mathsf{T}}\mathbf{A}\mathbf{P},$$

and $\mathbf{B}^{\mathsf{T}} = \mathbf{P}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{P} = \mathbf{B}$ is symmetric of order $n-1$.

Step (c): induct. By hypothesis $\mathbf{B} = \mathbf{Q}_2\mathbf{\Lambda}_2\mathbf{Q}_2^{\mathsf{T}}$ with $\mathbf{Q}_2$ orthogonal and $\mathbf{\Lambda}_2$ real diagonal. Put

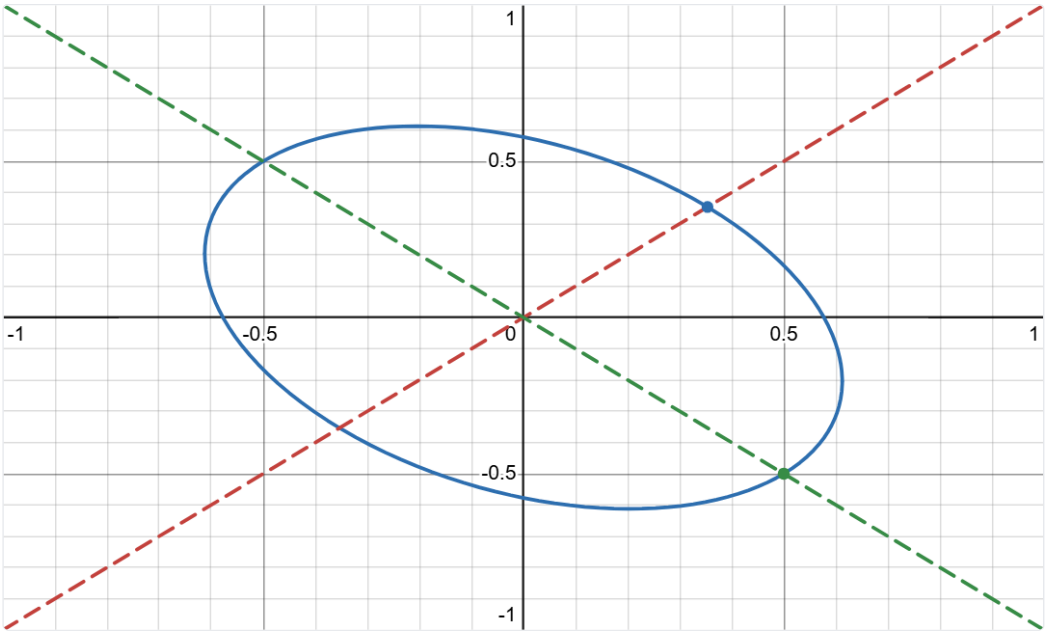
$$\mathbf{Q} = \mathbf{Q}_1 \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{Q}_2 \end{bmatrix}, \qquad \mathbf{\Lambda} = \begin{bmatrix} \lambda_1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{\Lambda}_2 \end{bmatrix}.$$

$\mathbf{Q}$ is a product of orthogonal matrices, hence orthogonal ($(\mathbf{Q}_a\mathbf{Q}_b)^{\mathsf{T}}\mathbf{Q}_a\mathbf{Q}_b = \mathbf{Q}_b^{\mathsf{T}}\mathbf{Q}_b = \mathbf{I}$), and

$$\mathbf{Q}^{\mathsf{T}}\mathbf{A}\mathbf{Q} = \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{Q}_2^{\mathsf{T}} \end{bmatrix} \begin{bmatrix} \lambda_1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{B} \end{bmatrix} \begin{bmatrix} 1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{Q}_2 \end{bmatrix} = \begin{bmatrix} \lambda_1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{Q}_2^{\mathsf{T}}\mathbf{B}\mathbf{Q}_2 \end{bmatrix} = \mathbf{\Lambda}.$$

Hence $\mathbf{A} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}$. Writing the product column by column gives $\mathbf{A} = \sum_i \lambda_i \mathbf{q}_i\mathbf{q}_i^{\mathsf{T}}$, and $\mathbf{A}\mathbf{Q} = \mathbf{Q}\mathbf{\Lambda}$ shows the columns $\mathbf{q}_i$ are orthonormal eigenvectors.

Hermitian case. Replace T by H and "orthogonal" by "unitary" throughout; Part 1 was already proved for $\mathbf{A}^{\mathsf{H}} = \mathbf{A}$, and Gram–Schmidt works in $\mathbb{C}^n$. $\blacksquare$



Level curve $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = 1$ for $\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix}$. The eigenvectors $(1,1)/\sqrt{2}$ (eigenvalue 4) and $(1,-1)/\sqrt{2}$ (eigenvalue 2) are orthogonal and lie along the principal axes, with semi-axes $1/\sqrt{\lambda_i} = 0.5$ and 0.707: in the rotated coordinates $\mathbf{y} = \mathbf{Q}^{\mathsf{T}}\mathbf{x}$ the form is $4y_1^2 + 2y_2^2$, with no cross term.

Remarks

- **Repeated eigenvalues are harmless here.** The induction never assumes distinct eigenvalues: it produces n orthonormal eigenvectors regardless. Contrast Theorem C.12, where distinctness was the easy sufficient condition. Within an eigenspace of dimension > 1 the orthonormal eigenvectors are not unique (any orthonormal basis of the eigenspace will do), but the spectral projectors $\sum_{\lambda_i = \lambda} \mathbf{q}_i \mathbf{q}_i^{\mathsf{T}}$ are.
- **Symmetry is essential, twice.** Without it eigenvalues can be complex ($\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$), eigenvectors can be non-orthogonal ($\begin{bmatrix} 1 & 1 \\ 0 & 2 \end{bmatrix}$ has eigenvectors $(1,0)$ and $(1,1)$), and the matrix can be defective ($\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$). In the induction, symmetry is what kills the top-right block in Step (b); for a general matrix the same construction gives only a block upper-triangular form, which iterated yields the **Schur decomposition** $\mathbf{A} = \mathbf{U}\mathbf{T}\mathbf{U}^{\mathsf{H}}$ with $\mathbf{T}$ upper triangular. A matrix is unitarily diagonalizable iff it is **normal**, $\mathbf{A}\mathbf{A}^{\mathsf{H}} = \mathbf{A}^{\mathsf{H}}\mathbf{A}$.
- **Rayleigh quotient.** From $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \sum \lambda_i y_i^2$ with $\mathbf{y} = \mathbf{Q}^{\mathsf{T}}\mathbf{x}$, $\|\mathbf{y}\| = \|\mathbf{x}\|$, one gets $\lambda_{\min} \le \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}/\mathbf{x}^{\mathsf{T}}\mathbf{x} \le \lambda_{\max}$, with the extremes attained at the corresponding eigenvectors (§10.5).
- **Uses.** Principal axes of quadratic forms and energy functions (§10.5); normal modes of LC networks and mass–spring systems, where $\mathbf{M}^{-1/2}\mathbf{K}\mathbf{M}^{-1/2}$ is symmetric (§10.8); principal component analysis and Karhunen–Loève expansions of covariance matrices (Ch. 20, Ch. 21); the convergence analysis of gradient descent on quadratics (§23.5). It is the foundation of §C.9 and §C.10.

C.9 Characterisations of positive-definite matrices

Positive definite

A real symmetric $\mathbf{A} \in \mathbb{R}^{n \times n}$ is **positive definite** ($\mathbf{A} \succ 0$) if $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$ for every $\mathbf{x} \neq \mathbf{0}$, and **positive semidefinite** ($\mathbf{A} \succeq 0$) if $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} \ge 0$ for every $\mathbf{x}$.

Theorem C.14 — Tests for positive definiteness

For real symmetric $\mathbf{A} \in \mathbb{R}^{n \times n}$ the following are equivalent:

1. (energy) $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$;
2. (eigenvalues) every eigenvalue of $\mathbf{A}$ is positive;
3. (Sylvester's criterion) every leading principal minor is positive: $\Delta_k = \det \mathbf{A}_k > 0$, $k = 1, \dots, n$;
4. (pivots) Gaussian elimination without row interchanges runs to completion with all pivots positive;
5. (Cholesky) $\mathbf{A} = \mathbf{L}\mathbf{L}^{\mathsf{T}}$ with $\mathbf{L}$ lower triangular with positive diagonal entries; this $\mathbf{L}$ is unique;
6. (Gram) $\mathbf{A} = \mathbf{R}^{\mathsf{T}}\mathbf{R}$ for some (possibly rectangular) $\mathbf{R}$ with linearly independent columns.

Proof

We prove $1 \Leftrightarrow 2$, then the cycle $1 \Rightarrow 3 \Rightarrow 4 \Rightarrow 5 \Rightarrow 6 \Rightarrow 1$.

$1 \Leftrightarrow 2$. By Theorem C.13, $\mathbf{A} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}$. Substituting $\mathbf{y} = \mathbf{Q}^{\mathsf{T}}\mathbf{x}$, which is a bijection of $\mathbb{R}^n$ mapping non-zero vectors to non-zero vectors,

$$\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{y}^{\mathsf{T}}\mathbf{\Lambda}\mathbf{y} = \sum_{i=1}^{n} \lambda_i y_i^2.$$

If all $\lambda_i > 0$, this is positive whenever $\mathbf{y} \neq \mathbf{0}$. Conversely, if 1 holds, take $\mathbf{x} = \mathbf{q}_i$ (i.e. $\mathbf{y} = \mathbf{e}_i$): $\lambda_i = \mathbf{q}_i^{\mathsf{T}}\mathbf{A}\mathbf{q}_i > 0$.

$1 \Rightarrow 3$. Fix k. For $\mathbf{z} \in \mathbb{R}^k$, $\mathbf{z} \neq \mathbf{0}$, pad it with $n-k$ zeros to $\mathbf{x} = (\mathbf{z}, \mathbf{0})$; then $\mathbf{z}^{\mathsf{T}}\mathbf{A}_k\mathbf{z} = \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$. So the symmetric matrix $\mathbf{A}_k$ satisfies 1, hence (by $1 \Rightarrow 2$ applied to $\mathbf{A}_k$) has positive eigenvalues $\mu_1, \dots, \mu_k$. By the spectral theorem and the product rule, $\Delta_k = \det(\mathbf{Q}_k\mathbf{M}\mathbf{Q}_k^{\mathsf{T}}) = \det \mathbf{M} = \mu_1 \cdots \mu_k > 0$, where $\det \mathbf{Q}_k \det \mathbf{Q}_k^{\mathsf{T}} = \det(\mathbf{Q}_k\mathbf{Q}_k^{\mathsf{T}}) = 1$.

$3 \Rightarrow 4$. All $\Delta_k \neq 0$, so Theorem C.3 gives $\mathbf{A} = \mathbf{L}_1\mathbf{U}$ (elimination without interchanges succeeds), with pivots $u_{kk} = \Delta_k/\Delta_{k-1} > 0$.

$4 \Rightarrow 5$. Let $\mathbf{A} = \mathbf{L}_1\mathbf{U}$ with $\mathbf{L}_1$ unit lower triangular and pivots $d_k = u_{kk} > 0$. Put $\mathbf{D} = \operatorname{diag}(d_1, \dots, d_n)$ and $\mathbf{U}_1 = \mathbf{D}^{-1}\mathbf{U}$, which is unit upper triangular. Then $\mathbf{A} = \mathbf{L}_1\mathbf{D}\mathbf{U}_1$ and, by symmetry,

$$\mathbf{A} = \mathbf{A}^{\mathsf{T}} = \mathbf{U}_1^{\mathsf{T}}\,(\mathbf{D}\mathbf{L}_1^{\mathsf{T}}).$$

This is a second factorisation of $\mathbf{A}$ into a unit lower triangular matrix $\mathbf{U}_1^{\mathsf{T}}$ and an upper triangular matrix $\mathbf{D}\mathbf{L}_1^{\mathsf{T}}$. Since the pivots are non-zero, $\Delta_k = d_1 \cdots d_k \neq 0$ and Theorem C.3 says the LU factorisation is unique; hence $\mathbf{U}_1^{\mathsf{T}} = \mathbf{L}_1$, i.e.

$$\mathbf{A} = \mathbf{L}_1\mathbf{D}\mathbf{L}_1^{\mathsf{T}}.$$

With $\mathbf{D}^{1/2} = \operatorname{diag}(\sqrt{d_k})$ — real because $d_k > 0$ — set $\mathbf{L} = \mathbf{L}_1\mathbf{D}^{1/2}$: lower triangular with diagonal $\sqrt{d_k} > 0$, and $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{L}_1\mathbf{D}\mathbf{L}_1^{\mathsf{T}} = \mathbf{A}$.

Uniqueness of $\mathbf{L}$. If $\mathbf{L}\mathbf{L}^{\mathsf{T}} = \mathbf{G}\mathbf{G}^{\mathsf{T}}$ with both factors lower triangular with positive diagonal, then $\mathbf{M} = \mathbf{G}^{-1}\mathbf{L} = \mathbf{G}^{\mathsf{T}}\mathbf{L}^{-\mathsf{T}}$. The left expression is lower triangular, the right upper triangular, so $\mathbf{M}$ is diagonal with positive diagonal; and $\mathbf{M}\mathbf{M}^{\mathsf{T}} = \mathbf{G}^{-1}\mathbf{L}\mathbf{L}^{\mathsf{T}}\mathbf{G}^{-\mathsf{T}} = \mathbf{I}$ gives $m_{ii}^2 = 1$, so $\mathbf{M} = \mathbf{I}$ and $\mathbf{L} = \mathbf{G}$.

$5 \Rightarrow 6$. Take $\mathbf{R} = \mathbf{L}^{\mathsf{T}}$; it is triangular with non-zero diagonal, hence invertible, so its columns are independent.

$6 \Rightarrow 1$. $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{x}^{\mathsf{T}}\mathbf{R}^{\mathsf{T}}\mathbf{R}\mathbf{x} = \|\mathbf{R}\mathbf{x}\|^2 \geq 0$, and it vanishes only if $\mathbf{R}\mathbf{x} = \mathbf{0}$, which by independence of the columns of $\mathbf{R}$ means $\mathbf{x} = \mathbf{0}$. ∎

Check. $\mathbf{A} = \begin{bmatrix} 4 & 2 & 0 \\ 2 & 5 & 3 \\ 0 & 3 & 10 \end{bmatrix}$ has $\Delta_1 = 4$, $\Delta_2 = 16$, $\Delta_3 = 124$, so it is positive definite with pivots $4,\ 4,\ 7.75$. The Cholesky factor is $\mathbf{L} = \begin{bmatrix} 2 & 0 & 0 \\ 1 & 2 & 0 \\ 0 & 1.5 & \sqrt{7.75} \end{bmatrix}$ with $\sqrt{7.75} = 2.7839$ (its diagonal is the square roots of the pivots, as the proof predicts), and the eigenvalues $1.941,\ 5.553,\ 11.507$ are indeed all positive with product 124.

Remarks

- **Symmetry is part of the hypothesis.** For non-symmetric $\mathbf{A}$, only the symmetric part $\tfrac{1}{2}(\mathbf{A} + \mathbf{A}^{\mathsf{T}})$ enters $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}$, and the tests come apart: $\begin{bmatrix} 1 & -4 \\ 0 & 1 \end{bmatrix}$ has positive eigenvalues and positive leading minors, yet $\mathbf{x} = (1, 1)$ gives $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = -2$.
- **Semidefinite: leading minors are not enough.** $\mathbf{A} = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}$ has $\Delta_1 = \Delta_2 = 0 \geq 0$ but is negative semidefinite. The correct semidefinite version of Sylvester's criterion requires **all** principal minors (every subset of rows with the same columns) to be ≥ 0; the eigenvalue and Gram tests carry over with $>$ replaced by $\geq$ and "independent columns" dropped. The proof of $3 \Rightarrow 1$ fails exactly because a zero pivot halts elimination.
- **Negative definite** is not "all $\Delta_k < 0$" but alternating signs, $(-1)^k\Delta_k > 0$, from applying the theorem to $-\mathbf{A}$ ($\det(-\mathbf{A}_k) = (-1)^k\Delta_k$).
- **Engineering reading.** For a passive RLC network, the inductance and capacitance matrices are positive definite because stored magnetic and electric energy $\tfrac{1}{2}\mathbf{i}^{\mathsf{T}}\mathbf{L}\mathbf{i}$, $\tfrac{1}{2}\mathbf{v}^{\mathsf{T}}\mathbf{C}\mathbf{v}$ is positive for any non-zero state. Nodal conductance matrices of connected resistive networks with a ground path are positive definite too, which is why Cholesky (half the work of LU, and stable without pivoting) can solve them (§8.9).
- **Uses.** Second-derivative test and convexity: a C^2 function is strictly convex where its Hessian is positive definite (§23.4, §23.7); covariance matrices are positive semidefinite (Ch. 19); the normal-equation matrix $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ is positive definite exactly when $\mathbf{A}$ has full column rank, by test 6 (§C.6); weighted inner products need $\mathbf{W} \succ 0$ (§9.8); Lyapunov stability, $\mathbf{A}^{\mathsf{T}}\mathbf{P} + \mathbf{P}\mathbf{A} \prec 0$ with $\mathbf{P} \succ 0$ (§10.9).

C.10 Existence of the singular value decomposition

Theorem C.15 — Singular value decomposition

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ have rank r. There are orthogonal $\mathbf{U} \in \mathbb{R}^{m \times m}$, $\mathbf{V} \in \mathbb{R}^{n \times n}$ and numbers $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$ such that

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}} = \sum_{i=1}^{r} \sigma_i\, \mathbf{u}_i\mathbf{v}_i^{\mathsf{T}}, \qquad \mathbf{\Sigma} = \begin{bmatrix} \operatorname{diag}(\sigma_1, \dots, \sigma_r) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \in \mathbb{R}^{m \times n}.$$

The σ_i^2 are the non-zero eigenvalues of $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ (and of $\mathbf{A}\mathbf{A}^{\mathsf{T}}$), so the singular values are uniquely determined by $\mathbf{A}$. Moreover

$$\|\mathbf{A}\|_2 = \max_{\mathbf{x} \neq \mathbf{0}} \frac{\|\mathbf{A}\mathbf{x}\|_2}{\|\mathbf{x}\|_2} = \sigma_1,$$

and if $\mathbf{A}$ is square and invertible ($r = n = m$), $\|\mathbf{A}^{-1}\|_2 = 1/\sigma_n$. (Complex case: $\mathsf{T} \to \mathsf{H}$, orthogonal $\to$ unitary; the σ_i remain real and positive.)

Proof

Step 1: eigen-decompose the Gram matrix. $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ is $n \times n$ and symmetric, so by Theorem C.13 it has orthonormal eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ with real eigenvalues $\mu_1, \dots, \mu_n$, which we order so that $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_n$. Each is non-negative:

$$\mu_i = \mu_i\mathbf{v}_i^{\mathsf{T}}\mathbf{v}_i = \mathbf{v}_i^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{v}_i = \|\mathbf{A}\mathbf{v}_i\|^2 \geq 0.$$

Step 2: exactly r of them are positive. In §C.6 we showed $\operatorname{null}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \operatorname{null}\mathbf{A}$, so by rank–nullity $\operatorname{rank}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = n - \dim\operatorname{null}\mathbf{A} = r$. The rank of the diagonalizable matrix $\mathbf{A}^{\mathsf{T}}\mathbf{A} = \mathbf{V}\mathbf{M}\mathbf{V}^{\mathsf{T}}$ equals the rank of $\mathbf{M} = \operatorname{diag}(\mu_i)$ (multiplying by invertible matrices does not change rank), which is the number of non-zero μ_i. So $\mu_1 \geq \cdots \geq \mu_r > 0 = \mu_{r+1} = \cdots = \mu_n$. Define $\sigma_i = \sqrt{\mu_i}$ for $i \leq r$.

Step 3: build orthonormal left vectors. For $i \leq r$ put $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i \in \mathbb{R}^m$. Then for $i, k \leq r$

$$\mathbf{u}_i^{\mathsf{T}}\mathbf{u}_k = \frac{\mathbf{v}_i^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{v}_k}{\sigma_i\sigma_k} = \frac{\mu_k\,\mathbf{v}_i^{\mathsf{T}}\mathbf{v}_k}{\sigma_i\sigma_k} = \frac{\sigma_k^2\,\delta_{ik}}{\sigma_i\sigma_k} = \delta_{ik},$$

so $\mathbf{u}_1,\dots,\mathbf{u}_r$ are orthonormal. By Theorem C.7 extend them to an orthonormal basis $\mathbf{u}_1,\dots,\mathbf{u}_m$ of $\mathbb{R}^m$ and let $\mathbf{U}=[\mathbf{u}_1,\dots,\mathbf{u}_m]$, $\mathbf{V}=[\mathbf{v}_1,\dots,\mathbf{v}_n]$; both are orthogonal.

Step 4: verify $\mathbf{AV}=\mathbf{U\Sigma}$. Column i of $\mathbf{U\Sigma}$ is $\sigma_i\mathbf{u}_i$ for $i\le r$ and $\mathbf{0}$ for $i>r$. Column i of $\mathbf{AV}$ is $\mathbf{A}\mathbf{v}_i$, which equals $\sigma_i\mathbf{u}_i$ for $i\le r$ by definition, and for $i>r$ satisfies $\|\mathbf{A}\mathbf{v}_i\|^2=\mu_i=0$, so $\mathbf{A}\mathbf{v}_i=\mathbf{0}$. Hence $\mathbf{AV}=\mathbf{U\Sigma}$; multiplying on the right by $\mathbf{V}^{\mathsf{T}}=\mathbf{V}^{-1}$ gives $\mathbf{A}=\mathbf{U\Sigma V}^{\mathsf{T}}$. Expanding the product by columns gives the rank-one sum.

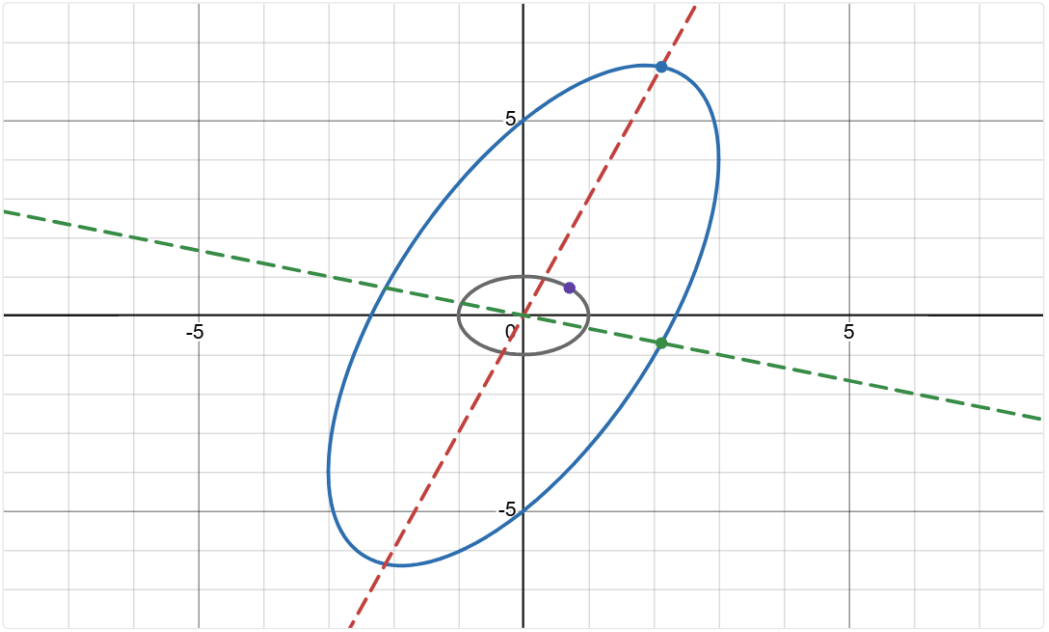
Step 5: uniqueness of the σ_i. From any SVD, $\mathbf{A}^{\mathsf{T}}\mathbf{A}=\mathbf{V\Sigma}^{\mathsf{T}}\mathbf{\Sigma V}^{\mathsf{T}}$, an orthogonal diagonalization with diagonal $\sigma_1^2,\dots,\sigma_r^2,0,\dots$; similarly $\mathbf{AA}^{\mathsf{T}}=\mathbf{U\Sigma\Sigma}^{\mathsf{T}}\mathbf{U}^{\mathsf{T}}$. So the σ_i^2 are the non-zero eigenvalues of either product, which depend only on $\mathbf{A}$.

Step 6: the 2-norm. For any $\mathbf{x}$ let $\mathbf{y}=\mathbf{V}^{\mathsf{T}}\mathbf{x}$; orthogonal matrices preserve length ($\|\mathbf{Q}\mathbf{z}\|^2=\mathbf{z}^{\mathsf{T}}\mathbf{Q}^{\mathsf{T}}\mathbf{Q}\mathbf{z}=\|\mathbf{z}\|^2$), so $\|\mathbf{y}\|=\|\mathbf{x}\|$ and

$$\|\mathbf{A}\mathbf{x}\|^2=\|\mathbf{U\Sigma}\mathbf{y}\|^2=\|\mathbf{\Sigma}\mathbf{y}\|^2=\sum_{i=1}^{r}\sigma_i^2y_i^2\le\sigma_1^2\|\mathbf{y}\|^2=\sigma_1^2\|\mathbf{x}\|^2,$$

with equality at $\mathbf{x}=\mathbf{v}_1$. Hence $\|\mathbf{A}\|_2=\sigma_1$. If $\mathbf{A}$ is square and invertible, $\mathbf{A}^{-1}=\mathbf{V\Sigma}^{-1}\mathbf{U}^{\mathsf{T}}$ is an SVD (after reversing the order of the columns) with singular values $1/\sigma_n\ge\cdots\ge1/\sigma_1$, so $\|\mathbf{A}^{-1}\|_2=1/\sigma_n$. ■

Check. $\mathbf{A}=\begin{bmatrix}3&0\\4&5\end{bmatrix}$: $\mathbf{A}^{\mathsf{T}}\mathbf{A}=\begin{bmatrix}25&20\\20&25\end{bmatrix}$ has eigenvalues 45 and 5 with eigenvectors $(1,1)/\sqrt{2}$ and $(1,-1)/\sqrt{2}$, so $\sigma_1=3\sqrt{5}=6.708$, $\sigma_2=\sqrt{5}=2.236$, and $\mathbf{u}_1=\mathbf{A}\mathbf{v}_1/\sigma_1=(1,3)/\sqrt{10}$, $\mathbf{u}_2=(3,-1)/\sqrt{10}$, which are orthogonal as Step 3 promises. Note $\sigma_1\sigma_2=15=|\det\mathbf{A}|$.



The SVD as geometry: $\mathbf{A}=\begin{bmatrix}3&0\\4&5\end{bmatrix}$ maps the unit circle onto the ellipse $\mathbf{y}^{\mathsf{T}}(\mathbf{AA}^{\mathsf{T}})^{-1}\mathbf{y}=1$, i.e. $41x^2-24xy+9y^2=225$. The right singular vector $\mathbf{v}_1$ on the circle lands on the long semi-axis $\sigma_1\mathbf{u}_1$ (length 6.708); $\mathbf{v}_2$ lands on the short one, $\sigma_2\mathbf{u}_2$ (length 2.236); the axes are perpendicular.

Remarks

- **No hypothesis at all.** Unlike diagonalization, the SVD exists for every matrix — rectangular, singular, defective — because it uses two different orthonormal bases and always works through the symmetric matrix $\mathbf{A}^{\mathsf{T}}\mathbf{A}$. The defective $\begin{bmatrix}1&1\\0&1\end{bmatrix}$, with no eigenvector basis, has singular values $(1\pm\sqrt{5})/2$ in absolute value, i.e. 1.618 and 0.618.
- **Singular values are not eigenvalue magnitudes** except for normal matrices. For $\begin{bmatrix}0&100\\0&0\end{bmatrix}$ both eigenvalues are 0 but $\sigma_1=100$. This gap between $|\lambda|$ and σ is exactly the transient-growth phenomenon of §C.12.
- **Do not compute the SVD this way.** Forming $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ squares the condition number and loses small singular values below $\sqrt{u}\,\sigma_1$ (with u the unit round-off). Practical algorithms bidiagonalise $\mathbf{A}$ with orthogonal transformations (§24.3); the proof above is an existence proof.
- **Uses.** Rank and the four fundamental subspaces, the pseudoinverse $\mathbf{A}^{+}=\mathbf{V\Sigma}^{+}\mathbf{U}^{\mathsf{T}}$ and minimum-norm least squares (§10.7); best rank-k approximation (Eckart–Young) behind PCA and data compression (Ch. 20); numerical rank (§8.5); and $\kappa_2=\sigma_1/\sigma_n$ in §C.11.

C.11 The condition-number error bound

Induced norm and condition number

Given a vector norm $\|\cdot\|$ on $\mathbb{F}^n$, the induced matrix norm is $\|\mathbf{A}\|=\max_{\mathbf{x}\neq\mathbf{0}}\|\mathbf{A}\mathbf{x}\|/\|\mathbf{x}\|$, and for nonsingular $\mathbf{A}$ the **condition number** is $\kappa(\mathbf{A})=\|\mathbf{A}\|\,\|\mathbf{A}^{-1}\|$ (§8.10).

The maximum exists because $\mathbf{x} \mapsto \|\mathbf{A}\mathbf{x}\|$ is continuous and the unit sphere of a finite-dimensional space is compact; by homogeneity the ratio takes the same values on the sphere as on all of $\mathbb{F}^n \setminus \{\mathbf{0}\}$. Two consequences are immediate from the definition: $\|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$ for every $\mathbf{x}$, and $\|\mathbf{A}\mathbf{B}\| \le \|\mathbf{A}\|\|\mathbf{B}\|$ (apply the first twice). With $\mathbf{B} = \mathbf{A}^{-1}$ this gives $\kappa(\mathbf{A}) \ge \|\mathbf{I}\| = 1$.

Theorem C.16 — Perturbation bounds for $\mathbf{A}\mathbf{x} = \mathbf{b}$

Let $\mathbf{A}$ be nonsingular, $\mathbf{b} \neq \mathbf{0}$, and $\mathbf{A}\mathbf{x} = \mathbf{b}$.

1. (right-hand side) If $\mathbf{A}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b} + \delta\mathbf{b}$, then

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A})\,\frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|}.$$

In the 2-norm the bound is sharp: there exist $\mathbf{b}$, $\delta\mathbf{b}$ attaining equality. 2. (residual) For any approximate solution $\hat{\mathbf{x}}$ with residual $\mathbf{r} = \mathbf{b} - \mathbf{A}\hat{\mathbf{x}}$: $\|\mathbf{x} - \hat{\mathbf{x}}\|/\|\mathbf{x}\| \le \kappa(\mathbf{A})\|\mathbf{r}\|/\|\mathbf{b}\|$. 3. (matrix) If $(\mathbf{A} + \delta\mathbf{A})(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b}$, then $\dfrac{\|\delta\mathbf{x}\|}{\|\mathbf{x} + \delta\mathbf{x}\|} \le \kappa(\mathbf{A})\dfrac{\|\delta\mathbf{A}\|}{\|\mathbf{A}\|}$.

Proof

Part 1. Subtracting $\mathbf{A}\mathbf{x} = \mathbf{b}$ from the perturbed equation gives $\mathbf{A}\,\delta\mathbf{x} = \delta\mathbf{b}$, so $\delta\mathbf{x} = \mathbf{A}^{-1}\delta\mathbf{b}$ and

$$\|\delta\mathbf{x}\| \le \|\mathbf{A}^{-1}\|\,\|\delta\mathbf{b}\|.$$

Also $\|\mathbf{b}\| = \|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$; since $\mathbf{b} \neq \mathbf{0}$ we have $\mathbf{x} \neq \mathbf{0}$, and

$$\frac{1}{\|\mathbf{x}\|} \le \frac{\|\mathbf{A}\|}{\|\mathbf{b}\|}.$$

Multiplying the two inequalities (both sides non-negative) gives the bound.

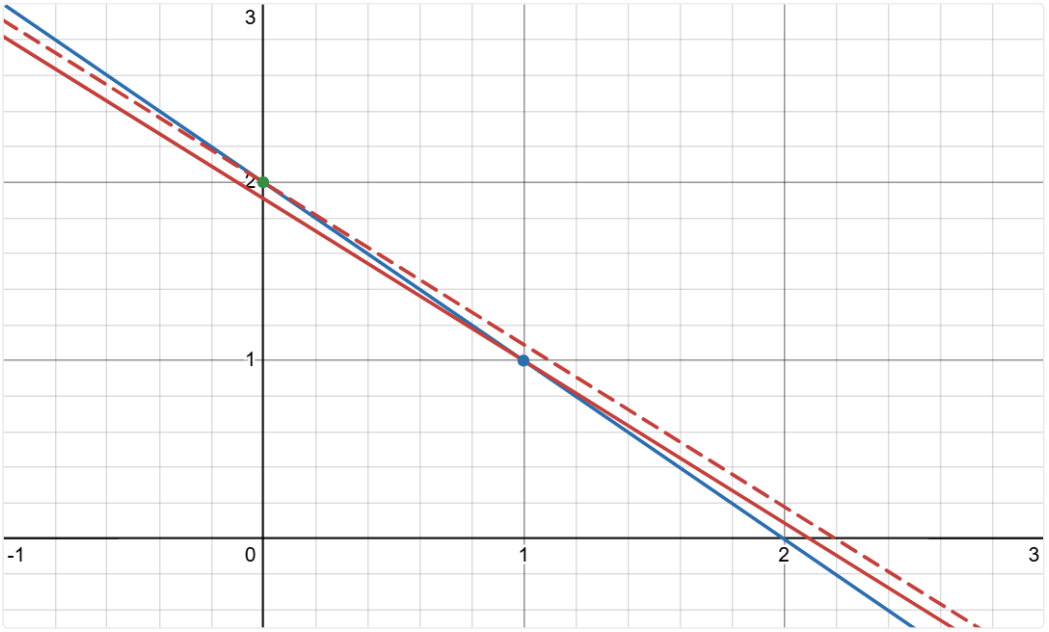
Sharpness in the 2-norm. Take the SVD of $\mathbf{A}$ (Theorem C.15), square of order n, with $\sigma_n > 0$. Choose $\mathbf{x} = \mathbf{v}_1$, so $\mathbf{b} = \sigma_1\mathbf{u}_1$ and $\|\mathbf{A}\mathbf{x}\| = \|\mathbf{A}\|_2\|\mathbf{x}\|$; and $\delta\mathbf{b} = \varepsilon\mathbf{u}_n$, so $\delta\mathbf{x} = \varepsilon\mathbf{v}_n/\sigma_n$ and $\|\delta\mathbf{x}\| = \|\mathbf{A}^{-1}\|_2\|\delta\mathbf{b}\|$. Both inequalities are then equalities:

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} = \frac{\varepsilon}{\sigma_n}, \qquad \kappa_2(\mathbf{A})\frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|} = \frac{\sigma_1}{\sigma_n}\cdot\frac{\varepsilon}{\sigma_1} = \frac{\varepsilon}{\sigma_n}.$$

Part 2. $\hat{\mathbf{x}}$ solves $\mathbf{A}\hat{\mathbf{x}} = \mathbf{b} - \mathbf{r}$ exactly; apply Part 1 with $\delta\mathbf{b} = -\mathbf{r}$ and $\delta\mathbf{x} = \hat{\mathbf{x}} - \mathbf{x}$.

