Appendix — Derivations and Proofs

Appendix A — Calculus and Complex Numbers
Appendix B — Vector Calculus and Field Theorems
Appendix C — Linear Algebra
Appendix D — Transforms, ODEs and Complex Analysis
Appendix E — Probability, Statistics and Numerical Methods

Notation and Conventions

These conventions hold throughout the book unless a chapter states otherwise.

Numbers and sets

Symbol	Meaning
$\mathbb{N}, \mathbb{Z}, \mathbb{Q}, \mathbb{R}, \mathbb{C}$	naturals, integers, rationals, reals, complex numbers
j	imaginary unit, $j^2 = -1$ (engineering convention; mathematics texts use i)
z^* or $\bar{z}$	complex conjugate
$\lvert z\rvert,\ \angle z$	magnitude and argument (phase) of z
$\mathrm{Re}\{z\},\ \mathrm{Im}\{z\}$	real and imaginary parts

Scalars, vectors, matrices

Symbol	Meaning
$a,\ x,\ \lambda$	scalars (italic)
$\mathbf{x},\ \mathbf{E}$	vectors (bold lowercase or field quantities)
$\hat{\mathbf{x}},\ \hat{\mathbf{n}}$	unit vectors
$\mathbf{A},\ \mathbf{L}$	matrices (bold uppercase)
$\mathbf{A}^{\mathsf{T}},\ \mathbf{A}^{\mathsf{H}}$	transpose, conjugate (Hermitian) transpose
$\mathbf{I}$	identity matrix
$\langle \mathbf{u}, \mathbf{v} \rangle$	inner product
$\lVert \mathbf{x} \rVert$	norm (Euclidean unless subscripted)

Coordinate systems

System	Coordinates	Notes
Cartesian	(x, y, z)	
Cylindrical	(r, ϕ, z)	r = distance from z-axis; keeps ρ free for charge density
Spherical	(R, θ, ϕ)	θ = polar angle from $+z$, ϕ = azimuth (physics/Cheng convention)

Calculus and operators

Symbol	Meaning
$\frac{dy}{dt},\ \dot{y},\ y'$	derivative (dot = time derivative)
$\frac{\partial f}{\partial x},\ f_x$	partial derivative
$\nabla f,\ \nabla \cdot \mathbf{F},\ \nabla \times \mathbf{F},\ \nabla^2 f$	gradient, divergence, curl, Laplacian
$\oint_C$	integral around a closed contour/curve

Signals and transforms

Symbol	Meaning
t, n	continuous time, discrete-time index
$u(t), u[n]$	unit step
$\delta(t), \delta[n]$	Dirac impulse, Kronecker (unit) impulse
$\omega = 2\pi f$	angular frequency (rad/s), f in Hz
$X(s) = \mathcal{L}\{x(t)\}$	Laplace transform, $s = \sigma + j\omega$
$X(\omega) = \mathcal{F}\{x(t)\}$	Fourier transform (angular-frequency convention, see Ch. 16)
$X(z) = \mathcal{Z}\{x[n]\}$	Z-transform
$x * h$	convolution

Probability

Symbol	Meaning
$P(A)$, $P(A \mid B)$	probability, conditional probability
X, Y	random variables (uppercase); x, y their values
$E[X]$, μ	expectation
$\mathrm{Var}(X)$, σ^2	variance
$X \sim \mathcal{N}(\mu, \sigma^2)$	X is Gaussian
$R_{XX}(\tau)$, $S_{XX}(\omega)$	autocorrelation, power spectral density

Units and dimensions

SI units throughout. Dimensions are written in brackets: $[V] = \mathrm{M\,L^2\,T^{-3}\,I^{-1}}$. Every equation in this book should be dimensionally consistent — checking this is the cheapest error detector you have (Ch. 1, Ch. 25).

Callouts

The book uses Obsidian callouts (they degrade to blockquotes on GitHub):

> **Definition**
>
> A precise statement of a concept.

> **Theorem**
>
> A result you can rely on.

> **Worked Example**
>
> A solved problem.

> **Engineering Note**
>
> Where the method shows up in EE practice.

> **Common Pitfall**
>
> A mistake worth avoiding.

> **? Missing clue**
>
> A question the chapter raises on purpose and leaves open, with a pointer to where it is answered (track chapters only).

Level 1 — Core

The original 25 chapters: the engineering-mathematics foundation every track builds on.

Part I — Mathematical Foundations

Chapter 1 — Mathematical Language and Algebra

> **Prerequisites:** Secondary-school arithmetic and algebra; read Notation & Conventions first. **Learning outcomes:** After this chapter you can
>
> - classify numbers, reason about precision and rounding, and use interval, set and absolute-value notation correctly;
> - rearrange, factor and simplify algebraic and rational expressions, including partial-fraction decomposition;
> - solve linear, quadratic, radical, exponential, logarithmic and absolute-value equations and inequalities, and recognise extraneous or lost roots;
> - work fluently with exponential, logarithmic, hyperbolic and trigonometric functions and their identities, including decibels and harmonic addition;
> - convert points and equations between Cartesian, polar, cylindrical (r, ϕ, z) and spherical (R, θ, ϕ) coordinates;
> - state domains and ranges, build inverse and composite functions, read mathematical notation precisely, and check any formula for dimensional consistency.

Every later chapter in this book is written in the language set out here. Very little of it is new mathematics, but experience in design reviews, laboratories and examination halls is unanimous: engineering errors are far more often algebra slips, sign errors, misplaced factors of ten and unit mistakes than misunderstandings of calculus. A transfer function with one wrong sign predicts a stable amplifier that oscillates; a decibel figure computed with 10 log instead of 20 log is off by a factor of ten in power. This chapter is therefore deliberately thorough. It revisits the familiar material with the precision that later chapters assume — exact definitions, the reasons the rules hold, and the traps that catch even experienced engineers — and it points forward to where each tool is used. Treat it as the toolkit you will reach for on every page that follows.

1.1 Real and complex number systems

Why the number system matters

An engineer measures a voltage as 3.30 V, a computer stores it as a 64-bit floating-point pattern, a theorem about limits assumes it is an exact real number, and an AC analysis represents its amplitude and phase as a single complex number. These are four different number systems, and moving between them without noticing is the source of many subtle mistakes. Knowing what each system can and cannot represent — and what operations are legal in each — is the first piece of mathematical language.

The standard number sets

The standard number sets

$$\mathbb{N} = \{1, 2, 3, \dots\} \subset \mathbb{Z} = \{\dots, -2, -1, 0, 1, 2, \dots\} \subset \mathbb{Q} = \left\{ \tfrac{p}{q} : p, q \in \mathbb{Z},\ q \neq 0 \right\} \subset \mathbb{R} \subset \mathbb{C}$$

- $\mathbb{N}$, the **natural numbers**, are the counting numbers.
- $\mathbb{Z}$, the **integers**, add zero and the negatives, so subtraction is always possible.
- $\mathbb{Q}$, the **rationals**, are ratios of integers, so division by any non-zero number is possible.
- $\mathbb{R}$, the **reals**, fill the gaps in $\mathbb{Q}$; real numbers that are not rational are **irrational** (e.g. $\sqrt{2}$, π, e).
- $\mathbb{C}$, the **complex numbers**, have the form $z = a + jb$ with $a, b \in \mathbb{R}$ and $j^2 = -1$.

Some authors include 0 in $\mathbb{N}$; this book does not, and writes $\mathbb{N}_0 = \{0, 1, 2, \dots\}$ when zero is needed (for example the index n of a discrete-time signal that starts at $n = 0$). Each enlargement of the number system is motivated by an equation that could not be solved in the smaller system: $x + 3 = 1$ has no solution in $\mathbb{N}$, $3x = 1$ none in $\mathbb{Z}$, $x^2 = 2$ none in $\mathbb{Q}$, and $x^2 = -1$ none in $\mathbb{R}$.

Decimal expansions of rationals

Decimal characterisation of $\mathbb{Q}$

A real number is rational if and only if its decimal expansion either terminates or eventually repeats.

Proof sketch. Long division of p by q produces at each step a remainder in $\{0, 1, \dots, q-1\}$. After at most q steps a remainder must recur (there are only q possibilities), and from then on the digits repeat. Conversely, a repeating decimal can be turned into a fraction by the shift-and-subtract trick in the next example. □

Worked Example 1.1 — Repeating decimals to fractions

(a) $x = 0.454545\dots$ The repeating block has length 2, so multiply by 10^2:

$$100x = 45.4545\dots, \qquad 100x - x = 45 \quad \Longrightarrow \quad x = \frac{45}{99} = \frac{5}{11}.$$

(b) $y = 1.2363636\dots$ Here one digit (2) precedes the repeating block 36. Shift so that the repeat starts at the decimal point, then shift by one block:

$$10y = 12.363636\dots, \qquad 1000y = 1236.363636\dots$$

Subtracting, $990y = 1224$, so $y = \dfrac{1224}{990} = \dfrac{68}{55}$.

Check: $68 \div 55 = 1.236363\dots$ ✓ and $5 \div 11 = 0.454545\dots$ ✓

Irrational numbers

Why $\sqrt{2}$ is irrational. Suppose $\sqrt{2} = p/q$ with p, q integers having no common factor. Then $p^2 = 2q^2$, so p^2 is even, hence p is even (the square of an odd number is odd), say $p = 2k$. Then $4k^2 = 2q^2$, so $q^2 = 2k^2$ and q is even too — contradicting "no common factor". $\square$

The same argument shows $\sqrt{n}$ is irrational whenever the integer n is not a perfect square. The numbers π and e are also irrational (indeed **transcendental**: they are not roots of any polynomial with integer coefficients), though the proofs are harder. In practice this means that π, e, $\sqrt{2}$ and $\sqrt{3}$ — which appear constantly in RMS values, three-phase power and time constants — can only ever be *approximated* in a calculation. Keep them symbolic as long as possible and round only at the end.

The real numbers as a complete ordered field

What exactly *is* $\mathbb{R}$? For engineering purposes it is enough to know the three groups of properties that every manipulation in this book relies on.

Axioms of the real numbers (summary)

Field axioms. Addition and multiplication are commutative and associative; multiplication distributes over addition, $a(b+c) = ab + ac$; there are identities 0 and 1; every a has a negative $-a$, and every $a \neq 0$ has a reciprocal a^{-1}.

Order axioms. For any a, b exactly one of $a < b$, $a = b$, $a > b$ holds; if $a < b$ then $a + c < b + c$; if $a < b$ and $c > 0$ then $ac < bc$.

Completeness. Every non-empty set of reals that is bounded above has a **least upper bound** (supremum) in $\mathbb{R}$.

$\mathbb{Q}$ satisfies the field and order axioms but not completeness: the set $\{x \in \mathbb{Q} : x^2 < 2\}$ is bounded above but has no least upper bound *in* $\mathbb{Q}$ — the "missing" bound is $\sqrt{2}$. Completeness is equivalent to the statement that every bounded, increasing sequence converges to a real limit, and it is what makes limits, continuity, the intermediate value theorem and hence all of calculus work (Ch. 4). It also guarantees that numerical algorithms such as bisection converge to an actual number.

Every rule of algebra in Section 1.2 is a consequence of the field axioms. For example, $a \cdot 0 = 0$ follows from $a \cdot 0 = a(0+0) = a \cdot 0 + a \cdot 0$ and subtracting $a \cdot 0$ from both sides; and $(-1)(-1) = 1$ follows from $0 = (-1) \cdot 0 = (-1)(1 + (-1)) = -1 + (-1)(-1)$. Nothing is arbitrary.

Intervals

Subsets of $\mathbb{R}$ that appear as domains, tolerance bands and solution sets are usually intervals.

Notation	Set	Notation	Set
$[a, b]$	$a \le x \le b$ (closed)	(a, b)	$a < x < b$ (open)
$[a, b)$	$a \le x < b$ (half-open)	$(a, b]$	$a < x \le b$
(a, ∞)	$x > a$	$[a, \infty)$	$x \ge a$
$(-\infty, b)$	$x < b$	$\mathbb{R}$	$(-\infty, \infty)$

The symbol ∞ is never a real number and never sits next to a square bracket. Unions such as $(-\infty, -2) \cup [1, \infty)$ describe solution sets of inequalities (Section 1.3).

Absolute value

Absolute value

$$|x| = \begin{cases} x, & x \ge 0 \\ -x, & x < 0 \end{cases}$$

Equivalently $|x| = \sqrt{x^2}$. Geometrically, $|x - a|$ is the distance between x and a on the number line.

Properties of absolute value

For all real x, y:

$$|x| \ge 0, \qquad |xy| = |x|\,|y|, \qquad \left|\frac{x}{y}\right| = \frac{|x|}{|y|} \ (y \neq 0),$$

$$|x + y| \le |x| + |y| \ \text{(triangle inequality)}, \qquad \big||x| - |y|\big| \le |x - y| \ \text{(reverse triangle inequality)}.$$

Proof of the triangle inequality. Since $-|x| \le x \le |x|$ and $-|y| \le y \le |y|$, adding gives $-(|x| + |y|) \le x + y \le |x| + |y|$, which is exactly $|x + y| \le |x| + |y|$. For the reverse form, write $x = (x - y) + y$ so $|x| \le |x - y| + |y|$, i.e. $|x| - |y| \le |x - y|$; swapping x and y gives $|y| - |x| \le |x - y|$, and together these are the claim. $\square$

The triangle inequality is the source of every **worst-case tolerance** bound in circuit design: if two errors are at most ε_1 and ε_2 in magnitude, their sum is at most $\varepsilon_1 + \varepsilon_2$ in magnitude — and no better guarantee is possible without further information.

Worked Example 1.2 — Worst-case tolerance

A $1.00\ \text{k}\Omega$ resistor with $\pm 5\%$ tolerance is placed in series with a $2.20\ \text{k}\Omega$ resistor with $\pm 1\%$ tolerance. Bound the error in the total resistance.

Step 1 — individual error bounds. $|e_1| \le 0.05 \times 1000 = 50\ \Omega$ and $|e_2| \le 0.01 \times 2200 = 22\ \Omega$.

Step 2 — triangle inequality. The total is $R = 3200 + e_1 + e_2$, and

$$|e_1 + e_2| \le |e_1| + |e_2| \le 72\ \Omega.$$

Step 3 — relative bound. $72/3200 = 2.25\%$. So $R \in [3128,\ 3272]\ \Omega$.

Check: the extreme values $1050 + 2222 = 3272$ and $950 + 2178 = 3128$ are attained, so the bound is tight.

Precision, significant figures and engineering notation

Measured quantities carry finite precision. The number of **significant figures** is the number of digits known reliably: $3.30\ \text{V}$ has three, $0.0047\ \mu\text{F}$ has two. **Scientific notation** writes a number as $m \times 10^{k}$ with $1 \le |m| < 10$; **engineering notation** restricts k to multiples of 3 so that the SI prefixes apply directly: $4.7 \times 10^{-9}\ \text{F} = 4.7\ \text{nF}$, $2.2 \times 10^{4}\ \Omega = 22\ \text{k}\Omega$. A result should not be quoted to more significant figures than the least precise input justifies, but intermediate calculations should carry two or three extra digits to avoid accumulating rounding error.

Real numbers in a computer

Computers do not store real numbers; they store a finite set of **floating-point** numbers of the form $\pm m \times 2^{e}$ with a fixed number of binary digits in m. IEEE 754 double precision uses a 53-bit significand, giving about 15–16 significant decimal digits; the gap between 1 and the next representable number is the **machine epsilon** $\varepsilon_{\text{mach}} = 2^{-52} \approx 2.2 \times 10^{-16}$.

Most decimal fractions are not representable exactly in binary, just as $\tfrac{1}{3}$ is not representable exactly in decimal. In binary, $0.1 = 0.000110011001100\ldots_{2}$ repeats forever, so the stored value is slightly off.

Worked Example 1.3 — Floating-point surprises

(a) In double precision, `0.1 + 0.2` evaluates to 0.30000000000000004, so the test `0.1 + 0.2 == 0.3` is **false**. Every term was rounded to the nearest binary fraction and the rounding errors did not cancel. Comparisons of floating-point results must use a tolerance: $|a - b| \le \varepsilon\ \max(|a|, |b|)$.

(b) Subtracting nearly equal numbers destroys relative accuracy. If $a = 1.0000001$ and $b = 1.0000000$ are each known to 8 significant figures, then $a - b = 1 \times 10^{-7}$ is known to only **one** significant figure. This is **catastrophic cancellation**; Section 1.3 shows how it ruins the textbook quadratic formula, and Ch. 22 treats it systematically.

Engineering Note — fixed point and quantisation

Microcontrollers and DSP chips often use **fixed-point** arithmetic: an N-bit integer interpreted as a fraction with a fixed binary point. An analogue-to-digital converter maps a continuous voltage range onto 2^{N} integer codes, so it replaces a real number by the nearest of a finite set — a quantisation error of at most half a step. An ideal 12-bit ADC spanning $3.3\ \text{V}$ has step $3.3/4096 = 0.806\ \text{mV}$ and therefore a worst-case quantisation error of $0.403\ \text{mV}$. Rational and real numbers are idealisations; the hardware works with integers.

Complex numbers — a preview

The equation $x^2 + 1 = 0$ has no real solution, because $x^2 \ge 0$ for every real x. Adjoining a new number j with $j^2 = -1$ and insisting that the field axioms still hold produces $\mathbb{C} = \{a + jb : a, b \in \mathbb{R}\}$, with

$$(a + jb) + (c + jd) = (a + c) + j(b + d), \qquad (a + jb)(c + jd) = (ac - bd) + j(ad + bc).$$

The payoff is remarkable: in $\mathbb{C}$, **every** polynomial equation has a solution (the fundamental theorem of algebra, Section 1.4). Complex numbers are the natural language of AC circuits, filters and signals and are developed fully in Ch. 2. For now note only that $z = a + jb$ has real part $\text{Re}\{z\} = a$ and imaginary part $\text{Im}\{z\} = b$ (both real), that $z^{*} = a - jb$ is its **conjugate**, and that $|z| = \sqrt{a^2 + b^2}$ is its **magnitude**, so that $zz^{*} = |z|^2$ is real and non-negative.

Common Pitfall — $\mathbb{C}$ is not ordered

There is no way to define "$<$" on $\mathbb{C}$ that respects the order axioms: if $j > 0$ then $j \cdot j = -1 > 0$, absurd; if $j < 0$ then $-j > 0$ and $(-j)(-j) = -1 > 0$, equally absurd. An inequality between complex numbers, such as $Z_1 < Z_2$ for two impedances, is meaningless. Compare **magnitudes** $|Z_1| < |Z_2|$ or **real parts** instead, and say which.

Common Pitfall — the letter j

Mathematics texts and many programming languages write i for $\sqrt{-1}$; electrical engineering uses j because i denotes current. Python writes `1j`, MATLAB accepts both `1i` and `1j`. Never use j simultaneously as a summation index and the imaginary unit.

1.2 Algebraic manipulation

Why fluency matters

Engineering formulas are rarely used in the form in which they are derived. Ohm's law is written $V = IR$ but used as $R = V/I$; a resonance formula gives frequency in terms of L and C but the designer needs C in terms of frequency; a transfer function must be put over a common denominator before its poles can be read off. Algebraic manipulation is the skill of transforming an expression or equation into an *equivalent* one that is more useful. Every transformation must be justified by the field axioms of Section 1.1 — and most mistakes come from "rules" that are not among them.

Order of operations and the distributive law

Expressions are evaluated in the conventional order: brackets, then powers and roots, then multiplication and division (left to right), then addition and subtraction (left to right). Two conventions trip people up:

- $-x^2$ means $-(x^2)$, not $(-x)^2$. So $-3^2 = -9$.
- a/bc is ambiguous in print. In this book a fraction bar or explicit brackets are always used: $\dfrac{a}{bc}$ or $(a/b)c$.