Part 3. Expanding, $\mathbf{A}\mathbf{x} + \mathbf{A}\,\delta\mathbf{x} + \delta\mathbf{A}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b}$, and $\mathbf{A}\mathbf{x} = \mathbf{b}$, so $\delta\mathbf{x} = -\mathbf{A}^{-1}\delta\mathbf{A}(\mathbf{x} + \delta\mathbf{x})$. Taking norms, $\|\delta\mathbf{x}\| \le \|\mathbf{A}^{-1}\|\|\delta\mathbf{A}\|\|\mathbf{x} + \delta\mathbf{x}\|$; divide by $\|\mathbf{x} + \delta\mathbf{x}\|$ (if it is zero, then $\mathbf{b} = \mathbf{0}$, excluded) and write $\|\mathbf{A}^{-1}\| = \kappa(\mathbf{A})/\|\mathbf{A}\|$. ■

Check. $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.1 \end{bmatrix}$, $\mathbf{b} = (2, 2.1)$, $\mathbf{x} = (1, 1)$. Changing b_2 to 2.2 ($\|\delta\mathbf{b}\|_2/\|\mathbf{b}\|_2 = 0.1/2.900 = 0.0345$) moves the solution to $(0, 2)$, a relative change $\|(-1, 1)\|/\|(1, 1)\| = 1$: an amplification of 29. The theorem allows up to $\kappa_2(\mathbf{A}) = 42.08$, i.e. a relative change of 1.45, so the bound holds and is of the right order. Making the $(2, 2)$ entry 1.0001 instead raises κ_2 to about 4.0×10^4.



Ill-conditioning seen geometrically: the two equations of $\mathbf{A}\mathbf{x} = \mathbf{b}$ are nearly parallel lines (blue and red). Shifting the red line by 0.1 in b_2 (dashed) slides the intersection from $(1, 1)$ to $(0, 2)$ — a 3.4% data change producing a 100% solution change.

Remarks

- **Sharpness in other norms.** For $\|\cdot\|_1$ and $\|\cdot\|_\infty$ the bound is also attained for suitable $\mathbf{b}$, $\delta\mathbf{b}$ (pick a vector achieving $\|\mathbf{A}\|$ and one achieving $\|\mathbf{A}^{-1}\|$; any induced norm attains its maximum). For a particular $\mathbf{b}$ the actual amplification can be much smaller — the bound is worst case over the data.

- **Part 3 is "first order".** Bounding $\|\delta\mathbf{x}\|/\|\mathbf{x}\|$ rather than $/\|\mathbf{x}+\delta\mathbf{x}\|$ requires $\kappa(\mathbf{A})\|\delta\mathbf{A}\|/\|\mathbf{A}\| < 1$, which also guarantees $\mathbf{A}+\delta\mathbf{A}$ is nonsingular; then the bound is $\kappa\epsilon_A/(1-\kappa\epsilon_A)$ with $\epsilon_A = \|\delta\mathbf{A}\|/\|\mathbf{A}\|$ (§8.10). Without that condition there is no bound at all: $\mathbf{A}+\delta\mathbf{A}$ may be singular.
- **Small residual does not mean small error.** Part 2 shows a residual at round-off level only guarantees about $\kappa(\mathbf{A})\cdot u$ relative accuracy. This is the rule of thumb "you lose $\log_{10}\kappa$ digits" (§22.2), and combined with backward stability of LU with pivoting it is the basis of all error estimates for linear solvers (§24.3).
- **Determinant is not the measure.** $\det \mathbf{A} = 0.1$ above, but scaling $\mathbf{A}$ by 10 changes the determinant by 100 and leaves κ unchanged; κ is scale- and unit-free, the determinant is neither.
- **Uses.** Sensitivity of nodal analysis to component tolerances, error analysis of least squares ($\kappa(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \kappa_2(\mathbf{A})^2$), convergence rates of iterative solvers and gradient descent, which scale with κ or $\sqrt{\kappa}$ (§23.5, §24.4).

C.12 Stability of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$

For $\mathbf{A}\in\mathbb{C}^{n\times n}$, the initial-value problem $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$, $\mathbf{x}(0) = \mathbf{x}_0$ has the unique solution $\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}_0$, where $e^{\mathbf{A}t} = \sum_{k\ge 0}\mathbf{A}^k t^k/k!$ (§10.4, §12.7). We use two properties of the series: $e^{\mathbf{S}\mathbf{B}\mathbf{S}^{-1}t} = \mathbf{S}e^{\mathbf{B}t}\mathbf{S}^{-1}$ (because $(\mathbf{S}\mathbf{B}\mathbf{S}^{-1})^k = \mathbf{S}\mathbf{B}^k\mathbf{S}^{-1}$ term by term), and $e^{(\lambda\mathbf{I}+\mathbf{N})t} = e^{\lambda t}e^{\mathbf{N}t}$ (because $\lambda\mathbf{I}$ commutes with $\mathbf{N}$). The **spectral abscissa** is $\alpha(\mathbf{A}) = \max_i \mathrm{Re}\{\lambda_i\}$. Stability is defined as in §10.9: asymptotically stable if every solution tends to $\mathbf{0}$, marginally stable if every solution is bounded but not all tend to $\mathbf{0}$, unstable if some solution is unbounded.

Theorem C.17 — Eigenvalue test, diagonalizable case

Let $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$ be diagonalizable. Then for all $t \ge 0$

$$\|e^{\mathbf{A}t}\mathbf{x}_0\|_2 \le \kappa_2(\mathbf{V})\, e^{\alpha(\mathbf{A})t}\,\|\mathbf{x}_0\|_2,$$

and

1. $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ is asymptotically stable $\iff$ $\mathrm{Re}\{\lambda_i\} < 0$ for all i;
2. every solution is bounded on $[0,\infty)$ $\iff$ $\mathrm{Re}\{\lambda_i\} \le 0$ for all i.

If $\mathbf{A}$ is real, the same equivalences hold when only real initial conditions are allowed.

Theorem C.18 — General case (Jordan form)

For arbitrary $\mathbf{A}\in\mathbb{C}^{n\times n}$:

1. $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ is asymptotically stable $\iff$ $\mathrm{Re}\{\lambda_i\} < 0$ for all i; in that case, for every β with $\alpha(\mathbf{A}) < \beta < 0$ there is C with $\|e^{\mathbf{A}t}\| \le Ce^{\beta t}$ for $t \ge 0$;
2. all solutions are bounded $\iff$ $\mathrm{Re}\{\lambda_i\} \le 0$ for all i and every eigenvalue with $\mathrm{Re}\{\lambda_i\} = 0$ is **semisimple** ($g = a$, i.e. all its Jordan blocks are 1×1).

Proof of Theorem C.17

The bound. By the similarity property, $e^{\mathbf{A}t} = \mathbf{V}e^{\mathbf{\Lambda}t}\mathbf{V}^{-1}$, and $e^{\mathbf{\Lambda}t} = \mathrm{diag}(e^{\lambda_1 t},\dots,e^{\lambda_n t})$ since powers of a diagonal matrix are diagonal. Equivalently, in modal coordinates $\mathbf{y} = \mathbf{V}^{-1}\mathbf{x}$ the system decouples into $\dot y_i = \lambda_i y_i$, with $y_i(t) = e^{\lambda_i t}y_i(0)$. The 2-norm of a diagonal matrix is its largest entry modulus (Theorem C.15, or directly), and $|e^{\lambda_i t}| = e^{\mathrm{Re}\{\lambda_i\}t} \le e^{\alpha t}$ for $t \ge 0$. Submultiplicativity gives

$$\|e^{\mathbf{A}t}\mathbf{x}_0\| \le \|\mathbf{V}\|\,\|e^{\mathbf{\Lambda}t}\|\,\|\mathbf{V}^{-1}\|\,\|\mathbf{x}_0\| \le \kappa_2(\mathbf{V})\,e^{\alpha t}\|\mathbf{x}_0\|.$$

Sufficiency. If all $\mathrm{Re}\{\lambda_i\} < 0$ then $\alpha < 0$, so the right-hand side tends to 0 for every $\mathbf{x}_0$. If all $\mathrm{Re}\{\lambda_i\} \le 0$ then $\alpha \le 0$ and every solution is bounded by $\kappa_2(\mathbf{V})\|\mathbf{x}_0\|$.

Necessity. Suppose some eigenvalue has $\mathrm{Re}\{\lambda_k\} \ge 0$, with eigenvector $\mathbf{v}_k$. The solution from $\mathbf{x}_0 = \mathbf{v}_k$ is $e^{\lambda_k t}\mathbf{v}_k$ (it satisfies the equation and the initial condition, and solutions are unique), whose norm $e^{\mathrm{Re}\{\lambda_k\}t}\|\mathbf{v}_k\| \ge \|\mathbf{v}_k\| > 0$ does not tend to 0. So asymptotic stability forces all $\mathrm{Re}\{\lambda_i\} < 0$. Likewise if $\mathrm{Re}\{\lambda_k\} > 0$ this solution is unbounded, so boundedness forces all $\mathrm{Re}\{\lambda_i\} \le 0$.

Real initial conditions. Let $\mathbf{A}$ be real and $\mathbf{v}_k = \mathbf{a} + j\mathbf{b}$ with $\mathbf{a},\mathbf{b}$ real. Because $\mathbf{A}$ is real, $e^{\mathbf{A}t}$ is real, so $e^{\lambda_k t}\mathbf{v}_k = e^{\mathbf{A}t}\mathbf{a} + j\,e^{\mathbf{A}t}\mathbf{b}$ splits into the two real solutions from $\mathbf{a}$ and from $\mathbf{b}$. If both tended to $\mathbf{0}$ (or both were bounded), so would their complex combination, contradicting the previous paragraph. Hence one of the real initial conditions $\mathbf{a}$, $\mathbf{b}$ already exhibits the failure. ■

Proof of Theorem C.18

We use the Jordan form (§10.3): $\mathbf{A} = \mathbf{S}\mathbf{J}\mathbf{S}^{-1}$ with $\mathbf{J}$ block diagonal, each block $\mathbf{J}_m = \lambda\mathbf{I}_m + \mathbf{N}_m$ of size m, where $\mathbf{N}_m$ has ones on the superdiagonal and $\mathbf{N}_m^m = \mathbf{0}$. Since $e^{\mathbf{A}t} = \mathbf{S}e^{\mathbf{J}t}\mathbf{S}^{-1}$ and $e^{\mathbf{J}t}$ is block diagonal with blocks

$$e^{\mathbf{J}_m t} = e^{\lambda t}\sum_{k=0}^{m-1}\frac{t^k}{k!}\mathbf{N}_m^k = e^{\lambda t}\begin{bmatrix} 1 & t & \frac{t^2}{2} & \cdots & \frac{t^{m-1}}{(m-1)!} \\ & 1 & t & \cdots & \vdots \\ & & \ddots & \ddots & \frac{t^2}{2} \\ & & & 1 & t \\ & & & & 1 \end{bmatrix}$$

(the series for $e^{\mathbf{N}_m t}$ terminates), every entry of $e^{\mathbf{A}t}$ is a finite combination of functions $t^k e^{\lambda t}$, where $k < m$ for an eigenvalue whose largest Jordan block has size m.

Part 1, sufficiency and the rate. Let $\alpha < \beta < 0$. For each term, $|t^k e^{\lambda t}| = t^k e^{\mathrm{Re}\{\lambda\}t} = e^{\beta t}\cdot t^k e^{-(\beta-\mathrm{Re}\{\lambda\})t}$, and since $\beta - \mathrm{Re}\{\lambda\} > 0$ the factor $t^k e^{-(\beta-\mathrm{Re}\{\lambda\})t}$ is continuous on $[0,\infty)$ and tends to 0 (exponentials beat polynomials), hence is bounded. A finite sum of such bounds, combined with $\|\mathbf{S}\|\|\mathbf{S}^{-1}\|$, gives $\|e^{\mathbf{A}t}\| \le Ce^{\beta t} \to 0$.

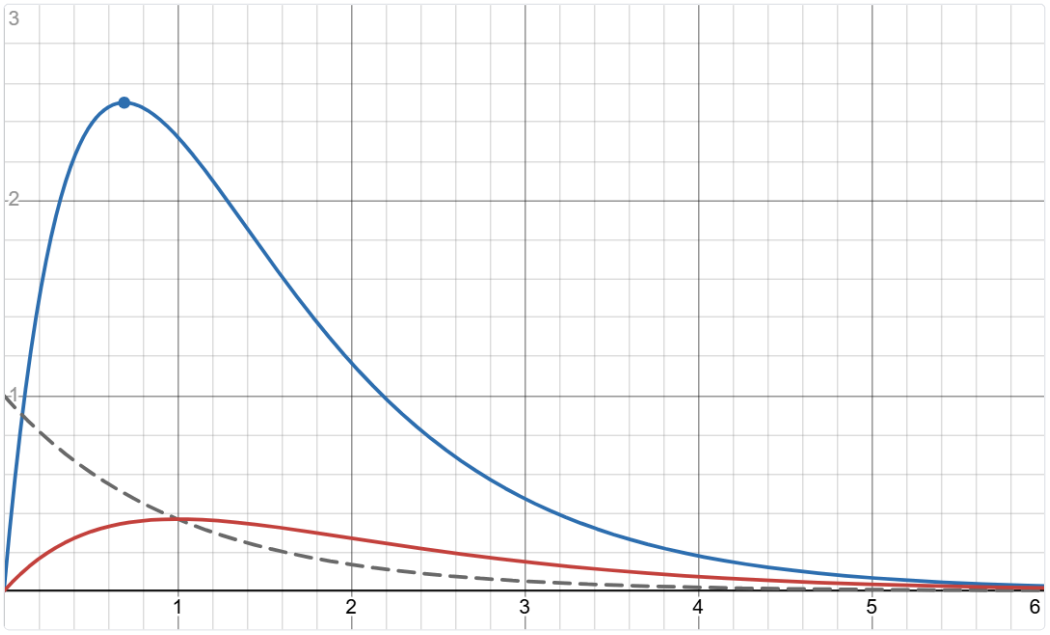
Part 1, necessity. As in C.17: an eigenvector $\mathbf{v}$ with $\mathrm{Re}\{\lambda\} \geq 0$ gives the non-decaying solution $e^{\lambda t}\mathbf{v}$.

Part 2, sufficiency. If $\mathrm{Re}\{\lambda\} < 0$, the block terms are bounded by Part 1's argument. If $\mathrm{Re}\{\lambda\} = 0$ and λ is semisimple, its blocks are 1×1 and contribute $e^{\lambda t}$, of modulus 1. So all entries of $e^{\mathbf{J}t}$, and hence of $e^{\mathbf{A}t}$, are bounded.

Part 2, necessity. If some $\mathrm{Re}\{\lambda\} > 0$, the eigenvector solution is unbounded. If $\mathrm{Re}\{\lambda\} = 0$ and λ has a Jordan block of size $m \geq 2$, let $\mathbf{s}_1, \mathbf{s}_2$ be the columns of $\mathbf{S}$ corresponding to the first two positions of that block, so $(\mathbf{A} - \lambda\mathbf{I})\mathbf{s}_1 = \mathbf{0}$ and $(\mathbf{A} - \lambda\mathbf{I})\mathbf{s}_2 = \mathbf{s}_1$. From the block formula, the solution with $\mathbf{x}_0 = \mathbf{s}_2$ is

$$\mathbf{x}(t) = e^{\lambda t}(\mathbf{s}_2 + t\,\mathbf{s}_1),$$

which can be verified directly: $\dot{\mathbf{x}} = \lambda\mathbf{x} + e^{\lambda t}\mathbf{s}_1$ and $\mathbf{A}\mathbf{x} = e^{\lambda t}(\lambda\mathbf{s}_2 + \mathbf{s}_1 + t\lambda\mathbf{s}_1) = \lambda\mathbf{x} + e^{\lambda t}\mathbf{s}_1$. Its norm is $\|\mathbf{s}_2 + t\mathbf{s}_1\| \geq t\|\mathbf{s}_1\| - \|\mathbf{s}_2\| \to \infty$ (triangle inequality, C.6). For real $\mathbf{A}$, real initial conditions suffice by the splitting argument of C.17. ■



Asymptotic stability says nothing about the size of the transient. For $\mathbf{A} = \begin{bmatrix} -1 & 10 \\ 0 & -2 \end{bmatrix}$ (eigenvalues $-1, -2$, eigenvector matrix with $\kappa_2(\mathbf{V}) \approx 102$), the first state component from $\mathbf{x}_0 = (0, 1)$ is $10(e^{-t} - e^{-2t})$ (blue): it rises to 2.5 before decaying at the eigenvalue rate e^{-t} (grey). The red curve te^{-t} is the extra polynomial factor carried by a 2×2 Jordan block at -1: still decaying, but more slowly than e^{-t}.

Remarks

- **Where the hypotheses bite.** The single criterion "$\mathrm{Re}\{\lambda\} < 0$" decides asymptotic stability whether or not $\mathbf{A}$ is diagonalizable; Jordan structure matters only on the boundary $\mathrm{Re}\{\lambda\} = 0$. The double integrator $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$ has both eigenvalues at 0 but $x_1(t) = x_1(0) + t\,x_2(0)$ is unbounded: a defective imaginary-axis eigenvalue, exactly the counterexample of Theorem C.18(2). An undamped LC tank, $\begin{bmatrix} 0 & 1 \\ -\omega_0^2 & 0 \end{bmatrix}$, has simple eigenvalues $\pm j\omega_0$ and is marginally stable. The same dichotomy appears for scalar ODEs as "repeated imaginary-axis roots are unstable" (§12.2).
- **Transient growth and non-normality.** The constant $\kappa_2(\mathbf{V})$ in Theorem C.17 is not decoration. For the matrix in the graph, $\max_{t \geq 0}\|e^{\mathbf{A}t}\|_2 \approx 2.56$ (near $t = 0.66$) even though every eigenvalue is negative; for highly non-normal matrices the peak can be orders of magnitude, which matters for saturating amplifiers and in fluid and power-system models. For normal (e.g. symmetric) $\mathbf{A}$, $\mathbf{V}$ can be taken unitary, $\kappa_2(\mathbf{V}) = 1$, and $\|e^{\mathbf{A}t}\|_2 = e^{\alpha t}$ exactly.
- **Discrete time.** The same proofs, with $e^{\lambda t}$ replaced by λ^k and $|e^{\lambda t}| = e^{\mathrm{Re}\{\lambda\}t}$ by $|\lambda^k| = |\lambda|^k$, show that $\mathbf{x}[k+1] = \mathbf{A}\mathbf{x}[k]$ is asymptotically stable iff all $|\lambda_i| < 1$ (§10.4, Ch. 17); this is also the convergence condition $\rho(\mathbf{G}) < 1$ for stationary iterative solvers (§24.4).
- **Nonlinear systems.** By Lyapunov's indirect method, an equilibrium of $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ is locally asymptotically stable if the Jacobian there has all $\mathrm{Re}\{\lambda\} < 0$, and unstable if some $\mathrm{Re}\{\lambda\} > 0$; the boundary case is inconclusive (§10.9, Ch. 11).
- **Uses.** Every stability statement in the book for LTI state models: natural response of RLC circuits (§12.8), pole locations and BIBO stability (Ch. 14), and modal analysis (§10.8).

Appendix D — Transforms, ODEs and Complex Analysis

This appendix gives complete proofs of the results that Chapters 11 and 14–18 state with only a sketch: existence and uniqueness for initial-value problems, the analytic foundations of the Laplace, Fourier and Z-transforms, the convergence theory of Fourier series (Bessel, Parseval, Dirichlet, Gibbs), the sampling theorem, and the core of complex analysis (Cauchy–Riemann, Cauchy's theorem and integral formula, residues, Jordan's lemma).

Prerequisites. Real analysis at the level of a first course: uniform convergence and the fact that a uniform limit of continuous functions is continuous, the Weierstrass M-test, Riemann (or Lebesgue) integration including improper integrals, and the interchange theorems of Fubini–Tonelli and dominated convergence. These are quoted, not proved. Green's theorem is taken from Ch. 7; Laurent's theorem from Ch. 18, §18.6.

Level of rigor. Every hypothesis is stated precisely and every nontrivial step is justified. Where the cleanest general proof needs measure theory (Plancherel on all of L^2, the density of continuous functions in L^2), the proof is given in full for a large class that covers every engineering signal, and the extension is described and cited. Notation follows the Notation and Conventions: $j^2=-1$, ω in rad/s, and the Fourier transform is $X(\omega)=\int_{-\infty}^{\infty} x(t)e^{-j\omega t}\,dt$ with inverse $x(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)e^{j\omega t}\,d\omega$, as in Ch. 16.

D.1 Picard–Lindelöf existence and uniqueness

Lipschitz condition

A function $f(t,y)$ defined on a set $R\subset\mathbb{R}^2$ is **Lipschitz in** y on R with constant $K\ge 0$ if

$$|f(t,y_1)-f(t,y_2)|\le K|y_1-y_2| \qquad \text{for all } (t,y_1),(t,y_2)\in R.$$

Picard–Lindelöf

Let $R=\{(t,y):|t-t_0|\le a,\ |y-y_0|\le b\}$ with $a,b>0$. Suppose f is continuous on R and Lipschitz in y on R with constant K. Let $M=\max_R|f|$ (if $M=0$ put $h=a$) and $h=\min(a,\ b/M)$. Then the initial-value problem

$$y'(t)=f(t,y(t)),\qquad y(t_0)=y_0$$

has exactly one solution y on $I=[t_0-h,\ t_0+h]$, and the Picard iterates $y_{k+1}(t)=y_0+\int_{t_0}^{t} f(s,y_k(s))\,ds$, $y_0(t)\equiv y_0$, converge to it uniformly on I.

The proof uses the contraction-mapping principle, which we prove first.

Banach fixed-point theorem

Let $(\mathcal{X},d)$ be a non-empty complete metric space and $\Phi:\mathcal{X}\to\mathcal{X}$ a **contraction**: $d(\Phi u,\Phi v)\le q\,d(u,v)$ for some $q<1$ and all u,v. Then Φ has exactly one fixed point $u^\star$, and for any u_0 the iterates $u_{k+1}=\Phi u_k$ converge to $u^\star$ with $d(u_k,u^\star)\le \dfrac{q^k}{1-q}\,d(u_1,u_0)$.

Proof of the fixed-point theorem. By induction $d(u_{k+1},u_k)\le q^k d(u_1,u_0)$. For $m>k$, the triangle inequality and the geometric series give

$$d(u_m,u_k)\le\sum_{i=k}^{m-1} d(u_{i+1},u_i)\le d(u_1,u_0)\sum_{i=k}^{\infty} q^i=\frac{q^k}{1-q}\,d(u_1,u_0)\xrightarrow[k\to\infty]{}0,$$

so (u_k) is Cauchy and, by completeness, converges to some $u^\star$. A contraction is continuous, so $\Phi u^\star=\lim \Phi u_k=\lim u_{k+1}=u^\star$. Letting $m\to\infty$ in the display gives the error bound. If $u^\star,v^\star$ are both fixed, $d(u^\star,v^\star)=d(\Phi u^\star,\Phi v^\star)\le q\,d(u^\star,v^\star)$, which forces $d(u^\star,v^\star)=0$. $\blacksquare$

Proof of Picard–Lindelöf.

Step 1 — integral equation. A continuous function y on I with graph in R solves the IVP if and only if

$$y(t)=y_0+\int_{t_0}^{t} f(s,y(s))\,ds \qquad (t\in I).$$

Indeed, if y solves the IVP then y' is continuous (a composition of continuous functions) and integrating from t_0 gives the equation; conversely, the right-hand side is differentiable by the fundamental theorem of calculus, because $s\mapsto f(s,y(s))$ is continuous, and differentiating gives $y'=f(t,y)$ with $y(t_0)=y_0$.

Step 2 — the space. Let $\mathcal{X}$ be the set of continuous $y:I\to\mathbb{R}$ with $|y(t)-y_0|\le b$ on I. Equip it with the **weighted (Bielecki) metric**

$$d(y,z)=\max_{t\in I} e^{-2K|t-t_0|}\,|y(t)-z(t)|.$$

Since $e^{-2Kh}\le e^{-2K|t-t_0|}\le 1$, this metric is equivalent to the sup metric: $e^{-2Kh}\|y-z\|_\infty\le d(y,z)\le\|y-z\|_\infty$. A sequence is Cauchy for d iff it is uniformly Cauchy, and a uniform limit of continuous functions is continuous and still satisfies $|y-y_0|\le b$. Hence $(\mathcal{X},d)$ is complete. It is non-empty (it contains the constant y_0).

Step 3 — Φ maps $\mathcal{X}$ into itself. Define $(\Phi y)(t)=y_0+\int_{t_0}^{t} f(s,y(s))\,ds$. For $y\in\mathcal{X}$ the integrand is continuous, so Φy is continuous, and

$$|(\Phi y)(t)-y_0|\le M|t-t_0|\le Mh\le b.$$

This is exactly why $h\le b/M$: the iterates cannot leave the rectangle where the bounds on f hold.

Step 4 — Φ is a contraction. Take $t\ge t_0$ (the case $t<t_0$ is symmetric). By the Lipschitz condition and the definition of d,

$$|(\Phi y)(t) - (\Phi z)(t)| \le \int_{t_0}^{t} K|y(s)-z(s)|\,ds \le K\,d(y,z)\int_{t_0}^{t} e^{2K(s-t_0)}\,ds$$
$$= \frac{d(y,z)}{2}\bigl(e^{2K(t-t_0)}-1\bigr) < \frac{1}{2}\,e^{2K(t-t_0)}\,d(y,z).$$

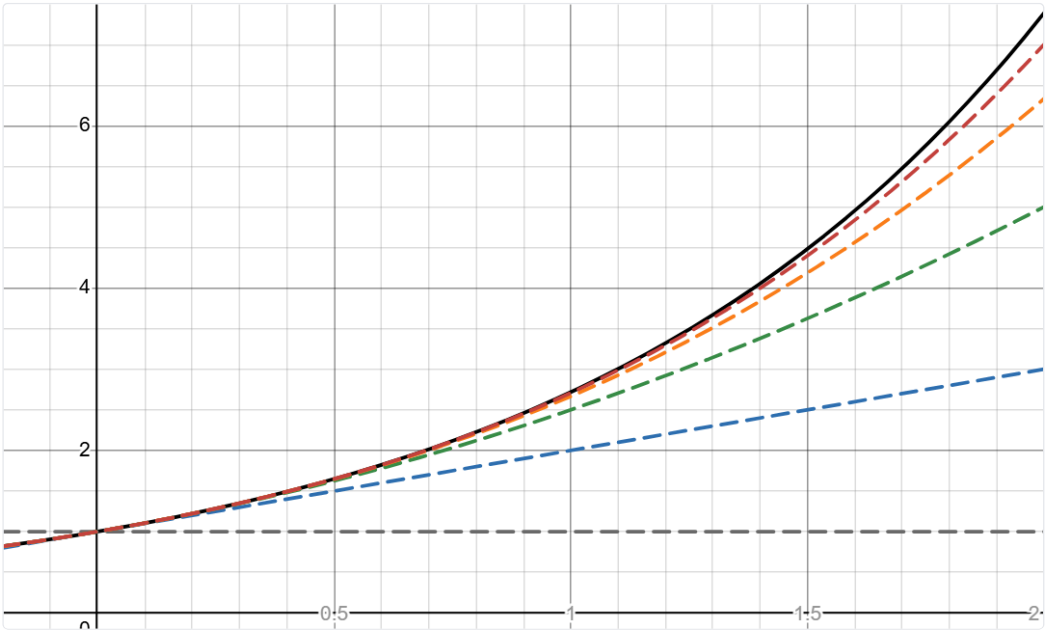
Multiplying by $e^{-2K(t-t_0)}$ and maximising over t gives $d(\Phi y,\Phi z) \le \tfrac12\, d(y,z)$. (If $K=0$ the integral is zero and the bound is trivial.)

Step 5 — existence. By the fixed-point theorem Φ has a fixed point $y \in \mathcal{X}$, which by Step 1 solves the IVP on I. The iterates $y_k = \Phi^k y_0$ converge to it in d, hence uniformly.

Step 6 — uniqueness among all solutions. The fixed-point theorem gives uniqueness only inside $\mathcal{X}$, so we must show that *every* solution z on I has its graph in R. Suppose z leaves the strip $|y-y_0| \le b$ at some $t > t_0$ in I, and let $\tau = \inf\{t > t_0 : |z(t)-y_0| > b\}$. On $[t_0,\tau]$ the graph is in R, so $|z(\tau)-y_0| \le M(\tau-t_0)$; by continuity $|z(\tau)-y_0| = b$. Hence $\tau - t_0 \ge b/M \ge h$, so $\tau \ge t_0 + h$ and z does not leave the strip inside I after all — a contradiction. The case $t < t_0$ is symmetric. So $z \in \mathcal{X}$ is a fixed point of Φ, and $z = y$. $\blacksquare$

Remarks.

1. *The Lipschitz condition is what buys uniqueness.* For $y' = 3y^{2/3}$, $y(0)=0$, the function f is continuous but not Lipschitz at $y=0$, and both $y \equiv 0$ and $y = t^3$ are solutions (indeed infinitely many, $y = (t-c)^3$ for $t \ge c$ and 0 before). Continuity alone still gives *existence* (Peano's theorem, proved by compactness rather than contraction), but not uniqueness.
2. *The result is local.* For $y' = y^2$, $y(0)=1$, f is Lipschitz on every bounded rectangle, yet the solution $y = 1/(1-t)$ blows up at $t=1$. The theorem's $h = \min(a, b/M)$ with $M = (1+b)^2$ is maximised at $b=1$, $a \ge 1/4$, giving $h = 1/4$; repeated application extends the solution as long as it stays bounded, never past $t=1$.
3. *Why the weighted metric.* With the plain sup metric Step 4 gives the factor Kh, so the proof would need $h < 1/K$ in addition. The weight $e^{-2K|t-t_0|}$ absorbs the exponential growth that Lipschitz feedback allows (the same growth that appears in Grönwall's inequality) and gives a contraction on the full interval.
4. *Systems.* The proof works verbatim for $\mathbf{y}' = \mathbf{f}(t,\mathbf{y})$ with $|\cdot|$ replaced by a vector norm; this covers every nth-order equation written as a first-order system, and hence the state equations of any lumped circuit. For a linear system $\mathbf{y}' = \mathbf{A}(t)\mathbf{y} + \mathbf{g}(t)$ with continuous coefficients, f is globally Lipschitz and a solution exists on the whole interval of continuity (Ch. 11, §11.9).
5. *Where it is used.* The theorem justifies the statement in Ch. 11, §11.7 that an RLC circuit's response is fixed by its initial capacitor voltages and inductor currents, and underlies the error analysis of the numerical ODE solvers of Ch. 22.



Picard iterates $y_0, \dots, y_4$ for $y' = y$, $y(0)=1$ (dashed) approaching the fixed point e^t (black); the error of y_k is bounded by $|t|^{k+1}e^{|t|}/(k+1)!$, the factorial being the hallmark of the contraction argument.

D.2 Existence of the Laplace transform

Piecewise continuity and exponential order

A function $x : [0,\infty) \to \mathbb{C}$ is **piecewise continuous** if every bounded interval $[0,\tau]$ contains only finitely many discontinuities of x, each a finite jump. It is of **exponential order** α if there are constants $M > 0$ and $T_0 \ge 0$ with $|x(t)| \le M e^{\alpha t}$ for all $t \ge T_0$.

Existence of the Laplace transform

If x is piecewise continuous on $[0,\infty)$ and of exponential order α, then

$$X(s)=\int_0^{\infty} x(t)\,e^{-st}\,dt$$

converges absolutely for every s with $\operatorname{Re}\{s\}>\alpha$. Moreover the convergence is uniform on every half-plane $\operatorname{Re}\{s\}\ge\sigma_1>\alpha$, X is analytic for $\operatorname{Re}\{s\}>\alpha$, and $X(s)\to 0$ as $\operatorname{Re}\{s\}\to+\infty$.

Proof. Write $s=\sigma+j\omega$, so $|e^{-st}|=e^{-\sigma t}$.

Absolute convergence. On $[0,T_0]$ the function x is piecewise continuous, hence bounded, say $|x|\le B$, and Riemann integrable; so $\int_0^{T_0}|x(t)|e^{-\sigma t}dt\le BT_0\max(1,e^{-\sigma T_0})<\infty$. On $[T_0,\infty)$,

$$\int_{T_0}^{\tau}|x(t)|e^{-\sigma t}\,dt\le M\int_{T_0}^{\tau}e^{-(\sigma-\alpha)t}\,dt\le\frac{M\,e^{-(\sigma-\alpha)T_0}}{\sigma-\alpha}\qquad(\sigma>\alpha),$$

a bound independent of τ. A non-negative integrand with bounded partial integrals has a convergent improper integral, so $\int_0^{\infty}|x|e^{-\sigma t}dt<\infty$, and absolute convergence implies convergence.

Uniformity. If $\sigma\ge\sigma_1>\alpha$ then $|x(t)e^{-st}|\le|x(t)|e^{-\sigma_1 t}$, an integrable majorant independent of s. Hence the tails satisfy $\left|\int_{\tau}^{\infty}xe^{-st}dt\right|\le\int_{\tau}^{\infty}|x|e^{-\sigma_1 t}dt\to 0$ uniformly in s (the Weierstrass M-test for integrals).

Analyticity. Each truncation $X_\tau(s)=\int_0^{\tau}x(t)e^{-st}dt$ is entire: differentiation under the integral sign over a bounded interval is permitted because $\partial_s(xe^{-st})=-t\,x\,e^{-st}$ is continuous in s and bounded on compact s-sets. By the uniformity just proved, $X_\tau\to X$ uniformly on each half-plane $\operatorname{Re}\{s\}\ge\sigma_1$, and a locally uniform limit of analytic functions is analytic (each X_τ integrates to zero around every triangle by §D.14, the limit passes inside the contour integral, and Morera's theorem applies).

Decay. For $\sigma>\max(\alpha,0)$,

$$|X(s)|\le B\int_0^{T_0}e^{-\sigma t}dt+M\int_{T_0}^{\infty}e^{-(\sigma-\alpha)t}dt\le\frac{B}{\sigma}+\frac{M}{\sigma-\alpha}\xrightarrow[\sigma\to\infty]{}0.$$

∎

Remarks.

1. *Sufficient, not necessary.* $x(t)=t^{-1/2}$ is not piecewise continuous at 0 (it is unbounded), yet its transform $\sqrt{\pi/s}$ exists because the singularity is integrable. The theorem extends to any x that is absolutely integrable on each $[0,\tau]$ and of exponential order at infinity, with the same proof.
2. *Growth control is essential.* $x(t)=e^{t^2}$ has no Laplace transform for any s: for real s the integrand $e^{t(t-s)}\to\infty$. More generally, the set of s where the integral converges absolutely is a right half-plane $\operatorname{Re}\{s\}>\sigma_a$ (possibly with its boundary line), because absolute convergence at σ implies it at every $\sigma'>\sigma$ by comparison.
3. *Consequence for rational transforms.* The decay $X(s)\to 0$ shows that a polynomial in s, or $s/(s+1)$, cannot be the transform of an ordinary function; transforms of ordinary functions with rational X are strictly proper. Constants and higher powers of s correspond to impulses and their derivatives at $t=0$.
4. Used in Ch. 14, §14.1.

D.3 The Laplace derivative theorem

Transform of a derivative

Let x be continuous on $[0,\infty)$ and of exponential order α, and let $\dot{x}$ be piecewise continuous on $[0,\infty)$ (at finitely many points in each bounded interval $\dot{x}$ may fail to exist; there x has a corner). Then $\mathcal{L}\{\dot{x}\}$ exists for $\operatorname{Re}\{s\}>\alpha$ and

$$\mathcal{L}\{\dot{x}(t)\}=sX(s)-x(0).$$

If $x,\dot{x},\dots,x^{(n-1)}$ are continuous and of exponential order α and $x^{(n)}$ is piecewise continuous, then

$$\mathcal{L}\{x^{(n)}\}=s^nX(s)-s^{n-1}x(0)-s^{n-2}\dot{x}(0)-\cdots-x^{(n-1)}(0).$$

Proof. Fix s with $\sigma=\operatorname{Re}\{s\}>\alpha$ and $\tau>0$. Let $0=t_0<t_1<\cdots<t_m=\tau$ include all points of $[0,\tau]$ where $\dot{x}$ is discontinuous or undefined. On each $[t_{i-1},t_i]$ the function x is continuously differentiable (with one-sided derivatives at the ends), so integration by parts is valid:

$$\int_{t_{i-1}}^{t_i}\dot{x}(t)e^{-st}\,dt=\Big[x(t)e^{-st}\Big]_{t_{i-1}}^{t_i}+s\int_{t_{i-1}}^{t_i}x(t)e^{-st}\,dt.$$

Summing over i, the boundary terms telescope **because x is continuous** at each interior t_i:

$$\int_0^{\tau}\dot{x}(t)e^{-st}\,dt=x(\tau)e^{-s\tau}-x(0)+s\int_0^{\tau}x(t)e^{-st}\,dt.$$

Now let $\tau\to\infty$. For $\tau\ge T_0$, $|x(\tau)e^{-s\tau}|\le Me^{-(\sigma-\alpha)\tau}\to 0$, and the last integral tends to $X(s)$ by §D.2. The right-hand side therefore has the limit $sX(s)-x(0)$, so the improper integral on the left converges and equals it. The nth-order formula follows by induction: applying the first-order result to $x^{(n-1)}$ gives $\mathcal{L}\{x^{(n)}\}=s\,\mathcal{L}\{x^{(n-1)}\}-x^{(n-1)}(0)$, and substituting the formula for $\mathcal{L}\{x^{(n-1)}\}$ yields the stated sum. ∎

Remarks.

1. *Continuity matters.* If x has a jump of size J at $t_1 > 0$, the boundary terms fail to telescope and an extra term $-Je^{-st_1}$ appears: the classical derivative misses the impulse $J\delta(t-t_1)$ that the generalized derivative contains. For a jump at the origin the book uses the 0^- convention, $\mathcal{L}\{\dot{x}\} = sX(s) - x(0^-)$, in which $\dot{x}$ includes the impulse $[x(0^+) - x(0^-)]\delta(t)$; the proof above with $x(0)$ replaced by $x(0^+)$ gives the 0^+ form, and the two differ exactly by that impulse (Ch. 14, §14.2).
2. *$\dot{x}$ need not be of exponential order.* The proof never bounds $\dot{x}$; the existence of $\mathcal{L}\{\dot{x}\}$, possibly as a conditionally convergent integral, is a conclusion. Example: $x(t) = \sin(e^{t^2})$ is bounded, so $\mathcal{L}\{x\}$ exists for $\mathrm{Re}\{s\} > 0$, while $\dot{x}(t) = 2te^{t^2}\cos(e^{t^2})$ grows faster than any exponential; nevertheless $\int_0^\infty \dot{x}\, e^{-st}dt$ converges for $\mathrm{Re}\{s\} > 0$.
3. This is the result that turns a linear constant-coefficient ODE with initial conditions into an algebraic equation in s (Ch. 14, §14.8).

D.4 The Laplace convolution theorem

Convolution theorem (Laplace)

Let f and g be piecewise continuous on $[0,\infty)$ and of exponential order α, and define

$$(f*g)(t) = \int_0^t f(\tau)\, g(t-\tau)\, d\tau \qquad (t \geq 0).$$

Then $f*g$ is continuous, of exponential order $\alpha + \varepsilon$ for every $\varepsilon > 0$, and for $\mathrm{Re}\{s\} > \alpha$

$$\mathcal{L}\{f*g\}(s) = F(s)\, G(s).$$

Proof. *Growth of $f*g$.* Enlarging M if necessary, we may take $|f(t)|, |g(t)| \leq Me^{\alpha t}$ for **all** $t \geq 0$ (on $[0,T_0]$ both functions are bounded and $e^{\alpha t}$ is bounded below). Then

$$|(f*g)(t)| \leq M^2 \int_0^t e^{\alpha\tau} e^{\alpha(t-\tau)} d\tau = M^2\, t\, e^{\alpha t} \leq \frac{M^2}{\varepsilon e}\, e^{(\alpha+\varepsilon)t},$$

using $te^{-\varepsilon t} \leq 1/(\varepsilon e)$. For continuity, fix $\tau_0 > 0$ and $t, t' \in [0,\tau_0]$; extending g by 0 on $t<0$, $(f*g)(t') - (f*g)(t) = \int_0^{\tau_0} f(\tau)[g(t'-\tau) - g(t-\tau)]d\tau$. As $t' \to t$ the bracket tends to 0 for all but finitely many τ (the points where $t-\tau$ is a jump of g) and is bounded, so the integral tends to 0 by dominated convergence. Hence $\mathcal{L}\{f*g\}$ exists for $\mathrm{Re}\{s\} > \alpha$ (choose $\varepsilon < \mathrm{Re}\{s\} - \alpha$).

The product formula. Fix s with $\sigma = \mathrm{Re}\{s\} > \alpha$. With $g = 0$ on $t<0$, $(f*g)(t) = \int_0^\infty f(\tau)g(t-\tau)d\tau$, so

$$\mathcal{L}\{f*g\}(s) = \int_0^\infty \int_0^\infty f(\tau)\, g(t-\tau)\, e^{-st}\, d\tau\, dt.$$

For the absolute integrand, Tonelli's theorem (iterated integrals of a non-negative function agree in either order) gives

$$\int_0^\infty \int_0^\infty |f(\tau)|\, |g(t-\tau)|\, e^{-\sigma t}\, dt\, d\tau = \int_0^\infty |f(\tau)| e^{-\sigma\tau}\, d\tau \cdot \int_0^\infty |g(u)| e^{-\sigma u}\, du < \infty,$$

where we substituted $u = t - \tau$ in the inner integral and used the absolute convergence of §D.2 for both factors. So Fubini's theorem allows the order of integration to be exchanged in the signed integral, and the same substitution gives

$$\mathcal{L}\{f*g\}(s) = \int_0^\infty f(\tau) e^{-s\tau} \left(\int_0^\infty g(u) e^{-su}\, du \right) d\tau = F(s)\, G(s).$$

∎

Remarks.

1. *Region of validity.* The formula holds on the intersection of the half-planes of absolute convergence of F and G. Absolute convergence is exactly the hypothesis that licenses Fubini; with only conditional convergence the exchange of integrals can fail.
2. *Why it matters.* With $g = h$ the impulse response of a causal LTI system and f its input, the theorem says the output transform is $H(s)F(s)$ — the definition of the transfer function. Geometrically, the region $0 \leq \tau \leq t$ of the (τ, t) plane can be swept by vertical lines (convolve first) or horizontal lines (transform first). See Ch. 14, §14.6.

D.5 Initial- and final-value theorems

Initial-value theorem (IVT)

Let x be continuous on $(0,\infty)$ with a finite right limit $x(0^+)$ and of exponential order, and let $\dot{x}$ be piecewise continuous and of exponential order α on $(0,\infty)$. Then, along real $s \to +\infty$,

$$\lim_{s \to +\infty} sX(s) = x(0^+).$$

Final-value theorem (FVT)

(a) Abelian form. If x is piecewise continuous on $[0,\infty)$ and the limit $x(\infty)=\lim_{t\to\infty}x(t)$ exists and is finite, then $X(s)$ exists for $\operatorname{Re}\{s\}>0$ and

$$\lim_{s\to 0^+} sX(s) = x(\infty) \qquad (s \text{ real}).$$

(b) Rational form. If $X(s)$ is a strictly proper rational function and **every pole of $sX(s)$ lies in the open left half-plane** $\operatorname{Re}\{s\}<0$, then $x(\infty)$ exists and equals $\lim_{s\to 0} sX(s)$.

Proof of the IVT. Redefine $x(0)=x(0^+)$; then x is continuous on $[0,\infty)$ and §D.3 gives, for real $s>\alpha$,

$$sX(s)-x(0^+)=\int_0^\infty \dot{x}(t)\,e^{-st}\,dt=\mathcal{L}\{\dot{x}\}(s).$$

Because $\dot{x}$ is piecewise continuous and of exponential order, §D.2 applies to $\dot{x}$ itself and gives $\mathcal{L}\{\dot{x}\}(s)\to 0$ as $s\to+\infty$. ■

Proof of FVT (a). Write $L=x(\infty)$. Since x converges it is bounded for large t, and it is bounded on any $[0,T]$ by piecewise continuity; so it is of exponential order 0 and $X(s)$ exists for $\operatorname{Re}\{s\}>0$. Using $s\int_0^\infty e^{-st}dt=1$ for $s>0$,

$$sX(s)-L=s\int_0^\infty \big(x(t)-L\big)e^{-st}\,dt.$$

Given $\varepsilon>0$ pick T with $|x(t)-L|<\varepsilon$ for $t>T$, and let $B=\sup_{[0,T]}|x-L|<\infty$. Then for $s>0$

$$|sX(s)-L|\le s\int_0^T B\,dt + s\int_T^\infty \varepsilon\,e^{-st}dt \le sBT+\varepsilon.$$

Letting $s\to 0^+$ gives $\limsup|sX(s)-L|\le\varepsilon$, and ε was arbitrary. ■

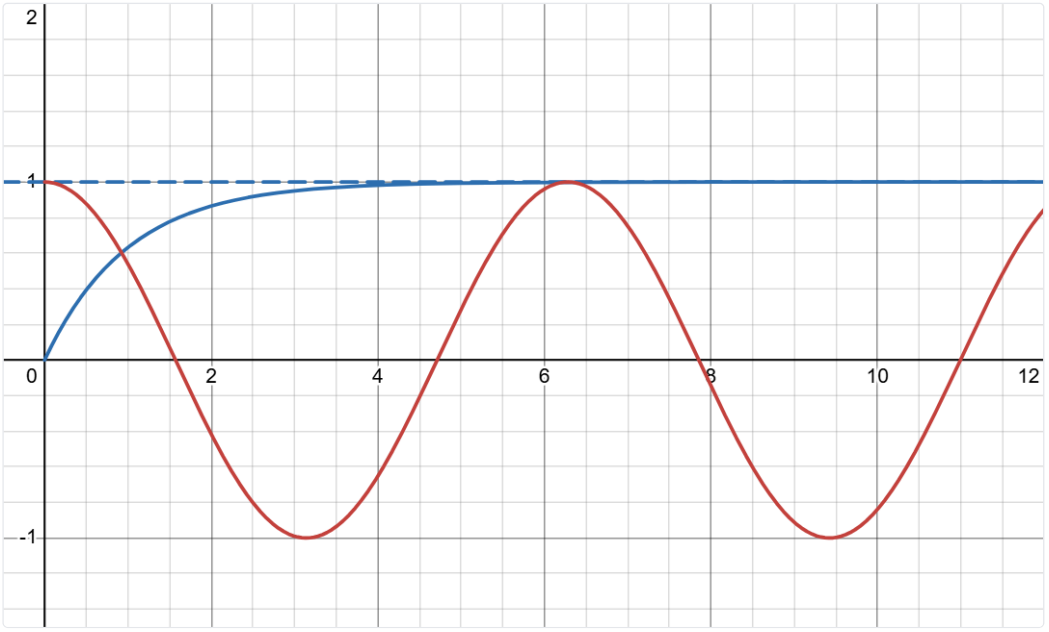
Proof of FVT (b). Let $X=N/D$ be strictly proper with distinct poles $p_1,\dots,p_r$ of multiplicities $m_1,\dots,m_r$. The partial-fraction expansion (Ch. 14, §14.5) and uniqueness of the inverse transform give

$$x(t)=\sum_{i=1}^{r}\sum_{k=1}^{m_i}\frac{A_{ik}}{(k-1)!}\,t^{k-1}e^{p_i t} \qquad (t>0).$$

The poles of $sX(s)$ are those of X, except that a pole of X at 0 has its order lowered by one (and disappears if it was simple). The hypothesis therefore says: every $p_i\neq 0$ has $\operatorname{Re}\{p_i\}<0$, and 0 is at most a *simple* pole of X. Each term with $\operatorname{Re}\{p_i\}<0$ tends to zero, since $t^{k-1}e^{\operatorname{Re}\{p_i\}t}\to 0$. If 0 is a simple pole, the remaining term is the constant $A_0=\lim_{s\to0}sX(s)$ (the residue of X at 0); if 0 is not a pole, there is no such term and $\lim_{s\to0}sX(s)=0\cdot X(0)=0$. In either case $x(t)\to\lim_{s\to0}sX(s)$. ■

Remarks — when the FVT fails.

1. *Poles on the imaginary axis.* $x(t)=\cos t$ has $X(s)=s/(s^2+1)$ and $sX(s)=s^2/(s^2+1)\to 0$ as $s\to 0$, but $\cos t$ has no limit. Hypothesis (b) fails because $sX(s)$ has poles at $\pm j$. The Abelian form (a) is not contradicted: it assumes the limit exists.
2. *Poles in the right half-plane.* $x(t)=e^{t}$ has $sX(s)=s/(s-1)\to 0$ as $s\to 0$, a meaningless "final value" for a signal that diverges. The Laplace integral does not converge near $s=0$; the formula $s/(s-1)$ there is an analytic continuation, which is why blind substitution misleads.
3. *Double pole at the origin.* $x(t)=t$ gives $sX(s)=1/s\to\infty$, correctly signalling divergence; hypothesis (b) fails because $sX(s)$ has a pole at 0.
4. *The converse of (a) is false.* That $sX(s)$ has a limit as $s\to0^+$ does not imply that $x(t)$ converges (Remark 1). Converse results need extra "Tauberian" hypotheses — for instance $t\,\dot{x}(t)$ bounded below (Hardy–Littlewood); for rational X, hypothesis (b) plays this role.
5. *IVT hypotheses.* If x contains an impulse at 0 then X is not strictly proper (e.g. $X=1+1/(s+1)$) and $sX(s)\to\infty$; the IVT applies to the regular part only. The limit in the IVT may be taken along any path with $\operatorname{Re}\{s\}\to\infty$, by the uniform estimate of §D.2.
6. Used in Ch. 14, §14.7 for steady-state errors of control loops and DC gains.



Blue: $x = 1 - e^{-t}$, $X = 1/[s(s+1)]$, whose sX has its only pole at -1, so the FVT correctly gives $x(\infty) = 1$. Red: $\cos t$, for which $sX(s) \to 0$ although no final value exists — the poles $\pm j$ violate the hypothesis.

D.6 Fourier coefficients from orthogonality; Bessel's inequality

Throughout §§D.6–D.9, x is T_0-periodic, $\omega_0 = 2\pi/T_0$, and $\int_{T_0}$ denotes integration over any interval of length T_0. For functions square-integrable over a period we use the normalised inner product and norm of Ch. 15, §15.1,

$$\langle x, y \rangle = \frac{1}{T_0}\int_{T_0} x(t)\, y^{*}(t)\, dt, \qquad \|x\|^2 = \frac{1}{T_0}\int_{T_0} |x(t)|^2 dt,$$

so $\|x\|^2$ is the mean-square value (the power) of x. Write $\varphi_n(t) = e^{jn\omega_0 t}$.

Orthonormality and the coefficient formula

(i) $\langle \varphi_m, \varphi_n \rangle = \delta_{mn}$ for all integers m, n.

(ii) If a series $\sum_{n=-\infty}^{\infty} d_n \varphi_n(t)$ converges **uniformly** on a period to $x(t)$, then necessarily

$$d_n = c_n := \langle x, \varphi_n \rangle = \frac{1}{T_0}\int_{T_0} x(t)\, e^{-jn\omega_0 t}\, dt,$$

and for real x the trigonometric coefficients are $a_n = 2\,\mathrm{Re}\{c_n\} = \frac{2}{T_0}\int_{T_0} x\cos n\omega_0 t\, dt$, $b_n = -2\,\mathrm{Im}\{c_n\} = \frac{2}{T_0}\int_{T_0} x \sin n\omega_0 t\, dt$.

Bessel's inequality

If $\int_{T_0}|x|^2 dt < \infty$ and $S_N = \sum_{n=-N}^{N} c_n \varphi_n$, then for every N

$$\|x - S_N\|^2 = \|x\|^2 - \sum_{n=-N}^{N} |c_n|^2 \;\geq 0, \qquad \text{hence} \qquad \sum_{n=-\infty}^{\infty} |c_n|^2 \leq \frac{1}{T_0}\int_{T_0} |x(t)|^2 dt.$$

In particular $c_n \to 0$ as $|n| \to \infty$. Moreover S_N is the unique trigonometric polynomial of degree $\leq N$ closest to x in mean square.

Proof. (i) For $m = n$ the integrand is 1. For $k = m - n \neq 0$, $\int_{t_1}^{t_1+T_0} e^{jk\omega_0 t} dt = e^{jk\omega_0 t_1}\big(e^{j2\pi k} - 1\big)/(jk\omega_0) = 0$.

(ii) Multiply $x(t) = \sum_m d_m \varphi_m(t)$ by the bounded function $\varphi_n^{*}(t)$; the product series still converges uniformly, so it may be integrated term by term (the integral of a uniform limit over a bounded interval is the limit of the integrals). By (i), $\langle x, \varphi_n\rangle = \sum_m d_m \langle \varphi_m, \varphi_n\rangle = d_n$. The real formulas follow from $\cos n\omega_0 t = \tfrac{1}{2}(\varphi_n + \varphi_{-n})$ and $\sin n\omega_0 t = \tfrac{1}{2j}(\varphi_n - \varphi_{-n})$.

Bessel. Let $p = \sum_{|n|\leq N} d_n \varphi_n$ be any trigonometric polynomial. Expanding the inner product and using (i),

$$\begin{aligned} \|x - p\|^2 &= \|x\|^2 - \sum_{|n|\leq N}\big(d_n^{*} c_n + d_n c_n^{*}\big) + \sum_{|n|\leq N} |d_n|^2 \\ &= \|x\|^2 - \sum_{|n|\leq N} |c_n|^2 + \sum_{|n|\leq N} |d_n - c_n|^2, \end{aligned}$$

the second line by completing the square, $|d_n - c_n|^2 = |d_n|^2 - d_n^{*}c_n - d_n c_n^{*} + |c_n|^2$. The last sum is ≥ 0 and vanishes only for $d_n = c_n$; this proves the best-approximation property. Taking $d_n = c_n$ gives the identity $\|x - S_N\|^2 = \|x\|^2 - \sum_{|n|\leq N}|c_n|^2$, whose left side is non-negative. The partial sums of the non-negative series $\sum |c_n|^2$ are therefore bounded by $\|x\|^2$, so the series converges with sum $\leq \|x\|^2$, and its terms tend to zero. $\blacksquare$

Remarks.

1. Part (ii) explains the *form* of the coefficient formula; the hypothesis of uniform convergence is there only so that the term-by-term integration is legitimate. For an arbitrary square-integrable x we *define* c_n by the formula and ask afterwards whether the series represents x — the subject of §§D.7–D.8.
2. Bessel's inequality is a statement about geometry, not Fourier analysis: it holds for any orthonormal set in any inner-product space, because S_N is the orthogonal projection of x on the span of $\varphi_{-N}, \dots, \varphi_N$ and projection cannot increase length. What is special about the trigonometric system is that equality holds (completeness), proved next.
3. The decay $c_n \to 0$ for square-integrable x is the Fourier-series form of the Riemann–Lebesgue lemma; §D.8 proves it for merely absolutely integrable x.
4. Used in Ch. 15, §15.1 and §15.7.

D.7 Parseval's theorem for Fourier series

Parseval's theorem

If x is T_0-periodic and $\int_{T_0}|x|^2 dt < \infty$, then $\|x - S_N\| \to 0$ as $N \to \infty$ and

$$\frac{1}{T_0}\int_{T_0} |x(t)|^2\, dt = \sum_{n=-\infty}^{\infty} |c_n|^2.$$

More generally $\langle x, y\rangle = \sum_n c_n\, d_n^{*}$ for two such functions with coefficients c_n, d_n.

By the identity in Bessel's inequality, Parseval's equality is *equivalent* to $\|x - S_N\| \to 0$. We prove that by approximating x first by a continuous function and then by Fejér means, which converge uniformly.

Fejér means and Fejér kernel

Take $T_0 = 2\pi$ (the general case follows by the change of variable $t \mapsto \omega_0 t$). The **Fejér mean** is the average of the first $N+1$ partial sums, $\sigma_N = \frac{1}{N+1}\sum_{k=0}^{N} S_k$. Since $S_k(t) = \frac{1}{2\pi}\int_{-\pi}^{\pi} x(t-u)D_k(u)\,du$ with the Dirichlet kernel $D_k(u) = \sum_{n=-k}^{k} e^{jnu}$ (§D.8),

$$\sigma_N(t) = \frac{1}{2\pi}\int_{-\pi}^{\pi} x(t-u)\,F_N(u)\,du, \qquad F_N(u) = \frac{1}{N+1}\sum_{k=0}^{N} D_k(u) = \frac{1}{N+1}\left(\frac{\sin\big((N+1)u/2\big)}{\sin(u/2)}\right)^2.$$

Lemma (closed form and properties of F_N). (a) the closed form above holds; (b) $F_N \ge 0$; (c) $\frac{1}{2\pi}\int_{-\pi}^{\pi} F_N = 1$; (d) for $0 < \delta \le |u| \le \pi$, $F_N(u) \le \dfrac{1}{(N+1)\sin^2(\delta/2)}$.

Proof. From §D.8, $D_k(u) = \sin\big((k+\tfrac12)u\big)/\sin(u/2)$. Using $2\sin(u/2)\sin\big((k+\tfrac12)u\big) = \cos ku - \cos(k+1)u$ and telescoping,

$$\sum_{k=0}^{N} D_k(u) = \frac{1-\cos(N+1)u}{2\sin^2(u/2)} = \frac{\sin^2\big((N+1)u/2\big)}{\sin^2(u/2)},$$

which is (a), and (b) is evident. Each D_k has mean value 1 over a period (only the $n=0$ term survives integration), so (c) follows. For (d), the numerator is at most 1 and $\sin^2(u/2) \ge \sin^2(\delta/2)$ on $\delta \le |u| \le \pi$. $\square$

Fejér's theorem. *If x is continuous and 2π-periodic, then $\sigma_N \to x$ uniformly.*

Proof. By (c), $\sigma_N(t) - x(t) = \frac{1}{2\pi}\int_{-\pi}^{\pi}\big[x(t-u)-x(t)\big]F_N(u)\,du$. A continuous periodic function is bounded, $|x| \le B$, and uniformly continuous: given $\varepsilon > 0$ there is $\delta > 0$ with $|x(t-u)-x(t)| < \varepsilon$ whenever $|u| < \delta$, for all t. Splitting the integral and using (b), (c), (d),

$$|\sigma_N(t) - x(t)| \le \frac{\varepsilon}{2\pi}\int_{|u|<\delta} F_N + \frac{2B}{2\pi}\int_{\delta\le|u|\le\pi} F_N \le \varepsilon + \frac{2B}{(N+1)\sin^2(\delta/2)},$$

uniformly in t. The last term is $< \varepsilon$ for N large. $\square$

Proof of Parseval's theorem.

Step 1 — continuous x. σ_N is a trigonometric polynomial of degree $\le N$. By the best-approximation property of §D.6 and Fejér's theorem,

$$\|x - S_N\| \le \|x - \sigma_N\| \le \max_t |x(t) - \sigma_N(t)| \xrightarrow[N\to\infty]{} 0,$$

the middle inequality because a mean-square value never exceeds the square of the maximum.

Step 2 — general square-integrable x. Continuous periodic functions are dense in mean square: for every $\varepsilon > 0$ there is a continuous periodic g with $\|x - g\| < \varepsilon$. (For Riemann-integrable x this is elementary: choose a step function ψ from a lower Darboux sum with $\frac{1}{T_0}\int|x-\psi|$ small and $|\psi| \le \sup|x|$, so that $\|x-\psi\|^2 \le 2\sup|x| \cdot \frac{1}{T_0}\int|x-\psi|$ is small, then replace each jump of ψ by a steep linear ramp, which changes $\|\cdot\|$ by an arbitrarily small amount; unbounded x are first truncated at a large level. For Lebesgue-square-integrable x it is a standard theorem of measure theory.) Let S_N^g be the partial sums of g. Since $x \mapsto S_N$ is an orthogonal projection, $\|S_N - S_N^g\| \le \|x - g\|$. Then

$$\|x - S_N\| \le \|x - g\| + \|g - S_N^g\| + \|S_N^g - S_N\| < 2\varepsilon + \|g - S_N^g\|,$$

and the last term tends to zero by Step 1. Hence $\limsup_N \|x - S_N\| \le 2\varepsilon$ for every ε.

Step 3 — the identity. By §D.6, $\|x\|^2 - \sum_{|n|\le N}|c_n|^2 = \|x - S_N\|^2 \to 0$.

Step 4 — the inner-product form. Apply the identity to $x + y$, $x - y$, $x + jy$, $x - jy$ and combine with the polarization identity $\langle x, y\rangle = \frac14\sum_{k=0}^{3} j^k\|x + j^k y\|^2$; the coefficient sequences combine the same way. ■

Remarks.

1. *Physical reading.* The left side is the average power of x; the right side distributes it over harmonics, $|c_n|^2 + |c_{-n}|^2$ being the power at frequency $n\omega_0$. For real x this is $\big(\frac{a_0}{2}\big)^2 + \frac12\sum_{n\ge1}(a_n^2 + b_n^2)$. Check: the unit square wave (±1) has $b_n = 4/(n\pi)$ for odd n and mean-square value 1; numerically $\frac12\sum_{n\ \text{odd}} 16/(n\pi)^2 = 1.0000$ (summing 10^5 terms gives 0.999998), equivalently $\sum_{n\ \text{odd}} 1/n^2 = \pi^2/8$.
2. *What Parseval does not say.* Mean-square convergence does not give convergence at any particular point: there are continuous functions whose Fourier series diverge at a point (du Bois-Reymond, 1873). Pointwise statements need the extra regularity of §D.8.
3. *Fejér versus Dirichlet.* F_N is non-negative while D_N oscillates in sign with $\frac{1}{2\pi}\int|D_N| \sim \frac{4}{\pi^2}\ln N \to \infty$; this is exactly why Cesàro averaging cures the Gibbs overshoot (Ch. 15, §15.6, "Taming Gibbs").
4. Used for RMS values, THD and power factor in Ch. 15, §15.8, and in §D.11 below.

D.8 Dirichlet's pointwise convergence theorem

Dirichlet kernel

For $T_0 = 2\pi$ and $N \ge 0$,

$$D_N(u) = \sum_{n=-N}^{N} e^{jnu} = \frac{\sin\big((N+\tfrac12)u\big)}{\sin(u/2)} \quad (u \notin 2\pi\mathbb{Z}), \qquad D_N(2\pi k) = 2N+1.$$

The closed form follows from the geometric sum: $(e^{ju/2} - e^{-ju/2})D_N(u) = e^{j(N+\frac12)u} - e^{-j(N+\frac12)u}$. D_N is even, 2π-periodic, and $\frac{1}{2\pi}\int_{-\pi}^{\pi} D_N(u)\,du = 1$, so $\frac{1}{2\pi}\int_0^{\pi} D_N = \frac12$ by evenness.

Riemann–Lebesgue lemma

If g is absolutely integrable on an interval (a, b) (bounded or not, Riemann-improper or Lebesgue), then

$$\lim_{\lambda \to \pm\infty} \int_a^b g(u)\, e^{j\lambda u}\, du = 0,$$

and hence also $\int_a^b g(u) \sin \lambda u \, du \to 0$ and $\int_a^b g(u) \cos \lambda u \, du \to 0$.

Proof of Riemann–Lebesgue. *Step functions.* For the indicator of an interval $[\alpha, \beta]$, $\left| \int_\alpha^\beta e^{j\lambda u} du \right| = |e^{j\lambda\beta} - e^{j\lambda\alpha}|/|\lambda| \le 2/|\lambda| \to 0$; by linearity the result holds for every step function (finite combination of indicators).

Approximation. Given $\varepsilon > 0$ there is a step function ψ with $\int_a^b |g - \psi| < \varepsilon$. (For a Riemann-integrable g on a bounded interval take ψ from a lower Darboux sum close to the integral, treating real and imaginary parts separately; for an improper integral first cut off a neighbourhood of each singularity and of infinity where $\int |g| < \varepsilon/2$; for Lebesgue-integrable g density of step functions is standard.) Then

$$\left| \int_a^b g\, e^{j\lambda u} du \right| \le \int_a^b |g - \psi|\, du + \left| \int_a^b \psi\, e^{j\lambda u} du \right| < \varepsilon + \left| \int_a^b \psi\, e^{j\lambda u} du \right|,$$

and the last term tends to zero. So the lim sup is at most ε for every ε. The sine and cosine versions are the imaginary and real parts when g is real, and linear combinations of λ and $-\lambda$ in general. ∎

Dirichlet's theorem (pointwise convergence)

Let x be 2π-periodic and absolutely integrable over a period. Fix t and suppose the one-sided limits $x(t^+), x(t^-)$ exist and that x satisfies one-sided Lipschitz (Hölder-type) bounds at t: there are $C, \delta > 0$ with

$$|x(t+u) - x(t^+)| \le C u, \qquad |x(t-u) - x(t^-)| \le C u \qquad (0 < u < \delta).$$

Then

$$\lim_{N \to \infty} S_N(t) = \frac{x(t^+) + x(t^-)}{2}.$$

In particular this holds at every point when x is piecewise smooth (piecewise C^1 with one-sided limits of x and x' at the break points), which covers the Dirichlet conditions as used in Ch. 15, §15.6 for all practical waveforms.

Proof. *Step 1 — the partial sum as a convolution.* Inserting the coefficient formula into S_N and exchanging the finite sum with the integral,

$$S_N(t) = \sum_{n=-N}^{N} \frac{1}{2\pi} \int_{-\pi}^{\pi} x(\tau) e^{-jn\tau} d\tau \; e^{jnt} = \frac{1}{2\pi} \int_{-\pi}^{\pi} x(\tau)\, D_N(t - \tau)\, d\tau = \frac{1}{2\pi} \int_{-\pi}^{\pi} x(t+u)\, D_N(u)\, du,$$

where we substituted $\tau = t + u$, used the evenness of D_N, and used periodicity to keep the interval $[-\pi, \pi]$.