The **distributive law** $a(b+c) = ab + ac$ is the only axiom that links addition and multiplication, so it is behind every expansion and every factorisation. Its two directions are **expanding** (left to right) and **factoring** (right to left). Repeated use gives $(a+b)(c+d) = ac + ad + bc + bd$ and, more generally, the product of two sums is the sum of all pairwise products of their terms.

Laws of exponents

For a positive integer n, a^n means $a \cdot a \cdots a$ (n factors). The laws below are obvious for positive integer exponents by counting factors; the definitions $a^0 = 1$, $a^{-n} = 1/a^n$ and $a^{p/q} = \sqrt[q]{a^p}$ are then *chosen* precisely so that the laws continue to hold.

Laws of exponents

For $a, b > 0$ and real m, n:

$$a^m a^n = a^{m+n}, \qquad \frac{a^m}{a^n} = a^{m-n}, \qquad (a^m)^n = a^{mn}, \qquad (ab)^n = a^n b^n, \qquad \left(\frac{a}{b}\right)^n = \frac{a^n}{b^n},$$

$$a^0 = 1, \qquad a^{-n} = \frac{1}{a^n}, \qquad a^{1/n} = \sqrt[n]{a}, \qquad a^{m/n} = \left(\sqrt[n]{a}\right)^m = \sqrt[n]{a^m}.$$

For example, requiring $a^{1/2}a^{1/2} = a^1$ forces $a^{1/2} = \sqrt{a}$, and requiring $a^0 a^n = a^n$ forces $a^0 = 1$. Irrational exponents such as $2^{\sqrt{2}}$ are defined by continuity — as the limit of 2^q over rationals $q \to \sqrt{2}$ — or, more cleanly, as $e^{\sqrt{2}\ln 2}$ (Section 1.5).

Common Pitfall — negative bases

The laws above require $a, b > 0$. With negative bases they fail: $\sqrt{(-2)^2} = 2 \neq -2$, and $\left((-8)^2\right)^{1/6} = 2$ while $\left((-8)^{1/6}\right)^2$ is not even real. In general $\sqrt{x^2} = |x|$, not x. Calculators and programming languages also differ on whether $(-8)^{1/3}$ returns the real cube root -2 or a complex number.

Expansion and factoring identities

The following identities should be recognisable instantly in both directions:

$$\begin{aligned}
(a \pm b)^2 &= a^2 \pm 2ab + b^2 \\
(a+b)^3 &= a^3 + 3a^2 b + 3ab^2 + b^3 \\
a^2 - b^2 &= (a-b)(a+b) \\
a^3 \pm b^3 &= (a \pm b)(a^2 \mp ab + b^2) \\
a^n - b^n &= (a-b)\left(a^{n-1} + a^{n-2}b + \cdots + ab^{n-2} + b^{n-1}\right)
\end{aligned}$$

The last identity, verified by multiplying out (all middle terms cancel in pairs), contains the geometric-series formula of Section 1.10 as the special case $a = 1$, $b = r$.

The binomial theorem

Binomial theorem

For any positive integer n,

$$(a+b)^n = \sum_{k=0}^{n} \binom{n}{k} a^{n-k} b^k, \qquad \binom{n}{k} = \frac{n!}{k!\,(n-k)!},$$

where $n! = 1 \cdot 2 \cdots n$ and $0! = 1$.

Proof sketch. Expanding $(a+b)(a+b)\cdots(a+b)$ (n factors) means choosing a or b from each factor and multiplying. A term $a^{n-k}b^k$ arises once for each way of choosing which k of the n factors supply b, and there are $\binom{n}{k}$ such choices. □

The coefficients form **Pascal's triangle**, in which each entry is the sum of the two above it, $\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}$:

n	coefficients $\binom{n}{0}, \dots, \binom{n}{n}$
0	1
1	1, 1
2	1, 2, 1
3	1, 3, 3, 1
4	1, 4, 6, 4, 1
5	1, 5, 10, 10, 5, 1

The binomial coefficients reappear as counts of outcomes in the binomial probability distribution (Ch. 19).

Worked Example 1.4 — A specific binomial term

Find the term independent of x in $\left(2x - \dfrac{1}{x}\right)^6$.

Step 1 — general term. With $a = 2x$, $b = -1/x$:

$$T_k = \binom{6}{k}(2x)^{6-k}\left(-\frac{1}{x}\right)^k = \binom{6}{k}2^{6-k}(-1)^k\,x^{6-2k}.$$

Step 2 — choose k. The power of x is zero when $6 - 2k = 0$, i.e. $k = 3$.

Step 3 — evaluate. $T_3 = \binom{6}{3}\,2^3(-1)^3 = 20 \cdot 8 \cdot (-1) = -160$.

Check: substituting $x = 1$ in the full expansion gives $(2-1)^6 = 1$; the seven coefficients $64, -192, 240, -160, 60, -12, 1$ do sum to 1. ✓

The binomial approximation

For small x the binomial expansion is dominated by its first two terms:

$$(1+x)^n \approx 1 + nx, \qquad |x| \ll 1.$$

Remarkably, this holds for **any real** n — negative and fractional included — as the Taylor series of Ch. 4 shows. The next term is $\frac{n(n-1)}{2}x^2$, which estimates the error. Special cases used constantly:

$$\frac{1}{1+x} \approx 1 - x, \qquad \sqrt{1+x} \approx 1 + \frac{x}{2}, \qquad \frac{1}{\sqrt{1+x}} \approx 1 - \frac{x}{2}.$$

Worked Example 1.5 — Loading of a voltage divider

A divider $R_1 = R_2 = 10\ \text{k}\Omega$ feeds a load $R_L = 100\ \text{k}\Omega$. Its output with the load attached can be written

$$V_{\text{out}} = V_{\text{in}}\frac{R_2}{R_1 + R_2}\cdot\frac{1}{1 + R_{\text{th}}/R_L}, \qquad R_{\text{th}} = \frac{R_1 R_2}{R_1 + R_2} = 5\ \text{k}\Omega.$$

Step 1. $x = R_{\text{th}}/R_L = 0.05$ is small, so $\dfrac{1}{1+x} \approx 1 - x = 0.95$.

Step 2. The loaded output is about 5% below the unloaded value $V_{\text{in}}/2$.

Check: the exact factor is $1/1.05 = 0.95238$; the approximation error 0.0024 matches the size of the neglected term $x^2 = 0.0025$. ✓ The approximation turns a messy expression into a rule of thumb: *loading error* $\approx R_{\text{th}}/R_L$.

Completing the square

Completing the square

For $a \neq 0$,

$$ax^2 + bx + c = a\left(x + \frac{b}{2a}\right)^2 + c - \frac{b^2}{4a}.$$

Derivation. Factor out a: $a\left(x^2 + \frac{b}{a}x\right) + c$. Since $\left(x + \frac{b}{2a}\right)^2 = x^2 + \frac{b}{a}x + \frac{b^2}{4a^2}$, adding and subtracting $\frac{b^2}{4a^2}$ inside the bracket gives the result. □

This single manipulation yields the quadratic formula (Section 1.3), locates the vertex $\left(-\frac{b}{2a},\ c - \frac{b^2}{4a}\right)$ of a parabola, converts the equation of a circle to centre–radius form (Section 1.7), and in Ch. 14 turns a second-order denominator $s^2 + 2\zeta\omega_n s + \omega_n^2$ into $(s + \zeta\omega_n)^2 + \omega_d^2$, the form that identifies a damped sinusoid.

Worked Example 1.6 — Completing the square

(a) $2x^2 - 8x + 3 = 2(x^2 - 4x) + 3 = 2\big[(x-2)^2 - 4\big] + 3 = 2(x-2)^2 - 5$. Minimum value -5 at $x = 2$.

(b) $s^2 + 6s + 13 = (s+3)^2 - 9 + 13 = (s+3)^2 + 2^2$. As a sum of squares it never vanishes for real s; its complex zeros are $s = -3 \pm j2$.

Check (a): expanding, $2(x^2 - 4x + 4) - 5 = 2x^2 - 8x + 3$. ✓ **Check (b):** $(-3 + j2)^2 + 6(-3 + j2) + 13 = (5 - j12) + (-18 + j12) + 13 = 0$. ✓

Algebraic fractions

The rules for fractions follow from the field axioms:

$$\frac{a}{b}+\frac{c}{d}=\frac{ad+bc}{bd}, \qquad \frac{a}{b}\cdot\frac{c}{d}=\frac{ac}{bd}, \qquad \frac{a/b}{c/d}=\frac{ad}{bc}, \qquad \frac{ac}{bc}=\frac{a}{b}\ (c\neq 0).$$

Three working principles:

1. **Combine over the lowest common denominator**, factoring denominators first so you do not create needlessly large products.
2. **Cancel only common factors**, never common terms. In $\dfrac{x(x+1)}{x(x+2)}$ the factor x cancels (for $x\neq 0$); in $\dfrac{x+1}{x+2}$ nothing cancels.
3. **Rationalise** surd denominators by multiplying by the conjugate, using $(\sqrt{a}-\sqrt{b})(\sqrt{a}+\sqrt{b})=a-b$:

$$\frac{1}{\sqrt{a}+\sqrt{b}}=\frac{\sqrt{a}-\sqrt{b}}{a-b}.$$

The same conjugate trick, applied to $a+jb$, is how complex division is done in Ch. 2.

Worked Example 1.7 — Simplifying fractions

(a) Compound fraction. Simplify $\dfrac{\frac{1}{x}-\frac{1}{y}}{\frac{1}{x^2}-\frac{1}{y^2}}$. Numerator $=\dfrac{y-x}{xy}$; denominator $=\dfrac{y^2-x^2}{x^2y^2}=\dfrac{(y-x)(y+x)}{x^2y^2}$. Dividing,

$$\frac{y-x}{xy}\cdot\frac{x^2y^2}{(y-x)(y+x)}=\frac{xy}{x+y} \qquad (x\neq y).$$

Check with $x=2, y=3$: original $=\dfrac{1/2-1/3}{1/4-1/9}=\dfrac{1/6}{5/36}=1.2$; result $=6/5=1.2$. ✓ (The result is the "parallel combination" of x and y.)

(b) Rationalising. $\dfrac{1}{\sqrt{5}-\sqrt{3}}=\dfrac{\sqrt{5}+\sqrt{3}}{5-3}=\dfrac{\sqrt{5}+\sqrt{3}}{2}\approx 1.98406$. **Check:** $1/(2.23607-1.73205)=1/0.50402=1.98406$. ✓

Worked Example 1.8 — Parallel resistors

Two resistors in parallel satisfy $\dfrac{1}{R}=\dfrac{1}{R_1}+\dfrac{1}{R_2}$. (a) Express R explicitly. (b) What R_2 must be paralleled with $R_1=10\ \text{k}\Omega$ to give $R=4\ \text{k}\Omega$?

(a) Common denominator: $\dfrac{1}{R}=\dfrac{R_2+R_1}{R_1R_2}$, so the familiar "product over sum"

$$R=\frac{R_1R_2}{R_1+R_2}.$$

(b) Solve $\dfrac{1}{R_2}=\dfrac{1}{R}-\dfrac{1}{R_1}=\dfrac{R_1-R}{RR_1}$, giving

$$R_2=\frac{RR_1}{R_1-R}=\frac{4\times 10}{10-4}\ \text{k}\Omega=6.667\ \text{k}\Omega.$$

Check: $\dfrac{10\times 6.667}{16.667}=4.000\ \text{k}\Omega$. ✓ Note that the formula requires $R<R_1$ — a parallel combination is always smaller than either branch.

Changing the subject of a formula

To make a variable the **subject**, apply the same operation to both sides repeatedly, undoing the operations that act on the variable in reverse order. Keep track of conditions (division by zero, square roots of negatives, sign of quantities) as you go.

Worked Example 1.9 — Two rearrangements

(a) Resonance. An LC tank resonates at $f_0=\dfrac{1}{2\pi\sqrt{LC}}$. Find C for $f_0=1$ MHz with $L=10\ \mu$H. Square both sides: $f_0^2=\dfrac{1}{4\pi^2LC}$, then solve: $C=\dfrac{1}{4\pi^2 f_0^2 L}$. Numerically

$$C=\frac{1}{4\pi^2\,(10^6)^2\,(10\times 10^{-6})}=2.533\times 10^{-9}\ \text{F}=2.533\ \text{nF}.$$

(b) Feedback. A negative-feedback amplifier has closed-loop gain $A_f=\dfrac{A}{1+A\beta}$. Find β for $A=10^5$ and $A_f=10$. Multiply out: $A_f+A_fA\beta=A$, so $\beta=\dfrac{A-A_f}{AA_f}=\dfrac{1}{A_f}-\dfrac{1}{A}=0.1-0.00001=0.09999$.

Checks: (a) $1/(2\pi\sqrt{10^{-5}\times 2.533\times 10^{-9}})=1.000\times 10^6$ Hz ✓; (b) $10^5/(1+10^5\times 0.09999)=10^5/10000=10$ ✓. The form $\beta=1/A_f-1/A$ also shows why $\beta\approx 1/A_f$ when A is huge.

Common Pitfall — illegal "simplifications"

$\dfrac{a+b}{a+c}\neq\dfrac{b}{c}$, $\sqrt{a^2+b^2}\neq a+b$, $(a+b)^{-1}\neq a^{-1}+b^{-1}$, $(a+b)^2\neq a^2+b^2$. Each of these cancels or distributes an operation across a **sum**, which is never allowed. A two-second numerical spot check (put $a=1, b=2, c=3$) exposes all of them.

Engineering Note — keep it symbolic

Rearrange symbolically first and substitute numbers last. The symbolic answer can be dimension-checked (Section 1.10), tested at limiting cases ($R_2 \to \infty$ in a parallel combination should give $R \to R_1$), and reused for other component values. Plugging numbers in early hides all of these checks.

1.3 Equations and inequalities

Equivalent equations

Solving an equation means finding every value of the unknown that makes it true — the **solution set**. The method is to replace the equation by a chain of simpler **equivalent** equations (equations with the same solution set). The safe operations are:

- adding the same quantity to both sides;
- multiplying or dividing both sides by the same **non-zero** quantity;
- applying a **one-to-one** function to both sides (e.g. ln to positive quantities, exp, cubing).

Two operations are *not* equivalence-preserving and must be handled with care:

- **Squaring** both sides (or applying any function that is not one-to-one) can introduce **extraneous roots**: $x = 2$ has one solution, but $x^2 = 4$ has two.
- **Dividing by an expression that may be zero** can **lose roots**: dividing $x^2 = 3x$ by x gives $x = 3$ and loses $x = 0$. Factor instead: $x(x - 3) = 0$.

Whenever a non-equivalent step is used, every candidate must be checked in the *original* equation.

Linear equations

A linear equation $ax + b = 0$ with $a \neq 0$ has the single root $x = -b/a$. If $a = 0$ there is no solution ($b \neq 0$) or every x is a solution ($b = 0$). This trivial trichotomy — one, none, or infinitely many — reappears unchanged for systems of linear equations in Ch. 8.

Quadratic equations

Quadratic formula

The roots of $ax^2 + bx + c = 0$, $a \neq 0$, are

$$x = \frac{-b \pm \sqrt{\Delta}}{2a}, \qquad \Delta = b^2 - 4ac.$$

- $\Delta > 0$: two distinct real roots;
- $\Delta = 0$: one repeated real root $x = -b/(2a)$;
- $\Delta < 0$: a complex-conjugate pair $x = \dfrac{-b}{2a} \pm j\dfrac{\sqrt{-\Delta}}{2a}$.

Derivation. By completing the square (Section 1.2), $ax^2 + bx + c = 0$ becomes $a\left(x + \frac{b}{2a}\right)^2 = \frac{b^2 - 4ac}{4a}$, i.e. $\left(x + \frac{b}{2a}\right)^2 = \frac{\Delta}{4a^2}$. Taking square roots, $x + \frac{b}{2a} = \pm\frac{\sqrt{\Delta}}{2a}$. □

Vieta's relations for a quadratic

If x_1, x_2 are the roots of $ax^2 + bx + c = 0$, then

$$x_1 + x_2 = -\frac{b}{a}, \qquad x_1 x_2 = \frac{c}{a}.$$

These follow from comparing coefficients in $a(x - x_1)(x - x_2) = ax^2 - a(x_1 + x_2)x + ax_1x_2$. They are the cheapest check on any computed pair of roots.

The sign of the discriminant decides whether a second-order circuit is over-, critically or under-damped (Ch. 12) — the same three cases, because the characteristic equation $LCs^2 + RCs + 1 = 0$ of a series RLC circuit is a quadratic.

Worked Example 1.10 — RLC characteristic roots

A series RLC circuit with $R = 200\ \Omega$, $L = 0.1$ H, $C = 2\ \mu$F has characteristic equation $s^2 + \frac{R}{L}s + \frac{1}{LC} = 0$, i.e. $s^2 + 2000s + 5 \times 10^6 = 0$. Solve it.

Step 1. $\Delta = 2000^2 - 4 \cdot 5 \times 10^6 = 4 \times 10^6 - 2 \times 10^7 = -1.6 \times 10^7 < 0$: complex roots, an under-damped response.

Step 2. $\sqrt{-\Delta} = 4000$, so

$$s = \frac{-2000 \pm j4000}{2} = -1000 \pm j2000\ \text{s}^{-1}.$$

Check (Vieta): sum $= -2000 = -b/a$ ✓; product $= 1000^2 + 2000^2 = 5 \times 10^6 = c/a$ ✓. The real part -1000 is the decay rate and the imaginary part 2000 rad/s the ringing frequency.

Numerically stable roots

The textbook formula is exact in exact arithmetic but can be disastrous in floating point. When $b^2 \gg |4ac|$, $\sqrt{\Delta} \approx |b|$, and one of $-b \pm \sqrt{\Delta}$ subtracts two nearly equal numbers — catastrophic cancellation (Section 1.1).

Stable quadratic formula

For real coefficients with $\Delta \geq 0$, compute

$$q = -\tfrac{1}{2}\left(b + \operatorname{sgn}(b)\sqrt{\Delta}\right), \qquad x_1 = \frac{q}{a}, \qquad x_2 = \frac{c}{q}.$$

The sum inside q never cancels, and x_2 follows from Vieta's product $x_1 x_2 = c/a$.

Worked Example 1.11 — Cancellation in the quadratic formula

Solve $x^2 - 10^8 x + 1 = 0$ in double precision.

Naive formula. $\sqrt{\Delta} = \sqrt{10^{16} - 4}$ rounds to exactly 10^8 in double precision. The small root $\left(10^8 - \sqrt{\Delta}\right)/2$ is computed as 7.45×10^{-9} — wrong by 25% (the true value is 1.0000×10^{-8}).

Stable formula. $q = -\tfrac{1}{2}\left(-10^8 - 10^8\right) = 10^8$, so $x_1 = 10^8$ and $x_2 = 1/10^8 = 10^{-8}$, correct to full precision.

Check: product $x_1 x_2 = 1 = c/a$ ✓; sum $\approx 10^8 = -b/a$ ✓.

Equations reducible to quadratics; radical equations

Many equations become quadratic after a substitution: $x^4 - 5x^2 + 4 = 0$ with $u = x^2$ gives $u^2 - 5u + 4 = 0$, so $u = 1$ or $u = 4$ and $x \in \{-2, -1, 1, 2\}$. Equations in e^x (Section 1.5) and $\sin x$ (Section 1.6) yield to the same trick.

Equations containing square roots are solved by isolating the root and squaring — a non-equivalent step, so every candidate must be checked.

Worked Example 1.12 — An extraneous root

Solve $\sqrt{x + 5} = x - 1$.

Step 1 — square. $x + 5 = x^2 - 2x + 1$, i.e. $x^2 - 3x - 4 = 0$, so $(x - 4)(x + 1) = 0$ and the candidates are $x = 4$ and $x = -1$.