Step 2 — fold onto $(0, \pi)$. Splitting at $u = 0$ and replacing u by $-u$ on $(-\pi, 0)$,

$$S_N(t) = \frac{1}{2\pi} \int_0^{\pi} \big[x(t+u) + x(t-u) \big] D_N(u)\, du.$$

Since $\frac{1}{2\pi} \int_0^\pi D_N = \frac{1}{2}$, subtracting $\frac{1}{2}[x(t^+) + x(t^-)]$ gives

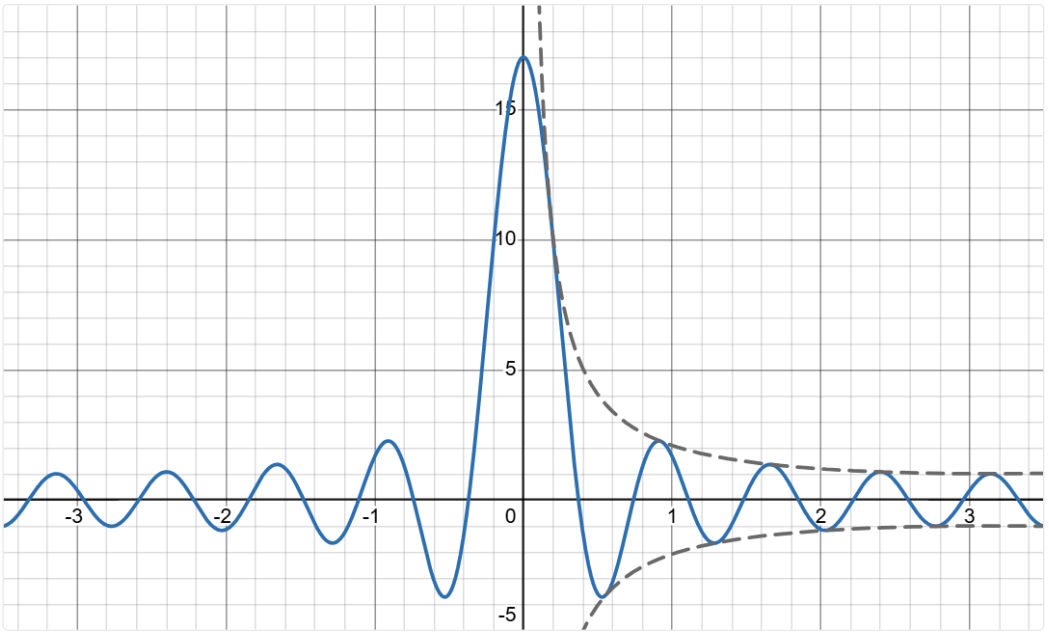
$$S_N(t) - \frac{x(t^+) + x(t^-)}{2} = \frac{1}{2\pi} \int_0^{\pi} g(u)\, \sin\big((N + \tfrac{1}{2})u\big)\, du, \qquad g(u) = \frac{x(t+u) - x(t^+) + x(t-u) - x(t^-)}{\sin(u/2)}.$$

Step 3 — g is absolutely integrable on $(0, \pi)$. On $(0, \delta)$, the numerator is at most $2Cu$ in modulus and $\sin(u/2) \ge u/\pi$ (Jordan's inequality, §D.16), so $|g(u)| \le 2\pi C$: bounded. On $[\delta, \pi]$, $\sin(u/2) \ge \sin(\delta/2) > 0$, so $|g| \le \big(|x(t+u)| + |x(t-u)| + |x(t^+)| + |x(t^-)|\big)/\sin(\delta/2)$, which is integrable because x is absolutely integrable over a period.

Step 4 — conclude. By the Riemann–Lebesgue lemma with $\lambda = N + \frac{1}{2} \to \infty$, the integral tends to zero. ∎

Remarks.

1. *Localisation.* The proof shows that convergence at t depends only on the behaviour of x in an arbitrarily small neighbourhood of t (the part of the integral over $[\delta, \pi]$ always tends to zero). Two functions that agree near t have Fourier series that converge or diverge together at t, even though their coefficients may be completely different.
2. *Why a regularity hypothesis is needed.* Continuity alone is not enough: there are continuous periodic functions whose Fourier series diverges at a point (Remark 2 of §D.7). The Lipschitz bound can be weakened to Dini's condition $\int_0^\delta |x(t \pm u) - x(t^\pm)|\, du/u < \infty$, or replaced by bounded variation near t (the Dirichlet–Jordan theorem, the version stated in Ch. 15 with "finitely many maxima and minima"); both proofs follow the same three steps.
3. *Midpoint value.* At a jump the series converges to the average because D_N is even: it weights the two sides of the jump equally.
4. *Uniform convergence.* If x is continuous and piecewise smooth, then $\sum |c_n| < \infty$ (since $c_n = c'_n/(jn)$ where c'_n are the coefficients of x', and Cauchy–Schwarz with Bessel for x' gives $\sum |c_n| \le |c_0| + (\sum |c'_n|^2)^{1/2} (2 \sum n^{-2})^{1/2}$), so by the M-test the series converges uniformly — necessarily to x, by Dirichlet's theorem.



The Dirichlet kernel $D_8(u) = \sin(8.5u)/\sin(u/2)$: a central peak of height $2N+1 = 17$ and width $\approx 2\pi/(N+\frac{1}{2})$, with side-lobes confined by the envelope $\pm 1/\sin(u/2)$ (dashed). Its area is fixed but its absolute area grows like $\ln N$ — the source of both localisation and Gibbs.

D.9 The Gibbs overshoot

Sine integral

$\operatorname{Si}(x) = \displaystyle\int_0^x \frac{\sin v}{v}\,dv$. Numerically $\operatorname{Si}(\pi) = 1.851937\ldots$ and $\operatorname{Si}(\infty) = \pi/2$.

Gibbs phenomenon for the square wave

Let x be the 2π-periodic square wave equal to 1 on $(0,\pi)$ and -1 on $(-\pi,0)$, a jump of size $J = 2$ at $t = 0$. Its Fourier series is $\frac{4}{\pi}\sum_{k\ge 1}\frac{\sin(2k-1)t}{2k-1}$; let S_m denote the sum of the first m terms. Then:

1. $S_m(t) = \dfrac{2}{\pi}\displaystyle\int_0^t \frac{\sin 2mu}{\sin u}\,du$;
2. on $(0,\pi)$ the maximum of S_m is attained at $t_m = \dfrac{\pi}{2m}$;
3. $\displaystyle\lim_{m\to\infty} S_m(t_m) = \frac{2}{\pi}\operatorname{Si}(\pi) = 1.178980\ldots$

So the overshoot above the value 1 tends to $\left(\frac{1}{\pi}\operatorname{Si}(\pi) - \frac{1}{2}\right)J = 0.0894899\,J$, about **8.95% of the jump**, while its location $t_m \to 0$.

Proof. *1.* Differentiating term by term (a finite sum),

$$S_m'(t) = \frac{4}{\pi}\sum_{k=1}^{m}\cos(2k-1)t = \frac{2}{\pi}\,\frac{\sin 2mt}{\sin t} \qquad (t \notin \pi\mathbb{Z}),$$

because $2\sin t\cos(2k-1)t = \sin 2kt - \sin(2k-2)t$, which telescopes to $\sin 2mt$. The quotient extends continuously to $t = 0$ (value $4m/\pi$), and $S_m(0) = 0$, so integration from 0 gives the formula.

2. On $(0,\pi)$ the critical points are the zeros of $\sin 2mt$, $t = k\pi/(2m)$, $k = 1,\ldots,2m-1$. Since $\sin t > 0$ there, S_m' has the sign of $\sin 2mt$: positive on $(0,\pi/2m)$, then alternating. So the local maxima are at $\tau_i = (2i-1)\pi/(2m)$. Between consecutive maxima,

$$S_m(\tau_{i+1}) - S_m(\tau_i) = \frac{2}{\pi}\left(\int_{\tau_i}^{i\pi/m} + \int_{i\pi/m}^{\tau_{i+1}}\right)\frac{\sin 2mu}{\sin u}\,du.$$

On the first sub-interval $\sin 2mu \le 0$, on the second $\sin 2mu \ge 0$, and the two half-lobes of $|\sin 2mu|$ are translates of each other by $\pi/(2m)$. If $\tau_{i+1} \le \pi/2$, the weight $1/\sin u$ is strictly decreasing over both, so the negative half-lobe outweighs the positive one and $S_m(\tau_{i+1}) < S_m(\tau_i)$. Thus the maxima decrease on $(0,\pi/2]$. Finally $S_m(\pi - t) = S_m(t)$, because $\sin\big((2k-1)(\pi-t)\big) = \sin(2k-1)t$, so the maxima on $[\pi/2,\pi)$ mirror those on $(0,\pi/2]$. Hence the largest is $S_m(\tau_1) = S_m(\pi/2m)$.

3. Substitute $v = 2mu$:

$$S_m\Big(\frac{\pi}{2m}\Big) = \frac{2}{\pi}\int_0^{\pi}\frac{\sin v}{2m\sin\left(v/2m\right)}\,dv.$$

For $0 < v \le \pi$, $2m\sin(v/2m) \to v$ as $m\to\infty$, and by Jordan's inequality $2m\sin(v/2m) \ge 2m\cdot\frac{2}{\pi}\cdot\frac{v}{2m} = \frac{2v}{\pi}$, so the integrand is bounded by $\frac{\pi}{2}\frac{\sin v}{v} \le \frac{\pi}{2}$. Dominated convergence (or, elementarily, uniform convergence of the integrand on $[0,\pi]$) gives

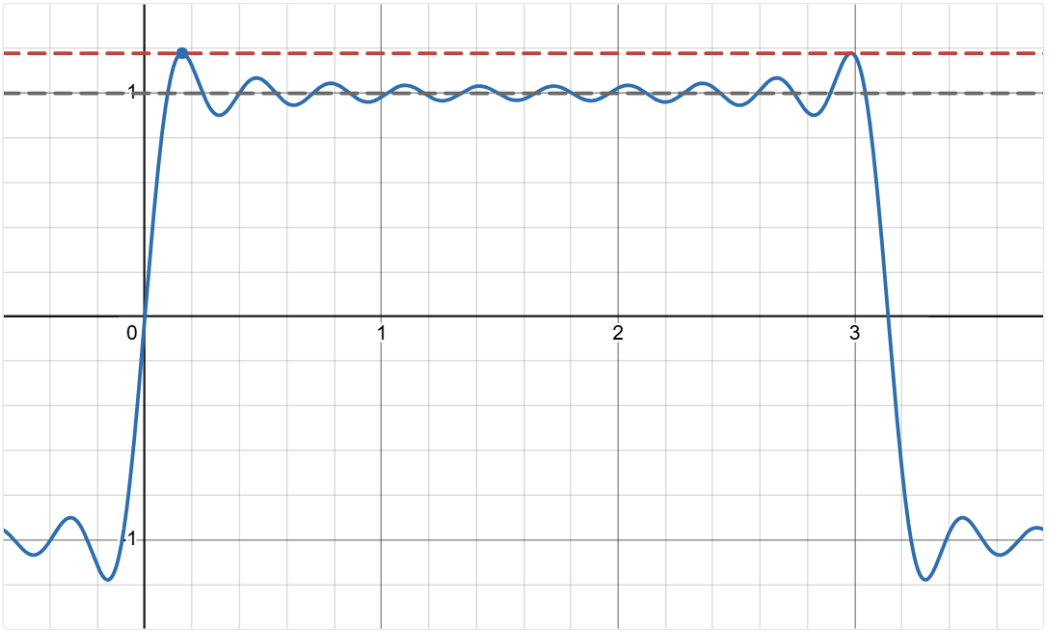
$$\lim_{m\to\infty} S_m\Big(\frac{\pi}{2m}\Big) = \frac{2}{\pi}\int_0^{\pi}\frac{\sin v}{v}\,dv = \frac{2}{\pi}\,\mathrm{Si}(\pi).$$

Numerically $\frac{2}{\pi}\,\mathrm{Si}(\pi) = 1.1789797$, an overshoot of $0.1789797 = 0.0894899 \times J$ with $J = 2$. ■

Numerical check. Direct summation gives $S_{10}(\pi/20) = 1.179814$, $S_{100}(\pi/200) = 1.178988$, $S_{1000}(\pi/2000) = 1.178980$; a dense grid search on $(0,\pi)$ for $m = 10$ confirms the global maximum at $t = 0.15708 = \pi/20$.

Remarks.

1. *General jumps.* If x is piecewise smooth with a jump $J = x(t_0^+) - x(t_0^-)$ at t_0, then $x - \frac{J}{2}\,q(t - t_0)$, with q the square wave above, is continuous and piecewise smooth near t_0; its Fourier series converges uniformly there (§D.8, Remark 4), so it contributes no overshoot, and the overshoot of x is $\frac{J}{2} \times 0.1789797 = 0.0895\,J$ on each side.
2. *Consistency with convergence theorems.* The peak moves to the jump as $m \to \infty$, so at each fixed $t \neq t_0$ the series converges (Dirichlet), and the overshoot region has width $O(1/m)$, so its contribution to the mean-square error vanishes (Parseval). What fails is *uniform* convergence: $\sup_t |S_m - x| \not\to 0$. No series of continuous functions can converge uniformly to a discontinuous limit.
3. *Engineering reading.* Truncating a spectrum with a brick-wall window causes 9% ringing on every edge, whatever the bandwidth — the same constant governs the step response of an ideal low-pass filter, whose peak is $\frac{1}{2} + \frac{1}{\pi}\,\mathrm{Si}(\pi) = 1.0895$ of the step. See Ch. 15, §15.6 and Ch. 16, §16.5.



Partial sum S_{10} of the square wave. The first peak at $t = \pi/20$ reaches 1.1798; the red line is the limiting value $\frac{2}{\pi}\,\mathrm{Si}(\pi) = 1.1790$, which is not reduced by taking more terms.

D.10 Fourier-transform convolution theorem and Plancherel–Parseval

Write L^1 for functions with $\int_{-\infty}^{\infty}|x|dt < \infty$ and L^2 for those with finite energy $\int|x|^2dt < \infty$. For $x \in L^1$ the transform $X(\omega) = \int x(t)e^{-j\omega t}dt$ exists for every ω, is bounded by $\|x\|_1$ and is continuous (Ch. 16, §16.1).

Convolution theorem (Fourier)

If $x, h \in L^1$, then $y(t) = (x * h)(t) = \int_{-\infty}^{\infty} x(\tau)h(t-\tau)\,d\tau$ converges absolutely for almost every t (for every t if one of the two is also bounded), $y \in L^1$ with $\|y\|_1 \le \|x\|_1\|h\|_1$, and

$$Y(\omega) = X(\omega)\,H(\omega) \qquad \text{for every } \omega.$$

Proof. By Tonelli's theorem and the substitution $u = t - \tau$,

$$\iint |x(\tau)|\,|h(t-\tau)|\,d\tau\,dt = \int |x(\tau)|\left(\int |h(u)|du\right)d\tau = \|x\|_1\|h\|_1 < \infty.$$

Hence the inner integral $\int|x(\tau)h(t-\tau)|d\tau$ is finite for almost every t, which defines $y(t)$, and $\int|y|dt \le \|x\|_1\|h\|_1$. (If $|h| \le B$, then $\int|x(\tau)h(t-\tau)|d\tau \le B\|x\|_1$ for every t.) Since $|e^{-j\omega t}| = 1$, the function $(\tau, t) \mapsto x(\tau)h(t-\tau)e^{-j\omega t}$ is absolutely integrable on $\mathbb{R}^2$, so Fubini's theorem allows

$$Y(\omega) = \int\left(\int x(\tau)h(t-\tau)\,d\tau\right)e^{-j\omega t}dt = \int x(\tau)e^{-j\omega\tau}\left(\int h(t-\tau)e^{-j\omega(t-\tau)}dt\right)d\tau = H(\omega)X(\omega).$$

■

Plancherel–Parseval

If $x \in L^1 \cap L^2$, then $X \in L^2$ and

$$\int_{-\infty}^{\infty} |x(t)|^2\,dt = \frac{1}{2\pi}\int_{-\infty}^{\infty} |X(\omega)|^2\,d\omega.$$

For $x, y \in L^1 \cap L^2$, $\displaystyle\int x(t)\,y^*(t)\,dt = \frac{1}{2\pi}\int X(\omega)\,Y^*(\omega)\,d\omega$. The map $x \mapsto X/\sqrt{2\pi}$ therefore extends uniquely to a norm-preserving map of all of L^2 onto L^2 (Plancherel's theorem).

Proof. *Step 1 — the autocorrelation.* Let $\tilde{x}(t) = x^*(-t)$ and $g = x * \tilde{x}$, i.e.

$$g(t) = \int x(\tau)\,x^*(\tau - t)\,d\tau.$$

Because $x \in L^2$, this integral converges absolutely for **every** t by Cauchy–Schwarz, with $|g(t)| \le \|x\|_2^2 = g(0)$. Moreover g is continuous: $|g(t) - g(t')| \le \|x\|_2\,\big(\int |x(\tau - t) - x(\tau - t')|^2 d\tau\big)^{1/2}$, and translation is continuous in L^2 (true for continuous compactly supported functions by uniform continuity, and for general x by density). Since $x \in L^1$, the convolution theorem gives $g \in L^1$ and, because $\tilde{X}(\omega) = \int x^*(-t)e^{-j\omega t}dt = X^*(\omega)$,

$$G(\omega) = X(\omega)X^*(\omega) = |X(\omega)|^2 \;\ge 0.$$

So the claim is $g(0) = \frac{1}{2\pi}\int G(\omega)\,d\omega$: an inversion formula at the single point $t = 0$ for a function whose transform is non-negative.

Step 2 — Gaussian regularisation. For $\varepsilon > 0$ the Gaussian $e^{-\varepsilon\omega^2}$ is the transform of

$$\phi_\varepsilon(t) = \frac{1}{2\pi}\int e^{-\varepsilon\omega^2}e^{j\omega t}d\omega = \frac{1}{\sqrt{4\pi\varepsilon}}\,e^{-t^2/(4\varepsilon)},$$

the standard Gaussian integral of Ch. 16 (complete the square, or use $\mathcal{F}\{e^{-at^2}\} = \sqrt{\pi/a}\,e^{-\omega^2/4a}$). Note that $\phi_\varepsilon > 0$, $\int \phi_\varepsilon = 1$, and ϕ_ε concentrates at 0 as $\varepsilon \to 0$. Because $g \in L^1$ and $e^{-\varepsilon\omega^2} \in L^1$, the double integral below is absolutely convergent and Fubini gives

$$\frac{1}{2\pi}\int G(\omega)e^{-\varepsilon\omega^2}d\omega = \frac{1}{2\pi}\iint g(t)e^{-j\omega t}e^{-\varepsilon\omega^2}\,dt\,d\omega = \int g(t)\,\phi_\varepsilon(-t)\,dt = \int g(t)\,\phi_\varepsilon(t)\,dt.$$

Step 3 — the limit $\varepsilon \to 0$. On the right: $\int g\phi_\varepsilon - g(0) = \int [g(t) - g(0)]\phi_\varepsilon(t)dt$. Given $\eta > 0$ choose δ with $|g(t) - g(0)| < \eta$ for $|t| < \delta$; the rest is bounded by $2g(0)\int_{|t|\ge\delta}\phi_\varepsilon \to 0$. So the right side tends to $g(0) = \|x\|_2^2$. On the left: $G\,e^{-\varepsilon\omega^2}$ increases to G as $\varepsilon \downarrow 0$ because $G \ge 0$, so by the monotone convergence theorem the left side tends to $\frac{1}{2\pi}\int G$ — which is therefore finite. Equating the limits gives $\|x\|_2^2 = \frac{1}{2\pi}\int |X|^2 d\omega$, and in particular $X \in L^2$.

Step 4 — inner products and extension. Polarization, as in §D.7 Step 4, gives the two-signal form. Since $L^1 \cap L^2$ is dense in L^2 (truncate to $[-T, T]$), the isometry $x \mapsto X/\sqrt{2\pi}$ extends by continuity to all of L^2; the extended transform is the mean-square limit of the truncated transforms $X_T(\omega) = \int_{-T}^{T} x(t)e^{-j\omega t}dt$, which is how Ch. 16, §16.1 defines it. That the extension is *onto* follows from applying the same argument to the inverse transform. ∎

Remarks.

1. *Why non-negativity is the trick.* The inversion formula can fail pointwise for general L^1 functions (the transform need not be integrable). Working with $G = |X|^2 \ge 0$ lets monotone convergence do the work that would otherwise require knowing $G \in L^1$ in advance.
2. *Check.* $x(t) = e^{-t}u(t)$ has energy $\int_0^\infty e^{-2t}dt = \frac{1}{2}$ and $X(\omega) = 1/(1 + j\omega)$; numerically $\frac{1}{2\pi}\int \frac{d\omega}{1+\omega^2} = 0.5000$.
3. *Convention.* The factor $1/(2\pi)$ belongs to the angular-frequency convention used in this book; in hertz, $\int |x|^2 dt = \int |X_f(f)|^2 df$.
4. Used for energy spectral density in Ch. 16, §16.7 and for LTI filtering in §16.5.

D.11 The Nyquist–Shannon sampling theorem

Notation follows Ch. 16, §16.8: sampling interval T, $\omega_s = 2\pi/T$, and $\operatorname{sinc}(u) = \sin(\pi u)/(\pi u)$.

Poisson summation (band-limited form)

Let $X \in L^1$ vanish outside a bounded interval and be square-integrable, and let $x(t) = \frac{1}{2\pi}\int X(\omega)e^{j\omega t}d\omega$ (a continuous function). Then the ω_s-periodic function $P(\omega) = \sum_{k=-\infty}^{\infty} X(\omega - k\omega_s)$ — a finite sum at each ω — has the mean-square convergent Fourier series

$$\sum_{k=-\infty}^{\infty} X(\omega - k\omega_s) = T\sum_{n=-\infty}^{\infty} x(nT)\,e^{-j\omega nT}.$$

Sampling theorem (Nyquist–Shannon)

Let x be as above with $X(\omega) = 0$ for $|\omega| > \omega_M$, and let the sampling rate satisfy $\omega_s > 2\omega_M$. Then x is uniquely determined by its samples $x(nT)$, the samples are square-summable, and for every real t

$$x(t) = \sum_{n=-\infty}^{\infty} x(nT)\,\operatorname{sinc}\!\left(\frac{t - nT}{T}\right),$$

the symmetric partial sums converging uniformly in t on all of $\mathbb{R}$.

Proof of Poisson summation. P is ω_s-periodic. On one period $I = [-\omega_s/2, \omega_s/2)$ only finitely many shifts $X(\omega - k\omega_s)$ are non-zero (the support of X is bounded), so P is square-integrable over I. Its Fourier series in the variable ω, with period ω_s and basis $e^{-j\omega nT}$ (note $\omega_s T = 2\pi$), has coefficients

$$d_n = \frac{1}{\omega_s}\int_I P(\omega)e^{j\omega nT}d\omega = \frac{1}{\omega_s}\sum_k \int_I X(\omega - k\omega_s)e^{j\omega nT}d\omega = \frac{1}{\omega_s}\int_{-\infty}^{\infty} X(\nu)e^{j\nu nT}d\nu = \frac{2\pi}{\omega_s}\,x(nT) = T\,x(nT).$$

In the third step we substituted $\nu = \omega - k\omega_s$, used $e^{jk\omega_s nT} = e^{j2\pi kn} = 1$, and observed that the translates $I + k\omega_s$ tile the line. By Parseval's theorem (§D.7, which applies to any square-integrable periodic function), the series $\sum_n d_n e^{-j\omega nT}$ converges to P in mean square over a period, and $\frac{1}{\omega_s}\int_I |P|^2 = \sum_n |d_n|^2$. ∎

Proof of the sampling theorem. *Step 1 — no aliasing.* Since $\omega_M < \omega_s/2$, for $\omega \in I = (-\omega_s/2, \omega_s/2)$ every shift with $k \neq 0$ is evaluated at $|\omega - k\omega_s| > \omega_s/2 > \omega_M$, where X vanishes. So $P = X$ on I, and Poisson summation gives, in mean square on I,

$$X(\omega) = T\sum_{n=-\infty}^{\infty} x(nT)\,e^{-j\omega nT} \qquad (|\omega| < \omega_s/2).$$

This already shows that the samples determine X on I (and $X = 0$ outside), hence determine x; and Parseval gives $\sum_n |x(nT)|^2 = \frac{1}{T^2\omega_s}\int_I |X|^2 < \infty$.

Step 2 — inversion term by term. Since $X = 0$ outside I,

$$x(t) = \frac{1}{2\pi}\int_I X(\omega)\,e^{j\omega t}\,d\omega = \frac{\omega_s}{2\pi}\,\langle X,\ e_t\rangle_I, \qquad e_t(\omega) = e^{-j\omega t},$$

with $\langle F, G\rangle_I = \frac{1}{\omega_s}\int_I F\,G^*$. An inner product with a fixed square-integrable function is continuous with respect to mean-square convergence (Cauchy–Schwarz), so we may insert the series of Step 1 and integrate term by term:

$$x(t) = \sum_n x(nT)\,\frac{T}{2\pi}\int_{-\omega_s/2}^{\omega_s/2} e^{j\omega(t-nT)}d\omega = \sum_n x(nT)\,\frac{T}{2\pi}\cdot\frac{2\sin\big(\omega_s(t-nT)/2\big)}{t-nT}.$$

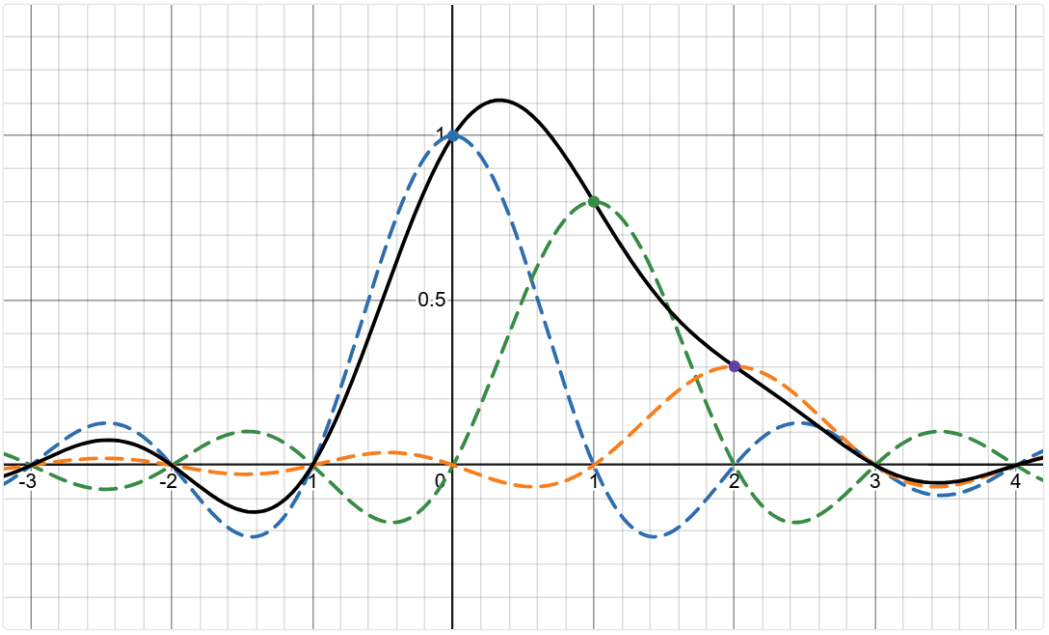
With $\omega_s/2 = \pi/T$, the coefficient is $\dfrac{\sin\big(\pi(t-nT)/T\big)}{\pi(t-nT)/T} = \operatorname{sinc}\big((t-nT)/T\big)$ (value 1 at $t = nT$).

Step 3 — uniform convergence. Let x_N be the partial sum over $|n| \le N$. By the same computation, $x(t) - x_N(t) = \frac{\omega_s}{2\pi}\langle X - X_N, e_t\rangle_I$, where X_N is the corresponding partial Fourier sum. Since $\|e_t\|_I = 1$ for every t, Cauchy–Schwarz gives $|x(t) - x_N(t)| \le \frac{\omega_s}{2\pi}\|X - X_N\|_I \to 0$, uniformly in t. ∎

Numerical check. $x(t) = \operatorname{sinc}^2(t/2)$ has a triangular spectrum supported on $|\omega| \le \pi$. With $T = 0.8$ ($\omega_s = 7.85 > 2\pi$) and $|n| \le 20000$, the reconstruction at $t = 0.37$ gives 0.8923548471, equal to $x(0.37)$ to ten digits.

Remarks.

1. *Why $\omega_s > 2\omega_M$.* If $\omega_s < 2\omega_M$, the shifted copies in P overlap on I, so $P \neq X$ there: the samples determine only the folded spectrum P, and different signals share the same samples (aliasing). For example $\cos(\omega_1 t)$ and $\cos\big((\omega_s - \omega_1)t\big)$ agree at every $t = nT$.
2. *The boundary case.* With $\omega_s = 2\omega_M$ the proof goes through whenever $X \in L^2$ is supported on $[-\omega_M, \omega_M]$, because the endpoints have measure zero. But it fails for spectra containing impulses at $\pm\omega_M$: $x(t) = \sin(\omega_M t)$ sampled at $T = \pi/\omega_M$ gives all-zero samples. This is why the theorem is stated with strict inequality.
3. *Interpretation.* The sinc functions $\operatorname{sinc}\big((t-nT)/T\big)$ are orthogonal and are the impulse responses of the ideal low-pass filter $H_r(\omega) = T\,\mathrm{rect}(\omega/\omega_s)$ shifted to the sampling instants. Reconstruction is "filter the impulse-sampled signal", exactly as derived with impulses in Ch. 16, §16.8; the proof here avoids generalized functions by working with Fourier series in ω.
4. *Practicality.* The sinc decays only like $1/|t|$, so truncating the series converges slowly, and real converters oversample and use smoother interpolation kernels.



Sinc reconstruction with $T = 1$ and three non-zero samples: each dashed sinc equals its sample at its own instant and vanishes at all the others, so the black sum passes exactly through every sample.

D.12 Z-transform: the ROC is an annulus; BIBO stability

Z-transform and ROC

For a sequence $x[n]$, $n \in \mathbb{Z}$, the Z-transform is $X(z) = \sum_{n=-\infty}^{\infty} x[n] z^{-n}$. Its **region of convergence** R_x is the set of $z \in \mathbb{C} \setminus \{0\}$ (with $z = \infty$ allowed when $x[n] = 0$ for $n < 0$, and $z = 0$ allowed when $x[n] = 0$ for $n > 0$) at which the series converges **absolutely**. A discrete-time LTI system with impulse response $h[n]$ is **BIBO stable** if every bounded input $|x[n]| \le B_x$ produces a bounded output $y = h * x$.

Shape of the ROC

Let

$$r_1 = \limsup_{n\to\infty} |x[n]|^{1/n}, \qquad \frac{1}{r_2} = \limsup_{m\to\infty} |x[-m]|^{1/m}$$

(with $1/0 = \infty$, $1/\infty = 0$). Then the series converges absolutely for $r_1 < |z| < r_2$ and diverges for $|z| < r_1$ and for $|z| > r_2$. Consequently R_x is an annulus $\{r_1 < |z| < r_2\}$, together possibly with some or all points of the boundary circles, and is empty if $r_1 > r_2$. On the open annulus X is analytic.

Stability and the unit circle

An LTI system is BIBO stable if and only if $\sum_n |h[n]| < \infty$, and this holds if and only if the unit circle $|z| = 1$ lies in R_h. A causal system with rational $H(z)$ is therefore stable if and only if all its poles satisfy $|p| < 1$.

Proof of the ROC theorem. Put $r = |z|$ and split $X(z) = \sum_{n\ge 0} x[n] z^{-n} + \sum_{m\ge 1} x[-m] z^{m}$. Absolute convergence of the whole series is equivalent to absolute convergence of both parts, and depends only on r because $|x[n] z^{-n}| = |x[n]| r^{-n}$.

Causal part. Apply the root test to $\sum_{n\ge 0} |x[n]| r^{-n}$: $\limsup_n \left(|x[n]| r^{-n}\right)^{1/n} = r_1/r$. If $r > r_1$ this is < 1 and the series converges (choose q with $r_1/r < q < 1$; then $|x[n]| r^{-n} \le q^n$ for large n, and compare with the geometric series). If $r < r_1$ it is > 1, so $|x[n]| r^{-n} \ge 1$ for infinitely many n, the terms do not tend to zero, and the series diverges.

Anticausal part. The same test on $\sum_{m\ge 1} |x[-m]| r^{m}$ gives $\limsup \left(|x[-m]| r^{m}\right)^{1/m} = r/r_2$: convergence for $r < r_2$, divergence for $r > r_2$.

Both parts converge for $r_1 < r < r_2$ and at least one diverges outside $[r_1, r_2]$; on the circles $r = r_1, r = r_2$ the test is inconclusive, which is why boundary points may or may not belong to R_x. Analyticity: on any closed sub-annulus $r_1 < \rho_1 \le |z| \le \rho_2 < r_2$ the terms are bounded by $|x[n]| \rho_1^{-n}$ ($n \ge 0$) and $|x[-m]| \rho_2^{m}$ ($m \ge 1$), which form convergent series by the above, so the Laurent series converges uniformly there (M-test) and its sum is analytic, each term being analytic on $\mathbb{C} \setminus \{0\}$. ∎

Proof of the stability theorem. *Sufficiency.* If $S = \sum |h[k]| < \infty$ and $|x[n]| \le B_x$, then

$$|y[n]| = \left| \sum_k h[k] x[n-k] \right| \le B_x \sum_k |h[k]| = B_x S,$$

and the series defining $y[n]$ converges absolutely for each n.

Necessity. Suppose $\sum |h[k]| = \infty$. Define the bounded input $x[n] = h^*[-n] / |h[-n]|$ where $h[-n] \neq 0$ and $x[n] = 0$ otherwise, so $|x[n]| \le 1$. Then

$$y[0] = \sum_k h[k] x[-k] = \sum_k \frac{h[k] h^*[k]}{|h[k]|} = \sum_k |h[k]| = \infty,$$

so this bounded input produces an output that is not even finite at $n = 0$, and the system is not BIBO stable. (To avoid a divergent defining sum, use instead the truncated inputs x_N, equal to x for $|n| \le N$ and 0 otherwise. Each satisfies $|x_N| \le 1$ and has a well-defined output with $y_N[0] = \sum_{|k|\le N} |h[k]|$. If the system were stable, the map $x \mapsto y$, being linear and time-invariant, would satisfy a bound $|y[n]| \le C \sup|x|$ — for a linear system, boundedness of outputs over the unit ball of inputs is equivalent to such a bound by the uniform boundedness principle — whereas $y_N[0] \to \infty$.)

The unit circle. On $|z| = 1$, $\sum_n |h[n] z^{-n}| = \sum_n |h[n]|$, so the unit circle lies in R_h (with absolute convergence, as in the definition) if and only if h is absolutely summable.

Causal rational case. If h is causal, $h[-m] = 0$ for $m \ge 1$, so $r_2 = \infty$ and $R_h \supseteq \{|z| > r_1\}$. For rational H, partial fractions give $h[n]$ as a finite sum of terms $n^k p^n u[n]$ (plus finitely many impulses), and $r_1 = \max|p|$ over the poles; X cannot be analytic at a pole, so no pole lies in the open ROC. Thus $R_h = \{|z| > \max|p|\}$ (including ∞), and it contains the unit circle iff $\max|p| < 1$. A pole exactly on the circle gives a term $n^k p^n$ with $|p| = 1$, which is not absolutely summable, so such a system is unstable even though the circle is the ROC's boundary. ∎

Remarks.

1. *The role of absolute convergence.* With a definition of the ROC by mere convergence, boundary points could be included for non-absolutely-summable sequences (e.g. $h[n] = u[n-1]/n$ converges on $|z| = 1$ except at $z = 1$), and the clean equivalence with stability would fail. Within the open annulus the two definitions agree.
2. *Analogy.* The continuous-time statement is that a causal LTI system is BIBO stable iff $\int |h| < \infty$ iff the $j\omega$-axis lies in the ROC of $H(s)$; the map $z = e^{sT}$ carries the axis onto the unit circle and the left half-plane into the disc (Ch. 17, §17.7).
3. Used in Ch. 17, §17.3 and §17.6.

D.13 Cauchy–Riemann equations: necessity and sufficiency

Complex differentiability

Let $f = u + jv$ be defined on an open set $D \subseteq \mathbb{C}$, with $z = x + jy$ and u, v real. f is **complex differentiable** at $z_0 \in D$ if

$$f'(z_0) = \lim_{\Delta z \to 0} \frac{f(z_0 + \Delta z) - f(z_0)}{\Delta z}$$

exists, the limit being taken as $\Delta z \to 0$ through **all** complex values. f is **analytic** on D if it is complex differentiable at every point of D.

Cauchy–Riemann equations

(Necessity.) If f is complex differentiable at $z_0 = x_0 + jy_0$, then the four partial derivatives u_x, u_y, v_x, v_y exist at (x_0, y_0) and satisfy

$$u_x = v_y, \qquad u_y = -v_x, \qquad \text{and} \qquad f'(z_0) = u_x + jv_x = v_y - ju_y.$$

(Sufficiency.) Conversely, if u and v are (real-)differentiable at (x_0, y_0) — in particular, if their first partials exist near (x_0, y_0) and are continuous at it — and satisfy the Cauchy–Riemann equations there, then f is complex differentiable at z_0.

Proof of necessity. Let $L = f'(z_0)$. Since the limit exists along every path, take $\Delta z = h$ real:

$$L = \lim_{h \to 0} \frac{u(x_0 + h, y_0) - u(x_0, y_0)}{h} + j\,\frac{v(x_0 + h, y_0) - v(x_0, y_0)}{h}.$$

A complex limit exists iff the limits of its real and imaginary parts exist, so u_x, v_x exist and $L = u_x + jv_x$. Now take $\Delta z = jh$, h real:

$$L = \lim_{h \to 0} \frac{u(x_0, y_0 + h) - u(x_0, y_0) + j\,[v(x_0, y_0 + h) - v(x_0, y_0)]}{jh} = \frac{1}{j}\,(u_y + jv_y) = v_y - ju_y.$$

Equating real and imaginary parts of the two expressions for L gives $u_x = v_y$ and $v_x = -u_y$. ∎

Proof of sufficiency. Real differentiability of u at (x_0, y_0) means that, with $\Delta z = h + jk$,

$$u(x_0 + h, y_0 + k) - u(x_0, y_0) = u_x h + u_y k + \varepsilon_1(h, k)\,|\Delta z|, \qquad \varepsilon_1 \to 0 \text{ as } \Delta z \to 0,$$

and similarly for v with a remainder ε_2. (If the partials are continuous near the point, this follows from the mean-value theorem applied separately in x and in y.) Using $v_x = -u_y$ and $v_y = u_x$,

$$\begin{aligned} f(z_0 + \Delta z) - f(z_0) &= (u_x h + u_y k) + j(v_x h + v_y k) + (\varepsilon_1 + j\varepsilon_2)|\Delta z| \\ &= (u_x h + u_y k) + j(-u_y h + u_x k) + (\varepsilon_1 + j\varepsilon_2)|\Delta z| \\ &= (u_x - ju_y)(h + jk) + (\varepsilon_1 + j\varepsilon_2)|\Delta z|. \end{aligned}$$

(Check the last line: $(u_x - ju_y)(h + jk) = u_x h + u_y k + j(u_x k - u_y h)$.) Dividing by Δz,

$$\frac{f(z_0 + \Delta z) - f(z_0)}{\Delta z} = (u_x - ju_y) + (\varepsilon_1 + j\varepsilon_2)\,\frac{|\Delta z|}{\Delta z},$$

and the last term has modulus $|\varepsilon_1 + j\varepsilon_2| \to 0$. So $f'(z_0) = u_x - ju_y = u_x + jv_x$. ∎

Remarks.

1. *Geometric meaning.* Real differentiability says the map $(x, y) \mapsto (u, v)$ is approximated by a 2×2 Jacobian $\begin{pmatrix} u_x & u_y \\ v_x & v_y \end{pmatrix}$. The Cauchy–Riemann equations say this matrix has the form $\begin{pmatrix} a & -b \\ b & a \end{pmatrix}$, i.e. it is multiplication by the complex number $a + jb$: a rotation combined with a scaling. That is why analytic maps are conformal where $f' \neq 0$.
2. *CR alone is not sufficient.* Let $f(z) = \sqrt{|xy|}$ (so $u = \sqrt{|xy|}$, $v = 0$). On the axes $u = 0$, so $u_x(0,0) = u_y(0,0) = 0 = v_x = v_y$ and the Cauchy–Riemann equations hold at the origin. But along $z = t(1 + j)$, $t > 0$, $\big(f(z) - f(0)\big)/z = t/\big(t(1 + j)\big) = 1/(1 + j)$, whereas along the real axis the quotient is 0; the limit does not exist. Here u is not real-differentiable at 0, which is the hypothesis that fails.
3. *Differentiability alone is not sufficient.* $f(z) = \bar{z}$ has $u = x$, $v = -y$, smooth, but $u_x = 1 \neq v_y = -1$; it is nowhere complex differentiable (the difference quotient is $\overline{\Delta z}/\Delta z$, which takes every value on the unit circle).
4. Used in Ch. 18, §18.3, and, through $\nabla^2 u = 0$, for the harmonic potentials of electrostatics.

D.14 Cauchy's integral theorem and integral formula

Contours and positive orientation

A **contour** is a continuous, piecewise continuously differentiable curve $z(\tau)$, $a \le \tau \le b$, and $\int_C f(z)\,dz = \int_a^b f(z(\tau))\,z'(\tau)\,d\tau$. A **simple closed** contour bounds a bounded region Ω (Jordan curve theorem); it is **positively oriented** when Ω lies to its left. A domain D is **simply connected** if the interior of every simple closed contour in D lies in D.

Cauchy's integral theorem (C^1 version)

Let f be analytic on a simply connected domain D, with f' continuous on D. Then for every simple closed contour C in D

$$\oint_C f(z)\,dz = 0.$$

More generally, if Ω is a bounded region whose boundary $\partial\Omega$ consists of finitely many disjoint simple closed contours, oriented with Ω to the left, and f is analytic with continuous f' on an open set containing $\overline{\Omega} = \Omega \cup \partial\Omega$, then $\oint_{\partial\Omega} f\,dz = 0$.

Cauchy's integral formula

Under the hypotheses of the first statement, for every z_0 inside C

$$f(z_0) = \frac{1}{2\pi j}\oint_C \frac{f(z)}{z - z_0}\,dz, \qquad \text{and} \qquad f^{(n)}(z_0) = \frac{n!}{2\pi j}\oint_C \frac{f(z)}{(z - z_0)^{n+1}}\,dz \quad (n \geq 1).$$

Proof of Cauchy's theorem. Write $f = u + jv$ and $dz = dx + j\,dy$. Then

$$\oint_C f\,dz = \oint_C (u\,dx - v\,dy) + j\oint_C (v\,dx + u\,dy).$$

Since $f' = u_x + jv_x = v_y - ju_y$ is continuous, the partials of u and v are continuous on D, and $\overline{\Omega}$ (the region bounded by C, together with C) lies in D by simple connectivity. Green's theorem $\oint_{\partial\Omega}(P\,dx + Q\,dy) = \iint_\Omega (Q_x - P_y)\,dx\,dy$ (Ch. 7), applied to each real line integral, gives

$$\oint_C f\,dz = \iint_\Omega (-v_x - u_y)\,dx\,dy + j\iint_\Omega (u_x - v_y)\,dx\,dy = 0,$$

since both integrands vanish identically by the Cauchy–Riemann equations (§D.13). Green's theorem holds verbatim for regions with finitely many holes (cut the region into simply connected pieces; the integrals along the cuts cancel in pairs), which proves the general statement. ∎

Proof of the integral formula. Fix z_0 inside C and choose $r > 0$ so small that the closed disc $|z - z_0| \leq r$ lies inside C. Let C_r be the circle $|z - z_0| = r$, positively oriented, and Ω_r the region between C and C_r. The function $g(z) = f(z)/(z - z_0)$ is analytic with continuous derivative on a neighbourhood of $\overline{\Omega_r}$, whose boundary is C (positive) together with C_r (negative). By the general form of Cauchy's theorem,

$$\oint_C \frac{f(z)}{z - z_0}\,dz = \oint_{C_r} \frac{f(z)}{z - z_0}\,dz \qquad \text{for every small } r > 0.$$

Now split the right side:

$$\oint_{C_r} \frac{f(z)}{z - z_0}\,dz = f(z_0)\oint_{C_r} \frac{dz}{z - z_0} + \oint_{C_r} \frac{f(z) - f(z_0)}{z - z_0}\,dz.$$

With $z = z_0 + re^{j\theta}$, $dz = jre^{j\theta}d\theta$, the first integral is $\int_0^{2\pi} j\,d\theta = 2\pi j$. The second is bounded, by the ML inequality (Ch. 18, §18.4), by $2\pi r \cdot \max_{C_r}|f(z) - f(z_0)|/r = 2\pi \max_{C_r}|f(z) - f(z_0)|$, which tends to 0 as $r \to 0$ by continuity of f. Since the left side does not depend on r, it equals $2\pi j\,f(z_0)$.

Derivatives. Let $F(w) = \frac{1}{2\pi j}\oint_C \frac{f(z)}{z-w}dz$ for w inside C; we have shown $F = f$ there. For w at distance $\geq d > 0$ from C, the difference quotient of the integrand,

$$\frac{1}{h}\left(\frac{1}{z - w - h} - \frac{1}{z - w}\right) = \frac{1}{(z - w - h)(z - w)} \longrightarrow \frac{1}{(z - w)^2}$$

uniformly for $z \in C$ as $h \to 0$ (for $|h| < d/2$ the denominators are bounded below by $d^2/2$, and the difference from the limit is $h/[(z - w - h)(z - w)^2]$, bounded by $2|h|/d^3$). Hence one may differentiate under the integral sign, and by induction $f^{(n)}(w) = \frac{n!}{2\pi j}\oint_C \frac{f(z)}{(z-w)^{n+1}}dz$. ∎

Remarks.

1. *Removing the C^1 hypothesis.* The Cauchy–Goursat theorem proves $\oint_C f\,dz = 0$ assuming only that f' exists at every point, by subdividing triangles and estimating — no continuity of f' and no Green's theorem. Combined with the derivative formula just proved, it shows that **an analytic function is automatically infinitely differentiable**, so the C^1 hypothesis used here costs no generality *a posteriori*. See Ch. 18, §18.5.
2. *Simple connectivity is essential.* $f(z) = 1/z$ is analytic on $\mathbb{C} \setminus \{0\}$, but $\oint_{|z|=1} dz/z = 2\pi j \neq 0$. The punctured plane is not simply connected — the hole at 0 is exactly what the integral detects, and the residue theorem turns this into a computational tool.
3. *Mean-value property.* With C a circle of radius r about z_0, the formula reads $f(z_0) = \frac{1}{2\pi}\int_0^{2\pi} f(z_0 + re^{j\theta})\,d\theta$: an analytic function (and hence its real part, a harmonic function) equals its average on every circle — the basis of the maximum-modulus principle and of Liouville's theorem in Ch. 18.
4. *Consequence for the Laplace transform.* The Bromwich inversion integral of Ch. 14, §14.4 is a contour integral of $X(s)e^{st}$; Cauchy's theorem is what allows the vertical line to be moved freely within the ROC.

D.15 The residue theorem

Residue

If f is analytic in a punctured disc $0 < |z - z_k| < \rho$, it has a Laurent expansion $f(z) = \sum_{n=-\infty}^{\infty} a_n (z - z_k)^n$ there, converging uniformly on every circle $|z - z_k| = r$, $0 < r < \rho$ (Ch. 18, §18.6). The **residue** of f at z_k is $\operatorname{Res}_{z=z_k} f = a_{-1}$.

Residue theorem

Let C be a positively oriented simple closed contour, and let f be analytic on an open set containing C and its interior, except at finitely many points $z_1, \dots, z_K$ inside C. Then

$$\oint_C f(z)\,dz = 2\pi j \sum_{k=1}^{K} \operatorname{Res}_{z=z_k} f.$$

Proof. *Step 1 — one circle.* Let C_k be the circle $|z - z_k| = r$, positively oriented, with r small. On C_k the Laurent series converges uniformly, so it may be integrated term by term. For each integer n, with $z = z_k + re^{j\theta}$,

$$\oint_{C_k} (z - z_k)^n\,dz = \int_0^{2\pi} r^n e^{jn\theta} \cdot jre^{j\theta}\,d\theta = jr^{n+1}\int_0^{2\pi} e^{j(n+1)\theta}\,d\theta = \begin{cases} 2\pi j, & n = -1, \\ 0, & n \neq -1. \end{cases}$$

Hence $\oint_{C_k} f\,dz = 2\pi j\, a_{-1} = 2\pi j \operatorname{Res}_{z=z_k} f$. Only the $(z - z_k)^{-1}$ term survives, because every other power has a single-valued antiderivative on the punctured disc.

Step 2 — deformation. Choose r so small that the closed discs $|z - z_k| \le r$ are disjoint and lie inside C. Let Ω be the region inside C and outside all the discs. Its boundary is C (positively oriented) together with the circles C_k traversed negatively, and f is analytic on a neighbourhood of $\overline{\Omega}$ (with continuous derivative, by Remark 1 of §D.14). By the general form of Cauchy's theorem,

$$\oint_C f\,dz - \sum_{k=1}^{K} \oint_{C_k} f\,dz = 0.$$

Substituting Step 1 completes the proof. ∎

Remarks.

1. *Computing residues.* At a simple pole, $\operatorname{Res} = \lim_{z\to z_k}(z - z_k)f(z)$; for $f = N/D$ with $D(z_k) = 0 \neq D'(z_k)$ this is $N(z_k)/D'(z_k)$; at a pole of order m, $\operatorname{Res} = \frac{1}{(m-1)!}\lim_{z\to z_k}\frac{d^{m-1}}{dz^{m-1}}\big[(z - z_k)^m f(z)\big]$. Each follows by reading off a_{-1} from the Laurent series (Ch. 18, §18.7).
2. *Hypotheses.* The singularities must be isolated and finite in number inside C, and none may lie *on* C. A pole on the contour makes the integral improper; one then uses indentations and principal values, each small semicircle contributing πj times the residue in the limit.
3. *Where it is used.* Inverse Laplace transforms by closing the Bromwich contour to the left (the Heaviside expansion is the sum of residues of $X(s)e^{st}$), inverse Z-transforms $x[n] = \frac{1}{2\pi j}\oint X(z)z^{n-1}dz$, real integrals (Ch. 18, §18.8), and the argument principle behind the Nyquist criterion (§18.9).

D.16 Jordan's lemma

Jordan's inequality and Jordan's lemma

(Inequality.) For $0 \le \theta \le \pi/2$, $\dfrac{2\theta}{\pi} \le \sin\theta \le \theta$.

(Lemma.) Let $\omega > 0$, let C_R be the upper semicircle $z = Re^{j\theta}$, $0 \le \theta \le \pi$, and let g be continuous on C_R for all large R with $M_R = \max_{C_R}|g| \to 0$ as $R \to \infty$. Then

$$\left|\int_{C_R} g(z)\,e^{j\omega z}\,dz\right| \le \frac{\pi}{\omega}\,M_R\big(1 - e^{-\omega R}\big) \le \frac{\pi M_R}{\omega} \xrightarrow[R\to\infty]{} 0.$$

Proof of the inequality. $\sin\theta \le \theta$ because $\frac{d}{d\theta}(\theta - \sin\theta) = 1 - \cos\theta \ge 0$ and equality holds at 0. For the lower bound, sin is concave on $[0, \pi/2]$ (its second derivative $-\sin\theta \le 0$), so its graph lies above the chord joining $(0, 0)$ and $(\pi/2, 1)$, which is the line $2\theta/\pi$. ∎

Proof of the lemma. On C_R, $z = R(\cos\theta + j\sin\theta)$, so $|e^{j\omega z}| = e^{-\omega R\sin\theta}$ and $|dz| = R\,d\theta$. Hence

$$\left|\int_{C_R} g\,e^{j\omega z}dz\right| \le M_R\,R\int_0^{\pi} e^{-\omega R\sin\theta}\,d\theta = 2M_R R\int_0^{\pi/2} e^{-\omega R\sin\theta}\,d\theta,$$

using the symmetry $\sin(\pi - \theta) = \sin\theta$. By Jordan's inequality $e^{-\omega R\sin\theta} \le e^{-2\omega R\theta/\pi}$ on $[0, \pi/2]$, so

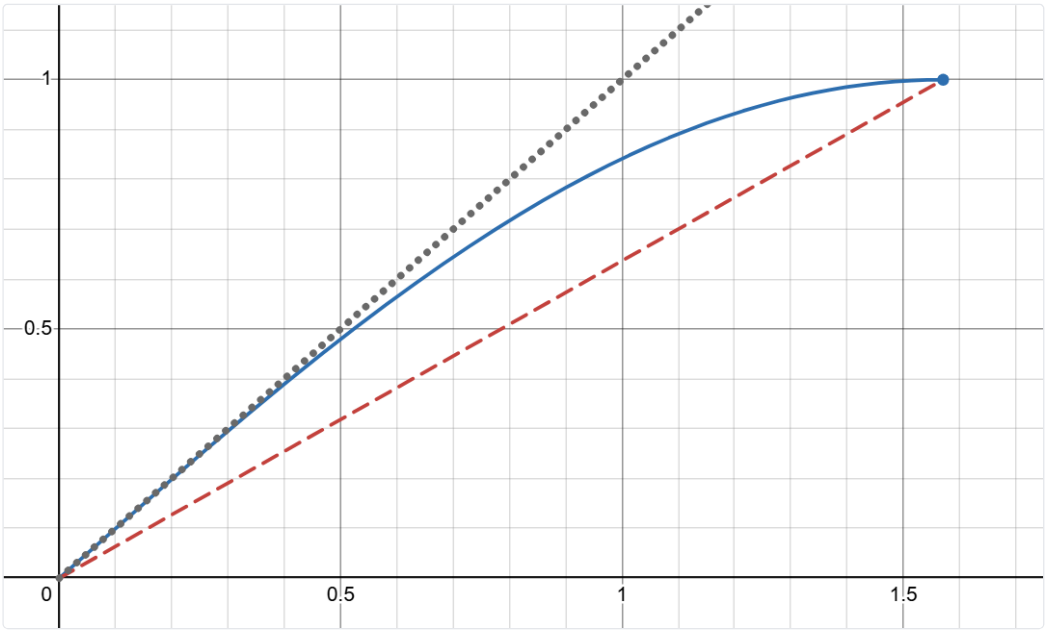
$$2M_R R\int_0^{\pi/2} e^{-2\omega R\theta/\pi}\,d\theta = 2M_R R\cdot\frac{\pi}{2\omega R}\big(1 - e^{-\omega R}\big) = \frac{\pi M_R}{\omega}\big(1 - e^{-\omega R}\big).$$

∎

Remarks.

1. *Why the lemma is sharper than ML.* The ML inequality gives only $|\int| \le \pi R M_R$, which tends to zero only if $M_R = o(1/R)$, e.g. $g = 1/z^2$. Jordan's lemma needs only $M_R \to 0$, e.g. $g = 1/z$: the factor R from the arc length is cancelled because $e^{j\omega z}$ is exponentially small except within an angle of order $1/(\omega R)$ of the real axis. Numerically, for $\omega = 1$ the key integral $\int_0^{\pi} e^{-R\sin\theta}d\theta$ equals 0.4208 at $R = 5$ and 0.0400 at $R = 50$, against Jordan's bounds $\frac{\pi}{R}(1 - e^{-R}) = 0.6241$ and 0.0628: both decay like $1/R$, as the proof predicts.
2. *The sign of ω dictates the half-plane.* For $\omega < 0$ the factor $e^{j\omega z}$ is small in the *lower* half-plane, and the contour must be closed there (clockwise, introducing a minus sign). The same rule closes the Bromwich contour for $X(s)e^{st}$: to the left for $t > 0$, to the right for $t < 0$, which is why causal signals have all their poles to the left of the ROC.

3. *Typical use.* For $\int_{-\infty}^{\infty} \frac{\cos x}{x^2+1}dx$, integrate $e^{jz}/(z^2+1)$ over $[-R,R]$ plus C_R. The only enclosed pole is $z=j$, with residue $e^{-1}/(2j)$; the arc vanishes by Jordan's lemma (here even ML suffices); so the integral is $2\pi j \cdot e^{-1}/(2j) = \pi/e = 1.15573$, which agrees with numerical quadrature. For $\int_{-\infty}^{\infty} \frac{\sin x}{x}dx = \pi$, the case $g = 1/z$, ML fails and Jordan's lemma is indispensable. See Ch. 18, §18.8 and the Fourier inversion of rational spectra in Ch. 16, §16.2.



Jordan's inequality: on $[0,\pi/2]$ the concave curve $\sin\theta$ (blue) lies between its chord $2\theta/\pi$ (red, dashed) and its tangent θ (grey). The lower bound is what turns $e^{-\omega R\sin\theta}$ into an integrable exponential.

Appendix E — Probability, Statistics and Numerical Methods

This appendix supplies complete proofs of the central results of Part VI (Chapters 19–21) and of the numerical chapters of Part VII (Chapters 22 and 24) that the chapters state with only a sketch. The probability results run from the elementary (Bayes' theorem, linearity of expectation) through the limit theorems (the weak law of large numbers and the central limit theorem) to the second-order theory of random processes (Wiener–Khinchin, filtering of noise). The statistics results are the unbiasedness of the sample variance, least squares and the Gauss–Markov theorem, and the GUM law of propagation of uncertainty. The numerical results are the convergence theorems for bisection, Newton–Raphson, the trapezoidal and Simpson rules, Euler's method and Monte Carlo integration.

Prerequisites. Calculus with Taylor's theorem and its remainder (Ch. 4–6), matrix algebra (Ch. 8), Fourier transforms (Ch. 16), and the probability vocabulary of Ch. 19.

Level of rigour. Every hypothesis is stated precisely, and every step is justified from those hypotheses. A few deep tools of measure-theoretic probability and analysis are *quoted* with a reference rather than proved: the linearity and monotonicity of the Lebesgue integral, Fubini's theorem, the dominated convergence theorem, Lévy's continuity theorem, and Fourier inversion. Each is named where it is used. Random variables are real-valued and defined on a probability space $(\Omega, \mathcal{F}, P)$ (Section 19.1). "i.i.d." means independent and identically distributed.

E.1 The law of total probability and Bayes' theorem

Conditional probability and partitions

For events A, B with $P(B) > 0$, the conditional probability of A given B is

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)}.$$

A finite or countable family of events $B_1, B_2, \ldots$ is a **partition** of Ω if the B_i are pairwise disjoint ($B_i \cap B_k = \varnothing$ for $i \neq k$) and $\bigcup_i B_i = \Omega$.

Statement

Law of total probability and Bayes' theorem

Let $B_1, B_2, \ldots$ be a finite or countable partition of Ω with $P(B_i) > 0$ for every i, and let A be any event.

1. **Total probability:**

$$P(A) = \sum_i P(A \mid B_i)\, P(B_i).$$

2. **Bayes' theorem:** if in addition $P(A) > 0$, then for every k

$$P(B_k \mid A) = \frac{P(A \mid B_k)\, P(B_k)}{\sum_i P(A \mid B_i)\, P(B_i)}.$$

Proof

Step 1 (decompose A). Because the B_i cover Ω,

$$A = A \cap \Omega = A \cap \Big(\bigcup_i B_i\Big) = \bigcup_i (A \cap B_i),$$

by the distributive law of intersection over union.

Step 2 (the pieces are disjoint). For $i \neq k$, $(A \cap B_i) \cap (A \cap B_k) \subseteq B_i \cap B_k = \varnothing$.

Step 3 (additivity). By the countable additivity axiom (Section 19.1), applied to the disjoint family of Step 2,

$$P(A) = \sum_i P(A \cap B_i).$$

Step 4 (multiplication rule). Since $P(B_i) > 0$, the definition of conditional probability rearranges to $P(A \cap B_i) = P(A \mid B_i) P(B_i)$. Substituting into Step 3 proves part 1.

Step 5 (Bayes). Since $P(A) > 0$ and $P(B_k) > 0$, the definition gives two expressions for the same joint probability:

$$P(B_k \mid A)\, P(A) = P(A \cap B_k) = P(A \mid B_k)\, P(B_k).$$

Divide by $P(A)$ and replace $P(A)$ by the sum from part 1. ■

Remarks

- *Why the hypotheses matter.* If the B_i overlap, Step 2 fails and the sum in part 1 counts the overlap twice. For example, with $B_1 = B_2 = \Omega$ the formula would give $P(A) = 2P(A)$. If the B_i do not cover Ω, the sum misses $A \setminus \bigcup_i B_i$. The condition $P(B_i) > 0$ is needed only so that $P(A \mid B_i)$ is defined. Cells with $P(B_i) = 0$ may simply be dropped, because they contribute $P(A \cap B_i) = 0$.

- *Base-rate effect.* Suppose a fault detector flags a faulty unit with probability 0.99, flags a healthy unit with probability 0.05, and 1% of units are faulty. Bayes' theorem gives

$$P(\text{faulty} \mid \text{flag}) = \frac{0.99 \cdot 0.01}{0.99 \cdot 0.01 + 0.05 \cdot 0.99} = \frac{1}{6} \approx 0.167.$$

So five out of six alarms are false, because the small prior is weighted against a comparatively large false-alarm rate. The chapter treats this in Section 19.3.

- *Continuous form.* If X has density f_X and the conditional densities exist, the same argument with integrals in place of sums gives $f_{X\mid A}(x) = P(A \mid X = x) f_X(x) / \int P(A \mid X = u) f_X(u)\, du$. Strictly, conditioning on the null event $\{X = x\}$ needs the measure-theoretic definition of conditional probability. The formula used in Section 19.7 is the limit of the discrete one over shrinking cells $\{x < X \le x + \Delta\}$.
- *Where used.* Total probability appears in Section 19.2. Bayes' theorem underlies the binary channel and MAP/ML detection in Section 19.3, and likelihood ratio tests in Section 20.8.

E.2 Linearity of expectation and the variance of a sum

Expectation, variance, covariance

A random variable X is **integrable** if $E|X| < \infty$. Its expectation is $E[X] = \int_\Omega X\, dP$. This equals $\sum_x x\, p_X(x)$ for a pmf and $\int x f_X(x)\, dx$ for a pdf (Section 19.9). If $E[X^2] < \infty$, the **variance** is $\operatorname{Var}(X) = E[(X - \mu_X)^2]$ with $\mu_X = E[X]$. For X, Y with finite second moments, the **covariance** is $\operatorname{Cov}(X, Y) = E[(X - \mu_X)(Y - \mu_Y)]$.

Statement

Linearity of expectation; variance of a sum

1. If X and Y are integrable and $a, b \in \mathbb{R}$, then $aX + bY$ is integrable and

$$E[aX + bY] = a\,E[X] + b\,E[Y].$$

No independence is assumed. 2. If $E[X^2] < \infty$ and $E[Y^2] < \infty$, then $\operatorname{Cov}(X, Y)$ is finite and

$$\operatorname{Var}(X + Y) = \operatorname{Var}(X) + \operatorname{Var}(Y) + 2\operatorname{Cov}(X, Y).$$

3. More generally, for a random vector $\mathbf{X} = (X_1, \dots, X_n)^{\mathsf{T}}$ with finite second moments, covariance matrix $\boldsymbol{\Sigma}$ with entries $\Sigma_{ik} = \operatorname{Cov}(X_i, X_k)$, and $\mathbf{a} \in \mathbb{R}^n$,

$$\operatorname{Var}(\mathbf{a}^{\mathsf{T}}\mathbf{X}) = \sum_{i=1}^{n}\sum_{k=1}^{n} a_i a_k \Sigma_{ik} = \mathbf{a}^{\mathsf{T}}\boldsymbol{\Sigma}\,\mathbf{a},$$

and $\boldsymbol{\Sigma}$ is symmetric positive semidefinite.

Proof

Part 1. Integrability follows from the triangle inequality, $|aX + bY| \le |a||X| + |b||Y|$, together with monotonicity of the integral. The identity is the linearity of the Lebesgue integral $\int_\Omega (\cdot)\, dP$, which we quote. The two cases used in this book can also be checked directly.

- *Joint pmf $p(x, y)$.* By the law of the unconscious statistician (Section 19.9),

$$E[aX + bY] = \sum_{x,y} (ax + by)\, p(x, y) = a \sum_x x \sum_y p(x, y) + b \sum_y y \sum_x p(x, y) = a \sum_x x\, p_X(x) + b \sum_y y\, p_Y(y).$$

The rearrangement is legitimate because the double series converges absolutely: $\sum |ax + by|\, p \le |a| E|X| + |b| E|Y| < \infty$.

- *Joint pdf $f(x, y)$.* The same computation with $\iint$ in place of $\sum\sum$ works, using Fubini's theorem (justified by the same absolute bound) and the marginalisation $\int f(x, y)\, dy = f_X(x)$.

Only the marginals p_X and p_Y survive the computation. The dependence between X and Y, which is encoded in $p(x, y)$, has been summed out. That is why independence is not needed.

Part 2. First, finiteness. From $(|x| - |y|)^2 \ge 0$ we get $|xy| \le \tfrac{1}{2}(x^2 + y^2)$, so $E|XY| \le \tfrac{1}{2}(E[X^2] + E[Y^2]) < \infty$. Likewise $E|X| \le \tfrac{1}{2}(1 + E[X^2]) < \infty$. All the expectations below therefore exist. Put $\tilde{X} = X - \mu_X$ and $\tilde{Y} = Y - \mu_Y$. By part 1, $E[X + Y] = \mu_X + \mu_Y$, so $X + Y - E[X + Y] = \tilde{X} + \tilde{Y}$ and

$$\operatorname{Var}(X + Y) = E\big[(\tilde{X} + \tilde{Y})^2\big] = E\big[\tilde{X}^2 + \tilde{Y}^2 + 2\tilde{X}\tilde{Y}\big] = E[\tilde{X}^2] + E[\tilde{Y}^2] + 2E[\tilde{X}\tilde{Y}],$$

where the last equality is part 1 again. The three terms are $\operatorname{Var} X$, $\operatorname{Var} Y$ and $\operatorname{Cov}(X, Y)$.

Part 3. With $\tilde{X}_i = X_i - \mu_i$, we have $\mathbf{a}^{\mathsf{T}}\mathbf{X} - E[\mathbf{a}^{\mathsf{T}}\mathbf{X}] = \sum_i a_i \tilde{X}_i$. Squaring the finite sum and applying part 1 term by term gives

$$E\Big[\Big(\sum_i a_i \tilde{X}_i\Big)^2\Big] = \sum_i \sum_k a_i a_k E[\tilde{X}_i \tilde{X}_k] = \mathbf{a}^{\mathsf{T}}\boldsymbol{\Sigma}\,\mathbf{a}.$$

Symmetry of $\boldsymbol{\Sigma}$ is clear from the definition. Positive semidefiniteness holds because $\mathbf{a}^{\mathsf{T}}\boldsymbol{\Sigma}\mathbf{a}$ is a variance, the expectation of a square, and so is ≥ 0 for every $\mathbf{a}$. $\blacksquare$

Remarks

- *Independent or uncorrelated terms.* If the X_i are pairwise **uncorrelated** ($\Sigma_{ik} = 0$ for $i \ne k$), part 3 reduces to $\operatorname{Var}(\sum a_i X_i) = \sum a_i^2 \operatorname{Var} X_i$. Independence implies uncorrelatedness (Section 19.9) but is not needed. This is the "quadrature addition" of tolerances and noise powers.