Step 2 — check in the original. $x = 4$: $\sqrt{9} = 3 = 4 - 1$ ✓. $x = -1$: $\sqrt{4} = 2$ but $-1 - 1 = -2$ ✗.

Solution: $x = 4$ only. The root $x = -1$ solves $\sqrt{x + 5} = -(x - 1)$, which squares to the same quadratic. Note the original equation also requires $x - 1 \geq 0$, which rules out $x = -1$ in advance.

Simultaneous equations

Two linear equations in two unknowns are solved by **substitution** (solve one for a variable, substitute in the other) or **elimination** (add multiples of the equations to remove a variable). Eliminating in general gives **Cramer's rule** for the 2×2 case:

$$\begin{aligned} a_1 x + b_1 y &= c_1 \\ a_2 x + b_2 y &= c_2 \end{aligned} \quad \Longrightarrow \quad x = \frac{c_1 b_2 - c_2 b_1}{a_1 b_2 - a_2 b_1}, \quad y = \frac{a_1 c_2 - a_2 c_1}{a_1 b_2 - a_2 b_1},$$

provided the **determinant** $D = a_1 b_2 - a_2 b_1 \neq 0$. Geometrically each equation is a line; $D \neq 0$ means the lines cross at one point, while $D = 0$ means they are parallel (no solution) or coincident (infinitely many). Larger systems, and the matrix language that organises them, are the subject of Ch. 8.

Worked Example 1.13 — Two-mesh circuit

Mesh analysis of a two-loop resistive circuit ($R_1 = 2\ \Omega$, $R_2 = 4\ \Omega$ shared, $R_3 = 6\ \Omega$, source 10 V in loop 1) gives

$$\begin{aligned} 6I_1 - 4I_2 &= 10 \\ -4I_1 + 10I_2 &= 0 \end{aligned}$$

Step 1 — determinant. $D = 6 \cdot 10 - (-4)(-4) = 60 - 16 = 44$.

Step 2 — Cramer. $I_1 = \dfrac{10 \cdot 10 - 0 \cdot (-4)}{44} = \dfrac{100}{44} = 2.273\ \text{A}$, $\quad I_2 = \dfrac{6 \cdot 0 - (-4) \cdot 10}{44} = \dfrac{40}{44} = 0.909\ \text{A}$.

Check: $6(2.273) - 4(0.909) = 13.636 - 3.636 = 10.000$ ✓ and $-4(2.273) + 10(0.909) = 0.000$ ✓.

Nonlinear simultaneous equations are usually reduced by substitution to a single equation in one unknown.

Worked Example 1.14 — Line meets circle

Find the intersections of $y = x + 1$ and $x^2 + y^2 = 25$.

Substitute: $x^2 + (x + 1)^2 = 25 \Rightarrow 2x^2 + 2x - 24 = 0 \Rightarrow x^2 + x - 12 = 0 \Rightarrow (x + 4)(x - 3) = 0$. So $x = 3,\ y = 4$ or $x = -4,\ y = -3$: the points $(3, 4)$ and $(-4, -3)$.

Check: $9 + 16 = 25$ ✓, $16 + 9 = 25$ ✓. A negative discriminant here would have meant the line misses the circle.

Inequalities

Inequalities obey the same rules as equations **except**:

1. multiplying or dividing by a **negative** number reverses the inequality ($-2 < 3$ but $4 > -6$);
2. taking reciprocals of two quantities of the same sign reverses it ($0 < a < b \Rightarrow 1/a > 1/b$);
3. squaring preserves an inequality only between **non-negative** quantities ($0 \le a < b \Rightarrow a^2 < b^2$, but $-3 < 2$ while $9 > 4$).

Each rule is a consequence of the order axioms in Section 1.1. For instance, if $a < b$ and $c < 0$, then $-c > 0$ so $-ac < -bc$, i.e. $ac > bc$.

Inequality	Solution set
$\lvert x - a\rvert < \delta$	$a - \delta < x < a + \delta$
$\lvert x - a\rvert > \delta$	$x < a - \delta$ or $x > a + \delta$
$(x - r_1)(x - r_2) < 0,\ r_1 < r_2$	$r_1 < x < r_2$ (between the roots)
$(x - r_1)(x - r_2) > 0,\ r_1 < r_2$	$x < r_1$ or $x > r_2$ (outside the roots)

For polynomial or rational inequalities use a **sign chart**: bring everything to one side as a single fraction compared with 0, find all zeros of numerator and denominator, split the real line at them, and determine the sign on each piece (each linear factor changes sign at its own zero; factors with even multiplicity do not).

Worked Example 1.15 — Three inequalities

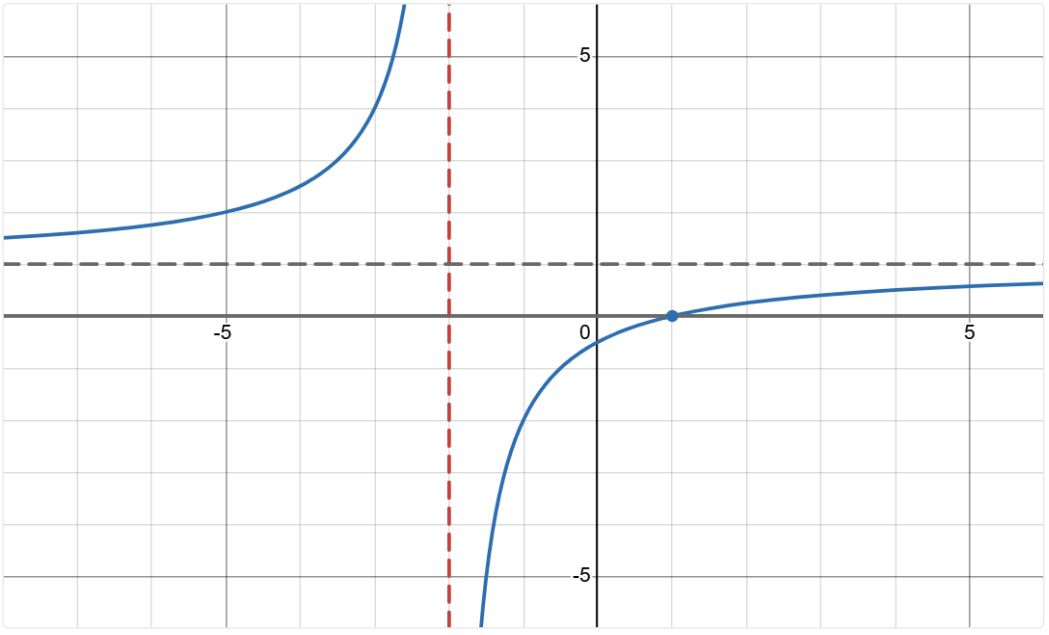
(a) $\lvert x - 2\rvert < 3 \iff -3 < x - 2 < 3 \iff -1 < x < 5$, i.e. $x \in (-1, 5)$.

(b) $x^2 - 5x + 6 \le 0 \iff (x - 2)(x - 3) \le 0 \iff x \in [2, 3]$.

(c) $\dfrac{x - 1}{x + 2} \ge 0$. Critical points $x = 1$ (zero of numerator, included) and $x = -2$ (zero of denominator, always excluded).

Interval	$x - 1$	$x + 2$	quotient
$x < -2$	$-$	$-$	$+$
$-2 < x < 1$	$-$	$+$	$-$
$x > 1$	$+$	$+$	$+$

Solution: $x \in (-\infty, -2) \cup [1, \infty)$. We may **not** multiply through by $x + 2$ without knowing its sign — doing so blindly gives $x \ge 1$ and loses the whole interval $x < -2$.



$y = (x - 1)/(x + 2)$: the curve is on or above the axis for $x < -2$ and $x \ge 1$, matching the sign chart. The red dashed line is the vertical asymptote where the denominator vanishes.

Worked Example 1.16 — Two absolute values

Solve $\lvert x - 1\rvert + \lvert x + 2\rvert \le 5$.

The expressions inside change sign at $x = 1$ and $x = -2$, so treat three cases.

- $x \ge 1$: $(x - 1) + (x + 2) = 2x + 1 \le 5 \Rightarrow x \le 2$. Combined: $1 \le x \le 2$.
- $-2 \le x < 1$: $-(x - 1) + (x + 2) = 3 \le 5$, always true. Combined: $-2 \le x < 1$.
- $x < -2$: $-(x - 1) - (x + 2) = -2x - 1 \le 5 \Rightarrow x \ge -3$. Combined: $-3 \le x < -2$.

Solution: $x \in [-3, 2]$. **Check:** at $x = 2$, $1 + 4 = 5$ ✓; at $x = -3$, $4 + 1 = 5$ ✓; at $x = 0$, $1 + 2 = 3 \le 5$ ✓. Geometrically, the sum of distances from x to 1 and to -2 is at most 5.

The AM–GM inequality and a design bound

Arithmetic–geometric mean inequality

For $a, b \geq 0$,

$$\frac{a+b}{2} \geq \sqrt{ab},$$

with equality if and only if $a = b$.

Proof. $(\sqrt{a} - \sqrt{b})^2 \geq 0$ expands to $a - 2\sqrt{ab} + b \geq 0$. Equality holds only when $\sqrt{a} = \sqrt{b}$. □

Inequalities like this one prove that a design is optimal *without calculus*.

Worked Example 1.17 — Maximum power transfer

A source of EMF V and internal resistance R_s drives a load R_L, delivering $P = \dfrac{V^2 R_L}{(R_s + R_L)^2}$. Show $P \leq \dfrac{V^2}{4R_s}$ and find when equality holds.

Step 1. By AM–GM with $a = R_s$, $b = R_L$: $R_s + R_L \geq 2\sqrt{R_s R_L}$, so $(R_s + R_L)^2 \geq 4R_s R_L$.

Step 2. Therefore $P = \dfrac{V^2 R_L}{(R_s + R_L)^2} \leq \dfrac{V^2 R_L}{4R_s R_L} = \dfrac{V^2}{4R_s}$, with equality iff $R_L = R_s$.

Numerical check: $V = 10$ V, $R_s = 50\ \Omega$: the bound is $100/200 = 0.5$ W, attained at $R_L = 50\ \Omega$ ($100 \cdot 50/100^2 = 0.5$ ✓). At $R_L = 100\ \Omega$: $100 \cdot 100/150^2 = 0.444$ W < 0.5 ✓.

Inequalities as specifications

Worked Example 1.18 — Choosing a component range

An RC timer needs $\tau = RC \in [0.85,\ 1.15]$ ms for **every** capacitor in a batch of nominal 100 nF $\pm$ 10%. Which resistances guarantee this?

Step 1. $C \in [90, 110]$ nF and $R > 0$, so τ ranges over $[90R,\ 110R]$ (nF times R).

Step 2. Both ends must satisfy the spec: $90 \times 10^{-9} R \geq 0.85 \times 10^{-3}$ and $110 \times 10^{-9} R \leq 1.15 \times 10^{-3}$.

Step 3. $R \geq 9.444$ kΩ and $R \leq 10.455$ kΩ. So $R \in [9.44,\ 10.45]$ kΩ, and a 10.0 kΩ $\pm$ 1% resistor (range 9.9–10.1 kΩ) qualifies.

Check: worst cases $9.9\ \text{k}\Omega \times 90\ \text{nF} = 0.891$ ms ≥ 0.85 ✓ and $10.1\ \text{k}\Omega \times 110\ \text{nF} = 1.111$ ms ≤ 1.15 ✓.

Engineering Note

Design specifications are inequalities: "gain within ±0.5 dB", "ripple below 50 mV", "phase margin at least 45°". Solving them gives the admissible range of component values, and the worst-case analysis above (check every combination of extremes) is the systematic way to guarantee them. When there are many parameters, the same problem becomes constrained optimisation (Ch. 23).

Common Pitfall

Never multiply both sides of an inequality by an expression whose sign you do not know, and never square both sides unless both are known to be non-negative. When in doubt, move everything to one side and use a sign chart.

1.4 Polynomials and rational expressions

Why polynomials and rational functions

Polynomials are the simplest functions that can be computed with nothing but addition and multiplication, which is why they are used to approximate everything else (Taylor series, Ch. 4; curve fitting, Ch. 22). Ratios of polynomials — **rational functions** — are even more central to electrical engineering: the impedance of any network of resistors, capacitors and inductors, and the transfer function of any linear time-invariant circuit, is a rational function of the complex frequency s. Its **zeros** and **poles** (roots of numerator and denominator) determine the circuit's frequency response and stability. Factoring polynomials and decomposing rational functions are therefore everyday skills.

Definitions and arithmetic

Polynomial

A **polynomial** of **degree** n in x is

$$p(x) = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_1 x + a_0, \qquad a_n \neq 0.$$

The a_k are the **coefficients**, a_n the **leading coefficient** (the polynomial is **monic** if $a_n = 1$), and a_0 the **constant term**. A **root** or **zero** is a number r with $p(r) = 0$.

Sums and products of polynomials are polynomials, with $\deg(pq) = \deg p + \deg q$. Division is like integer division: it leaves a quotient and a remainder.

Division algorithm

For polynomials p and d with $d \neq 0$ there are unique polynomials q (quotient) and r (remainder) with

$$p(x) = d(x)\,q(x) + r(x), \qquad \deg r < \deg d \ \ (\text{or } r = 0).$$

The quotient and remainder are found by **long division**: repeatedly divide the leading term of what remains by the leading term of d, multiply back, and subtract. When $d(x) = x - r$ the bookkeeping shrinks to **synthetic division**, which keeps only the coefficients.

Worked Example 1.19 — Long and synthetic division

(a) Divide $p(x) = x^3 + 2$ by $d(x) = x^2 - 1$. Leading terms: $x^3/x^2 = x$. Subtract $x(x^2 - 1) = x^3 - x$ from $x^3 + 0x^2 + 0x + 2$ to leave $x + 2$, whose degree is below 2. So

$$x^3 + 2 = (x^2 - 1)\,x + (x + 2), \qquad q(x) = x, \quad r(x) = x + 2.$$

(b) Divide $2x^3 - 3x^2 - 11x + 6$ by $x - 3$ synthetically. Write the coefficients, bring down the leading one, and repeatedly multiply by 3 and add:

	2	−3	−11	6
×3		6	9	−6
sum	2	3	−2	**0**

Quotient $2x^2 + 3x - 2$, remainder 0.

Check: $(x - 3)(2x^2 + 3x - 2) = 2x^3 + 3x^2 - 2x - 6x^2 - 9x + 6 = 2x^3 - 3x^2 - 11x + 6$ ✓.

Remainder and factor theorems

Remainder and factor theorems

- **Remainder theorem:** dividing $p(x)$ by $(x - r)$ leaves the constant remainder $p(r)$.
- **Factor theorem:** $(x - r)$ is a factor of $p(x)$ if and only if $p(r) = 0$.

Proof. By the division algorithm $p(x) = (x - r)q(x) + c$ with c constant (degree below 1). Setting $x = r$ gives $p(r) = c$. The factor theorem is the case $c = 0$. □

So the remainder of $x^5 - 3x + 2$ on division by $x + 1$ is $p(-1) = -1 + 3 + 2 = 4$, found without dividing.

The fundamental theorem of algebra

Fundamental theorem of algebra

Every polynomial of degree $n \geq 1$ with complex (in particular, real) coefficients has exactly n complex roots counted with multiplicity, and factors completely as

$$p(x) = a_n(x - r_1)(x - r_2)\cdots(x - r_n).$$

If all coefficients are **real**, non-real roots occur in **conjugate pairs** $\alpha \pm j\beta$.

The existence of at least one root is the deep part (it needs completeness of $\mathbb{R}$ and is proved with complex analysis in Ch. 18); the full factorisation then follows by applying the factor theorem repeatedly. The conjugate-pair property has a one-line proof: conjugating $\sum a_k r^k = 0$ with real a_k gives $\sum a_k (r^*)^k = 0$, so r^* is a root too.

Consequently every **real** polynomial factors into real linear factors and real **irreducible quadratics** $x^2 + bx + c$ with $b^2 < 4c$, since $(x - \alpha - j\beta)(x - \alpha + j\beta) = (x - \alpha)^2 + \beta^2$. A real polynomial of odd degree therefore always has at least one real root.

A root r has **multiplicity** m if $(x - r)^m$ divides p but $(x - r)^{m+1}$ does not. On a graph, the curve crosses the axis at a root of odd multiplicity and touches it (turning back) at a root of even multiplicity; higher multiplicity makes the curve flatter at the root.

Vieta's relations

For $p(x) = a_n x^n + \cdots + a_0$ with roots $r_1, \dots, r_n$:

$$\sum_{i} r_i = -\frac{a_{n-1}}{a_n}, \qquad \sum_{i<k} r_i r_k = \frac{a_{n-2}}{a_n}, \qquad \prod_{i} r_i = (-1)^n \frac{a_0}{a_n}.$$

These follow from expanding $a_n \prod (x - r_i)$ and comparing coefficients. In a control system, the sum of the closed-loop poles is fixed by one coefficient, which is why moving one pole to the left forces another to the right.

Finding roots: the rational-root test

Rational-root test

If p has integer coefficients and a rational root u/v in lowest terms, then u divides a_0 and v divides a_n.

Proof. Multiply $p(u/v)=0$ by v^n: $a_n u^n + a_{n-1}u^{n-1}v + \cdots + a_0 v^n = 0$. Every term except $a_0 v^n$ contains u, so u divides $a_0 v^n$; as u, v share no factor, u divides a_0. Similarly v divides $a_n u^n$, hence a_n. □

Worked Example 1.20 — Factoring a cubic

Factor $p(x) = 2x^3 - 3x^2 - 11x + 6$ completely.

Step 1 — candidates. $u \mid 6$ and $v \mid 2$: $\pm1, \pm2, \pm3, \pm6, \pm\tfrac{1}{2}, \pm\tfrac{3}{2}$.

Step 2 — test. $p(1) = -6$, $p(-1) = 12$, $p(3) = 54 - 27 - 33 + 6 = 0$. ✓

Step 3 — deflate. By the synthetic division of Example 1.19(b), $p(x) = (x-3)(2x^2 + 3x - 2)$, and $2x^2 + 3x - 2 = (2x-1)(x+2)$.

Result: $p(x) = (x-3)(2x-1)(x+2)$, roots $3,\ \tfrac{1}{2},\ -2$.

Check (Vieta): sum $3 + \tfrac{1}{2} - 2 = \tfrac{3}{2} = -(-3)/2$ ✓; product $3 \cdot \tfrac{1}{2} \cdot (-2) = -3 = (-1)^3 \cdot 6/2$ ✓.

Worked Example 1.21 — Characteristic polynomial with complex roots

A third-order system has characteristic polynomial $D(s) = s^3 + 4s^2 + 6s + 4$. Find its roots.

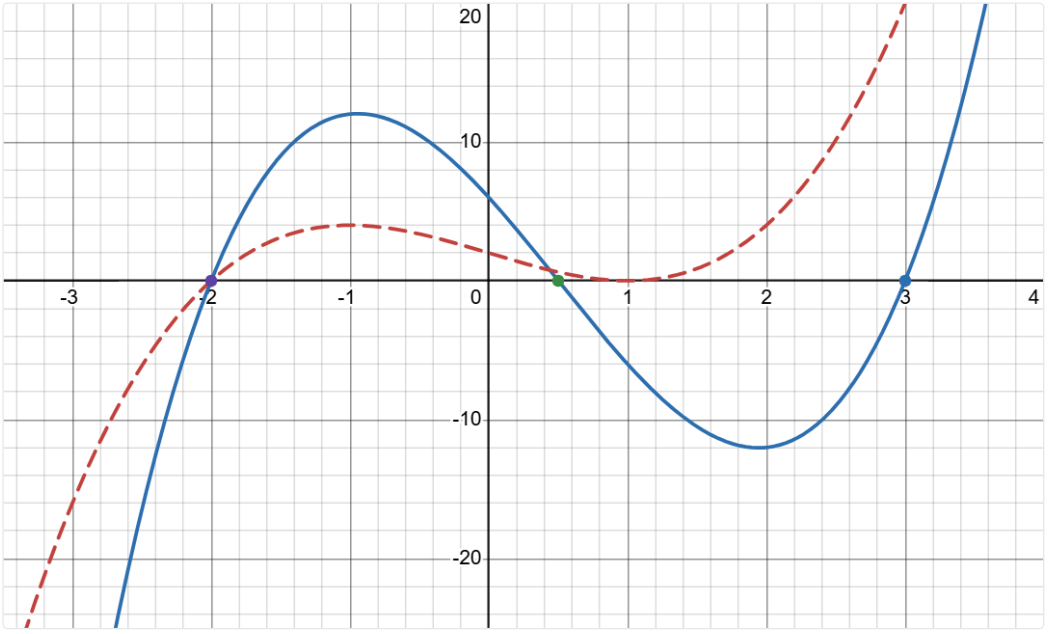
Step 1. Rational candidates $\pm1, \pm2, \pm4$. All coefficients are positive, so no positive real root is possible; try negatives: $D(-1) = -1 + 4 - 6 + 4 = 1$, $D(-2) = -8 + 16 - 12 + 4 = 0$. ✓

Step 2. Deflate: $D(s) = (s+2)(s^2 + 2s + 2)$.

Step 3. Complete the square: $s^2 + 2s + 2 = (s+1)^2 + 1$, so $s = -1 \pm j$.

Roots: $-2,\ -1 + j,\ -1 - j$ — all with negative real part, so the system is stable (Ch. 14). **Check:** sum $= -4 = -a_2/a_3$ ✓; product $(-2)\big((-1)^2 + 1^2\big) = -4 = (-1)^3 \cdot 4$ ✓.

For degree 5 and above there is no general formula in radicals (Abel–Ruffini theorem), and even the cubic and quartic formulas are rarely worth using. In practice, high-degree roots are found numerically — Newton's method or the eigenvalues of a companion matrix (Ch. 22).



The cubic of Example 1.20 (blue) crosses the axis at its three simple roots. The red dashed cubic $(x-1)^2(x+2)$ touches the axis at its double root $x = 1$ without crossing.

Rational functions

Rational function

A **rational function** is $R(x) = \dfrac{N(x)}{D(x)}$ with polynomials N, D and $D \not\equiv 0$. It is **proper** if $\deg N < \deg D$ and **improper** otherwise. After cancelling common factors, zeros of N are the **zeros** of R and zeros of D are its **poles**.

An improper rational function is reduced by long division to a polynomial plus a proper part: $R(x) = q(x) + \dfrac{r(x)}{D(x)}$. This also identifies the **asymptotes** of its graph:

- **vertical asymptotes** at the real poles, where $|R(x)| \to \infty$;
- a **horizontal asymptote** $y = a_n/b_n$ if $\deg N = \deg D$, or $y = 0$ if $\deg N < \deg D$;
- an **oblique** (slant) asymptote $y = q(x)$ if $\deg N = \deg D + 1$.

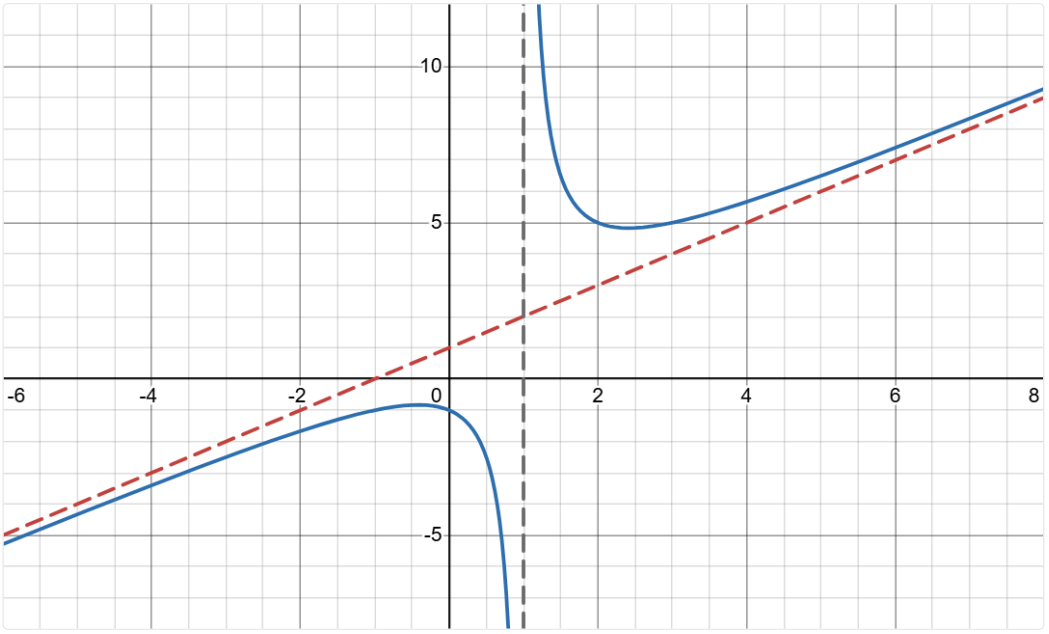
Worked Example 1.22 — Asymptotes

$R(x) = \dfrac{x^2+1}{x-1}$. Division gives $x^2 + 1 = (x-1)(x+1) + 2$, so

$$R(x) = x + 1 + \frac{2}{x-1}.$$

Vertical asymptote $x = 1$ (pole); oblique asymptote $y = x + 1$, approached from above as $x \to +\infty$ (since $\frac{2}{x-1} > 0$) and from below as $x \to -\infty$. No real zeros, as $x^2 + 1 > 0$.

Check: at $x = 3$, $R = 10/2 = 5$ and $3 + 1 + 2/2 = 5$ ✓.



$R(x) = (x^2+1)/(x-1)$ (blue) hugs its oblique asymptote $y = x + 1$ (red) far from the pole at $x = 1$.

Common Pitfall — cancelled factors

$\dfrac{x^2-1}{x-1} = x + 1$ only for $x \neq 1$. The left side is undefined at $x = 1$ (a "hole", not a pole). In a transfer function, cancelling a pole against a zero is mathematically legal but can hide an internal mode that still exists in the hardware — an unstable cancelled pole is still unstable.

Partial-fraction decomposition

Adding fractions over a common denominator is easy; partial fractions run the process **backwards**, splitting a complicated proper rational function into a sum of simple terms, each of which can be integrated, inverse-transformed or interpreted on its own.

Partial-fraction decomposition

Every proper real rational function $N(x)/D(x)$ can be written uniquely as a sum of terms, one group for each factor of D:

Factor in $D(x)$	Terms in the decomposition
$(x-a)$	$\dfrac{A}{x-a}$
$(x-a)^m$	$\dfrac{A_1}{x-a} + \dfrac{A_2}{(x-a)^2} + \cdots + \dfrac{A_m}{(x-a)^m}$
x^2+bx+c (irreducible)	$\dfrac{Bx+C}{x^2+bx+c}$
$(x^2+bx+c)^m$	$\displaystyle\sum_{k=1}^{m} \frac{B_k x + C_k}{(x^2+bx+c)^k}$

The number of unknown constants always equals $\deg D$, which is why the decomposition is unique: multiplying out gives $\deg D$ linear equations in $\deg D$ unknowns. There are three ways to find them, often combined:

1. **Cover-up rule** (distinct linear factor). Multiply both sides by $(x-a)$ and set $x=a$; every other term vanishes:

$$A = \Big[(x-a)R(x)\Big]_{x=a} = \left.\frac{N(x)}{D(x)/(x-a)}\right|_{x=a}.$$

2. **Substituting convenient values** of x into the cleared-of-fractions identity.
3. **Equating coefficients** of like powers of x.

For a repeated factor $(x-a)^m$, the cover-up rule gives the top coefficient $A_m = \big[(x-a)^m R(x)\big]_{x=a}$, and the others follow by differentiation:

$$A_{m-k} = \frac{1}{k!}\frac{d^k}{dx^k}\Big[(x-a)^m R(x)\Big]_{x=a}, \qquad k = 1, \dots, m-1.$$

(Differentiation is introduced in Ch. 4; until then, method 3 always works.)

Worked Example 1.23 — Distinct and repeated linear factors

(a) $\dfrac{s+3}{(s+1)(s+2)} = \dfrac{A}{s+1} + \dfrac{B}{s+2}$. Cover-up: $A = \dfrac{-1+3}{-1+2} = 2$, $B = \dfrac{-2+3}{-2+1} = -1$. **Check:** $2(s+2) - (s+1) = s+3$ ✓.

(b) $\dfrac{1}{s(s+1)^2} = \dfrac{A}{s} + \dfrac{B}{s+1} + \dfrac{C}{(s+1)^2}$. Clear fractions: $1 = A(s+1)^2 + Bs(s+1) + Cs$. $s=0$: $A=1$. $s=-1$: $C=-1$. Coefficient of s^2: $0 = A + B \Rightarrow B = -1$. (By the derivative formula: $B = \frac{d}{ds}\big[1/s\big]_{s=-1} = -1/s^2\big|_{-1} = -1$ ✓.) **Check** at $s=1$: LHS $= \frac{1}{4}$; RHS $= 1 - \frac{1}{2} - \frac{1}{4} = \frac{1}{4}$ ✓.

Worked Example 1.24 — An irreducible quadratic factor

Decompose $\dfrac{s+2}{(s+1)(s^2+2s+5)}$.

Step 1. $s^2+2s+5 = (s+1)^2 + 4$ has $\Delta = 4 - 20 < 0$, so it is irreducible. Write

$$\frac{s+2}{(s+1)(s^2+2s+5)} = \frac{A}{s+1} + \frac{Bs+C}{s^2+2s+5}.$$

Step 2 — cover-up for A. $A = \dfrac{-1+2}{1-2+5} = \dfrac{1}{4}$.

Step 3 — equate coefficients in $s+2 = \frac{1}{4}(s^2+2s+5) + (Bs+C)(s+1)$: s^2: $0 = \frac{1}{4} + B \Rightarrow B = -\frac{1}{4}$. Constant: $2 = \frac{5}{4} + C \Rightarrow C = \frac{3}{4}$.

Step 4 — check the unused coefficient (s^1): $\frac{2}{4} + B + C = \frac{1}{2} - \frac{1}{4} + \frac{3}{4} = 1$ ✓.

Result, with the quadratic term arranged for later use in Laplace inversion:

$$\frac{1/4}{s+1} + \frac{-\frac{1}{4}s + \frac{3}{4}}{(s+1)^2+4} = \frac{1/4}{s+1} - \frac{1}{4}\cdot\frac{s+1}{(s+1)^2+2^2} + \frac{1}{2}\cdot\frac{2}{(s+1)^2+2^2}.$$

Worked Example 1.25 — An improper fraction

Decompose $\dfrac{x^3+2}{x^2-1}$.

Step 1 — divide first (Example 1.19a): $\dfrac{x^3+2}{x^2-1} = x + \dfrac{x+2}{(x-1)(x+1)}$.

Step 2 — cover-up on the proper part: at $x=1$, $\dfrac{1+2}{1+1} = \dfrac{3}{2}$; at $x=-1$, $\dfrac{-1+2}{-1-1} = -\dfrac{1}{2}$.

Result: $\dfrac{x^3+2}{x^2-1} = x + \dfrac{3/2}{x-1} - \dfrac{1/2}{x+1}$.

Check at $x=2$: LHS $= 10/3 = 3.333$; RHS $= 2 + 1.5 - \frac{1}{6} = 3.333$ ✓.

Partial fractions are the workhorse of Laplace and Z-transform inversion (Ch. 14, Ch. 17) and of integrating rational functions (Ch. 5); in transfer functions the variable is conventionally s, and the coefficients A are called **residues**.

Engineering Note — partial fractions as parallel decomposition

Each term $\frac{A}{s-p}$ corresponds to a first-order mode Ae^{pt} in the time response. A partial-fraction expansion therefore splits a high-order system into a **parallel bank of simple subsystems**, one per pole. Software such as MATLAB's `residue` or SciPy's `scipy.signal.residue` performs the decomposition numerically; the hand method remains essential for checking it and for symbolic work.

Common Pitfall

Partial fractions apply only to **proper** fractions: $\dfrac{x^2}{x^2-1}$ must first become $1 + \dfrac{1}{x^2-1}$. Also, an irreducible quadratic needs a **linear** numerator $Bx + C$, not a constant — using only C leaves too few unknowns and the equations become inconsistent.

1.5 Exponential and logarithmic functions

Why exponentials and logarithms

Whenever the rate of change of a quantity is proportional to the quantity itself, the result is exponential: a capacitor discharging through a resistor, current building up in an inductor, a radioactive source decaying, a population of charge carriers being swept out of a junction. The diode current grows exponentially with voltage, and the open-loop growth of an oscillator is exponential until it saturates. Logarithms, the inverse operation, turn multiplication into addition, which is why engineers measure gains in decibels, plot frequency responses on logarithmic axes, and quote signal-to-noise ratios as logarithms. These two functions are as fundamental to engineering as the four arithmetic operations.

Exponential functions

Exponential function

For a fixed base $a > 0$, $a \neq 1$, the **exponential function** $f(x) = a^x$ is defined for all real x by the exponent laws of Section 1.2 (extended to irrational x by continuity). It satisfies

$$a^{x+y} = a^x a^y, \qquad a^0 = 1, \qquad a^x > 0 \text{ for all } x.$$

For $a > 1$ it is strictly increasing, with $a^x \to \infty$ as $x \to \infty$ and $a^x \to 0$ as $x \to -\infty$; for $0 < a < 1$ it is strictly decreasing.

The functional equation $f(x+y) = f(x)f(y)$ is the essential property: equal steps in x multiply f by equal factors. A quantity that halves every 5 ms is $f(t) = f(0)\,2^{-t/5\,\text{ms}}$.

The natural base e

Among all bases one is singled out by calculus. Consider interest at a nominal rate of 100% per year compounded n times a year: one unit grows to $\left(1 + \tfrac{1}{n}\right)^n$.

n	1	10	100	1000	10^6
$\left(1+\frac{1}{n}\right)^n$	2	2.59374	2.70481	2.71692	2.71828

Euler's number

$$e = \lim_{n\to\infty}\left(1+\frac{1}{n}\right)^n = \sum_{k=0}^{\infty}\frac{1}{k!} = 1 + 1 + \frac{1}{2} + \frac{1}{6} + \frac{1}{24} + \cdots = 2.718281828\ldots$$

The **natural exponential** is $\exp(x) = e^x$, and more generally $e^x = \lim_{n\to\infty}\left(1+\frac{x}{n}\right)^n = \sum_{k=0}^{\infty}\frac{x^k}{k!}$.

The series converges very fast: the first eight terms already give 2.71825. What makes e natural is that e^x is the unique function equal to its own derivative with value 1 at $x = 0$ (Ch. 4). Consequently the solution of $\dot{y} = -y/\tau$ is $y = y(0)e^{-t/\tau}$, which is why e — not 2 or 10 — appears in every first-order circuit (Ch. 11). Any other exponential can be rewritten in base e: $a^x = e^{x \ln a}$.

Logarithms

Logarithm

For $a > 0$, $a \neq 1$, the **logarithm to base** a is the inverse of a^x:

$$y = a^x \iff x = \log_a y, \qquad y > 0.$$

The **natural logarithm** is $\ln x = \log_e x$; the **common logarithm** is $\log_{10} x$; $\log_2 x$ is used in information theory and digital design.

So $\log_a y$ answers the question "to what power must a be raised to give y?" Immediately, $\log_a 1 = 0$, $\log_a a = 1$, $a^{\log_a y} = y$ and $\log_a(a^x) = x$. The domain of $\log_a$ is $(0,\infty)$ and its range is all of $\mathbb{R}$.

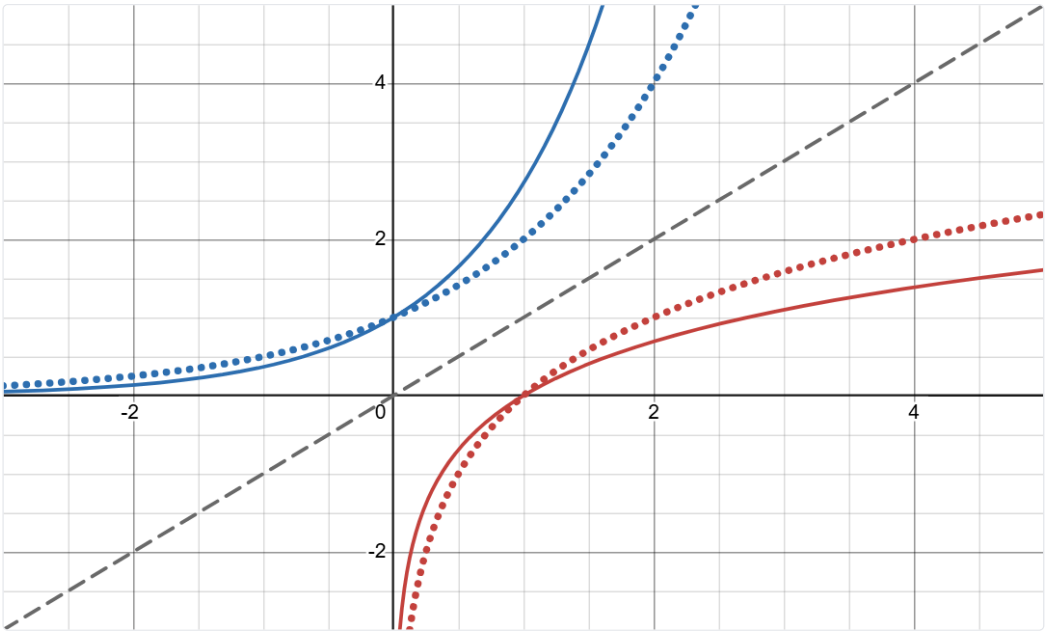
Laws of logarithms ($x, y > 0$, any real p)

$$\log_a(xy) = \log_a x + \log_a y, \qquad \log_a\frac{x}{y} = \log_a x - \log_a y, \qquad \log_a x^p = p\log_a x,$$

$$\log_a x = \frac{\log_b x}{\log_b a} \quad \text{(change of base)}, \qquad \text{in particular} \quad \log_a x = \frac{\ln x}{\ln a}.$$

Proof. Let $u = \log_a x$ and $v = \log_a y$, so $x = a^u$, $y = a^v$. Then $xy = a^{u+v}$, so $\log_a(xy) = u + v$; $x^p = a^{pu}$, so $\log_a x^p = pu$. For change of base, take $\log_b$ of $x = a^u$: $\log_b x = u \log_b a$. $\square$

Each law is just an exponent law read backwards. Two useful consequences: $\log_{10} 2 = 0.30103$, so $2^{10} = 1024 \approx 10^3$ ("ten bits per factor of a thousand"), and the number of bits needed to index N items is $\lceil \log_2 N \rceil$; a million items need $\lceil 19.93 \rceil = 20$ bits.



e^x (blue) and $\ln x$ (red) are mirror images in $y = x$, as every function and its inverse must be (Section 1.9). Base-2 versions (dotted) have the same shapes. Exponentials all pass through $(0, 1)$ and logarithms through $(1, 0)$.

Solving exponential and logarithmic equations

The strategy is to isolate the exponential (or logarithm), then apply the inverse function. Because exp and ln are one-to-one, these steps are equivalences — provided arguments of logarithms are positive.

Worked Example 1.26 — Exponential equations

(a) Solve $2^{x+1} = 3^x$. Take natural logs: $(x+1)\ln 2 = x \ln 3$, so $x(\ln 3 - \ln 2) = \ln 2$ and

$$x = \frac{\ln 2}{\ln 3 - \ln 2} = \frac{0.69315}{0.40547} = 1.7095.$$

Check: $2^{2.7095} = 6.541$ and $3^{1.7095} = 6.541$ ✓.