- *Counterexample to "variances always add".* Take $Y = -X$. Then $\operatorname{Var}(X+Y) = 0$, while $\operatorname{Var} X + \operatorname{Var} Y = 2\operatorname{Var} X$. The covariance term $-2\operatorname{Var} X$ accounts for the difference exactly. Differential signalling exploits this. Common-mode noise is positively correlated on the two wires, so it cancels in the difference.
- *Finite moments are essential.* If X is Cauchy, $E|X| = \infty$, and $E[X] + E[-X]$ is the meaningless $\infty - \infty$, even though $X + (-X) = 0$.
- *Where used.* Section 19.9 (sums, tolerance stack-up), Section 20.3 (covariance matrix), and every later section of this appendix.

E.3 Markov and Chebyshev inequalities

Statement

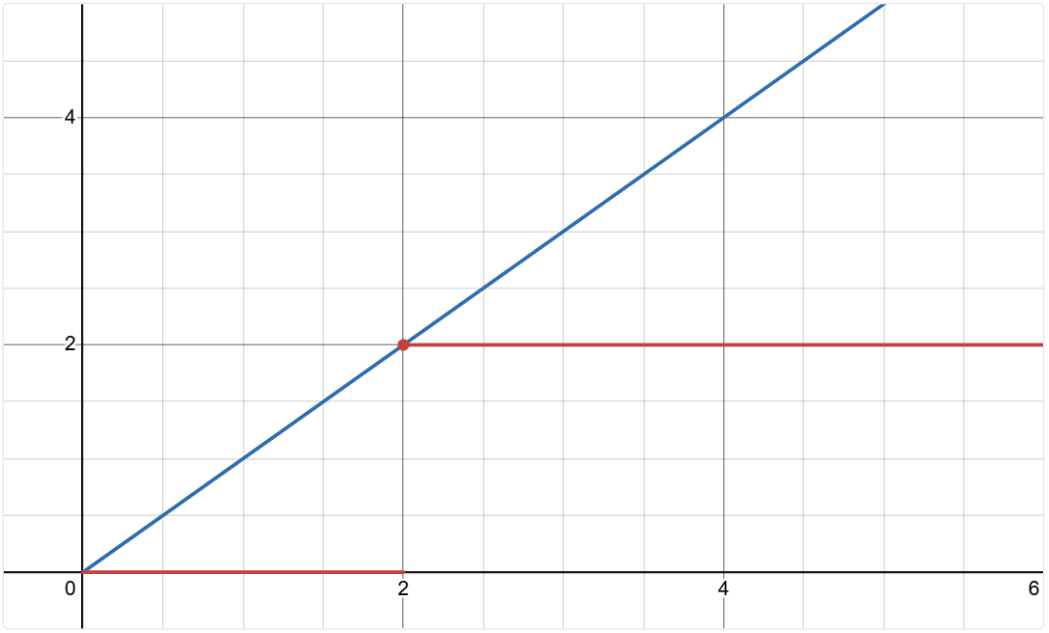
Markov and Chebyshev inequalities

1. **Markov.** If $X \geq 0$ and $a > 0$, then
$$P(X \geq a) \leq \frac{E[X]}{a}.$$
2. **Chebyshev.** If $E[X^2] < \infty$, $\mu = E[X]$, $\sigma^2 = \operatorname{Var} X$ and $\varepsilon > 0$, then
$$P(|X-\mu| \geq \varepsilon) \leq \frac{\sigma^2}{\varepsilon^2}, \qquad \text{equivalently} \qquad P(|X-\mu| \geq k\sigma) \leq \frac{1}{k^2} \quad (k>0,\ \sigma>0).$$

Proof

Markov. Let $I = \mathbf{1}_{\{X \geq a\}}$ be the indicator of the event $\{X \geq a\}$. We claim that $aI \leq X$ at every outcome ω. If $X(\omega) \geq a$, then $aI(\omega) = a \leq X(\omega)$. Otherwise $aI(\omega) = 0 \leq X(\omega)$, because $X \geq 0$. Expectation is monotone: if $U \leq V$, then $E[V] - E[U] = E[V-U] \geq 0$ by E.2 and the non-negativity of the integral of a non-negative function. Hence $E[aI] \leq E[X]$. But $E[aI] = a\,P(X \geq a)$. Divide by $a > 0$. If $E[X] = \infty$, there is nothing to prove.

Chebyshev. The variable $Y = (X-\mu)^2$ is non-negative with $E[Y] = \sigma^2$. The events $\{|X-\mu| \geq \varepsilon\}$ and $\{Y \geq \varepsilon^2\}$ are identical, because $t \mapsto t^2$ is increasing on $t \geq 0$. Markov with $a = \varepsilon^2$ gives $P(Y \geq \varepsilon^2) \leq \sigma^2/\varepsilon^2$. Setting $\varepsilon = k\sigma$ gives the second form. ■



The pointwise inequality behind Markov's bound for $a = 2$: the step $a\,\mathbf{1}_{\{x \geq a\}}$ (red) never exceeds x (blue) on $x \geq 0$. Taking expectations of both sides gives $aP(X \geq a) \leq E[X]$.

Remarks

- *Sharpness.* Both inequalities are attained, so they cannot be improved without more information about the distribution. For Markov, let $X = a$ with probability p and $X = 0$ otherwise. Then $E[X]/a = p = P(X \geq a)$. For Chebyshev with $k \geq 1$, take the three-point law $P(X = \pm k\sigma) = \frac{1}{2k^2}$, $P(X = 0) = 1 - \frac{1}{k^2}$. It has mean 0, variance σ^2 and $P(|X| \geq k\sigma) = 1/k^2$.
- *Non-negativity matters for Markov.* For $X = \pm 1$ with equal probability, $E[X] = 0$ but $P(X \geq 1) = \frac{1}{2} > 0$. The proof breaks at $aI \leq X$ when $X(\omega) = -1$.
- *Generalisations.* Applying Markov to $|X-\mu|^r$ gives $P(|X-\mu| \geq \varepsilon) \leq E|X-\mu|^r/\varepsilon^r$. Applying it to e^{sX} gives the Chernoff bound $P(X \geq a) \leq e^{-sa}M_X(s)$ for $s > 0$, the basis of the exponential error bounds of coding theory.
- *Where used.* Distribution-free yield guarantees (Section 19.9, Example 19.43), the weak law in E.4, and the non-asymptotic Monte Carlo error bound in E.14.

E.4 The weak law of large numbers

Convergence in probability and in distribution

$Z_n \to c$ **in probability** if $P(|Z_n - c| \geq \varepsilon) \to 0$ as $n \to \infty$ for every $\varepsilon > 0$. $Z_n \to Z$ **in distribution** if $F_{Z_n}(z) \to F_Z(z)$ at every point z where F_Z is continuous.

Statement

Weak law of large numbers

Let $\bar{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i$.

1. **(L^2 version.)** If $X_1, X_2, \ldots$ are pairwise uncorrelated with common mean μ and variances $\operatorname{Var} X_i \leq \sigma^2 < \infty$, then for every $\varepsilon > 0$

$$P\big(|\bar{X}_n - \mu| \geq \varepsilon\big) \leq \frac{\sigma^2}{n\varepsilon^2} \;\longrightarrow\; 0.$$

2. **(Khinchin's version.)** If $X_1, X_2, \ldots$ are i.i.d. with $E|X_1| < \infty$ and $\mu = E[X_1]$, then $\bar{X}_n \to \mu$ in probability. No variance is assumed.

Proof

Part 1. By linearity (E.2), $E[\bar{X}_n] = \frac{1}{n}\sum E[X_i] = \mu$. Because the X_i are pairwise uncorrelated, E.2 part 3 with $a_i = 1/n$ gives

$$\operatorname{Var}(\bar{X}_n) = \frac{1}{n^2}\sum_{i=1}^{n} \operatorname{Var} X_i \leq \frac{n\sigma^2}{n^2} = \frac{\sigma^2}{n}.$$

Chebyshev's inequality (E.3) applied to $\bar{X}_n$ gives $P(|\bar{X}_n - \mu| \geq \varepsilon) \leq \operatorname{Var}(\bar{X}_n)/\varepsilon^2 \leq \sigma^2/(n\varepsilon^2)$.

Part 2. We use characteristic functions $\varphi_X(\omega) = E[e^{j\omega X}]$ (Section 19.9), Lévy's continuity theorem (stated in E.5), the product Lemma E.5a (proved in E.5), and one elementary fact:

- (ii) If $Z_n \to c$ in distribution and c is a constant, then $Z_n \to c$ in probability.

For (ii), note that the limit CDF $\mathbf{1}_{\{z \geq c\}}$ is continuous at $c - \varepsilon$ and at $c + \varepsilon/2$. So $P(|Z_n - c| \geq \varepsilon) \leq F_{Z_n}(c - \varepsilon) + 1 - F_{Z_n}(c + \varepsilon/2) \to 0 + 1 - 1 = 0$.

Step 1 (first-order expansion). Let $\varphi = \varphi_{X_1}$. For real x, $|e^{jx} - 1| \leq \min(|x|, 2)$, and hence $|e^{jx} - 1 - jx| \leq \min(x^2/2,\, 2|x|)$. The bounds $|x|$ and $x^2/2$ come from writing $e^{jx} - 1 = \int_0^x j e^{ju}\,du$ and $e^{jx} - 1 - jx = \int_0^x j(e^{ju} - 1)\,du$ and using $|e^{ju}| = 1$. The bounds 2 and $2|x|$ come from the triangle inequality. Hence

$$\big|\varphi(\omega) - 1 - j\omega\mu\big| = \big|E\big[e^{j\omega X_1} - 1 - j\omega X_1\big]\big| \leq |\omega|\, E\Big[\min\Big(\tfrac{|\omega| X_1^2}{2},\, 2|X_1|\Big)\Big].$$

The random variable inside the last expectation tends to 0 pointwise as $\omega \to 0$ and is dominated by $2|X_1|$, which is integrable. By dominated convergence, the expectation tends to 0. Therefore $\varphi(\omega) = 1 + j\omega\mu + \omega\, r(\omega)$ with $r(\omega) \to 0$ as $\omega \to 0$.

Step 2 (product). By independence, the characteristic function of a sum is the product of the characteristic functions, so $\varphi_{\bar{X}_n}(\omega) = \varphi(\omega/n)^n$. Fix ω. Lemma E.5a needs factors of modulus at most 1. Characteristic functions satisfy $|\varphi| \leq 1$, and so does $e^{j\omega\mu/n}$. Using Step 1 and $|e^{jx} - 1 - jx| \leq x^2/2$,

$$\big|\varphi(\omega/n) - e^{j\omega\mu/n}\big| \leq \frac{|\omega|}{n}\,|r(\omega/n)| + \frac{\omega^2\mu^2}{2n^2}.$$

Lemma E.5a with n equal factors then gives

$$\big|\varphi(\omega/n)^n - e^{j\omega\mu}\big| \leq n\,\big|\varphi(\omega/n) - e^{j\omega\mu/n}\big| \leq |\omega|\,|r(\omega/n)| + \frac{\omega^2\mu^2}{2n} \;\longrightarrow\; 0.$$

Step 3 (conclusion). $e^{j\omega\mu}$ is the characteristic function of the constant μ. By Lévy's theorem $\bar{X}_n \to \mu$ in distribution, and by (ii) in probability. ∎

Remarks

- *What the law says and does not say.* Part 1 gives a *rate*, $P(|\bar{X}_n - \mu| \geq \varepsilon) = O(1/n)$, with an explicit constant. It justifies the relative-frequency interpretation of Section 19.1. With $X_i = \mathbf{1}_A$ on independent trials, $\bar{X}_n = N_A/n \to P(A)$. It says nothing about a *single* infinite run of experiments converging. That is the strong law ($\bar{X}_n \to \mu$ with probability one), whose proof is harder and which is quoted in Section 24.6.
- *Counterexample without a mean.* If the X_i are i.i.d. standard Cauchy, then $\varphi(\omega) = e^{-|\omega|}$ and $\varphi(\omega/n)^n = e^{-|\omega|}$. So $\bar{X}_n$ is again standard Cauchy for every n and does not concentrate at all. Averaging does not help against impulsive noise of this kind. Median filters do.
- *Correlation matters.* If $X_i = X_1$ for all i (perfect correlation), then $\bar{X}_n = X_1$ and nothing converges. Part 1 needs the variance of the average to vanish. The same principle, with correlation that decays in time, gives the mean-ergodic theorem of Section 21.7.
- *Where used.* Consistency of estimators (Section 20.6), Monte Carlo (E.14), ergodicity (Section 21.7).

E.5 The central limit theorem

Statement

Central limit theorem (Lindeberg–Lévy)

Let $X_1, X_2, \dots$ be i.i.d. with mean μ and finite variance $\sigma^2 > 0$. Put

$$Z_n = \frac{\sum_{i=1}^{n} X_i - n\mu}{\sigma\sqrt{n}} = \frac{\bar{X}_n - \mu}{\sigma/\sqrt{n}}.$$

Then $Z_n \to \mathcal{N}(0,1)$ in distribution, i.e. $P(Z_n \le z) \to \Phi(z)$ for every $z \in \mathbb{R}$.

The proof rests on one quoted theorem and two lemmas.

Lévy's continuity theorem (quoted)

Let Z_n have characteristic functions φ_n. If $\varphi_n(\omega) \to \psi(\omega)$ for every $\omega \in \mathbb{R}$, and ψ is continuous at $\omega = 0$, then ψ is the characteristic function of some random variable Z, and $Z_n \to Z$ in distribution.

For a proof, see Billingsley (*Probability and Measure*, §26) or Durrett (*Probability: Theory and Examples*, §3.3). It is the probabilistic counterpart of the uniqueness of the Fourier transform (Ch. 16). The characteristic function is the Fourier transform of the pdf, with the sign of the exponent reversed.

Lemma E.5a (products of numbers in the unit disc)

If $a_1, \dots, a_n, b_1, \dots, b_n \in \mathbb{C}$ all have modulus at most 1, then

$$\Big|\prod_{i=1}^{n} a_i - \prod_{i=1}^{n} b_i\Big| \le \sum_{i=1}^{n} |a_i - b_i|.$$

Proof. Use induction on n. The case $n = 1$ is trivial. For the inductive step, write $A_m = \prod_{i \le m} a_i$ and $B_m = \prod_{i \le m} b_i$, both of modulus ≤ 1. Then

$$A_n - B_n = a_n(A_{n-1} - B_{n-1}) + (a_n - b_n)B_{n-1},$$

so $|A_n - B_n| \le |A_{n-1} - B_{n-1}| + |a_n - b_n|$, which together with the induction hypothesis proves the claim. ∎

Lemma E.5b (second-order expansion of a characteristic function)

If $E[Y] = 0$ and $E[Y^2] = 1$, then $\varphi_Y(\omega) = 1 - \frac{\omega^2}{2} + \omega^2 r(\omega)$ with $r(\omega) \to 0$ as $\omega \to 0$.

Proof. For real x,

$$\Big|e^{jx} - 1 - jx + \frac{x^2}{2}\Big| \le \min\Big(\frac{|x|^3}{6},\, x^2\Big).$$

For the first bound, note that $e^{jx} - 1 - jx + \frac{x^2}{2} = \int_0^x j\big(e^{ju} - 1 - ju\big)\,du$. The integrand has modulus at most $u^2/2$ (E.4, Step 1), which integrates to $|x|^3/6$. For the second bound, $|e^{jx} - 1 - jx| \le x^2/2$ plus $|x^2/2|$ gives x^2. Now set $x = \omega Y$ and take expectations. Using $E[Y] = 0$ and $E[Y^2] = 1$,

$$\Big|\varphi_Y(\omega) - 1 + \frac{\omega^2}{2}\Big| \le E\Big[\min\Big(\frac{|\omega|^3|Y|^3}{6},\, \omega^2 Y^2\Big)\Big] = \omega^2\, E\Big[\min\Big(\frac{|\omega|\,|Y|^3}{6},\, Y^2\Big)\Big].$$

Define $r(\omega) = \big(\varphi_Y(\omega) - 1 + \omega^2/2\big)/\omega^2$ for $\omega \neq 0$. The display says that $|r(\omega)|$ is at most the last expectation. The variable inside that expectation tends to 0 pointwise as $\omega \to 0$ and is dominated by the integrable Y^2, so by dominated convergence $r(\omega) \to 0$. ∎

Proof of the theorem

Step 1 (standardise). Let $Y_i = (X_i - \mu)/\sigma$. The Y_i are i.i.d. with $E[Y_i] = 0$ and $E[Y_i^2] = 1$, and $Z_n = n^{-1/2}\sum_{i=1}^{n} Y_i$. Let φ be the common characteristic function of the Y_i.

Step 2 (characteristic function of Z_n). By independence, the expectation of a product of functions of independent variables factorises (Section 19.9). Hence

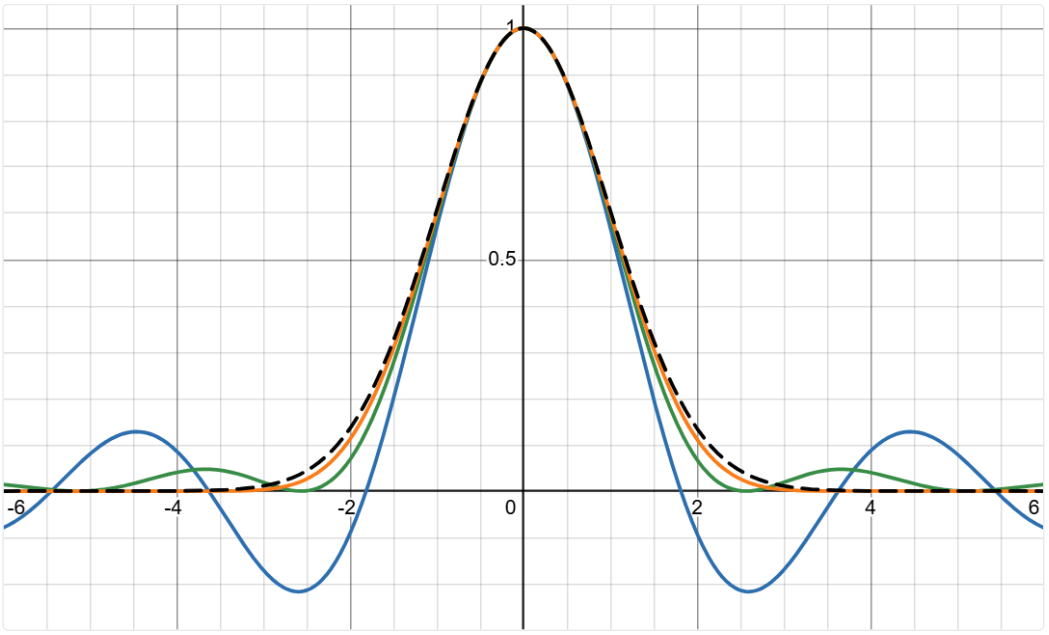
$$\varphi_{Z_n}(\omega) = E\Big[\prod_{i=1}^{n} e^{j\omega Y_i/\sqrt{n}}\Big] = \prod_{i=1}^{n} E\big[e^{j\omega Y_i/\sqrt{n}}\big] = \varphi\Big(\frac{\omega}{\sqrt{n}}\Big)^n.$$

Step 3 (compare with a simple product). Fix ω and let $n \ge \omega^2/2$, so that $b_n = 1 - \frac{\omega^2}{2n} \in [0,1]$. Every characteristic function satisfies $|\varphi| \le E|e^{j\omega Y}| = 1$. Lemma E.5a with n equal factors and Lemma E.5b give

$$\Big|\varphi\Big(\frac{\omega}{\sqrt{n}}\Big)^n - b_n^n\Big| \le n\,\Big|\varphi\Big(\frac{\omega}{\sqrt{n}}\Big) - 1 + \frac{\omega^2}{2n}\Big| = n\cdot\frac{\omega^2}{n}\Big|r\Big(\frac{\omega}{\sqrt{n}}\Big)\Big| = \omega^2\Big|r\Big(\frac{\omega}{\sqrt{n}}\Big)\Big| \;\longrightarrow\; 0.$$

Step 4 (the limit). $b_n^n = \big(1 - \frac{\omega^2}{2n}\big)^n \to e^{-\omega^2/2}$, the standard limit $(1 + c/n)^n \to e^c$ (Ch. 4). Together with Step 3, $\varphi_{Z_n}(\omega) \to e^{-\omega^2/2}$ for every ω.

Step 5 (identify and conclude). $e^{-\omega^2/2}$ is continuous and is the characteristic function of $\mathcal{N}(0,1)$ (Section 19.9). By Lévy's continuity theorem, $Z_n \to \mathcal{N}(0,1)$ in distribution. Since Φ is continuous everywhere, $P(Z_n \le z) \to \Phi(z)$ at every z. ∎



The proof in pictures. The characteristic function $\varphi(\omega) = \sin(\sqrt{3}\,\omega)/(\sqrt{3}\,\omega)$ of a unit-variance uniform variable (blue) and $\varphi(\omega/\sqrt{n})^n$ for $n = 2$ (green) and $n = 5$ (orange) close in on $e^{-\omega^2/2}$ (dashed). At $\omega = 1.5$ the values are $0.199,\ 0.276,\ 0.307$, and 0.320 for $n = 20$, against 0.325.

Remarks

- *Finite variance is essential.* For i.i.d. standard Cauchy variables, $\varphi(\omega) = e^{-|\omega|}$ and $\varphi(\omega/\sqrt{n})^n = e^{-\sqrt{n}|\omega|}$. This tends to 0 for $\omega \neq 0$ and to 1 at $\omega = 0$, a limit that is not continuous at 0, so Lévy's theorem does not apply. Indeed Z_n (with $\mu = 0$, $\sigma = 1$ inserted formally) is Cauchy with scale $\sqrt{n}$, and its mass escapes to infinity. The correct normalisation for Cauchy sums is $1/n$, under which $\bar{X}_n$ stays Cauchy (E.4). Lemma E.5b is exactly where $E[Y^2] < \infty$ is used.
- *Independence is essential.* If $X_i = X_1$ for all i, then $Z_n = \sqrt{n}\,(X_1 - \mu)/\sigma$, which never becomes Gaussian unless X_1 already is. Weak dependence is allowed in versions for mixing sequences, which matter for correlated noise samples (Section 21.7).
- *Identical distribution can be relaxed.* The Lindeberg condition allows independent, non-identical summands provided no single term dominates the variance. This is why the sum of many small, independent physical contributions (electron motions in a resistor, Section 21.8) is Gaussian.
- *Rate.* The proof gives no rate. The Berry–Esseen theorem, $\sup_z |P(Z_n \le z) - \Phi(z)| \le C\,E|Y|^3/\sqrt{n}$, needs a third moment (Section 20.5).
- *Where used.* Sampling distributions and confidence intervals (Sections 20.5 and 20.7), Gaussian noise models (Section 21.5), and Monte Carlo error bars (E.14).

E.6 The sample variance with divisor $n - 1$ is unbiased

Statement

Unbiasedness of S^2

Let $X_1, \dots, X_n$ ($n \ge 2$) be pairwise uncorrelated with common mean μ and common finite variance σ^2. Let $\bar{X} = \frac{1}{n}\sum X_i$ and

$$S^2 = \frac{1}{n-1}\sum_{i=1}^{n}(X_i - \bar{X})^2.$$

Then $E[S^2] = \sigma^2$.

Proof

Step 1 (algebraic identity). Write $X_i - \bar{X} = (X_i - \mu) - (\bar{X} - \mu)$ and expand the square:

$$\sum_{i=1}^{n}(X_i - \bar{X})^2 = \sum_{i=1}^{n}(X_i - \mu)^2 - 2(\bar{X} - \mu)\sum_{i=1}^{n}(X_i - \mu) + n(\bar{X} - \mu)^2.$$

Since $\sum_i (X_i - \mu) = n(\bar{X} - \mu)$, the middle term is $-2n(\bar{X} - \mu)^2$. Therefore

$$\sum_{i=1}^{n}(X_i - \bar{X})^2 = \sum_{i=1}^{n}(X_i - \mu)^2 - n(\bar{X} - \mu)^2.$$

Step 2 (expectations). $E[(X_i - \mu)^2] = \sigma^2$ by definition. $E[\bar{X}] = \mu$ by linearity, so $E[(\bar{X} - \mu)^2] = \operatorname{Var}\bar{X} = \sigma^2/n$ by E.2, part 3, using pairwise uncorrelatedness.

Step 3 (combine). By linearity,

$$E\Big[\sum_{i=1}^{n}(X_i - \bar{X})^2\Big] = n\sigma^2 - n\cdot\frac{\sigma^2}{n} = (n-1)\sigma^2,$$

and dividing by $n - 1$ gives $E[S^2] = \sigma^2$. ∎

Remarks

- *The divisor n is biased.* $\hat\sigma^2 = \frac{1}{n}\sum (X_i - \bar X)^2$ has $E[\hat\sigma^2] = \frac{n-1}{n}\sigma^2$, an underestimate by σ^2/n. A simulation with $n = 5$ standard Gaussian samples (2×10^5 replications) gives mean values 0.999 for S^2 and 0.799 for $\hat\sigma^2$, against the predicted 1 and 0.8. The bias comes from Step 1. The data sit closer to their own mean $\bar X$ than to μ, and the deficit is exactly $n(\bar X - \mu)^2$, with expectation σ^2.
- *Counterexample: correlated samples.* If the X_i are equicorrelated, $\operatorname{Cov}(X_i, X_k) = \rho\sigma^2$ for $i \neq k$, then $\operatorname{Var}\bar X = \sigma^2\big(1 + (n-1)\rho\big)/n$. Step 3 becomes $n\sigma^2 - \sigma^2\big(1 + (n-1)\rho\big) = (n-1)(1-\rho)\sigma^2$, so $E[S^2] = (1-\rho)\sigma^2$. Positively correlated samples, such as noise sampled faster than its correlation time (Section 21.3), make S^2 underestimate the variance. Slow drift is invisible to it.
- *S is biased for σ.* $\sqrt{\cdot}$ is strictly concave, so Jensen's inequality gives $E[S] < \sqrt{E[S^2]} = \sigma$ unless S is almost surely constant.
- *Where used.* Section 20.2 ("Why divide by $n-1$?"), the χ^2_{n-1} sampling distribution in Section 20.5, Type A uncertainty in Section 20.10, and the Monte Carlo standard error in Section 24.6. The regression analogue, divisor $n - p$, is proved in E.7.

E.7 Least-squares regression and the Gauss–Markov theorem

Linear model

The **linear model** is $\mathbf{y} = \mathbf{X}\boldsymbol\beta + \boldsymbol\varepsilon$. Here $\mathbf{y} \in \mathbb{R}^n$ is observed, the **design matrix** $\mathbf{X} \in \mathbb{R}^{n \times p}$ is known and deterministic, $\boldsymbol\beta \in \mathbb{R}^p$ is unknown, and the errors satisfy $E[\boldsymbol\varepsilon] = \mathbf{0}$ and $\operatorname{Cov}(\boldsymbol\varepsilon) = \sigma^2\mathbf{I}$, i.e. they are uncorrelated with equal variance (*homoscedastic*). Simple linear regression $Y_i = \beta_0 + \beta_1 x_i + \varepsilon_i$ is the case $p = 2$, where row i of $\mathbf{X}$ is $(1,\ x_i)$.

Statement

Least squares and its sampling properties

Suppose $\operatorname{rank}\mathbf{X} = p$ (so $n \geq p$).

1. $\mathbf{X}^{\mathsf T}\mathbf{X}$ is invertible, and $S(\boldsymbol\beta) = \|\mathbf{y} - \mathbf{X}\boldsymbol\beta\|^2$ has the **unique** minimiser
$$\hat{\boldsymbol\beta} = (\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}\mathbf{X}^{\mathsf T}\mathbf{y}.$$

The residual $\mathbf{e} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol\beta}$ satisfies $\mathbf{X}^{\mathsf T}\mathbf{e} = \mathbf{0}$. For simple regression, the rank condition says that the x_i are not all equal ($S_{xx} > 0$), and

$$\hat\beta_1 = \frac{S_{xy}}{S_{xx}}, \qquad \hat\beta_0 = \bar y - \hat\beta_1 \bar x, \qquad S_{xx} = \sum (x_i - \bar x)^2,\ \ S_{xy} = \sum (x_i - \bar x)(y_i - \bar y).$$

2. Under the linear model, $E[\hat{\boldsymbol\beta}] = \boldsymbol\beta$, $\operatorname{Cov}(\hat{\boldsymbol\beta}) = \sigma^2(\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}$, and $E[\mathrm{SSE}] = (n-p)\sigma^2$, where $\mathrm{SSE} = \|\mathbf{e}\|^2$. In simple regression, $\operatorname{Var}\hat\beta_1 = \sigma^2/S_{xx}$ and $\operatorname{Var}\hat\beta_0 = \sigma^2\sum x_i^2/(nS_{xx})$.
3. **Gauss–Markov.** Let $\tilde{\boldsymbol\beta} = \mathbf{C}\mathbf{y}$, with $\mathbf{C} \in \mathbb{R}^{p \times n}$ deterministic, be any linear estimator that is unbiased for every $\boldsymbol\beta$. Then $\operatorname{Cov}(\tilde{\boldsymbol\beta}) - \operatorname{Cov}(\hat{\boldsymbol\beta})$ is positive semidefinite. In particular, $\operatorname{Var}(\mathbf{a}^{\mathsf T}\tilde{\boldsymbol\beta}) \geq \operatorname{Var}(\mathbf{a}^{\mathsf T}\hat{\boldsymbol\beta})$ for every $\mathbf{a} \in \mathbb{R}^p$. Least squares is the **best linear unbiased estimator** (BLUE).

Proof

Part 1 (invertibility). If $\mathbf{X}^{\mathsf T}\mathbf{X}\mathbf{v} = \mathbf{0}$, then $0 = \mathbf{v}^{\mathsf T}\mathbf{X}^{\mathsf T}\mathbf{X}\mathbf{v} = \|\mathbf{X}\mathbf{v}\|^2$, so $\mathbf{X}\mathbf{v} = \mathbf{0}$. Full column rank then forces $\mathbf{v} = \mathbf{0}$. A square matrix with trivial null space is invertible (Ch. 8).

Part 1 (minimiser). Define $\hat{\boldsymbol\beta}$ by the formula. Then $\mathbf{X}^{\mathsf T}\mathbf{X}\hat{\boldsymbol\beta} = \mathbf{X}^{\mathsf T}\mathbf{y}$ (the **normal equations**), i.e. $\mathbf{X}^{\mathsf T}\mathbf{e} = \mathbf{0}$. For any $\boldsymbol\beta$, write $\mathbf{y} - \mathbf{X}\boldsymbol\beta = \mathbf{e} + \mathbf{X}(\hat{\boldsymbol\beta} - \boldsymbol\beta)$ and expand:

$$S(\boldsymbol\beta) = \|\mathbf{e}\|^2 + 2(\hat{\boldsymbol\beta} - \boldsymbol\beta)^{\mathsf T}\mathbf{X}^{\mathsf T}\mathbf{e} + \|\mathbf{X}(\hat{\boldsymbol\beta} - \boldsymbol\beta)\|^2 = S(\hat{\boldsymbol\beta}) + \|\mathbf{X}(\hat{\boldsymbol\beta} - \boldsymbol\beta)\|^2.$$

The last term is ≥ 0, with equality iff $\mathbf{X}(\hat{\boldsymbol\beta} - \boldsymbol\beta) = \mathbf{0}$, iff $\boldsymbol\beta = \hat{\boldsymbol\beta}$ (full rank again). So $\hat{\boldsymbol\beta}$ is the unique minimiser. This argument needs no calculus. It is Pythagoras' theorem for the orthogonal projection $\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol\beta}$ of $\mathbf{y}$ onto the column space of $\mathbf{X}$ (Ch. 9).

Part 1 (simple regression). The first row of $\mathbf{X}^{\mathsf T}\mathbf{e} = \mathbf{0}$ is $\sum e_i = 0$, i.e. $\bar y = \hat\beta_0 + \hat\beta_1 \bar x$. The second row is $\sum x_i e_i = 0$. Subtract $\bar x$ times the first row to get $\sum (x_i - \bar x)e_i = 0$. Substituting $e_i = (y_i - \bar y) - \hat\beta_1(x_i - \bar x)$ gives $S_{xy} - \hat\beta_1 S_{xx} = 0$. The two columns $(1, \dots, 1)^{\mathsf T}$ and $(x_1, \dots, x_n)^{\mathsf T}$ are linearly independent iff the x_i are not all equal, iff $S_{xx} > 0$.