(b) Solve $e^{2x} - 3e^x + 2 = 0$. With $u = e^x > 0$: $u^2 - 3u + 2 = (u-1)(u-2) = 0$, so $e^x = 1$ or $e^x = 2$, i.e. $x = 0$ or $x = \ln 2 = 0.6931$. (Had a root $u \le 0$ appeared, it would be rejected, since $e^x > 0$.)

(c) Solve $\log_{10}(x) + \log_{10}(x-3) = 1$. Combine: $\log_{10}\big(x(x-3)\big) = 1$, so $x^2 - 3x - 10 = 0$, $(x-5)(x+2) = 0$. The candidate $x = -2$ is rejected (logarithm of a negative number), leaving $x = 5$. **Check:** $\log_{10} 5 + \log_{10} 2 = \log_{10} 10 = 1$ ✓.

First-order transients

The step and natural responses of every first-order circuit are built from $e^{-t/\tau}$, where the **time constant** is $\tau = RC$ or $\tau = L/R$. Useful landmarks follow directly from the logarithm:

Elapsed time	$e^{-t/\tau}$	$1 - e^{-t/\tau}$
τ	0.368	0.632
2τ	0.135	0.865
3τ	0.050	0.950
5τ	0.0067	0.9933
$\tau \ln 2 = 0.693\tau$	0.5	0.5

Worked Example 1.27 — Capacitor discharge and rise time

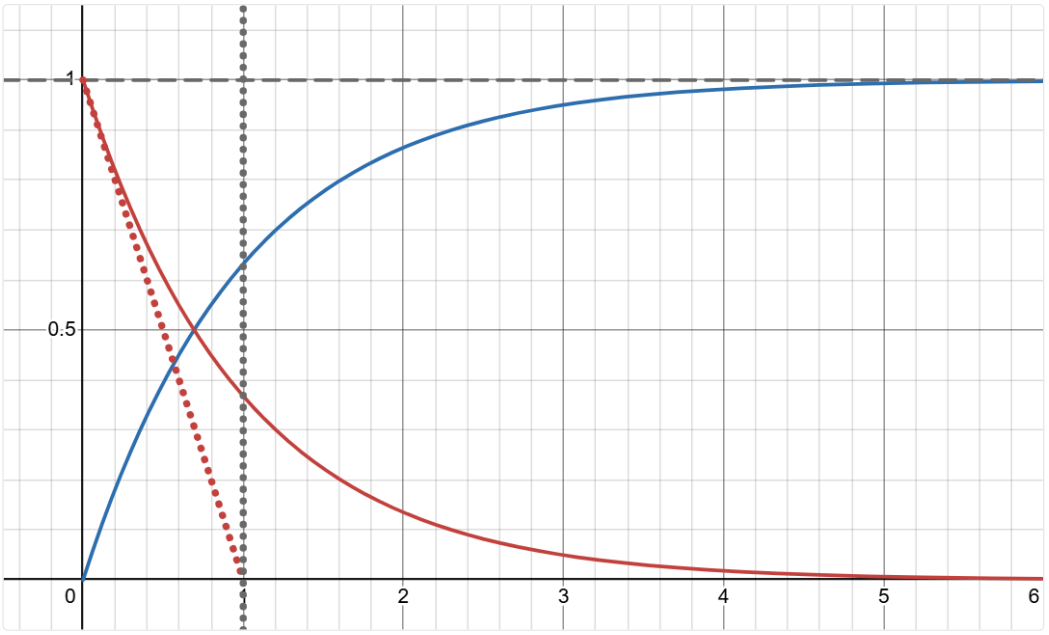
(a) A capacitor discharges as $v(t) = V_0 e^{-t/\tau}$ with $R = 10\ \text{k}\Omega$, $C = 100\ \text{nF}$. How long until v falls to 10% of V_0? $\tau = 10^4 \times 10^{-7} = 10^{-3}$ s. Set $e^{-t/\tau} = 0.1$ and take ln: $-t/\tau = \ln 0.1 = -\ln 10$, so

$$t = \tau \ln 10 = 2.303\ \text{ms}.$$

(b) The **10–90 % rise time** of a charging response $v = V_\infty(1 - e^{-t/\tau})$: solve $1 - e^{-t_1/\tau} = 0.1$ and $1 - e^{-t_2/\tau} = 0.9$, giving $t_1 = \tau \ln \frac{1}{0.9}$ and $t_2 = \tau \ln 10$. Hence

$$t_r = t_2 - t_1 = \tau\left(\ln 10 - \ln \tfrac{10}{9}\right) = \tau \ln 9 = 2.197\,\tau.$$

Check: $e^{-2.303} = 0.100$ ✓ and $\ln 9 = 2.1972$ ✓. Combined with the bandwidth of the same circuit, $f_{3\text{dB}} = 1/(2\pi\tau)$, this gives the well-known rule $t_r f_{3\text{dB}} \approx 0.35$.



Charging $1 - e^{-t/\tau}$ (blue) and discharging $e^{-t/\tau}$ (red) against t/τ. The dotted tangent at $t = 0$ reaches zero at exactly one time constant; after 5τ the transient is within 1% of its final value.

Worked Example 1.28 — Inverting the diode equation

The Shockley diode equation is $I = I_S\left(e^{V/(nV_T)} - 1\right)$. Find V for $I = 1$ mA when $I_S = 10^{-14}$ A, $n = 1$, $V_T = 25.85$ mV, and find how much V changes per decade of current.

Step 1 — isolate the exponential. $e^{V/(nV_T)} = 1 + I/I_S$, so

$$V = nV_T \ln\left(1 + \frac{I}{I_S}\right).$$

Step 2 — evaluate. $I/I_S = 10^{11}$, $\ln(10^{11} + 1) = 25.328$, so $V = 0.02585 \times 25.328 = 0.6547$ V.

Step 3 — per decade. For $I \gg I_S$, $V \approx nV_T \ln(I/I_S)$, and multiplying I by 10 adds $nV_T \ln 10 = 59.5$ mV.

Check: $10^{-14}\left(e^{0.6547/0.02585} - 1\right) \approx 1.00 \times 10^{-3}$ A ✓. The "60 mV per decade" rule of analogue design is just $\ln 10$ in disguise.

Decibels and logarithmic scales

Power ratios in electronics span many orders of magnitude — a radio receiver may handle signals from 10^{-15} W to 10^{-3} W — so engineers use the **decibel**:

Decibel

$$G_{\text{dB}} = 10\log_{10}\frac{P_2}{P_1} = 20\log_{10}\frac{V_2}{V_1} \quad \text{(voltages across equal resistances)}.$$

Absolute levels use a stated reference: dBm is relative to 1 mW, dBW to 1 W, dBV to 1 V, dBμV to 1 μV.

The factor 20 for voltage comes from $P \propto V^2$ and the law $\log x^2 = 2\log x$. Useful anchors: $\times 2$ in power $= +3.01$ dB; $\times 2$ in voltage $= +6.02$ dB; $\times 10$ in voltage $= +20$ dB; $1/\sqrt{2}$ in voltage $= -3.01$ dB (the "half-power" or "-3 dB" point that defines bandwidth). Since 0 dBm $= 1$ mW, $+30$ dBm $= 1$ W.

Gains in cascade **multiply**, so their dB values **add** — the whole point of the logarithm.

Worked Example 1.29 — A receiver chain

A signal of -90 dBm passes through a low-noise amplifier ($+15$ dB), a mixer (-7 dB conversion loss) and an IF amplifier ($+25$ dB). Find the output power in dBm and in watts, and the overall voltage gain factor.

Step 1 — add. $-90 + 15 - 7 + 25 = -57$ dBm.

Step 2 — convert. $P = 10^{-57/10}$ mW $= 1.995 \times 10^{-6}$ mW $= 1.995$ nW.

Step 3 — overall gain. $+33$ dB; as a power ratio $10^{3.3} = 1995$; as a voltage ratio (equal impedances) $10^{33/20} = 44.7$.

Check: multiplying the linear power gains $31.62 \times 0.1995 \times 316.2 = 1995$ ✓.

Logarithmic axes. Plotting $\log y$ against $\log x$ turns a **power law** $y = ax^b$ into a straight line, $\log y = \log a + b\log x$, of slope b. Plotting $\log y$ against x (semi-log) turns an exponential $y = ae^{kx}$ into a straight line of slope $k\log e$. Bode plots (Ch. 16) use dB against $\log\omega$, so that a pole contributes a straight-line slope of -20 dB per decade.

Worked Example 1.30 — Fitting a power law from two points

A measured quantity gives $y = 5.0$ at $x = 2$ and $y = 158.1$ at $x = 20$. Assuming $y = ax^b$, find a and b.

Step 1 — slope on log–log axes. $b = \dfrac{\log_{10} 158.1 - \log_{10} 5.0}{\log_{10} 20 - \log_{10} 2} = \dfrac{\log_{10} 31.62}{1} = 1.500.$

Step 2 — intercept. $a = 5.0/2^{1.5} = 1.768.$

Check: $1.768 \times 20^{1.5} = 1.768 \times 89.44 = 158.1$ ✓.

Hyperbolic functions

Certain combinations of exponentials occur so often — in transmission-line theory, catenary cables, and the solution of $y'' = k^2 y$ — that they have names.

Hyperbolic functions

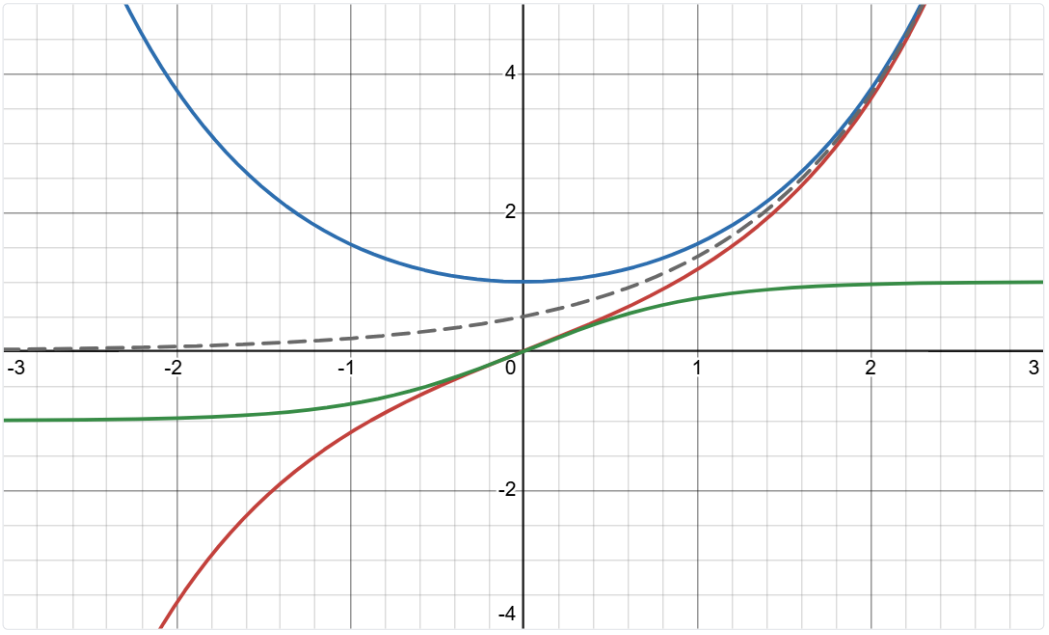
$$\cosh x = \frac{e^x + e^{-x}}{2}, \qquad \sinh x = \frac{e^x - e^{-x}}{2}, \qquad \tanh x = \frac{\sinh x}{\cosh x} = \frac{e^x - e^{-x}}{e^x + e^{-x}}.$$

Hyperbolic identities

$$\cosh^2 x - \sinh^2 x = 1, \qquad \cosh x + \sinh x = e^x, \qquad \sinh 2x = 2\sinh x \cosh x, \qquad \cosh 2x = \cosh^2 x + \sinh^2 x.$$

Proof of the first. $\cosh^2 x - \sinh^2 x = \frac{1}{4}\left[(e^{2x} + 2 + e^{-2x}) - (e^{2x} - 2 + e^{-2x})\right] = 1.$ □

They mirror the trigonometric identities with some sign changes — no coincidence: with complex arguments $\cosh(jx) = \cos x$ and $\sinh(jx) = j\sin x$ (Ch. 2). The parametrisation $(\cosh t, \sinh t)$ traces the hyperbola $x^2 - y^2 = 1$, just as $(\cos t, \sin t)$ traces the circle. Note cosh is even, sinh and tanh are odd, $\cosh x \geq 1$, and $\tanh x \in (-1, 1)$ — the soft-saturation shape used to model a differential pair (Section 1.8). Numerically, $\cosh 1 = 1.5431$, $\sinh 1 = 1.1752$, $\tanh 1 = 0.7616$.



cosh x (blue), sinh x (red) and tanh x (green). For large x both cosh x and sinh x approach $e^x/2$ (grey dashed), while tanh x saturates at ± 1.

Common Pitfall

$\ln(x + y) \neq \ln x + \ln y$, $\ln(xy) \neq \ln x \cdot \ln y$, and ln is undefined for $x \leq 0$. Before taking logs of both sides of an equation, make sure both sides are positive. In decibels, never use 20 log for a power ratio or 10 log for a voltage ratio, and remember that "dB" alone is a ratio while "dBm" is an absolute power.

Engineering Note — logarithms of dimensional quantities

Strictly, only dimensionless numbers have logarithms (Section 1.10). An expression like $\ln I$ is shorthand for $\ln(I/I_0)$ with some reference I_0, and $\ln I_1 - \ln I_2 = \ln(I_1/I_2)$ is then reference-independent. This is exactly why decibel levels always state a reference (dBm, dBV): without it the number is meaningless.

1.6 Trigonometric functions and identities

Why trigonometry

Alternating current, radio carriers, audio tones, rotating machines and the components of a Fourier series are all sinusoids. Angles also enter through geometry: the phase difference between two phasors, the direction of a field vector, the bearing of an antenna beam. Trigonometric identities are the algebra of these quantities — they let a product of two signals be rewritten as a sum of tones (the principle of every mixer), a sum of a sine and a cosine be rewritten as a single shifted sinusoid, and a squared signal be rewritten in terms of its average power. This section gathers the functions and identities used throughout the book; Ch. 3 develops sinusoids and periodic signals in depth, and Ch. 2 shows how Euler's formula derives every identity below from one exponential law.

Angles and radians

Radian

The **radian** measure of an angle is the length of the arc it subtends on a circle divided by the radius: $\theta = s/r$. A full turn is 2π rad, so

$$\pi \text{ rad} = 180^\circ, \qquad 1 \text{ rad} = 57.2958^\circ, \qquad 1^\circ = 0.0174533 \text{ rad}.$$

Being a ratio of two lengths, the radian is dimensionless, which is what allows $\sin\theta$ to have a power-series expansion (Section 1.10). In calculus, angles are **always** in radians: the derivative $\frac{d}{d\theta}\sin\theta = \cos\theta$ holds only in radians (in degrees it acquires a factor $\pi/180$). The arc length $s = r\theta$ and the sector area $A = \frac{1}{2}r^2\theta$ also assume radians.

Definitions on the unit circle

Sine, cosine and tangent

Let the ray at angle θ, measured anticlockwise from the positive x-axis, meet the unit circle $x^2 + y^2 = 1$ at the point P. Then

$$P = (\cos\theta,\ \sin\theta), \qquad \tan\theta = \frac{\sin\theta}{\cos\theta} \quad (\cos\theta \neq 0).$$

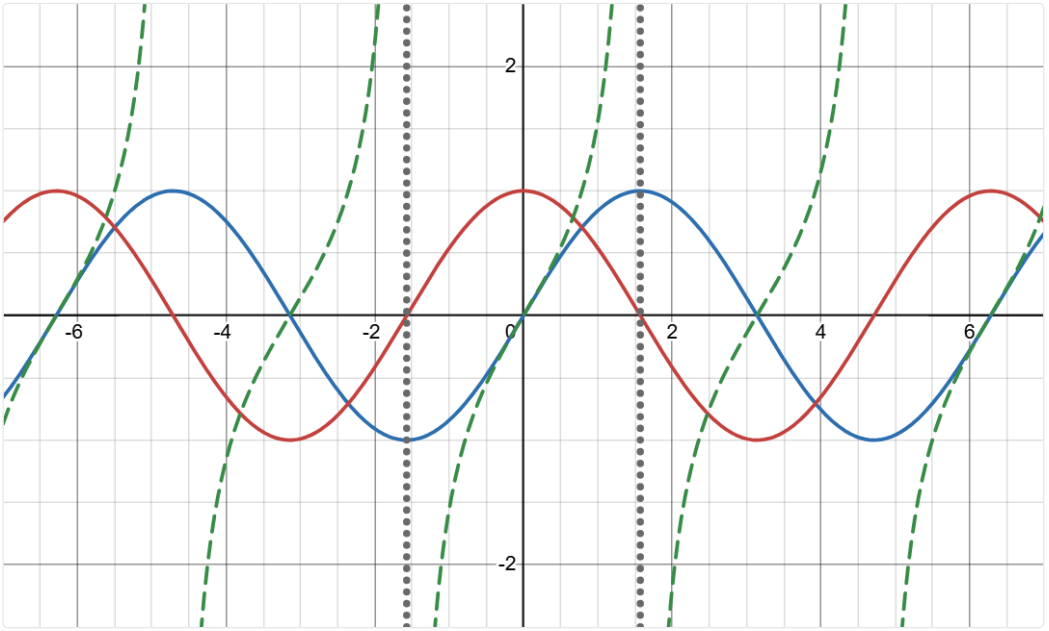
The reciprocal functions are $\sec\theta = 1/\cos\theta$, $\csc\theta = 1/\sin\theta$, $\cot\theta = 1/\tan\theta$.

For an acute angle in a right triangle this agrees with "opposite over hypotenuse" etc., but the unit-circle definition works for every real θ, including negative angles and angles beyond 2π. Immediately:

- sin and cos are **periodic** with period 2π; tan has period π.
- $-1 \le \sin\theta \le 1$ and $-1 \le \cos\theta \le 1$; tan takes every real value.
- cos is **even** and sin, tan are **odd**: $\cos(-\theta) = \cos\theta$, $\sin(-\theta) = -\sin\theta$.
- Shifts: $\sin\left(\theta + \frac{\pi}{2}\right) = \cos\theta$, $\cos\left(\theta + \frac{\pi}{2}\right) = -\sin\theta$, $\sin(\theta + \pi) = -\sin\theta$, $\cos(\pi - \theta) = -\cos\theta$, $\sin(\pi - \theta) = \sin\theta$.
- Signs by quadrant: all positive in the first; only sin in the second; only tan in the third; only cos in the fourth.

The exact values below follow from the 45° isosceles right triangle and the half-equilateral 30°–60° triangle.

θ	0	$\pi/6$	$\pi/4$	$\pi/3$	$\pi/2$	$2\pi/3$	$3\pi/4$	π
$\sin\theta$	0	$1/2$	$\sqrt{2}/2$	$\sqrt{3}/2$	1	$\sqrt{3}/2$	$\sqrt{2}/2$	0
$\cos\theta$	1	$\sqrt{3}/2$	$\sqrt{2}/2$	$1/2$	0	$-1/2$	$-\sqrt{2}/2$	-1
$\tan\theta$	0	$1/\sqrt{3}$	1	$\sqrt{3}$	undef.	$-\sqrt{3}$	-1	0



$\sin x$ (blue), $\cos x$ (red, the sine shifted left by $\pi/2$) and $\tan x$ (green, period π, vertical asymptotes where $\cos x = 0$, marked at $\pm\pi/2$).

The fundamental identities

Pythagorean identities

$$\sin^2\theta + \cos^2\theta = 1, \qquad 1 + \tan^2\theta = \sec^2\theta, \qquad 1 + \cot^2\theta = \csc^2\theta.$$

Proof. The point $(\cos\theta, \sin\theta)$ lies on $x^2 + y^2 = 1$. Divide by $\cos^2\theta$ or $\sin^2\theta$ for the other two. □

Compound-angle formulas

$$\begin{aligned}\cos(A \pm B) &= \cos A\cos B \mp \sin A\sin B\\ \sin(A \pm B) &= \sin A\cos B \pm \cos A\sin B\\ \tan(A \pm B) &= \frac{\tan A \pm \tan B}{1 \mp \tan A\tan B}\end{aligned}$$

Proof of $\cos(A-B)$. The points $P = (\cos A, \sin A)$ and $Q = (\cos B, \sin B)$ on the unit circle are separated by the angle $A - B$. By the distance formula,

$$|PQ|^2 = (\cos A - \cos B)^2 + (\sin A - \sin B)^2 = 2 - 2(\cos A\cos B + \sin A\sin B).$$

Rotating the picture so that Q lies at $(1, 0)$ moves P to $(\cos(A-B), \sin(A-B))$ without changing distances, so also $|PQ|^2 = (\cos(A-B) - 1)^2 + \sin^2(A-B) = 2 - 2\cos(A-B)$. Comparing gives $\cos(A-B) = \cos A\cos B + \sin A\sin B$. Replacing B by $-B$ gives $\cos(A+B)$; replacing A by $\frac{\pi}{2} - A$ converts cosines to sines and gives the sine formulas; dividing gives the tangent formula. □

Every other identity in this section follows from these by algebra.

Double-angle and power-reduction formulas

$$\begin{aligned}\sin 2\theta &= 2\sin\theta\cos\theta\\ \cos 2\theta &= \cos^2\theta - \sin^2\theta = 1 - 2\sin^2\theta = 2\cos^2\theta - 1\\ \sin^2\theta &= \tfrac{1}{2}(1 - \cos 2\theta), \qquad \cos^2\theta = \tfrac{1}{2}(1 + \cos 2\theta)\end{aligned}$$

(Set $A = B = \theta$ in the compound formulas, then use $\sin^2 + \cos^2 = 1$.)

Product-to-sum and sum-to-product

$$\begin{aligned}\cos A\cos B &= \tfrac{1}{2}[\cos(A-B) + \cos(A+B)]\\ \sin A\sin B &= \tfrac{1}{2}[\cos(A-B) - \cos(A+B)]\\ \sin A\cos B &= \tfrac{1}{2}[\sin(A-B) + \sin(A+B)]\\ \sin P + \sin Q &= 2\sin\tfrac{P+Q}{2}\cos\tfrac{P-Q}{2}, \qquad \cos P + \cos Q = 2\cos\tfrac{P+Q}{2}\cos\tfrac{P-Q}{2}\end{aligned}$$

Each product formula follows by adding or subtracting a pair of compound-angle formulas (e.g. $\cos(A-B) + \cos(A+B) = 2\cos A\cos B$). The sum-to-product forms are the same identities read backwards with $P = A + B$, $Q = A - B$.

Worked Example 1.31 — Exact values from identities

(a) $\cos 75^\circ = \cos(45^\circ + 30^\circ) = \dfrac{\sqrt{2}}{2}\cdot\dfrac{\sqrt{3}}{2} - \dfrac{\sqrt{2}}{2}\cdot\dfrac{1}{2} = \dfrac{\sqrt{6}-\sqrt{2}}{4}$. **Check:** $(2.44949 - 1.41421)/4 = 0.25882 = \cos 75^\circ$ ✓.

(b) If $\sin\theta = \frac{3}{5}$ with θ in the second quadrant, find $\cos\theta$ and $\sin 2\theta$. From $\cos^2\theta = 1 - \frac{9}{25} = \frac{16}{25}$ and $\cos\theta < 0$ in quadrant II, $\cos\theta = -\frac{4}{5}$. Then $\sin 2\theta = 2\cdot\frac{3}{5}\cdot\left(-\frac{4}{5}\right) = -\frac{24}{25}$. **Check:** $\theta = \pi - \arcsin 0.6 = 2.4981$ rad, $\sin(4.9962) = -0.96 = -24/25$ ✓.

Harmonic addition: $a\cos\theta + b\sin\theta$

A sum of a cosine and a sine at the **same** frequency is a single sinusoid with a phase shift. This identity is the bridge between the rectangular and polar descriptions of a sinusoid.

Harmonic addition

For real a, b not both zero,

$$a\cos\theta + b\sin\theta = R\cos(\theta - \alpha), \qquad R = \sqrt{a^2 + b^2}, \quad \alpha = \operatorname{atan2}(b, a).$$

Derivation. Expand the right side: $R\cos\theta\cos\alpha + R\sin\theta\sin\alpha$. Matching coefficients requires $R\cos\alpha = a$ and $R\sin\alpha = b$, i.e. (a, b) has polar coordinates (R, α) (Section 1.7). Squaring and adding gives $R^2 = a^2 + b^2$; the quadrant of α is fixed by the signs of a and b, which is exactly what atan2 provides. □

Worked Example 1.32 — Combining two components

Write $v(t) = 3\cos\omega t + 4\sin\omega t$ as a single cosine.

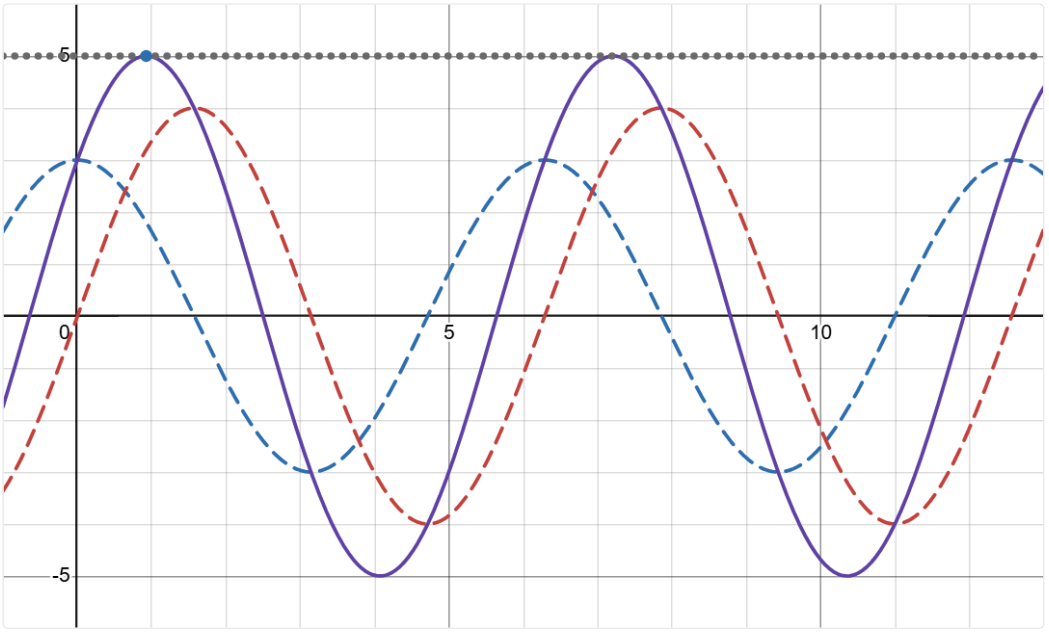
Step 1. $R = \sqrt{9+16} = 5$.

Step 2. $\alpha = \operatorname{atan2}(4, 3) = 0.9273$ rad $= 53.13°$ (first quadrant, since $a, b > 0$).

Result: $v(t) = 5\cos(\omega t - 0.9273)$: amplitude 5, lagging the reference cosine by $53.13°$.

Check at $\omega t = 0.5$: $3\cos 0.5 + 4\sin 0.5 = 4.5504$; $5\cos(0.5 - 0.9273) = 4.5504$ ✓.

Had the signal been $-3\cos\omega t + 4\sin\omega t$, $\alpha = \operatorname{atan2}(4, -3) = 126.87°$ — **not** $\arctan(4/(-3)) = -53.13°$, which would put the phase in the wrong quadrant.



$3\cos x$ (blue) plus $4\sin x$ (red) is a single sinusoid (purple) of amplitude 5, peaking at $x = \alpha = 0.927$ rad: harmonic addition made visible.

Products of sinusoids: mixing, beats and power

Worked Example 1.33 — A mixer and beats

(a) Mixing. Multiplying two tones,

$$\cos(\omega_1 t)\cos(\omega_2 t) = \tfrac{1}{2}\cos\big((\omega_1 - \omega_2)t\big) + \tfrac{1}{2}\cos\big((\omega_1 + \omega_2)t\big),$$

produces components at the **difference** and **sum** frequencies. With $f_1 = 10.7$ MHz and $f_2 = 10.0$ MHz the outputs are at 0.7 MHz and 20.7 MHz. This identity is the entire mathematical content of frequency conversion in a superheterodyne receiver.

(b) Beats. Adding two nearby tones, sum-to-product gives

$$\cos(2\pi \cdot 440\, t) + \cos(2\pi \cdot 444\, t) = 2\cos(2\pi \cdot 2\, t)\cos(2\pi \cdot 442\, t)\ :$$

a 442 Hz tone whose envelope $|2\cos(2\pi \cdot 2t)|$ swells and fades **4 times per second** (the envelope magnitude has period 0.25 s).

Check (b) at $t = 0.1$ s: LHS $= \cos(88\pi) + \cos(88.8\pi) = 1 + \cos(0.8\pi) = 1 - 0.80902 = 0.19098$; RHS $= 2\cos(0.4\pi)\cos(88.4\pi) = 2(0.30902)(0.30902) = 0.19098$ ✓.

Worked Example 1.34 — Average power of a sinusoid

A voltage $v(t) = V_m\cos\omega t$ across a resistor R delivers instantaneous power

$$p(t) = \frac{v^2}{R} = \frac{V_m^2}{R}\cos^2\omega t = \frac{V_m^2}{2R}\big(1 + \cos 2\omega t\big)$$

by power reduction. The $\cos 2\omega t$ term averages to zero over a period, so the mean power is $\bar{P} = \dfrac{V_m^2}{2R}$. Writing $\bar{P} = V_{\text{rms}}^2/R$ defines the **RMS value** $V_{\text{rms}} = V_m/\sqrt{2}$. For the 230 V (RMS) mains, $V_m = 230\sqrt{2} = 325.3$ V. Note also that the power fluctuates at **twice** the supply frequency — the origin of the 100/120 Hz hum in poorly filtered supplies. (Averages of functions are treated formally in Ch. 5.)

Solving trigonometric equations

Because trigonometric functions are periodic, a solvable trigonometric equation has **infinitely many** solutions. Find all solutions in one period, then add multiples of the period.

General solutions

For an integer k:

$$\sin x = \sin\alpha \iff x = \alpha + 2k\pi \ \text{ or } \ x = \pi - \alpha + 2k\pi; \qquad \cos x = \cos\alpha \iff x = \pm\alpha + 2k\pi; \qquad \tan x = \tan\alpha \iff x = \alpha + k\pi.$$

Worked Example 1.35 — A quadratic in $\sin x$

Solve $2\sin^2 x - \sin x - 1 = 0$.

Step 1. With $u = \sin x$: $2u^2 - u - 1 = (2u+1)(u-1) = 0$, so $\sin x = 1$ or $\sin x = -\tfrac{1}{2}$.

Step 2. $\sin x = 1 \Rightarrow x = \tfrac{\pi}{2} + 2k\pi$. $\sin x = -\tfrac{1}{2} = \sin\left(-\tfrac{\pi}{6}\right) \Rightarrow x = -\tfrac{\pi}{6} + 2k\pi$ or $x = \pi + \tfrac{\pi}{6} + 2k\pi = \tfrac{7\pi}{6} + 2k\pi$.

In $[0, 2\pi)$: $x \in \left\{\tfrac{\pi}{2},\ \tfrac{7\pi}{6},\ \tfrac{11\pi}{6}\right\}$.

Check $x = 7\pi/6$: $\sin x = -0.5$, $2(0.25) + 0.5 - 1 = 0$ ✓.

Small-angle approximations

For $|\theta| \ll 1$ (in radians),

$$\sin\theta \approx \theta, \qquad \tan\theta \approx \theta, \qquad \cos\theta \approx 1 - \frac{\theta^2}{2}.$$

These are the first terms of the Taylor series (Ch. 4). At $\theta = 0.1$ rad (5.7°): $\sin 0.1 = 0.099833$ (error 0.17%), $\tan 0.1 = 0.100335$ (error 0.33%), $\cos 0.1 = 0.995004$ versus 0.995. They linearise pendulums, phase-locked loops near lock, and small phase errors in modulators.

Triangles: the laws of sines and cosines

For a triangle with sides a, b, c opposite angles A, B, C:

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}, \qquad c^2 = a^2 + b^2 - 2ab\cos C.$$

The law of cosines generalises Pythagoras ($C = 90^\circ$) and is the quickest way to add two phasors graphically.

Worked Example 1.36 — Adding two phasors geometrically

Two voltages of magnitude 10 V and 6 V differ in phase by 60°. Find the magnitude and phase of their sum relative to the 10 V phasor.

Step 1 — triangle. Placing the phasors head to tail, the angle *inside* the triangle between them is $180^\circ - 60^\circ = 120^\circ$. The law of cosines gives

$$|V|^2 = 10^2 + 6^2 - 2(10)(6)\cos 120^\circ = 100 + 36 + 60 = 196, \qquad |V| = 14 \text{ V}.$$

Step 2 — angle. By the law of sines, $\sin\beta = \dfrac{6\sin 120^\circ}{14} = 0.3712$, so $\beta = 21.79^\circ$.

Check by components: $10 + 6\cos 60^\circ = 13$, $6\sin 60^\circ = 5.196$; $\sqrt{13^2 + 5.196^2} = 14.00$ ✓ and $\operatorname{atan2}(5.196, 13) = 21.79^\circ$ ✓. Ch. 2 does such sums with complex numbers, which avoids the triangle entirely.

Common Pitfall

Calculators default to degrees or radians unpredictably — $\sin(30)$ is 0.5 in degree mode and -0.988 in radian mode. Programming languages always use radians. Also, $\sin(A+B) \neq \sin A + \sin B$ and $\sin 2\theta \neq 2\sin\theta$; and an equation like $\sin x = 0.5$ has infinitely many solutions, not just the one the calculator returns.

Engineering Note — identities as circuit operations

Product-to-sum is what a nonlinear device (a diode or transistor mixer) does to two inputs; power reduction explains why squaring a sinusoid produces DC plus a second harmonic, the basis of RMS detectors and frequency doublers; harmonic addition is how two quadrature signals ($I\cos\omega t + Q\sin\omega t$) carry amplitude and phase in a digital radio.

1.7 Coordinate systems

Why several coordinate systems

A coordinate system is a rule that labels each point of the plane or of space by numbers. The Cartesian system is the default, but it is not always the most convenient: the field of a long straight wire depends only on the distance from the wire, the radiation pattern of an antenna depends on direction, and a complex number is often best described by a length and an angle. Choosing coordinates that match the **symmetry** of a problem can turn an intractable calculation into a short one. This section fixes the conventions used throughout the book — cylindrical (r, ϕ, z) and spherical (R, θ, ϕ), as in Notation & Conventions — and gives the conversion formulas; the calculus in these coordinates (Jacobians, gradient, divergence) comes in Ch. 6 and Ch. 7.

The Cartesian plane

A point P is labelled (x, y) by its signed distances from two perpendicular axes. The basic formulas follow from Pythagoras:

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}, \qquad M = \left(\frac{x_1 + x_2}{2}, \, \frac{y_1 + y_2}{2} \right),$$

for the distance between two points and their midpoint.

Straight lines

- **Slope** through (x_1, y_1) and (x_2, y_2): $m = \dfrac{y_2 - y_1}{x_2 - x_1}$ (undefined for a vertical line).
- **Slope–intercept form:** $y = mx + c$. **Point–slope form:** $y - y_1 = m(x - x_1)$. **General form:** $ax + by + c = 0$.
- Lines are **parallel** iff $m_1 = m_2$ and **perpendicular** iff $m_1 m_2 = -1$.
- **Distance from a point** (x_0, y_0) to the line $ax + by + c = 0$:

$$d = \frac{|ax_0 + by_0 + c|}{\sqrt{a^2 + b^2}}.$$

Circle

The circle with centre (h, k) and radius $\rho_0 > 0$ is the set of points at distance ρ_0 from the centre:

$$(x - h)^2 + (y - k)^2 = \rho_0^2.$$

Worked Example 1.37 — Lines and circles

(a) Load line. A transistor's collector circuit satisfies $V_{CE} = V_{CC} - I_C R_C$. With $V_{CC} = 12$ V, $R_C = 2\ \text{k}\Omega$, plotted with I_C (mA) on the vertical axis and V_{CE} (V) on the horizontal, this is the line $I_C = 6 - 0.5 V_{CE}$: slope $-1/R_C = -0.5$ mA/V, intercepts $(0, 6)$ and $(12, 0)$. The operating point must lie on it.

(b) Circle from a general equation. Find the centre and radius of $x^2 + y^2 - 4x + 6y - 12 = 0$. Complete the square in each variable:

$$(x^2 - 4x + 4) + (y^2 + 6y + 9) = 12 + 4 + 9 \quad \Longrightarrow \quad (x - 2)^2 + (y + 3)^2 = 25.$$

Centre $(2, -3)$, radius 5.

(c) Point-to-line distance. The distance from $(1, 2)$ to $3x + 4y - 1 = 0$ is $\dfrac{|3 + 8 - 1|}{\sqrt{9 + 16}} = \dfrac{10}{5} = 2$.

Check (b): the point $(7, -3)$ is 5 units right of the centre; $49 + 9 - 28 - 18 - 12 = 0$ ✓.

Plane polar coordinates

Polar coordinates

A point is labelled (r, θ), where $r \geq 0$ is its distance from the origin (the **pole**) and θ the angle from the positive x-axis, anticlockwise positive.

$$x = r\cos\theta, \quad y = r\sin\theta; \qquad r = \sqrt{x^2 + y^2}, \quad \theta = \operatorname{atan2}(y, x).$$

The angle is not unique — (r, θ) and $(r, \theta + 2k\pi)$ are the same point — so a **principal value** is chosen, usually $\theta \in (-\pi, \pi]$. The origin has $r = 0$ and any θ.

Two-argument arctangent

$$\operatorname{atan2}(y, x) = \begin{cases} \arctan(y/x), & x > 0 \\ \arctan(y/x) + \pi, & x < 0,\ y \geq 0 \\ \arctan(y/x) - \pi, & x < 0,\ y < 0 \\ +\pi/2, & x = 0,\ y > 0 \\ -\pi/2, & x = 0,\ y < 0 \end{cases}$$

It returns the angle in $(-\pi, \pi]$ in the **correct quadrant** (undefined at the origin).

The single-argument $\arctan(y/x)$ only sees the ratio y/x, so it cannot distinguish $(1, 1)$ from $(-1, -1)$; it always returns an angle in $(-\pi/2, \pi/2)$. Every programming language provides `atan2(y, x)` — note the order of arguments.

Worked Example 1.38 — Polar conversion

(a) $(3, 4)$: $r = 5$, $\theta = \operatorname{atan2}(4, 3) = \arctan(4/3) = 0.9273$ rad $= 53.13°$.