Part 2. Let $\mathbf{A} = (\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}\mathbf{X}^{\mathsf T}$, so that $\mathbf{A}\mathbf{X} = \mathbf{I}_p$ and $\hat{\boldsymbol\beta} = \mathbf{A}\mathbf{y} = \boldsymbol\beta + \mathbf{A}\boldsymbol\varepsilon$. Linearity gives $E[\hat{\boldsymbol\beta}] = \boldsymbol\beta$. For any deterministic matrix $\mathbf{M}$, $\operatorname{Cov}(\mathbf{M}\boldsymbol\varepsilon) = \mathbf{M}\operatorname{Cov}(\boldsymbol\varepsilon)\mathbf{M}^{\mathsf T}$. This is E.2, part 3, applied to each linear combination. So

$$\operatorname{Cov}(\hat{\boldsymbol\beta}) = \sigma^2\mathbf{A}\mathbf{A}^{\mathsf T} = \sigma^2(\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}\mathbf{X}^{\mathsf T}\mathbf{X}(\mathbf{X}^{\mathsf T}\mathbf{X})^{-1} = \sigma^2(\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}.$$

For the residuals, let $\mathbf{H} = \mathbf{X}\mathbf{A}$ (the hat matrix). It is symmetric and idempotent ($\mathbf{H}^2 = \mathbf{H}$), and $(\mathbf{I} - \mathbf{H})\mathbf{X} = \mathbf{0}$. Hence $\mathbf{e} = (\mathbf{I} - \mathbf{H})\mathbf{y} = (\mathbf{I} - \mathbf{H})\boldsymbol\varepsilon$ and $\mathrm{SSE} = \boldsymbol\varepsilon^{\mathsf T}(\mathbf{I} - \mathbf{H})\boldsymbol\varepsilon$. For any square $\mathbf{M}$, $E[\boldsymbol\varepsilon^{\mathsf T}\mathbf{M}\boldsymbol\varepsilon] = \sum_{i,k} M_{ik}E[\varepsilon_i\varepsilon_k] = \sigma^2 \operatorname{tr}\mathbf{M}$. Using $\operatorname{tr}(\mathbf{P}\mathbf{Q}) = \operatorname{tr}(\mathbf{Q}\mathbf{P})$,

$$E[\mathrm{SSE}] = \sigma^2 \operatorname{tr}(\mathbf{I}_n - \mathbf{H}) = \sigma^2\big(n - \operatorname{tr}\left((\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}\mathbf{X}^{\mathsf T}\mathbf{X}\right)\big) = \sigma^2(n - \operatorname{tr}\mathbf{I}_p) = (n-p)\sigma^2.$$

For simple regression, $\mathbf{X}^{\mathsf T}\mathbf{X} = \begin{pmatrix} n & \sum x_i \\ \sum x_i & \sum x_i^2 \end{pmatrix}$ has determinant $n\sum x_i^2 - (\sum x_i)^2 = nS_{xx}$. Its inverse is $\frac{1}{nS_{xx}}\begin{pmatrix} \sum x_i^2 & -\sum x_i \\ -\sum x_i & n \end{pmatrix}$, whose diagonal gives the two variances.

Part 3 (Gauss–Markov). Unbiasedness for every $\boldsymbol\beta$ means $E[\mathbf{C}\mathbf{y}] = \mathbf{C}\mathbf{X}\boldsymbol\beta = \boldsymbol\beta$ for all $\boldsymbol\beta$, i.e. $\mathbf{C}\mathbf{X} = \mathbf{I}_p$. Put $\mathbf{D} = \mathbf{C} - \mathbf{A}$. Then $\mathbf{D}\mathbf{X} = \mathbf{I}_p - \mathbf{I}_p = \mathbf{0}$, and therefore

$$\mathbf{A}\mathbf{D}^{\mathsf T} = (\mathbf{X}^{\mathsf T}\mathbf{X})^{-1}(\mathbf{D}\mathbf{X})^{\mathsf T} = \mathbf{0}, \qquad \mathbf{D}\mathbf{A}^{\mathsf T} = (\mathbf{A}\mathbf{D}^{\mathsf T})^{\mathsf T} = \mathbf{0}.$$

Since $\tilde{\boldsymbol\beta} = \mathbf{C}\mathbf{X}\boldsymbol\beta + \mathbf{C}\boldsymbol\varepsilon$,

$$\operatorname{Cov}(\tilde{\boldsymbol{\beta}}) = \sigma^2 \mathbf{C}\mathbf{C}^{\mathsf{T}} = \sigma^2 (\mathbf{A}+\mathbf{D})(\mathbf{A}+\mathbf{D})^{\mathsf{T}} = \sigma^2 \left(\mathbf{A}\mathbf{A}^{\mathsf{T}} + \mathbf{D}\mathbf{D}^{\mathsf{T}}\right) = \operatorname{Cov}(\hat{\boldsymbol{\beta}}) + \sigma^2 \mathbf{D}\mathbf{D}^{\mathsf{T}}.$$

Finally, $\mathbf{a}^{\mathsf{T}}\mathbf{D}\mathbf{D}^{\mathsf{T}}\mathbf{a} = \|\mathbf{D}^{\mathsf{T}}\mathbf{a}\|^2 \geq 0$, so the difference is positive semidefinite, and $\operatorname{Var}(\mathbf{a}^{\mathsf{T}}\tilde{\boldsymbol{\beta}}) - \operatorname{Var}(\mathbf{a}^{\mathsf{T}}\hat{\boldsymbol{\beta}}) = \sigma^2 \|\mathbf{D}^{\mathsf{T}}\mathbf{a}\|^2 \geq 0$. Equality for every $\mathbf{a}$ holds iff $\mathbf{D} = \mathbf{0}$, so least squares is the *unique* BLUE. ■

Remarks

- *No Gaussian assumption.* Gauss–Markov uses only the first two moments of $\boldsymbol{\varepsilon}$. With Gaussian errors, $\hat{\boldsymbol{\beta}}$ is also the maximum-likelihood estimator and attains the Cramér–Rao bound, so it is best among *all* unbiased estimators, linear or not (Section 20.6). Without Gaussianity, nonlinear estimators can win. For heavy-tailed (e.g. Laplacian) errors, least-absolute-deviation fitting has smaller variance than least squares.
- *Each hypothesis matters.*
  - **Equal variance.** If $\operatorname{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{V}$ with known $\mathbf{V} \neq \mathbf{I}$, then ordinary least squares is still unbiased but no longer best. Applying the theorem to the whitened model $\mathbf{V}^{-1/2}\mathbf{y} = \mathbf{V}^{-1/2}\mathbf{X}\boldsymbol{\beta} + \mathbf{V}^{-1/2}\boldsymbol{\varepsilon}$ shows that the BLUE is generalised least squares, $(\mathbf{X}^{\mathsf{T}}\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{V}^{-1}\mathbf{y}$. With diagonal $\mathbf{V}$ this is the weighted least squares of Section 20.9.
  - **Unbiasedness.** Biased linear estimators can have smaller mean-square error. Ridge regression $(\mathbf{X}^{\mathsf{T}}\mathbf{X} + \lambda \mathbf{I})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{y}$ does, for suitable $\lambda > 0$, when $\mathbf{X}^{\mathsf{T}}\mathbf{X}$ is ill-conditioned.
  - **Full rank.** With collinear regressors, $\boldsymbol{\beta}$ is not identifiable. Many $\boldsymbol{\beta}$ give the same $\mathbf{X}\boldsymbol{\beta}$ (Section 25.8).
- *Divisor $n-p$.* Part 2 shows that $s^2 = \mathrm{SSE}/(n-p)$ is unbiased for σ^2. E.6 is the special case $p = 1$, $\mathbf{X} = (1, \dots, 1)^{\mathsf{T}}$, $\hat{\beta} = \bar{y}$.
- *Numerics.* The formula $(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{y}$ is for analysis. Compute $\hat{\boldsymbol{\beta}}$ by QR factorisation (Section 24.3), because $\kappa(\mathbf{X}^{\mathsf{T}}\mathbf{X}) = \kappa(\mathbf{X})^2$.
- *Where used.* Section 20.9, discrete least squares in Section 22.6, and parameter identification in Section 25.8.

E.8 The law of propagation of uncertainty (GUM)

Measurement model

A measurand is modelled as $Y = f(\mathbf{X})$, where $\mathbf{X} = (X_1, \dots, X_N)^{\mathsf{T}}$ is a random vector of input quantities. The input **estimates** are $\mathbf{x} = E[\mathbf{X}]$, the **standard uncertainties** are $u(x_i) = \sqrt{\operatorname{Var} X_i}$, and the **covariances** are $u(x_i, x_k) = \operatorname{Cov}(X_i, X_k)$. Together they form the input covariance matrix $\boldsymbol{\Sigma}_x$. The **sensitivity coefficients** are $c_i = \partial f / \partial x_i$ evaluated at $\mathbf{x}$, and $\mathbf{c} = \nabla f(\mathbf{x})$.

Statement

First-order propagation of uncertainty and its accuracy

Let $f : \mathbb{R}^N \to \mathbb{R}$ be twice continuously differentiable, with Hessian bounded in the spectral norm, $\|\nabla^2 f(\boldsymbol{\xi})\|_2 \leq M$ for all $\boldsymbol{\xi}$. Let $\mathbf{X}$ have mean $\mathbf{x}$, covariance $\boldsymbol{\Sigma}_x$, and finite fourth moments, $m_4 = E\|\mathbf{X} - \mathbf{x}\|^4 < \infty$. Define the linearised model $Y_{\mathrm{lin}} = f(\mathbf{x}) + \mathbf{c}^{\mathsf{T}}(\mathbf{X} - \mathbf{x})$ and the **combined standard uncertainty**

$$u_c^2(y) = \mathbf{c}^{\mathsf{T}} \boldsymbol{\Sigma}_x \mathbf{c} = \sum_{i=1}^{N} c_i^2 u^2(x_i) + 2 \sum_{i=1}^{N-1} \sum_{k=i+1}^{N} c_i c_k \, u(x_i, x_k).$$

Then:

1. $E[Y_{\mathrm{lin}}] = f(\mathbf{x})$ and $\operatorname{Var}(Y_{\mathrm{lin}}) = u_c^2(y)$ **exactly**;
2. $|Y - Y_{\mathrm{lin}}| \leq \tfrac{M}{2}\|\mathbf{X} - \mathbf{x}\|^2$ at every outcome, hence $|E[Y] - f(\mathbf{x})| \leq \tfrac{M}{2} \operatorname{tr} \boldsymbol{\Sigma}_x$;
3. the true standard deviation σ_Y of Y satisfies

$$\left|\sigma_Y - u_c(y)\right| \leq \frac{M}{2} \sqrt{m_4}.$$

If all input deviations scale with a small parameter u ($\mathbf{X} - \mathbf{x} = u\mathbf{W}$ with $\mathbf{W}$ fixed), then $u_c = O(u)$ while the errors in parts 2 and 3 are $O(u^2)$. The relative error of the GUM formula is therefore $O(u)$, provided $\mathbf{c} \neq \mathbf{0}$.

Proof

Part 1. Y_{lin} is the constant $f(\mathbf{x}) - \mathbf{c}^{\mathsf{T}}\mathbf{x}$ plus the linear form $\mathbf{c}^{\mathsf{T}}\mathbf{X}$. By linearity of expectation, $E[Y_{\mathrm{lin}}] = f(\mathbf{x}) + \mathbf{c}^{\mathsf{T}}(E\mathbf{X} - \mathbf{x}) = f(\mathbf{x})$. Adding a constant does not change a variance, so E.2, part 3, gives $\operatorname{Var}(Y_{\mathrm{lin}}) = \mathbf{c}^{\mathsf{T}}\boldsymbol{\Sigma}_x\mathbf{c}$. Written out, the double sum $\sum_{i,k} c_i c_k (\boldsymbol{\Sigma}_x)_{ik}$ has diagonal terms $c_i^2 u^2(x_i)$ and each off-diagonal pair (i,k), (k,i) appearing twice. That is the displayed formula.

Part 2 (Taylor's theorem). Fix an outcome and put $\mathbf{d} = \mathbf{X} - \mathbf{x}$ and $g(t) = f(\mathbf{x} + t\mathbf{d})$ for $t \in [0,1]$. Then $g \in C^2$, $g'(t) = \nabla f(\mathbf{x} + t\mathbf{d})^{\mathsf{T}}\mathbf{d}$ and $g''(t) = \mathbf{d}^{\mathsf{T}} \nabla^2 f(\mathbf{x} + t\mathbf{d})\, \mathbf{d}$ (chain rule, Ch. 6). Taylor's theorem with Lagrange remainder (Ch. 4) gives $g(1) = g(0) + g'(0) + \tfrac{1}{2} g''(\theta)$ for some $\theta \in (0,1)$, i.e.

$$R := Y - Y_{\mathrm{lin}} = \tfrac{1}{2}\, \mathbf{d}^{\mathsf{T}} \nabla^2 f(\mathbf{x} + \theta \mathbf{d})\, \mathbf{d}, \qquad |R| \leq \tfrac{1}{2}\|\nabla^2 f\|_2 \|\mathbf{d}\|^2 \leq \tfrac{M}{2}\|\mathbf{X} - \mathbf{x}\|^2.$$

The quadratic-form bound $|\mathbf{d}^{\mathsf{T}}\mathbf{B}\mathbf{d}| \leq \|\mathbf{B}\|_2 \|\mathbf{d}\|^2$ is the Cauchy–Schwarz inequality (Ch. 9). Taking expectations, $|E[Y] - f(\mathbf{x})| = |E[R]| \leq E|R| \leq \tfrac{M}{2} E\|\mathbf{X} - \mathbf{x}\|^2 = \tfrac{M}{2} \operatorname{tr} \boldsymbol{\Sigma}_x$.

Part 3. First, Y has a finite second moment, because $|Y| \leq |f(\mathbf{x})| + \|\mathbf{c}\|\|\mathbf{d}\| + \tfrac{M}{2}\|\mathbf{d}\|^2$ and $m_4 < \infty$. Write $\|Z\|_2 = \sqrt{E[Z^2]}$, which is a norm on random variables with finite second moment (Minkowski's inequality). Then $\sigma_Y = \|Y - EY\|_2$ and $u_c = \|Y_{\mathrm{lin}} - f(\mathbf{x})\|_2$, and

$$Y - E[Y] = \big(Y_{\mathrm{lin}} - f(\mathbf{x})\big) + \big(R - E[R]\big).$$

By the reverse triangle inequality for the norm,

$$|\sigma_Y - u_c| \leq \|R - E[R]\|_2 = \sqrt{\operatorname{Var} R} \leq \sqrt{E[R^2]} \leq \frac{M}{2} \sqrt{E\|\mathbf{X} - \mathbf{x}\|^4}.$$

Scaling. With $\mathbf{d} = u\mathbf{W}$, $u_c = u\sqrt{\mathbf{c}^{\mathsf{T}} \operatorname{Cov}(\mathbf{W})\, \mathbf{c}}$ is proportional to u, while $\operatorname{tr} \boldsymbol{\Sigma}_x$ and $\sqrt{m_4}$ are proportional to u^2. ■

Remarks

- *Products and quotients.* For $Y = A\,X_1^{p_1}\cdots X_N^{p_N}$ with $x_i \neq 0$, $c_i = p_i y/x_i$. For uncorrelated inputs, part 1 becomes the relative-uncertainty rule $(u_c/y)^2 = \sum (p_i u(x_i)/x_i)^2$ of Section 20.10. Such f do not have a globally bounded Hessian. The theorem then applies with M the bound over a region that contains $\mathbf{X}$ with overwhelming probability, and the part of the distribution outside that region must be handled separately. This is the usual situation in practice.
- *Counterexample: vanishing sensitivity.* Let $Y = X^2$ with $X \sim \mathcal{N}(x, u^2)$. Then exactly $\operatorname{Var} Y = 4x^2u^2 + 2u^4$, while $u_c = 2|x|u$. At $x = 1$, $u = 0.1$: $\sigma_Y = 0.20050$ against $u_c = 0.2$, well inside the bound $\frac{M}{2}\sqrt{m_4} = \sqrt{3}\,u^2 = 0.0173$ ($M = 2$, $m_4 = 3u^4$). At $x = 0$, however, $c = 0$ and $u_c = 0$, yet $\sigma_Y = \sqrt{2}\,u^2$. The first-order term has vanished, and the "$O(u^2)$ error" is the whole answer. The GUM then requires second-order terms or Monte Carlo propagation (Section 24.8).
- *Second-order mean correction.* The proof also shows that $E[Y] = f(\mathbf{x}) + \frac{1}{2}\operatorname{tr}\left(\nabla^2 f(\mathbf{x})\boldsymbol{\Sigma}_x\right) + o(u^2)$ when $\nabla^2 f$ is continuous. A curved model *biases* the output. For example, $E[X^2] = x^2 + u^2$ exactly.
- *Correlation.* Part 1 is an identity for the linearised model, so the covariance terms are not optional. With $r = \pm 1$ they turn root-sum-of-squares addition into linear addition or cancellation, as the chapter discusses.
- *Where used.* Section 20.10, propagation of errors in Section 22.2, and linearised uncertainty propagation in Section 24.8.

E.9 The Wiener–Khinchin theorem and filtered noise

Power spectral density

Let $X(t)$ be a real wide-sense stationary (WSS) process with autocorrelation $R_{XX}(\tau) = E[X(t+\tau)X(t)]$. Assume X is **mean-square continuous** (R_{XX} is continuous at 0, hence everywhere, Section 21.3) and has jointly measurable sample paths. For $T > 0$, let $X_T(\omega) = \int_{-T}^{T} X(t)e^{-j\omega t}\,dt$. The **power spectral density** is

$$S_{XX}(\omega) = \lim_{T\to\infty} \frac{E\left[|X_T(\omega)|^2\right]}{2T},$$

whenever the limit exists.

Statement

Wiener–Khinchin

Under the assumptions of the definition, suppose $R_{XX} \in L^1(\mathbb{R})$, i.e. $\int_{-\infty}^{\infty}|R_{XX}(\tau)|\,d\tau < \infty$. Then for every ω the limit defining $S_{XX}(\omega)$ exists and

$$S_{XX}(\omega) = \int_{-\infty}^{\infty} R_{XX}(\tau)\, e^{-j\omega\tau}\,d\tau.$$

S_{XX} is real, even, non-negative, continuous and bounded by $\|R_{XX}\|_1$. If also $S_{XX} \in L^1$, then for every τ

$$R_{XX}(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{XX}(\omega)e^{j\omega\tau}\,d\omega, \qquad E[X^2(t)] = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{XX}(\omega)\,d\omega.$$

Lemma E.9a (diagonal integration)

If g is integrable on $[-2T, 2T]$, then

$$\int_{-T}^{T}\int_{-T}^{T} g(t-s)\,dt\,ds = \int_{-2T}^{2T} \big(2T - |\tau|\big)\,g(\tau)\,d\tau.$$

Proof. In the inner integral substitute $\tau = t - s$ for fixed s. This gives $\int_{-T}^{T}\int_{-T-s}^{T-s} g(\tau)\,d\tau\,ds$, the integral of $g(\tau)$ over the region $\{(\tau, s) : |s| \le T,\ |s+\tau| \le T\}$. By Fubini's theorem, which applies because $\iint |g(t-s)|\,dt\,ds \le 2T\int_{-2T}^{2T}|g| < \infty$, we may integrate over s first. For fixed τ with $|\tau| \le 2T$, the admissible s form the interval $[\max(-T, -T-\tau),\ \min(T, T-\tau)]$. Its length is $2T - |\tau|$. ∎

Proof of the theorem

Step 1 (X_T exists and $E|X_T|^2$ is a double integral). By Cauchy–Schwarz, $E|X(t)X(s)| \le \sqrt{E[X^2(t)]E[X^2(s)]} = R_{XX}(0)$. Therefore

$$E\int_{-T}^{T}\int_{-T}^{T}|X(t)X(s)|\,dt\,ds \le 4T^2 R_{XX}(0) < \infty.$$

So, with probability one, X is integrable on $[-T, T]$, $X_T(\omega)$ exists, and Fubini's theorem allows expectation and integration to be interchanged:

$$E|X_T(\omega)|^2 = E\Big[\int_{-T}^{T}\int_{-T}^{T} X(t)X(s)e^{-j\omega(t-s)}\,dt\,ds\Big] = \int_{-T}^{T}\int_{-T}^{T} R_{XX}(t-s)\,e^{-j\omega(t-s)}\,dt\,ds.$$

Here $|X_T|^2 = X_T\overline{X_T}$ was used, and X is real.

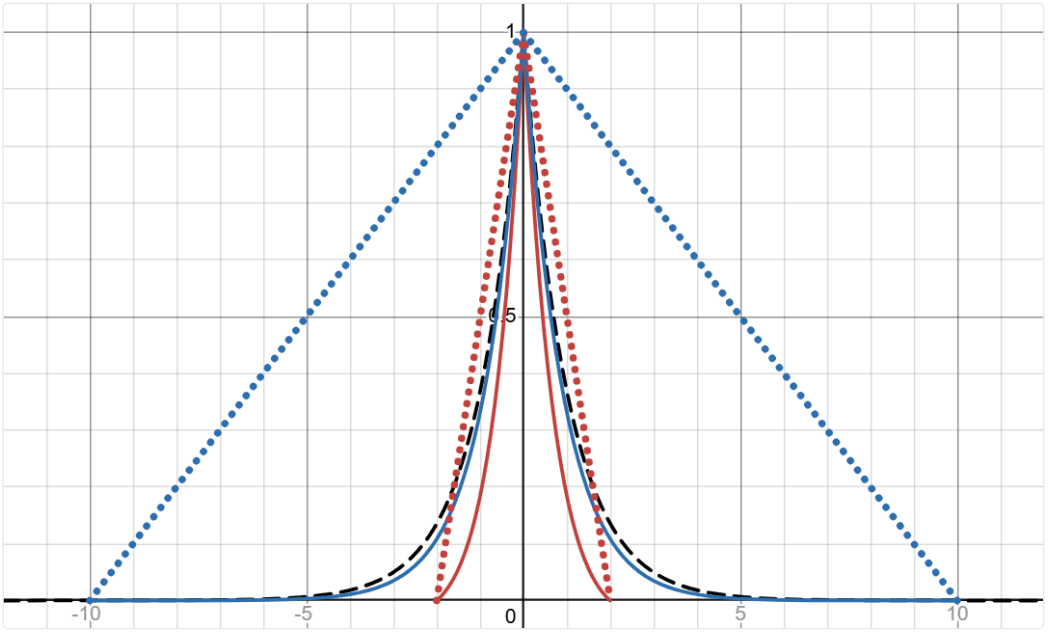
Step 2 (reduce to one integral). Lemma E.9a with $g(\tau) = R_{XX}(\tau)e^{-j\omega\tau}$ gives

$$\frac{E|X_T(\omega)|^2}{2T} = \int_{-\infty}^{\infty} w_T(\tau)\,R_{XX}(\tau)e^{-j\omega\tau}\,d\tau, \qquad w_T(\tau) = \Big(1 - \frac{|\tau|}{2T}\Big)\mathbf{1}_{\{|\tau|\le 2T\}}.$$

Step 3 (limit). For every τ, $w_T(\tau) \to 1$ as $T \to \infty$, and $|w_T R_{XX} e^{-j\omega\tau}| \le |R_{XX}(\tau)|$, which is integrable. The dominated convergence theorem gives the stated limit.

Step 4 (properties). R_{XX} is even, since $R_{XX}(-\tau) = E[X(t-\tau)X(t)] = R_{XX}(\tau)$ by stationarity. So $S_{XX}(\omega) = \int R_{XX}(\tau)\cos\omega\tau\, d\tau$ is real and even. It is non-negative as a limit of the non-negative numbers $E|X_T|^2/(2T)$. Also $|S_{XX}| \le \|R_{XX}\|_1$, and continuity in ω follows by dominated convergence again.

Step 5 (inversion). If $S_{XX} \in L^1$, the Fourier inversion theorem for L^1 functions with L^1 transforms (Ch. 16) gives $R_{XX}(\tau) = \frac{1}{2\pi}\int S_{XX} e^{j\omega\tau} d\omega$ for almost every τ. Both sides are continuous in τ (the right by dominated convergence), so equality holds for every τ. At $\tau = 0$ we get $E[X^2] = R_{XX}(0)$. ■



Step 2 in pictures for $R_{XX}(\tau) = e^{-|\tau|}$ (dashed): a record of length $2T$ sees the autocorrelation through the triangular window w_T (dotted), giving the products shown for $T = 1$ (red) and $T = 5$ (blue). As $T \to \infty$ the window flattens to 1. At $\omega = 0.5$, $E|X_T|^2/2T = 1.082,\ 1.504,\ 1.590$ for $T = 1, 5, 50$, against $S_{XX}(0.5) = 2/(1+0.25) = 1.6$.

Random signals through LTI systems

Let X satisfy the hypotheses of the Wiener–Khinchin theorem. Let h be real with $h \in L^1(\mathbb{R})$, i.e. the system is BIBO stable (Ch. 14), and let $H(\omega) = \int h(t)e^{-j\omega t}\, dt$. Define $Y(t) = \int_{-\infty}^{\infty} h(\alpha)X(t-\alpha)\, d\alpha$. Then:

1. Y is a well-defined WSS process with $E[Y] = \mu_X H(0)$ and

$$R_{YY}(\tau) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(\alpha)h(\beta)\, R_{XX}(\tau - \alpha + \beta)\, d\alpha\, d\beta,$$

a continuous function in L^1 with $\|R_{YY}\|_1 \le \|h\|_1^2\|R_{XX}\|_1$; 2. $S_{YY}(\omega) = |H(\omega)|^2 S_{XX}(\omega)$ for every ω; 3. if $S_{XX} \in L^1$, then $E[Y^2] = \frac{1}{2\pi}\int_{-\infty}^{\infty} |H(\omega)|^2 S_{XX}(\omega)\, d\omega$.

Proof

Part 1. By Cauchy–Schwarz, $E|X(t)| \le \sqrt{R_{XX}(0)}$, so $E\int|h(\alpha)||X(t-\alpha)|\, d\alpha \le \|h\|_1\sqrt{R_{XX}(0)} < \infty$. Hence the integral defining $Y(t)$ converges absolutely with probability one. By Fubini, $E[Y(t)] = \int h(\alpha)\mu_X\, d\alpha = \mu_X H(0)$. For the correlation, the integrand of

$$E[Y(t+\tau)Y(t)] = E\Big[\iint h(\alpha)h(\beta)X(t+\tau-\alpha)X(t-\beta)\, d\alpha\, d\beta\Big]$$

is dominated in expectation by $|h(\alpha)h(\beta)|R_{XX}(0)$, whose double integral is $\|h\|_1^2 R_{XX}(0) < \infty$. So Fubini again moves E inside, and $E[X(t+\tau-\alpha)X(t-\beta)] = R_{XX}(\tau-\alpha+\beta)$. The result depends on τ only, and $E[Y^2] = R_{YY}(0) \le \|h\|_1^2 R_{XX}(0) < \infty$, so Y is WSS. Integrating $|R_{YY}|$ over τ and using Tonelli's theorem with the substitution $u = \tau - \alpha + \beta$ gives $\|R_{YY}\|_1 \le \|h\|_1^2\|R_{XX}\|_1$. Continuity of R_{YY} follows from continuity of R_{XX}, the bound $|R_{XX}| \le R_{XX}(0)$, and dominated convergence.

Part 2. By part 1, Y satisfies the hypotheses of the Wiener–Khinchin theorem, so $S_{YY}(\omega) = \int R_{YY}(\tau)e^{-j\omega\tau}\, d\tau$. Insert the double integral. The triple integral converges absolutely (the bound in part 1), so Fubini permits any order of integration. Integrate over τ first with $u = \tau - \alpha + \beta$, noting $e^{-j\omega\tau} = e^{-j\omega u}e^{-j\omega\alpha}e^{j\omega\beta}$:

$$S_{YY}(\omega) = \int h(\alpha)e^{-j\omega\alpha}d\alpha \cdot \int h(\beta)e^{j\omega\beta}d\beta \cdot \int R_{XX}(u)e^{-j\omega u}du = H(\omega)\,\overline{H(\omega)}\,S_{XX}(\omega).$$

The middle factor is $\overline{H(\omega)}$ because h is real. Hence $S_{YY} = |H|^2 S_{XX}$.

Part 3. $|H(\omega)| \le \|h\|_1$, so $S_{YY} \le \|h\|_1^2 S_{XX} \in L^1$. The inversion part of the Wiener–Khinchin theorem at $\tau = 0$ applies to Y. ■

Remarks

- *Why $R_{XX} \in L^1$.* The hypothesis excludes components with a discrete spectrum. For the random-phase sinusoid $X(t) = A\cos(\omega_0 t + \Theta)$, $\Theta \sim \mathcal{U}(0, 2\pi)$, we have $R_{XX} = \frac{A^2}{2}\cos\omega_0\tau \notin L^1$. Then $E|X_T(\omega_0)|^2/(2T)$ grows like T, and the PSD exists only as the generalised function $\frac{\pi A^2}{2}[\delta(\omega-\omega_0) + \delta(\omega+\omega_0)]$. A non-zero mean behaves the same way, contributing $2\pi\mu_X^2\delta(\omega)$. The chapter's table of transform pairs (Section 21.4) uses this distributional extension. The chapter's sufficient condition $\int|\tau R_{XX}| < \infty$ (together with $R_{XX} \in L^1$) gives the stronger conclusion that the convergence is $O(1/T)$, because $\big|E|X_T|^2/(2T) - S_{XX}\big| \le \frac{1}{2T}\int|\tau R_{XX}|\, d\tau + \int_{|\tau|>2T}|R_{XX}|\, d\tau$.

- *Non-negativity for free.* Step 4 shows that the Fourier transform of a valid autocorrelation is non-negative. This is the easy half of Bochner's theorem. For example, a rectangular "autocorrelation" $\mathbf{1}_{\{|\tau|\le 1\}}$ has transform $2\sin\omega/\omega$, which takes negative values, so no WSS process has it.
- *White noise.* $R = \frac{N_0}{2}\delta$ is not a function, so white noise lies outside the theorem. Its role is as a limit: band-limited white noise satisfies the hypotheses, and letting the bandwidth grow in part 2 gives $S_{YY} = \frac{N_0}{2}|H|^2$ for every stable H with $\int |H|^2 < \infty$. For the RC low-pass $H = 1/(1 + j\omega RC)$, part 3 gives $E[Y^2] = \frac{1}{2\pi}\int \frac{N_0/2}{1+\omega^2R^2C^2}\,d\omega = \frac{N_0}{4RC}$, confirmed by numerical quadrature. This matches the chapter's worked example.
- *Where used.* Section 21.4 (PSD, LTI systems with random inputs), noise-equivalent bandwidth and coloured noise in Section 21.6, and the matched filter in Section 21.8.

E.10 Quadratic convergence of Newton–Raphson

Newton's iteration for $f(x) = 0$ is $x_{k+1} = x_k - f(x_k)/f'(x_k)$ (Section 22.4). Write $e_k = x_k - x^*$ for the error.

Statement

Local quadratic convergence of Newton's method

Let $f(x^*) = 0$, and let f be twice continuously differentiable on $I = [x^* - r,\ x^* + r]$ with $f' \neq 0$ on I (a **simple root**; if only $f'(x^*) \neq 0$ is known, shrink r using continuity of f'). Put

$$m = \min_I |f'| > 0, \qquad M = \max_I |f''|, \qquad K = \frac{M}{2m}, \qquad \delta = \min\left(r,\ \frac{1}{2K}\right) \quad (\delta = r \text{ if } M = 0).$$

If $|x_0 - x^*| \le \delta$, then all iterates are defined and lie in I, and

1. $|e_{k+1}| \le K\,e_k^2$ and $|e_{k+1}| \le \tfrac{1}{2}|e_k|$ for every k, so $x_k \to x^*$;
2. $K|e_k| \le \big(K|e_0|\big)^{2^k} \le 2^{-2^k}$: the number of correct digits roughly doubles at every step;
3. if $e_k \neq 0$ for all k, then $\lim\limits_{k\to\infty} \dfrac{e_{k+1}}{e_k^2} = \dfrac{f''(x^*)}{2f'(x^*)}$.

Proof

Step 1 (one-step error identity). Suppose $x_k \in I$. Then $f'(x_k) \neq 0$, so x_{k+1} is defined. Taylor's theorem with Lagrange remainder (Ch. 4), expanding about x_k and evaluating at x^*, gives

$$0 = f(x^*) = f(x_k) + f'(x_k)(x^* - x_k) + \tfrac{1}{2}f''(\xi_k)(x^* - x_k)^2$$

for some ξ_k between x_k and x^*, hence $\xi_k \in I$. Divide by $f'(x_k)$ and use $f(x_k)/f'(x_k) = x_k - x_{k+1}$:

$$0 = (x_k - x_{k+1}) + (x^* - x_k) + \frac{f''(\xi_k)}{2f'(x_k)}e_k^2 \quad\Longrightarrow\quad e_{k+1} = \frac{f''(\xi_k)}{2f'(x_k)}\,e_k^2.$$

So $|e_{k+1}| \le K e_k^2$.

Step 2 (induction: the iterates stay in I). Suppose $|e_k| \le \delta$, which holds for $k = 0$. Then $x_k \in I$, and by Step 1, $|e_{k+1}| \le (K|e_k|)|e_k| \le (K\delta)|e_k| \le \tfrac{1}{2}|e_k| \le \delta$. By induction every iterate satisfies $|e_k| \le \delta$, and $|e_k| \le 2^{-k}|e_0| \to 0$. This proves part 1. (If some $e_k = 0$, all later errors are 0, since $f(x^*) = 0$.)

Step 3 (doubling of digits). Let $q_k = K|e_k|$. Step 1 gives $q_{k+1} \le q_k^2$, so by induction $q_k \le q_0^{2^k}$, and $q_0 \le K\delta \le \tfrac{1}{2}$.

Step 4 (the limit). As $k \to \infty$, $x_k \to x^*$ and $\xi_k \to x^*$ (it lies between them). By continuity of f'' and f', the factor $f''(\xi_k)/(2f'(x_k))$ tends to $f''(x^*)/(2f'(x^*))$. ∎

Remarks

- *Numerical check.* For $f(x) = x^3 - x - 2$ (Worked Example 22.14), the root is $x^* = 1.5213797$. The predicted constant is $f''(x^*)/(2f'(x^*)) = 6x^*/(2(3x^{*2} - 1)) = 0.768$, matching the observed ratios $0.79,\ 0.77,\ 0.77$ in the chapter's table.
- *Counterexample 1: multiple roots.* For $f(x) = x^2$ (double root, $f'(0) = 0$) Newton gives $x_{k+1} = x_k/2$. The convergence is only linear with rate $\tfrac{1}{2}$. In general, a root of multiplicity p gives the linear rate $1 - 1/p$ (Section 22.4, "Multiple roots"). The hypothesis $f'(x^*) \neq 0$ is what makes $m > 0$.
- *Counterexample 2: the result is local.* For $f(x) = \arctan x$, the iteration is $x_{k+1} = x_k - (1 + x_k^2)\arctan x_k$. It converges for $|x_0| < x_c$ and diverges with growing oscillation for $|x_0| > x_c$. Here $x_c = 1.39175$ solves $2x = (1 + x^2)\arctan x$. From $x_0 = 1.5$ the iterates are $-1.694,\ 2.321,\ -5.114,\ 32.3, \ldots$. From $x_0 = 1.3$ they are $-1.162,\ 0.859,\ -0.374,\ 0.034,\ -2.6 \times 10^{-5},\ 1.2 \times 10^{-14}$. The theorem's δ is a safe radius, not the exact basin.
- *Smoothness.* Suppose that instead of $f \in C^2$ we only know that f' is Hölder continuous with exponent $\alpha \in (0, 1]$. Writing the Taylor remainder as $\int_{x_k}^{x^*}(f'(s) - f'(x_k))\,ds = O(|e_k|^{1+\alpha})$, Step 1 gives order $1 + \alpha$ instead of 2. At the other extreme, if $f''(x^*) = 0$ and $f \in C^3$, the same expansion carried one order further gives cubic convergence.
- *Where used.* Section 22.4 (including diode circuit analysis), Gauss–Newton in Section 24.7, and Newton steps inside implicit ODE solvers (Section 22.9).

E.11 The bisection error bound

Bisection starts from $[a_0, b_0]$ with $f(a_0)f(b_0) < 0$. At step k it sets $m_k = \tfrac{1}{2}(a_k + b_k)$. It stops if $f(m_k) = 0$. Otherwise it keeps the half on which f changes sign (Section 22.4).

Statement

Convergence of bisection

Let f be continuous on $[a_0, b_0]$ with $f(a_0)f(b_0) < 0$. If the algorithm never stops at an exact zero, then:

1. $a_0 \le a_1 \le \cdots \le a_k < b_k \le \cdots \le b_1 \le b_0$, $f(a_k)f(b_k) < 0$, and $b_k - a_k = (b_0 - a_0)/2^k$;
2. a_k and b_k converge to a common limit x^* with $f(x^*) = 0$, and $a_k \le x^* \le b_k$ for every k;
3. $|m_k - x^*| \le \dfrac{b_0 - a_0}{2^{k+1}}$ for every k. Hence $|m_k - x^*| \le \tau$ is guaranteed as soon as $k \ge \log_2 \dfrac{b_0 - a_0}{\tau} - 1$.

Proof

Part 1 (induction). The case $k = 0$ is the hypothesis. Suppose part 1 holds at step k. Since $f(m_k) \ne 0$ and $f(a_k)f(b_k) < 0$, exactly one of $f(a_k)f(m_k) < 0$ and $f(m_k)f(b_k) < 0$ holds: $f(m_k)$ has the sign of one endpoint value and the opposite sign of the other. The algorithm keeps that half. So $[a_{k+1}, b_{k+1}]$ is either $[a_k, m_k]$ or $[m_k, b_k]$. In both cases the sign condition holds, the new interval is nested in the old one, and its width is $\frac{1}{2}(b_k - a_k) = (b_0 - a_0)/2^{k+1}$.

Part 2. (a_k) is non-decreasing and bounded above by b_0. (b_k) is non-increasing and bounded below by a_0. Monotone bounded sequences converge (completeness of $\mathbb{R}$, Ch. 4). Since $b_k - a_k \to 0$, the limits coincide; call the common limit x^*. Monotonicity gives $a_k \le x^* \le b_k$. By continuity, $f(a_k)f(b_k) \to f(x^*)^2$. Each term is negative, so the limit satisfies $f(x^*)^2 \le 0$, i.e. $f(x^*) = 0$.

Part 3. x^* and m_k both lie in $[a_k, b_k]$, and m_k is its centre. So $|m_k - x^*| \le \frac{1}{2}(b_k - a_k) = (b_0 - a_0)/2^{k+1}$. The iteration count follows by solving $(b_0 - a_0)/2^{k+1} \le \tau$ for k. ∎

Remarks

- *Stronger than "some root".* Part 2 identifies one root x^* that is the limit and that satisfies the bound at *every* step. The intermediate value theorem by itself would only give a root in each bracket, possibly a different one each time.
- *Counterexample: continuity is essential.* $f(x) = 1/x$ on $[-1, 2]$ has $f(-1)f(2) < 0$ but no root. Bisection keeps the sign change and converges to the pole $x = 0$ (brackets $[-1, 0.5]$, $[-0.25, 0.5]$, $[-0.25, 0.125]$, ...). Part 2 fails exactly at the step "by continuity".
- *Sharpness.* The bound cannot be improved in general. If the root sits arbitrarily close to an endpoint of the current bracket, the midpoint is almost half a width away.
- *Floating point.* In finite precision the bracket stops shrinking at about one unit in the last place of x^*. Correct sign evaluation is all that is needed for the bound to hold until then (Section 22.1).
- *Where used.* Section 22.4 (Example 22.13). It is also the safeguard inside hybrid root finders that fall back to bisection when Newton or secant steps leave the bracket.

E.12 Error terms of the trapezoidal and Simpson rules

Throughout, the error of a rule Q for $I = \int_a^b f\,dx$ is defined as $E = I - Q$.

Statement

Trapezoidal and Simpson error terms

1. **Trapezoidal rule.** If $f \in C^2[a, b]$, then for some $\xi \in (a, b)$
$$\int_a^b f\,dx - \frac{b-a}{2}\big(f(a) + f(b)\big) = -\frac{(b-a)^3}{12} f''(\xi).$$
2. **Simpson's rule.** If $f \in C^4[a, b]$, $h = \frac{b-a}{2}$ and $m = \frac{a+b}{2}$, then for some $\xi \in (a, b)$
$$\int_a^b f\,dx - \frac{h}{3}\big(f(a) + 4f(m) + f(b)\big) = -\frac{h^5}{90} f^{(4)}(\xi).$$
3. **Composite rules.** With $h = (b-a)/n$ and nodes $x_i = a + ih$, for some $\xi, \xi' \in (a, b)$
$$I - T_n = -\frac{(b-a)h^2}{12} f''(\xi) \quad (f \in C^2), \qquad I - S_n = -\frac{(b-a)h^4}{180} f^{(4)}(\xi') \quad (f \in C^4,\ n \text{ even}).$$

Two lemmas carry the proof.

Lemma E.12a (weighted mean value theorem)

Let ϕ be continuous on $[a, b]$, and let $w \le 0$ be integrable on $[a, b]$. Let q be a function with $q\,w$ integrable and $\min \phi \le q(x) \le \max \phi$ wherever $w(x) \ne 0$. Then $\int_a^b q\,w\,dx = \phi(\xi) \int_a^b w\,dx$ for some $\xi \in [a, b]$.

Proof. Let $\underline{\phi} = \min \phi$ and $\overline{\phi} = \max \phi$. Since $w \le 0$, we have $\overline{\phi}\,w \le q\,w \le \underline{\phi}\,w$ pointwise. Integrating gives $\overline{\phi} W \le \int qw \le \underline{\phi} W$ with $W = \int w \le 0$. If $W = 0$, then $w = 0$ almost everywhere, both sides vanish, and any ξ works. Otherwise divide by $W < 0$, which reverses the inequalities: $\underline{\phi} \le \int qw / W \le \overline{\phi}$. The intermediate value theorem then gives ξ with $\phi(\xi) = \int qw / W$. ∎

Lemma E.12b (interpolation errors)

(i) If $f \in C^2[a,b]$ and p_1 is the linear interpolant at a, b, then for each $x \in (a,b)$ there is $\eta_x \in (a,b)$ with $f(x) - p_1(x) = \tfrac{1}{2} f''(\eta_x)(x-a)(x-b)$.

(ii) If $f \in C^4[a,b]$, there is a unique cubic p_3 with $p_3 = f$ at a, m, b and $p_3'(m) = f'(m)$. For each $x \in (a,b) \setminus \{m\}$ there is $\eta_x \in (a,b)$ with $f(x) - p_3(x) = \tfrac{1}{24} f^{(4)}(\eta_x)(x-a)(x-m)^2(x-b)$.

Proof. (ii) *Existence.* Let p_2 interpolate f at a, m, b, and put $p_3 = p_2 + c\,(x-a)(x-m)(x-b)$. The cubic term vanishes at the three nodes, and its derivative at m is $(m-a)(m-b) = -h^2 \neq 0$. So exactly one c makes $p_3'(m) = f'(m)$. Uniqueness follows because the difference of two such cubics would have a double zero at m and simple zeros at a, b, which is four zeros counted with multiplicity, so it is identically zero.

Error. Fix $x \notin \{a, m, b\}$ and let $\omega(t) = (t-a)(t-m)^2(t-b)$, so $\omega(x) \neq 0$. Choose κ with $F(t) = f(t) - p_3(t) - \kappa\,\omega(t)$ vanishing at $t = x$. Then F vanishes at the four distinct points a, m, b, x, and also $F'(m) = 0$. Rolle's theorem on the three gaps between consecutive points gives three zeros of F', each strictly inside a gap and therefore different from m. Together with m itself, F' has at least four distinct zeros. Repeating Rolle, F'' has three, F''' two, and $F^{(4)}$ at least one, $\eta_x \in (a,b)$. Since $p_3^{(4)} = 0$ and $\omega^{(4)} = 24$, we get $0 = f^{(4)}(\eta_x) - 24\kappa$. (i) is the same argument with $\omega(t) = (t-a)(t-b)$, three zeros a, x, b, and two differentiations. ∎

Proof of the theorem

Part 1. By Lemma E.12b(i), $I - Q = \int_a^b (f - p_1)\,dx$, because the trapezoidal rule is the exact integral of p_1. Apply Lemma E.12a with $\phi = \tfrac{1}{2} f''$, $w = (x-a)(x-b) \leq 0$ on $[a,b]$, and $q = (f - p_1)/w$ on (a,b). This q is continuous on (a,b), takes values $\tfrac{1}{2} f''(\eta_x)$ between $\min \phi$ and $\max \phi$, and $qw = f - p_1$ is integrable. Since $\int_a^b (x-a)(x-b)\,dx = -\tfrac{(b-a)^3}{6}$,

$$I - Q = \tfrac{1}{2} f''(\xi) \cdot \Big(-\frac{(b-a)^3}{6} \Big) = -\frac{(b-a)^3}{12} f''(\xi).$$

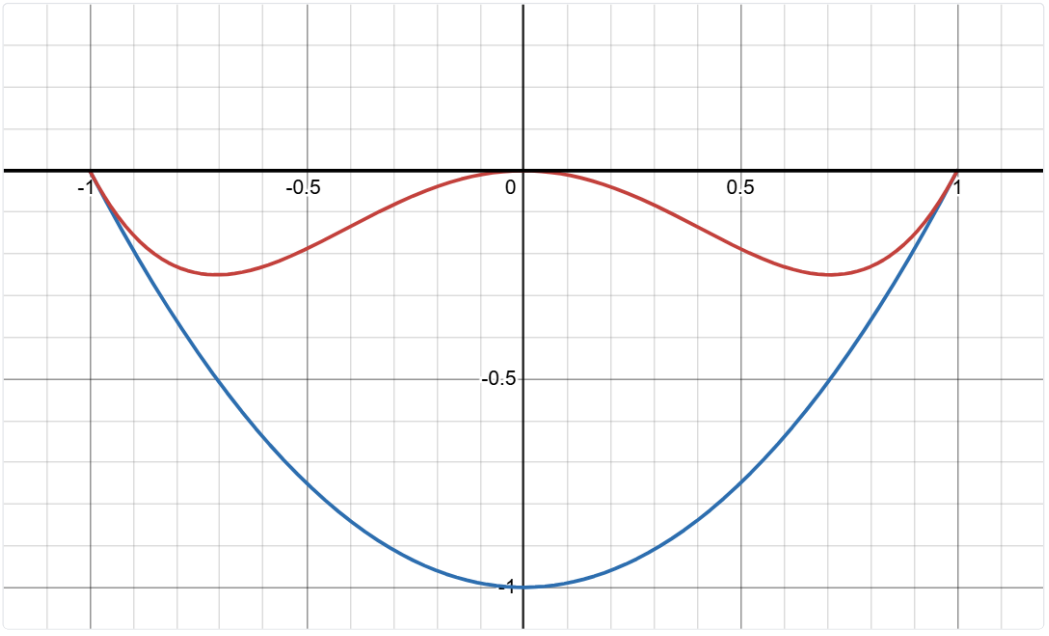
If ξ lands on an endpoint, the intermediate value theorem applied on (a,b) to the continuous f'' moves it inside.

Part 2. **Simpson's rule is exact for cubics.** By linearity it suffices to check the basis $1,\ (x-m),\ (x-m)^2,\ (x-m)^3$. The exact integrals over $[m-h, m+h]$ are $2h,\ 0,\ \tfrac{2}{3}h^3,\ 0$. The rule gives $\tfrac{h}{3}(1+4+1) = 2h$, $\tfrac{h}{3}(-h+0+h) = 0$, $\tfrac{h}{3}(h^2+0+h^2) = \tfrac{2}{3}h^3$ and $\tfrac{h}{3}(-h^3+0+h^3) = 0$. **Reduction.** The rule uses only $f(a), f(m), f(b)$, where $f = p_3$. So $Q(f) = Q(p_3) = \int_a^b p_3\,dx$, and $I - Q = \int_a^b (f - p_3)\,dx$. **Weighted mean value.** Lemma E.12a applies with $\phi = f^{(4)}/24$ and $w = (x-a)(x-m)^2(x-b) \leq 0$ on $[a,b]$. With $x = m + t$,

$$\int_a^b w\,dx = \int_{-h}^{h} (t+h)\,t^2\,(t-h)\,dt = \int_{-h}^{h} \big(t^4 - h^2 t^2\big)\,dt = \frac{2h^5}{5} - \frac{2h^5}{3} = -\frac{4h^5}{15},$$

so $I - Q = \tfrac{f^{(4)}(\xi)}{24} \cdot \big(-\tfrac{4h^5}{15} \big) = -\tfrac{h^5}{90} f^{(4)}(\xi)$.

Part 3. The composite trapezoidal error is the sum of the n panel errors, each $-\tfrac{h^3}{12} f''(\xi_i)$ by part 1. The average $\tfrac{1}{n}\sum_i f''(\xi_i)$ lies between $\min f''$ and $\max f''$, so it equals $f''(\xi)$ for some ξ by the intermediate value theorem. The total is $-\tfrac{nh^3}{12} f''(\xi) = -\tfrac{(b-a)h^2}{12} f''(\xi)$, since $nh = b - a$. For Simpson, the $n/2$ double panels each contribute $-\tfrac{h^5}{90} f^{(4)}(\xi_i)$ by part 2, and the same averaging gives $-\tfrac{n}{2} \cdot \tfrac{h^5}{90} f^{(4)}(\xi') = -\tfrac{(b-a)h^4}{180} f^{(4)}(\xi')$. ∎



The error kernels on $[-1,1]$: $(x-a)(x-b)$ for the trapezoidal rule (blue) and $(x-a)(x-m)^2(x-b)$ for Simpson's rule (red). Neither changes sign, which is exactly what Lemma E.12a needs. Their integrals, $-\tfrac{4}{3}$ and $-\tfrac{4}{15}$, produce the constants $\tfrac{1}{12}$ and $\tfrac{1}{90}$.

Remarks

- *Numerical check.* For $\int_0^1 e^x\,dx = e - 1$, the single trapezoid has error $-0.14086 = -\tfrac{1}{12} e^{\xi}$, giving $\xi = 0.525 \in (0,1)$. Single-panel Simpson has error $-5.79 \times 10^{-4} = -\tfrac{(0.5)^5}{90} e^{\xi}$, giving $\xi = 0.512$. Both are consistent with the theorem.

- *Counterexample: smoothness matters.* For $f(x) = \sqrt{x}$ on $[0, 1]$, f'' is unbounded and part 3 does not apply. The composite trapezoidal errors for $n = 8, 16, 32, 64$ are $8.5 \times 10^{-3},\ 3.1 \times 10^{-3},\ 1.1 \times 10^{-3},\ 4.0 \times 10^{-4}$. They shrink by about $2.8 \approx 2^{1.5}$ per halving, an $O(h^{1.5})$ rate instead of $O(h^2)$. A singularity at an endpoint degrades the order. Subtracting the singularity, changing variables, or Gaussian quadrature restores it (Section 22.8).
- *The bound is not always sharp.* For smooth periodic integrands over a full period, the trapezoidal rule converges far faster than h^2. Every term of the Euler–Maclaurin expansion vanishes (Section 22.8). The theorem gives a guarantee, not the true error in every case.
- *Where used.* Section 22.8 (Newton–Cotes and composite rules, Richardson/Romberg). The same Rolle-counting proof gives the general interpolation error formula of Section 22.5.

E.13 Euler's method: global $O(h)$ convergence and absolute stability

Consider the initial-value problem $y' = f(t, y)$, $y(t_0) = y_0$, on $[t_0, T]$. Euler's method with step $h > 0$ is $y_{n+1} = y_n + h f(t_n, y_n)$ with $t_n = t_0 + nh$ (Section 22.9). The global error is $e_n = y(t_n) - y_n$.

Statement

Convergence of Euler's method

Assume that f is continuous on $[t_0, T] \times \mathbb{R}$ and **Lipschitz** in y, i.e. $|f(t, u) - f(t, v)| \le L|u - v|$ for all t, u, v, with $L > 0$. Assume also that the exact solution y is twice continuously differentiable with $|y''| \le M$ on $[t_0, T]$. If the method is started from y_0 with initial error e_0, then for every n with $t_n \le T$

$$|e_n| \le e^{L(t_n - t_0)}|e_0| + \frac{Mh}{2L}\Big(e^{L(t_n - t_0)} - 1\Big).$$

In particular, with $e_0 = 0$, $\max_{t_n \le T}|e_n| \le C\,h$ with $C = \frac{M}{2L}(e^{L(T - t_0)} - 1)$ independent of h. Euler's method is convergent of order one.

Lemma E.13a (discrete Gronwall inequality)

If $a_n \ge 0$ and $a_{n+1} \le (1 + hL)a_n + B$ for $n \ge 0$, with $h, L > 0$ and $B \ge 0$, then

$$a_n \le (1 + hL)^n a_0 + B\,\frac{(1 + hL)^n - 1}{hL} \le e^{nhL}a_0 + \frac{B}{hL}\big(e^{nhL} - 1\big).$$

Proof. Induction gives $a_n \le (1 + hL)^n a_0 + B\sum_{k=0}^{n-1}(1 + hL)^k$. The geometric sum equals $\big((1 + hL)^n - 1\big)/(hL)$. Finally, $1 + x \le e^x$ for all real x, because e^x is convex and $1 + x$ is its tangent at 0. Hence $(1 + hL)^n \le e^{nhL}$. ∎

Proof of the theorem

Step 1 (local truncation error). By Taylor's theorem with Lagrange remainder and $y'(t_n) = f(t_n, y(t_n))$,

$$y(t_{n+1}) = y(t_n) + h f\big(t_n, y(t_n)\big) + \tau_{n+1}, \qquad \tau_{n+1} = \tfrac{h^2}{2}y''(\xi_n), \qquad |\tau_{n+1}| \le \tfrac{M}{2}h^2.$$

Step 2 (error recursion). Subtract the Euler step $y_{n+1} = y_n + h f(t_n, y_n)$:

$$e_{n+1} = e_n + h\big[f(t_n, y(t_n)) - f(t_n, y_n)\big] + \tau_{n+1}.$$

By the Lipschitz condition, the bracket is at most $L|e_n|$ in modulus. So $|e_{n+1}| \le (1 + hL)|e_n| + \frac{M}{2}h^2$.

Step 3 (accumulate). Apply Lemma E.13a with $a_n = |e_n|$ and $B = \frac{M}{2}h^2$. Then $B/(hL) = Mh/(2L)$, and $nh = t_n - t_0$. ∎

The structure of the proof is the general principle "consistency + stability ⟹ convergence" of Section 22.11. There are $O(1/h)$ local errors, each $O(h^2)$. Each is amplified by at most $e^{L(T - t_0)}$ by the time it reaches T.

Statement (absolute stability)

Absolute stability of Euler's method

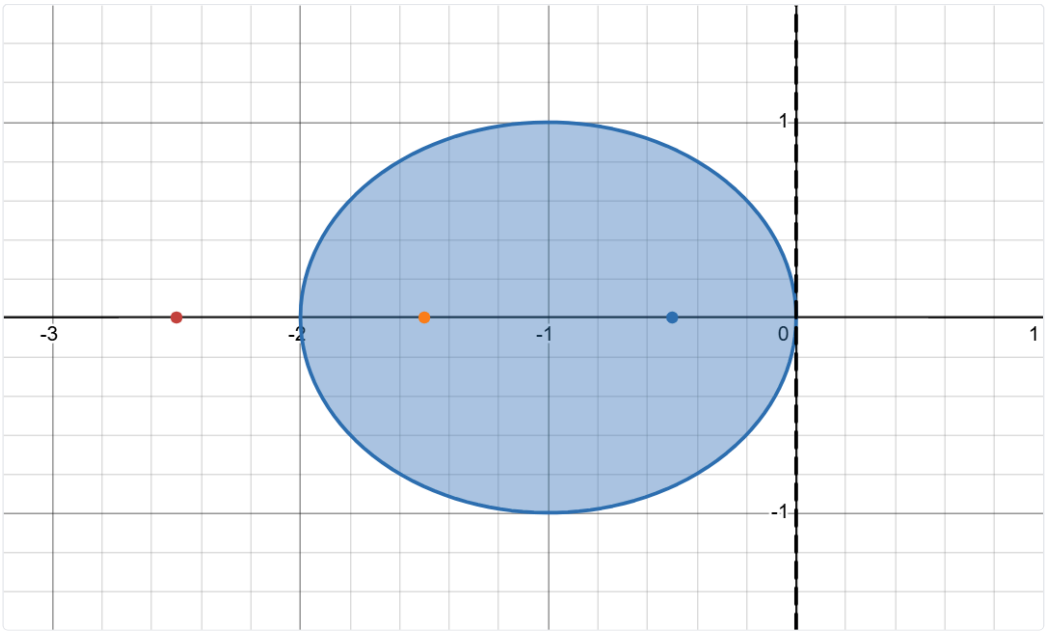
1. For the test equation $y' = \lambda y$, $\lambda \in \mathbb{C}$, Euler's method gives $y_n = (1 + h\lambda)^n y_0$. The numerical solution is bounded for every y_0 iff $|1 + h\lambda| \le 1$, and tends to 0 for every y_0 iff $|1 + h\lambda| < 1$. The region of absolute stability $\{z = h\lambda : |1 + z| \le 1\}$ is the closed disc of radius 1 centred at -1.
2. For real $\lambda < 0$ the condition is $0 < h \le 2/|\lambda|$. The numerical solution decays without sign changes iff $h \le 1/|\lambda|$.
3. For $\mathbf{y}' = \mathbf{A}\mathbf{y}$ with $\mathbf{A}$ diagonalisable, with eigenvalues $\lambda_1, \dots, \lambda_N$, the Euler iterates $\mathbf{y}_n = (\mathbf{I} + h\mathbf{A})^n \mathbf{y}_0$ are bounded for every $\mathbf{y}_0$ iff $|1 + h\lambda_i| \le 1$ for every i.

Proof

Part 1. With $f(t, y) = \lambda y$ the Euler step is $y_{n+1} = (1 + h\lambda)y_n$, so by induction $y_n = (1 + h\lambda)^n y_0$ and $|y_n| = |1 + h\lambda|^n |y_0|$. For $y_0 \ne 0$, a geometric sequence ρ^n with $\rho \ge 0$ is bounded iff $\rho \le 1$ and tends to 0 iff $\rho < 1$. Writing $z = h\lambda = x + jy$, the condition $|1 + z| \le 1$ reads $(x + 1)^2 + y^2 \le 1$.

Part 2. For real $z = h\lambda < 0$, $|1 + z| \le 1$ means $-1 \le 1 + z \le 1$, i.e. $-2 \le z \le 0$, i.e. $h \le 2/|\lambda|$. The factor $1 + z$ is non-negative, so the iterates keep the sign of y_0, iff $z \ge -1$.

Part 3. Write $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$ with $\mathbf{V}$ invertible. Then $\mathbf{I} + h\mathbf{A} = \mathbf{V}(\mathbf{I} + h\mathbf{\Lambda})\mathbf{V}^{-1}$ and $(\mathbf{I} + h\mathbf{A})^n = \mathbf{V}(\mathbf{I} + h\mathbf{\Lambda})^n\mathbf{V}^{-1}$. In the coordinates $\mathbf{w} = \mathbf{V}^{-1}\mathbf{y}$, the iteration decouples into $w_{i,n} = (1 + h\lambda_i)^n w_{i,0}$, and part 1 applies to each component. Since $\|\mathbf{V}^{-1}\|^{-1}\|\mathbf{y}_n\| \le \|\mathbf{w}_n\| \le \|\mathbf{V}^{-1}\|\|\mathbf{y}_n\|$, the sequence $\mathbf{y}_n$ is bounded iff $\mathbf{w}_n$ is. ∎



Region of absolute stability of explicit Euler in the complex $z = h\lambda$ plane: the disc $|1 + z| \le 1$. The three points are the step sizes of the chapter's figure for $y' = -2y$. $z = -0.5$ gives monotone decay, $z = -1.5$ oscillating decay, and $z = -2.5$ lies outside the disc, so the iterates grow.

Remarks

- *Numerical check of the convergence bound.* For $y' = y$, $y(0) = 1$ on $[0, 1]$, take $L = 1$ and $M = e$. At $t = 1$ the bound is $\frac{eh}{2}(e - 1) = 2.335h$. The actual errors $e - (1 + h)^{1/h}$ are $0.1245,\ 0.0650,\ 0.01347$ for $h = 0.1,\ 0.05,\ 0.01$. Each is below the bound, and the ratio error$/h$ tends to $e/2 = 1.359$, confirming first order.
- *Counterexample: the Lipschitz hypothesis.* $y' = \sqrt{|y|}$, $y(0) = 0$, is not Lipschitz at $y = 0$. It has the solutions $y \equiv 0$ and $y = t^2/4$ (among others). Euler from $y_0 = 0$ produces $y_n \equiv 0$ and converges to one solution. If $y_0 = \varepsilon > 0$, it follows the other branch instead. Without uniqueness, "the error" is not even well defined.
- *Convergence versus stability.* The convergence theorem is about $h \to 0$ at fixed T. Its constant $e^{L(T - t_0)}$ can be astronomically large. The stability theorem is about fixed h and $n \to \infty$. For a stiff system with $\lambda = -1000$, part 2 forces $h \le 2 \times 10^{-3}$ for as long as the integration runs, even after the fast mode has decayed. That is the motivation for implicit methods (Section 22.9, "Stiffness").
- *Counterexample: diagonalisability in part 3.* For $\mathbf{A} = \begin{pmatrix} \lambda & 1 \\ 0 & \lambda \end{pmatrix}$ with $|1 + h\lambda| = 1$, $(\mathbf{I} + h\mathbf{A})^n = \begin{pmatrix} r^n & nhr^{n-1} \\ 0 & r^n \end{pmatrix}$ with $r = 1 + h\lambda$. It grows linearly in n although every eigenvalue lies on the boundary of the stability disc. Strict inequality $|1 + h\lambda_i| < 1$ suffices in general.
- *Rounding.* If each step also commits a rounding error of size ϵ, then $B = \frac{M}{2}h^2 + \epsilon$ in Step 3, and the bound becomes $\left(\frac{Mh}{2} + \frac{\epsilon}{h}\right)\frac{e^{L(T - t_0)} - 1}{L}$. It is minimised near $h = \sqrt{2\epsilon/M}$. Making h smaller beyond this point makes the answer worse.
- *Where used.* Euler's method and absolute stability in Section 22.9, zero-stability and the Lax equivalence theorem in Section 22.11, and solver choice in Section 25.9.

E.14 The Monte Carlo $1/\sqrt{N}$ error rate

Statement

Error of the Monte Carlo estimator

Let $\mathbf{X}_1, \dots, \mathbf{X}_N$ be i.i.d. copies of a random vector $\mathbf{X}$, and let g be a function with $\mu = E[g(\mathbf{X})]$ and $\sigma^2 = \operatorname{Var} g(\mathbf{X}) < \infty$. Let

$$\hat{\mu}_N = \frac{1}{N}\sum_{i=1}^{N} g(\mathbf{X}_i), \qquad s_N^2 = \frac{1}{N - 1}\sum_{i=1}^{N} \big(g(\mathbf{X}_i) - \hat{\mu}_N\big)^2.$$

Then:

1. $E[\hat{\mu}_N] = \mu$, and the root-mean-square error is **exactly** $\sqrt{E[(\hat{\mu}_N - \mu)^2]} = \sigma/\sqrt{N}$;
2. for every N and every $k > 0$, $P\big(|\hat{\mu}_N - \mu| \ge k\sigma/\sqrt{N}\big) \le 1/k^2$;
3. if $\sigma > 0$, then for every $z > 0$, $P\big(|\hat{\mu}_N - \mu| \le z\sigma/\sqrt{N}\big) \to 2\Phi(z) - 1$ as $N \to \infty$;
4. $E[s_N^2] = \sigma^2$ and $s_N \to \sigma$ in probability. Consequently, part 3 also holds with σ replaced by s_N, and $\hat{\mu}_N \pm 1.96\, s_N/\sqrt{N}$ is an asymptotic 95% confidence interval.

Proof

Part 1. The $Y_i = g(\mathbf{X}_i)$ are i.i.d. with mean μ and variance σ^2. By E.4 (part 1 of the proof), $E[\hat{\mu}_N] = \mu$ and $\operatorname{Var}\hat{\mu}_N = \sigma^2/N$. Independence implies uncorrelatedness, so the variance identity is exact, not just a bound. Since $E[\hat{\mu}_N] = \mu$, the mean-square error equals the variance.

Part 2. Chebyshev's inequality (E.3) applied to $\hat{\mu}_N$, whose standard deviation is $\sigma/\sqrt{N}$.

Part 3. By the central limit theorem (E.5) applied to the Y_i, $Z_N = \sqrt{N}(\hat{\mu}_N - \mu)/\sigma \to \mathcal{N}(0,1)$ in distribution. Because Φ is continuous, $P(-z \le Z_N \le z) = F_{Z_N}(z) - F_{Z_N}(-z) + P(Z_N = -z)$. The first two terms converge to $\Phi(z) - \Phi(-z)$. For the atom term, $0 \le P(Z_N = -z) \le F_{Z_N}(-z) - F_{Z_N}(-z-\eta) \to \Phi(-z) - \Phi(-z-\eta)$ for every $\eta > 0$, which can be made arbitrarily small. So $P(|Z_N| \le z) \to 2\Phi(z) - 1$.

Part 4. Unbiasedness is E.6. For consistency, expand as in E.6, Step 1:

$$s_N^2 = \frac{N}{N-1}\Big[\frac{1}{N}\sum_{i=1}^{N} Y_i^2 - \hat{\mu}_N^2\Big].$$

By Khinchin's weak law (E.4, part 2), which applies because $E|Y_i^2| = \sigma^2 + \mu^2 < \infty$, we have $\frac{1}{N}\sum Y_i^2 \to \sigma^2 + \mu^2$ and $\hat{\mu}_N \to \mu$ in probability. Continuous functions preserve convergence in probability (the continuous mapping theorem, quoted). So $s_N^2 \to (\sigma^2 + \mu^2) - \mu^2 = \sigma^2$, and $s_N = \sqrt{s_N^2} \to \sigma$. Slutsky's theorem (quoted: if $Z_N \to Z$ in distribution and $C_N \to c \neq 0$ in probability, then $Z_N/C_N \to Z/c$ in distribution) applied with $C_N = s_N/\sigma \to 1$ shows that $\sqrt{N}(\hat{\mu}_N - \mu)/s_N \to \mathcal{N}(0,1)$. The interval statement follows as in part 3. ■

Remarks

- *The rate is exact.* Part 1 is an identity, not a bound. For plain Monte Carlo with i.i.d. samples, the RMS error is $\sigma N^{-1/2}$ for every N and cannot be improved by any choice of N. Halving the error costs four times the samples, and one more decimal digit costs a hundred times. The only levers are σ (variance reduction, which replaces g by an estimator with the same mean and smaller variance) and abandoning independence (quasi-Monte Carlo) (Section 24.6).
- *No dimension in the rate.* Neither the dimension of $\mathbf{X}$ nor the smoothness of g appears in the theorem. Only σ does. By contrast, a product trapezoidal rule in d dimensions has error $O(N^{-2/d})$ (E.12, part 3, in each coordinate). This is why Monte Carlo wins for $d > 4$.
- *Numerical check.* For $\int_0^1 e^x\,dx$ with uniform samples, $\sigma = \sqrt{\frac{1}{2}(e^2-1) - (e-1)^2} = 0.49197$. Over 2000 independent repetitions, the observed RMS errors were $0.0496,\ 0.0152,\ 0.00481$ for $N = 10^2,\ 10^3,\ 10^4$. The predicted values $\sigma/\sqrt{N}$ are $0.0492,\ 0.0156,\ 0.00492$.
- *Counterexample: infinite variance.* For $g(x) = x^{-1/2}$ with $X \sim \mathcal{U}(0,1)$, $\mu = 2$ is finite but $E[g^2] = \int_0^1 x^{-1}dx = \infty$. Khinchin's law still gives $\hat{\mu}_N \to 2$ in probability, but parts 1–4 fail. The error decays more slowly than $N^{-1/2}$ (here like $N^{-1/2}\sqrt{\log N}$), and s_N systematically misreports it. Importance sampling with a density $\propto x^{-1/2}$ removes the singularity and gives zero variance.
- *Chebyshev versus CLT.* Part 2 holds for every N but is conservative. With $k = 4.47$ it guarantees 95% coverage. Part 3 needs only $z = 1.96$, but it is asymptotic, and for skewed integrands with small N the actual coverage can fall short (Berry–Esseen, E.5).
- *Where used.* Section 24.6 (the basic estimator and its error bar), Monte Carlo tolerance analysis and uncertainty propagation (Sections 24.6 and 24.8), and GUM Supplement 1 in Section 20.10.