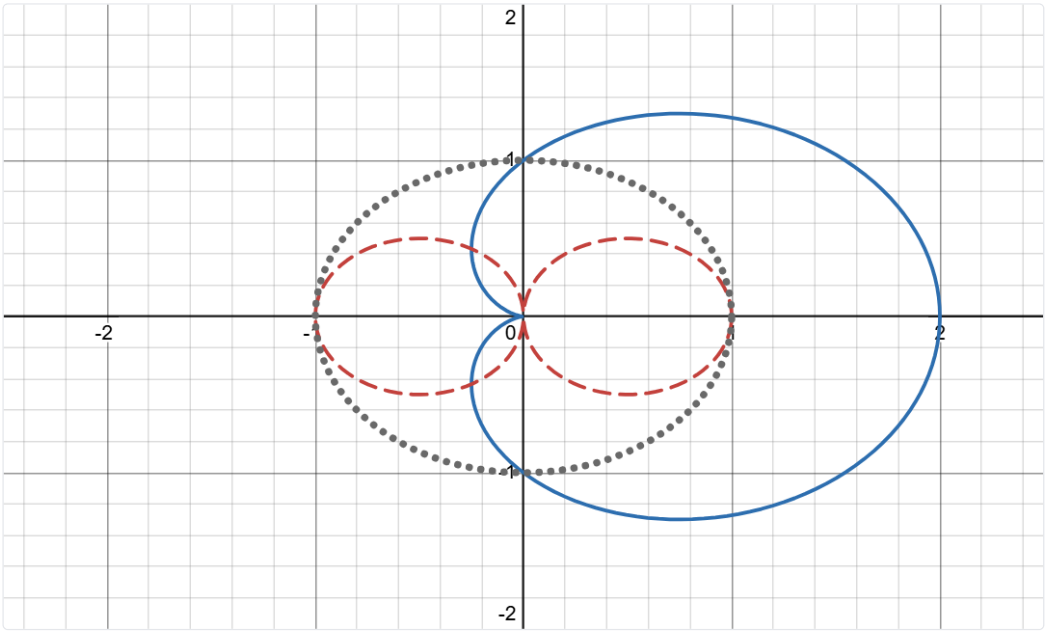
(b) $(-3, -4)$: $r = 5$, but $\theta = \operatorname{atan2}(-4, -3) = \arctan(4/3) - \pi = -2.2143$ rad $= -126.87°$, not $53.13°$.

(c) $(r, \theta) = (2,\ 5\pi/6)$: $x = 2\cos 150° = -\sqrt{3} = -1.732$, $y = 2\sin 150° = 1$.

Check (b): $5\cos(-2.2143) = -3.000$, $5\sin(-2.2143) = -4.000$ ✓.

This is exactly the rectangular-to-polar conversion of complex numbers in Ch. 2, where $(x, y) \leftrightarrow x + jy$ and $(r, \theta) \leftrightarrow re^{j\theta}$.

Curves in polar form. Equations convert using $x = r\cos\theta$, $y = r\sin\theta$, $x^2 + y^2 = r^2$. For instance the circle $x^2 + y^2 = 4x$ (centre $(2, 0)$, radius 2) becomes $r^2 = 4r\cos\theta$, i.e. $r = 4\cos\theta$. Polar plots are the natural way to show **radiation patterns**: the cardioid $r = 1 + \cos\theta$ is the pattern of a simple directional (cardioid) microphone or of two suitably phased antenna elements, with full response forward ($\theta = 0$) and a null behind ($\theta = \pi$).



Polar patterns: the cardioid $r = 1 + \cos\theta$ (blue) has a single null at $\theta = \pi$; the figure-eight $r = |\cos\theta|$ (red) of a dipole-like element has nulls at $\pm\pi/2$; the grey circle is an omnidirectional pattern.

Three-dimensional Cartesian coordinates

A point in space is (x, y, z) with respect to three mutually perpendicular axes forming a **right-handed** system: curling the fingers of the right hand from $+x$ towards $+y$, the thumb points along $+z$. The distance formula extends directly: $d = \sqrt{\Delta x^2 + \Delta y^2 + \Delta z^2}$.

Cylindrical coordinates (r, ϕ, z)

Cylindrical coordinates

$r \geq 0$ is the perpendicular distance from the z-axis, $\phi \in [0, 2\pi)$ (or $(-\pi, \pi]$) the azimuthal angle measured from the $+x$ axis in the xy-plane, and z the usual height.

$$x = r\cos\phi, \quad y = r\sin\phi, \quad z = z; \qquad r = \sqrt{x^2 + y^2}, \quad \phi = \operatorname{atan2}(y, x).$$

Cylindrical coordinates are plane polar coordinates with a z axis added. The surfaces $r = \text{const}$ are coaxial cylinders, $\phi = \text{const}$ half-planes hinged on the z-axis, and $z = \text{const}$ horizontal planes. This book uses r (not ρ) for the cylindrical radius so that ρ remains free for charge density.

Spherical coordinates (R, θ, ϕ)

Spherical coordinates

$R \geq 0$ is the distance from the origin, $\theta \in [0, \pi]$ the **polar angle** measured from the $+z$ axis, and ϕ the **azimuth**, the same angle as in cylindrical coordinates.

$$x = R\sin\theta\cos\phi, \quad y = R\sin\theta\sin\phi, \quad z = R\cos\theta;$$

$$R = \sqrt{x^2 + y^2 + z^2}, \qquad \theta = \arccos\frac{z}{R}, \qquad \phi = \operatorname{atan2}(y, x).$$

Derivation. Drop a perpendicular from P to the xy-plane. The right triangle formed by the origin, P and the z-axis has hypotenuse R and angle θ at the origin, so $z = R\cos\theta$ and the distance from the z-axis is $r = R\sin\theta$. Within the xy-plane, that distance r and the azimuth ϕ give $x = r\cos\phi$, $y = r\sin\phi$. □

The bridge between the two systems is therefore

$$r = R\sin\theta, \qquad z = R\cos\theta, \qquad \phi \text{ unchanged.}$$

The surfaces $R = \text{const}$ are spheres, $\theta = \text{const}$ cones about the z-axis (the plane $z = 0$ when $\theta = \pi/2$), and $\phi = \text{const}$ half-planes. On the Earth, θ is the **colatitude** (90° minus latitude) and ϕ the longitude.

System	Coordinates	To Cartesian	Line element ds^2	Volume element
Cartesian	(x, y, z)	—	$dx^2 + dy^2 + dz^2$	$dx\,dy\,dz$

System	Coordinates	To Cartesian	Line element ds^2	Volume element
Cylindrical	(r, ϕ, z)	$x = r\cos\phi,\ y = r\sin\phi,\ z = z$	$dr^2 + r^2 d\phi^2 + dz^2$	$r\, dr\, d\phi\, dz$
Spherical	(R, θ, ϕ)	$x = R\sin\theta\cos\phi,\ y = R\sin\theta\sin\phi,\ z = R\cos\theta$	$dR^2 + R^2 d\theta^2 + R^2\sin^2\theta\, d\phi^2$	$R^2\sin\theta\, dR\, d\theta\, d\phi$

The line elements follow geometrically: in cylindrical coordinates a small change $d\phi$ moves a point along an arc of radius r, a distance $r\, d\phi$; in spherical coordinates $d\theta$ moves it along a circle of radius R (distance $R\, d\theta$), and $d\phi$ along a circle of radius $R\sin\theta$ (distance $R\sin\theta\, d\phi$). Multiplying the three perpendicular displacements gives the volume elements. For example, integrating $R^2\sin\theta$ over $\theta \in [0, \pi]$ and $\phi \in [0, 2\pi)$ gives the sphere's surface area $4\pi R^2$ (Ch. 6).

Worked Example 1.39 — Converting points

(a) Cartesian to cylindrical. $(x, y, z) = (-2,\ 2\sqrt{3},\ 5)$: $r = \sqrt{4 + 12} = 4$, $\phi = \operatorname{atan2}(2\sqrt{3}, -2) = 2\pi/3$ (second quadrant), $z = 5$. So $(r, \phi, z) = (4,\ 2\pi/3,\ 5)$.

(b) Cartesian to spherical. $(1, 1, \sqrt{2})$: $R = \sqrt{1 + 1 + 2} = 2$; $\theta = \arccos(\sqrt{2}/2) = \pi/4$; $\phi = \operatorname{atan2}(1, 1) = \pi/4$.

(c) Spherical to cylindrical. $(R, \theta, \phi) = (6,\ \pi/3,\ \pi/2)$: $r = 6\sin\frac{\pi}{3} = 5.196$, $z = 6\cos\frac{\pi}{3} = 3$, $\phi = \pi/2$.

Checks: (a) $4\cos(2\pi/3) = -2$, $4\sin(2\pi/3) = 3.464 = 2\sqrt{3}$ ✓. (b) $x = 2\sin\frac{\pi}{4}\cos\frac{\pi}{4} = 2\cdot\frac{1}{2} = 1$ ✓, $z = 2\cos\frac{\pi}{4} = \sqrt{2}$ ✓. (c) $r^2 + z^2 = 27 + 9 = 36 = R^2$ ✓.

Worked Example 1.40 — Distance between two points given in spherical form

Find the distance between $P_1 = (R, \theta, \phi) = (2,\ \pi/2,\ 0)$ and $P_2 = (3,\ \pi/3,\ \pi/2)$.

Step 1 — convert. $P_1 = (2\cdot 1\cdot 1,\ 0,\ 0) = (2, 0, 0)$. $P_2 = (3\sin\frac{\pi}{3}\cos\frac{\pi}{2},\ 3\sin\frac{\pi}{3}\sin\frac{\pi}{2},\ 3\cos\frac{\pi}{3}) = (0,\ 2.598,\ 1.5)$.

Step 2 — distance. $d = \sqrt{2^2 + 2.598^2 + 1.5^2} = \sqrt{4 + 6.75 + 2.25} = \sqrt{13} = 3.606$.

Check by the spherical law of cosines. The angle γ between the two position vectors satisfies $\cos\gamma = \sin\theta_1\sin\theta_2\cos(\phi_1 - \phi_2) + \cos\theta_1\cos\theta_2 = 1\cdot 0.866\cdot 0 + 0 = 0$, so $d^2 = R_1^2 + R_2^2 - 2R_1R_2\cos\gamma = 4 + 9 = 13$ ✓.

Note that one may **not** subtract spherical coordinates component by component: $(3 - 2,\ \pi/3 - \pi/2,\ \pi/2 - 0)$ is meaningless as a displacement.

Worked Example 1.41 — Converting surfaces

Surface	Cartesian	Cylindrical	Spherical
Sphere of radius a	$x^2 + y^2 + z^2 = a^2$	$r^2 + z^2 = a^2$	$R = a$
Cylinder of radius 3 about z	$x^2 + y^2 = 9$	$r = 3$	$R\sin\theta = 3$
Cone, half-angle 45°	$z = \sqrt{x^2 + y^2}$	$z = r$	$\theta = \pi/4$
Half-plane $y = x,\ x > 0$	$y = x,\ x > 0$	$\phi = \pi/4$	$\phi = \pi/4$

For the cone: $z = r$ means $R\cos\theta = R\sin\theta$, so $\tan\theta = 1$ and $\theta = \pi/4$. Each surface has the simplest equation in the system matched to its symmetry.

Common Pitfall — conventions differ

Many mathematics texts swap the roles of θ and ϕ in spherical coordinates (using θ for azimuth), and some use ρ for the spherical radius. This book follows the physics/electromagnetics convention: θ is the polar angle from $+z$, ϕ the azimuth. Also, the cylindrical r (distance from the z-axis) is **not** the spherical R (distance from the origin): $r = R\sin\theta$. Always check a source's convention before using its formulas.

Engineering Note — let symmetry choose

Choose coordinates to match the geometry: cylindrical for coaxial cables, long wires, solenoids and optical fibres; spherical for point charges, antennas and far-field radiation; Cartesian for parallel-plate capacitors and rectangular waveguides. The field of a line charge, a messy expression in (x, y, z), is simply proportional to $1/r$ in cylindrical coordinates; the far field of an antenna is a function of (θ, ϕ) times e^{-jkR}/R.

1.8 Functions, domains, and ranges

Why the function concept

A circuit, a sensor, an amplifier or a filter is, to a mathematician, a **function**: a rule that takes an input (a voltage, a temperature, a signal) and produces exactly one output. Signals themselves are functions of time. Speaking precisely about functions — what inputs are allowed, what outputs can occur, how graphs are transformed by delays and gains — is the vocabulary of signals and systems. Questions like "for what input range is this amplifier linear?" or "can this sensor reading be inverted to give a unique temperature?" are questions about domains, ranges and one-to-one functions.

Definition

Function

A **function** $f : A \to B$ assigns to each element x of the set A (the **domain**) exactly one element $f(x)$ of the set B (the **codomain**). The **range** (or image) is the set of values actually taken,

$$f(A) = \{f(x) : x \in A\} \subseteq B.$$

x is the **independent variable** (argument, input) and $y = f(x)$ the **dependent variable** (value, output).

The essential word is *exactly one*. The relation $y^2 = x$ does not define y as a function of x, because $x = 4$ gives $y = \pm 2$; it defines two functions, $y = \sqrt{x}$ and $y = -\sqrt{x}$. Graphically, a curve in the xy-plane is the graph of a function of x if and only if every vertical line meets it at most once — the **vertical-line test**.

A function is not the same thing as a formula. The same formula on different domains gives different functions (with different ranges and different inverses), and one function may need several formulas (a piecewise definition). Notation such as $f : \mathbb{R} \to \mathbb{R},\ x \mapsto x^2$ ("x maps to x^2") states domain, codomain and rule together.

Natural domain

When a formula is given without a stated domain, the **natural domain** is the largest set of reals for which it makes sense. Exclude:

- zeros of denominators;
- negative arguments of even roots ($\sqrt{\ }$, $\sqrt[4]{\ }$, …);
- non-positive arguments of logarithms;
- points where tan or sec is undefined ($\cos = 0$), or cot, csc ($\sin = 0$);
- arguments outside $[-1, 1]$ for arcsin and arccos.

In a physical model the domain is further restricted by physics: a resistance is positive, a probability lies in $[0, 1]$, a model of a transistor is valid only in its active region.

Worked Example 1.42 — Natural domains

(a) $f(x) = \dfrac{\ln(4 - x^2)}{\sqrt{x + 1}}$ needs $4 - x^2 > 0$, i.e. $-2 < x < 2$, and $x + 1 > 0$ (strictly, since the root is in a denominator), i.e. $x > -1$. Intersection: domain $(-1, 2)$.

(b) $g(x) = \sqrt{\dfrac{x - 1}{x + 2}}$ needs $\dfrac{x - 1}{x + 2} \geq 0$, which by the sign chart of Example 1.15(c) gives $(-\infty, -2) \cup [1, \infty)$.

(c) $h(x) = \arcsin(2x - 1)$ needs $-1 \leq 2x - 1 \leq 1$, i.e. $0 \leq x \leq 1$.

Finding the range

The range is usually harder than the domain. Three systematic methods:

1. **Solve for x.** Set $y = f(x)$ and ask for which y the equation has a solution x in the domain.
2. **Complete the square** or otherwise rewrite f in a form whose extreme values are obvious.
3. **Use monotonicity**: a continuous increasing function on $[a, b]$ has range $[f(a), f(b)]$. (Calculus gives a general method in Ch. 4.)

Worked Example 1.43 — Three ranges

(a) By completing the square. $f(x) = x^2 - 4x + 7$ on $[0, 5]$. Since $f(x) = (x - 2)^2 + 3$, the minimum is 3 at $x = 2$; the maximum over $[0, 5]$ is at the end farther from 2, $f(5) = 12$ (while $f(0) = 7$). Range $[3, 12]$.

(b) By solving for x. $f(x) = \dfrac{x}{x^2 + 1}$ on $\mathbb{R}$. Setting $y = \dfrac{x}{x^2 + 1}$ gives $yx^2 - x + y = 0$. If $y = 0$, then $x = 0$ works. If $y \neq 0$, this quadratic in x has a real root iff its discriminant $1 - 4y^2 \geq 0$, i.e. $|y| \leq \frac{1}{2}$. Range $\left[-\frac{1}{2}, \frac{1}{2}\right]$, with $y = \frac{1}{2}$ at $x = 1$ and $y = -\frac{1}{2}$ at $x = -1$.

(c) From bounded functions. $g(x) = 2 + 3\sin x$: since $-1 \leq \sin x \leq 1$, the range is $[-1, 5]$.

Check (b): $f(1) = 1/2$ ✓; $f(3) = 0.3 < 0.5$ ✓.

Properties worth naming

Even, odd, periodic, monotonic, bounded

- **Even:** $f(-x) = f(x)$ for all x (graph symmetric about the y-axis; x^2, $\cos x$, $|x|$, $\cosh x$).
- **Odd:** $f(-x) = -f(x)$ (graph symmetric under a half-turn about the origin; x^3, $\sin x$, $\tan x$, $\sinh x$).
- **Periodic** with period $T > 0$: $f(x + T) = f(x)$ for all x; the smallest such T is the **fundamental period**.
- **Increasing** on an interval: $x_1 < x_2 \Rightarrow f(x_1) \leq f(x_2)$ (**strictly** if $<$); **decreasing** similarly. **Monotonic** means one or the other.
- **Bounded:** $|f(x)| \leq M$ for some M and all x in the domain.

Even–odd decomposition

Every function f defined on a symmetric domain splits uniquely as $f = f_e + f_o$ with f_e even and f_o odd:

$$f_e(x) = \tfrac{1}{2}\big[f(x) + f(-x)\big], \qquad f_o(x) = \tfrac{1}{2}\big[f(x) - f(-x)\big].$$

Proof. The formulas clearly give an even and an odd function summing to f. For uniqueness, if $f = g_e + g_o$, then $f(-x) = g_e(x) - g_o(x)$; adding and subtracting recovers the formulas. □

Products follow sign rules: even×even and odd×odd are even, even×odd is odd. This is used constantly in Fourier analysis (Ch. 15), where an even signal has only cosine terms and an odd one only sine terms.

Worked Example 1.44 — Even and odd parts

(a) For $f(x) = e^x$: $f_e = \tfrac{1}{2}(e^x + e^{-x}) = \cosh x$ and $f_o = \tfrac{1}{2}(e^x - e^{-x}) = \sinh x$, recovering $e^x = \cosh x + \sinh x$ (Section 1.5).

(b) For the decaying exponential pulse $x(t) = e^{-t}u(t)$ (zero for $t < 0$):

$$x_e(t) = \tfrac{1}{2}e^{-|t|}, \qquad x_o(t) = \tfrac{1}{2}\operatorname{sgn}(t)\, e^{-|t|},$$

where $\operatorname{sgn}(t)$ is $+1$ for $t > 0$ and -1 for $t < 0$.

Check at $t = 1$: $x_e + x_o = \tfrac{1}{2}e^{-1} + \tfrac{1}{2}e^{-1} = e^{-1} = x(1)$ ✓; at $t = -1$: $\tfrac{1}{2}e^{-1} - \tfrac{1}{2}e^{-1} = 0 = x(-1)$ ✓.

Transformations of graphs

Given the graph of $y = f(x)$, the graph of

$$y = A\, f\big(b(x - c)\big) + d$$

is obtained by: horizontal scaling by a factor $1/b$ (compression if $|b| > 1$, with reflection in the y-axis if $b < 0$); horizontal **shift** right by c; vertical scaling by A (reflection in the x-axis if $A < 0$); and vertical shift up by d. Changes **inside** the function act on x and work "backwards" ($f(x - 3)$ moves the graph *right*); changes **outside** act on y and work as expected.

In signal language with t for time: $x(t - t_0)$ is a **delay** by t_0 (for $t_0 > 0$), $x(at)$ is time compression ($a > 1$) or expansion ($0 < a < 1$), $x(-t)$ is time reversal, and $Ax(t)$ is amplification.

Worked Example 1.45 — Order of shift and scale

Describe $y(t) = x(2t - 4)$ in terms of $x(t)$.

Step 1 — factor the inner coefficient. $x(2t - 4) = x\big(2(t - 2)\big)$.

Step 2 — interpret. Compress x by a factor 2 in time, then delay by 2 — **not** by 4. A feature of x at time $t = \tau$ appears in y at the time where $2t - 4 = \tau$, i.e. $t = (\tau + 4)/2$.

Check: if x has a peak at $t = 0$, then y peaks where $2t - 4 = 0$, i.e. $t = 2$ ✓.

Piecewise-defined functions

Many engineering functions are defined by different formulas on different sub-domains. Two that matter everywhere in EE are the unit step and the saturation (clipping) function:

$$u(t) = \begin{cases} 0, & t < 0 \\ 1, & t \geq 0 \end{cases} \qquad \operatorname{sat}(x) = \begin{cases} -1, & x < -1 \\ x, & |x| \leq 1 \\ 1, & x > 1 \end{cases}$$

(The value of $u(0)$ is a convention; some texts use $\tfrac{1}{2}$. It never affects integrals.) Steps are the building blocks of piecewise signals: the rectangular pulse of width T starting at 0 is $u(t) - u(t - T)$, and the ramp is $r(t) = t\,u(t)$. Absolute value, sgn, and $\max(0, x)$ (the ideal rectifier, and the "ReLU" of machine learning) are other common piecewise functions: $\max(0, x) = \tfrac{1}{2}(x + |x|)$.

Worked Example 1.46 — Building a signal from steps

Express the signal that is 0 for $t < 0$, rises linearly to 2 at $t = 1$, stays at 2 until $t = 3$, then drops to 0.

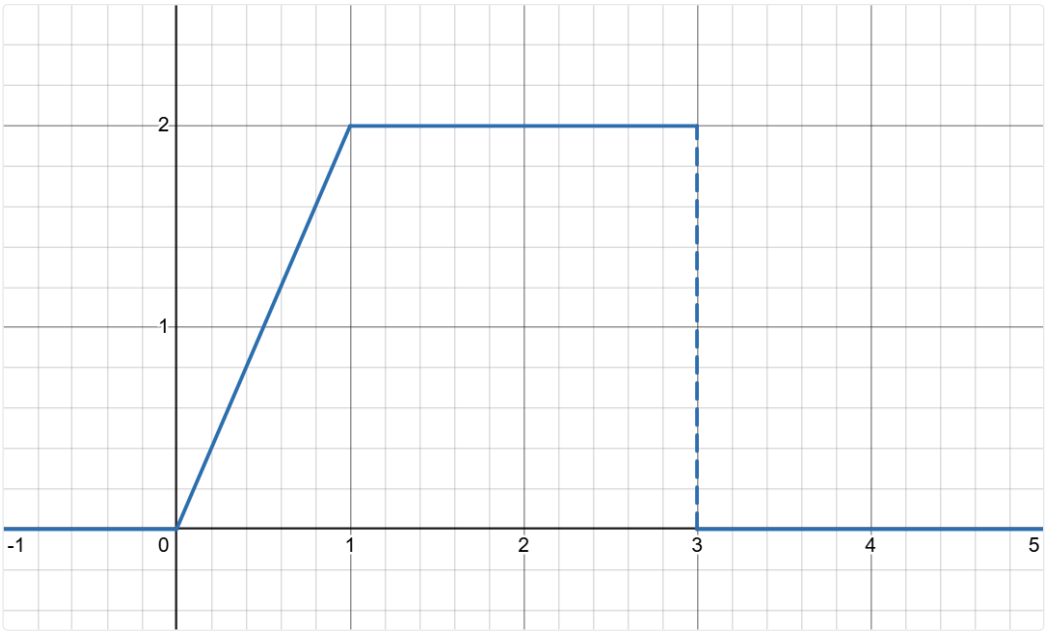
Step 1. The ramp $2t\,u(t)$ produces the rise but keeps going.

Step 2. At $t = 1$ cancel the slope with $-2(t - 1)u(t - 1)$; for $t > 1$ the sum is $2t - 2(t - 1) = 2$ ✓.

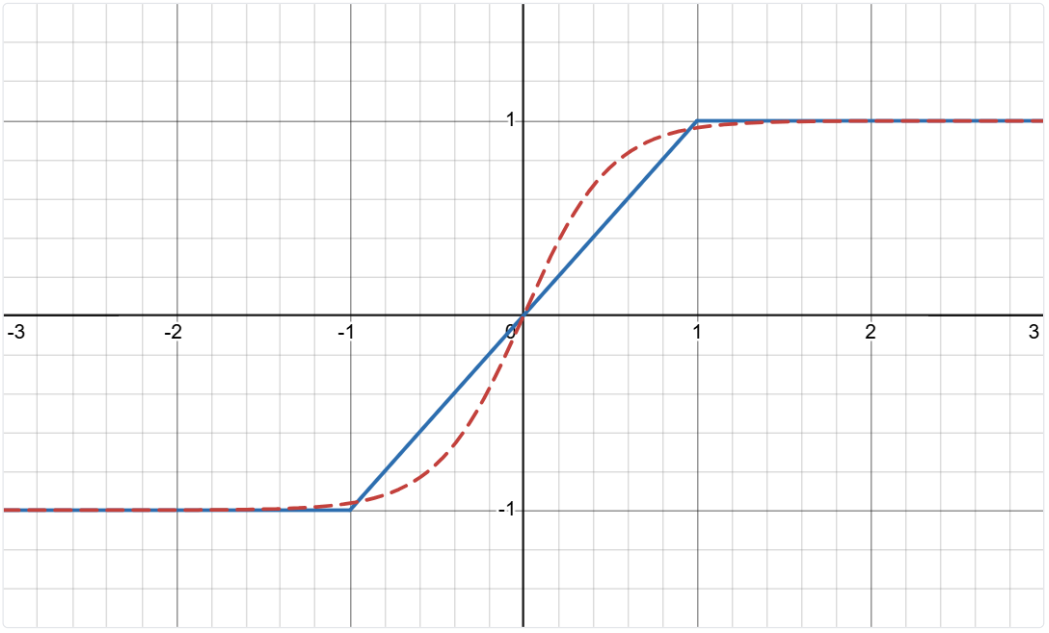
Step 3. At $t = 3$ subtract the level: $-2u(t - 3)$.

Result: $x(t) = 2t\,u(t) - 2(t - 1)\,u(t - 1) - 2\,u(t - 3)$.

Check at $t = 0.5$: $1 - 0 - 0 = 1$ ✓; at $t = 2$: $4 - 2 - 0 = 2$ ✓; at $t = 4$: $8 - 6 - 2 = 0$ ✓.



The trapezoidal-ramp signal of Example 1.46, built from a ramp, a delayed ramp and a delayed step. The dashed segment marks the jump at $t = 3$.



The ideal saturation function (blue) and the smooth $\tanh(2x)$ (red), often used to model an amplifier driven into its supply rails. Domain $\mathbb{R}$, range $[-1, 1]$; the linear region is the domain sub-interval $|x| \le 1$.

Functions of several variables

A function may take several inputs: the power $P(V, R) = V^2/R$ has domain $\{(V, R) : R > 0\}$ and the potential of a point charge $\Phi(x, y, z)$ is defined everywhere except at the charge. The ideas of domain and range carry over unchanged; differentiation and integration of such functions are the subject of Ch. 6.

Common Pitfall — the formula is not the domain

Simplifying a formula can silently enlarge its domain. $\dfrac{x^2 - 1}{x - 1}$ and $x + 1$ agree except at $x = 1$, where the first is undefined; $(\sqrt{x})^2$ and x agree only for $x \ge 0$; $e^{\ln x}$ and x agree only for $x > 0$. State the domain before simplifying, and keep it afterwards.

Engineering Note — domains as operating regions

A device model is a function with a restricted domain. The small-signal model of a transistor is valid only near its bias point; the Shockley equation fails at reverse breakdown; an op-amp's linear model $v_o = A(v_+ - v_-)$ holds only while $|v_o|$ is below the rails. Many design failures are evaluations of a function outside its domain.

1.9 Inverse and composite functions

Why composition and inversion

Engineering systems are built by connecting blocks in series: a sensor converts temperature to resistance, a bridge converts resistance to voltage, an amplifier scales the voltage, an ADC converts it to a number. The overall input–output relation is a **composite function**. Measurement is the reverse problem: from the number read out, recover the temperature. That requires the **inverse** of each block — and it is possible only if each block is one-to-one on the range of interest. Composition also underlies the chain rule of differentiation (Ch. 4) and substitution in integration (Ch. 5), both of which require recognising a function as "an outer function of an inner function".

Composite functions

Composite function

The **composition** of f with g is

$$(f \circ g)(x) = f\big(g(x)\big),$$

read "f after g". Its domain is the set of x in the domain of g for which $g(x)$ lies in the domain of f.

Composition is **associative**, $(f \circ g) \circ h = f \circ (g \circ h)$, but in general **not commutative**: $f \circ g \neq g \circ f$. A signal chain $x \to g \to f \to y$ is the composite $y = (f \circ g)(x)$ — note that the block applied first is written on the right.

Worked Example 1.47 — Composition and its domain

Let $f(x) = \sqrt{x}$ and $g(x) = 1 - x^2$.

(a) $(f \circ g)(x) = \sqrt{1 - x^2}$. Need $g(x) \geq 0$: $1 - x^2 \geq 0$, so the domain is $[-1, 1]$; the range is $[0, 1]$ (the upper unit semicircle).

(b) $(g \circ f)(x) = 1 - (\sqrt{x})^2 = 1 - x$, but only for x in the domain of f: the domain is $[0, \infty)$, even though the simplified formula $1 - x$ looks defined everywhere.

(c) $f \circ g \neq g \circ f$: at $x = 0.5$, $(f \circ g)(0.5) = \sqrt{0.75} = 0.866$ while $(g \circ f)(0.5) = 0.5$.

Worked Example 1.48 — Decomposing a function

Write $h(t) = e^{-(t-2)^2}$ and $k(x) = \ln\left(1 + \cos^2 x\right)$ as compositions of simpler functions.

$h = f_1 \circ f_2 \circ f_3$ with $f_3(t) = t - 2$ (delay), $f_2(u) = -u^2$, $f_1(w) = e^w$.

$k = F_1 \circ F_2 \circ F_3$ with $F_3(x) = \cos x$, $F_2(u) = 1 + u^2$, $F_1(w) = \ln w$. The domain is all of $\mathbb{R}$, since $1 + \cos^2 x \geq 1 > 0$.

Recognising this nesting — innermost to outermost — is exactly the skill needed to apply the chain rule.

One-to-one functions

One-to-one (injective), onto (surjective)

$f : A \to B$ is **one-to-one** if $f(x_1) = f(x_2) \Rightarrow x_1 = x_2$ — distinct inputs give distinct outputs. Graphically, every horizontal line meets the graph at most once (the **horizontal-line test**). f is **onto** B if its range is all of B. A function that is both is a **bijection**.

Strict monotonicity implies one-to-one

A function that is strictly increasing (or strictly decreasing) on an interval is one-to-one there.

Proof. If $x_1 \neq x_2$, say $x_1 < x_2$, then strict increase gives $f(x_1) < f(x_2)$, so $f(x_1) \neq f(x_2)$. $\square$

So x^3, e^x, $\ln x$ and $\tanh x$ are one-to-one on their whole domains, while x^2 and $\sin x$ are not — but become so when restricted to $[0, \infty)$ and $[-\pi/2, \pi/2]$ respectively.

Inverse functions

Inverse function

If f is one-to-one with domain A and range B, its **inverse** $f^{-1} : B \to A$ is defined by

$$f^{-1}(y) = x \iff f(x) = y.$$

Equivalently, $f^{-1}\big(f(x)\big) = x$ for all $x \in A$ and $f\big(f^{-1}(y)\big) = y$ for all $y \in B$. The domain of f^{-1} is the range of f, and vice versa.

The graph of f^{-1} is the reflection of the graph of f in the line $y = x$, because the point (a, b) lies on the graph of f exactly when (b, a) lies on the graph of f^{-1}. If f is increasing, so is f^{-1}.

Procedure. To find f^{-1}: write $y = f(x)$; solve for x in terms of y (if the solution is not unique, f is not one-to-one — restrict its domain); state the domain of f^{-1} as the range of f; and, if desired, rename the variable.

Worked Example 1.49 — A fractional-linear inverse

$f(x) = \dfrac{2x+1}{x-3}$, $x \neq 3$.

Step 1. $y(x-3) = 2x+1 \Rightarrow xy - 3y = 2x+1 \Rightarrow x(y-2) = 3y+1$.

Step 2. For $y \neq 2$,

$$f^{-1}(y) = \frac{3y+1}{y-2}.$$

Step 3 — domain/range. The step fails only at $y = 2$, so the range of f is $\mathbb{R} \setminus \{2\}$ — the horizontal asymptote of f, which it never reaches.

Check: $f(0) = -\frac{1}{3}$ and $f^{-1}\left(-\frac{1}{3}\right) = \dfrac{-1+1}{-\frac{7}{3}} = 0$ ✓.

Worked Example 1.50 — Inverting the logistic and decibel functions

(a) The logistic (sigmoid) function $\sigma(x) = \dfrac{1}{1+e^{-x}}$ maps $\mathbb{R}$ onto $(0,1)$ and is strictly increasing. Solve $y = \dfrac{1}{1+e^{-x}}$: $1 + e^{-x} = \dfrac{1}{y}$, $e^{-x} = \dfrac{1-y}{y}$, so

$$\sigma^{-1}(y) = \ln \frac{y}{1-y}, \qquad 0 < y < 1.$$

Check: $\sigma^{-1}(0.8) = \ln 4 = 1.3863$ and $\sigma(1.3863) = 1/(1+0.25) = 0.8$ ✓.

(b) Voltage gain in dB is $G = 20 \log_{10} A$ for $A > 0$. Its inverse is $A = 10^{G/20}$; a gain of 26 dB is a voltage ratio $10^{1.3} = 19.95$.

Worked Example 1.51 — Inverting a measurement chain

A platinum RTD has $R(T) = R_0(1 + \alpha T)$ with $R_0 = 100\ \Omega$, $\alpha = 0.00385\ ^\circ\text{C}^{-1}$. It forms a divider with a fixed 100 Ω resistor across 5 V, giving $V = \dfrac{5R}{R+100}$, read by a 10-bit ADC as the integer $N = \lfloor 1024\, V/5 \rfloor$.

(a) Forward (composite). At $T = 50.39\ ^\circ$C: $R = 119.4\ \Omega$, $V = 5 \times 119.4/219.4 = 2.7211$ V, $N = \lfloor 557.27 \rfloor = 557$.

(b) Inverse. Each block is strictly increasing on its operating range, so invert them in reverse order:

$$V \approx \frac{5N}{1024}, \qquad R = \frac{100\,V}{5-V}, \qquad T = \frac{R/R_0 - 1}{\alpha}.$$

From $N = 557$: $V = 2.7197$ V, $R = 119.27\ \Omega$, $T = 50.06\ ^\circ$C.

Interpretation. The recovered $50.06\ ^\circ$C differs from the true $50.39\ ^\circ$C because the floor function in the ADC is **not** one-to-one: every voltage in a 4.9 mV band maps to the same code. Its "inverse" can only return a representative value — here a $0.33\ ^\circ$C quantisation error. The general rule: $(f \circ g)^{-1} = g^{-1} \circ f^{-1}$ — undo the last operation first.

Inverse of a composite

If f and g are one-to-one and $f \circ g$ is defined, then

$$(f \circ g)^{-1} = g^{-1} \circ f^{-1}.$$

(To undo "put on socks, then shoes", take off the shoes first.)

Inverse trigonometric functions

sin, cos and tan are periodic, hence far from one-to-one. Their inverses are defined by restricting each to a **principal** interval on which it is strictly monotonic and takes every value once.

Function	Domain	Range (principal values)	Restriction inverted
$\arcsin x$	$[-1, 1]$	$[-\pi/2, \pi/2]$	sin on $[-\pi/2, \pi/2]$
$\arccos x$	$[-1, 1]$	$[0, \pi]$	cos on $[0, \pi]$
$\arctan x$	$\mathbb{R}$	$(-\pi/2, \pi/2)$	tan on $(-\pi/2, \pi/2)$

Useful identities, valid on the stated domains:

$$\arcsin x + \arccos x = \frac{\pi}{2}, \qquad \arctan x + \arctan \frac{1}{x} = \frac{\pi}{2}\ (x > 0), \qquad \arcsin(-x) = -\arcsin x, \qquad \arccos(-x) = \pi - \arccos x.$$

Worked Example 1.52 — Compositions with inverse trig functions

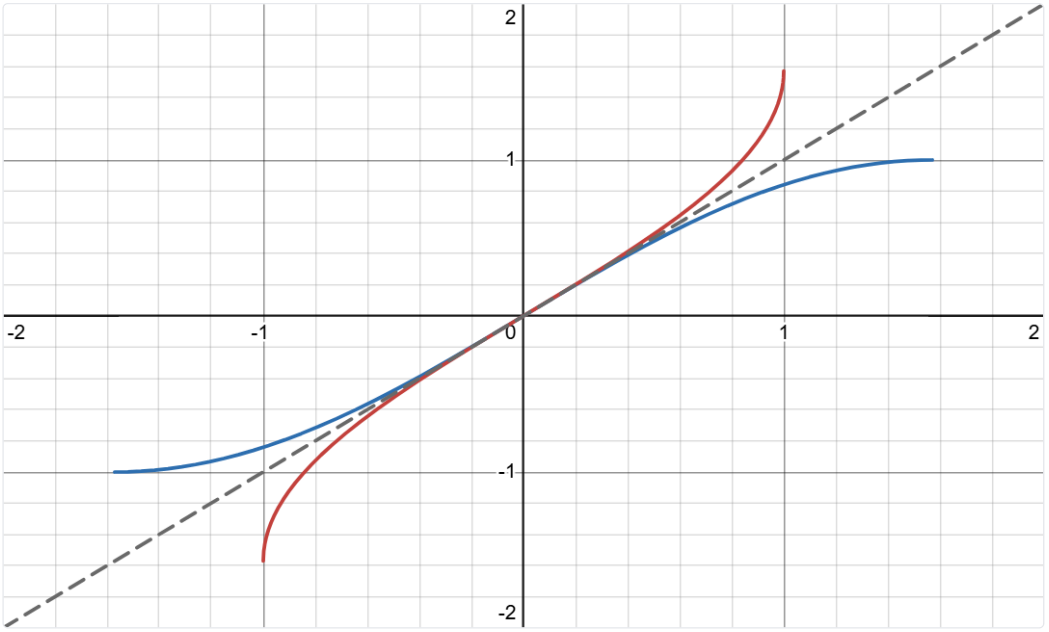
(a) Simplify $\cos(\arctan x)$. Let $\theta = \arctan x \in (-\pi/2, \pi/2)$, so $\tan\theta = x$ and $\cos\theta > 0$. From $1 + \tan^2\theta = \sec^2\theta$,

$$\cos(\arctan x) = \frac{1}{\sqrt{1+x^2}}.$$

(A right triangle with opposite side x and adjacent side 1 gives the same result.) **Check** at $x = 2$: $\cos(1.1071) = 0.4472 = 1/\sqrt{5}$ ✓.

(b) Similarly $\sin(\arccos x) = \sqrt{1-x^2}$, positive because $\arccos x \in [0, \pi]$.

(c) $\arcsin(\sin 2.5)$ is **not** 2.5, since $2.5 \notin [-\pi/2, \pi/2]$. Using $\sin(\pi - \theta) = \sin\theta$, $\sin 2.5 = \sin(\pi - 2.5)$ with $\pi - 2.5 = 0.6416$ in the principal range, so $\arcsin(\sin 2.5) = 0.6416$.



$\sin x$ restricted to $[-\pi/2, \pi/2]$ (blue) and its inverse $\arcsin x$ (red) are reflections of each other in $y = x$.

Inverse hyperbolic functions

sinh is strictly increasing on $\mathbb{R}$ and tanh on $\mathbb{R}$ (onto $(-1, 1)$); cosh is one-to-one on $[0, \infty)$. Since they are built from exponentials, their inverses are logarithms.

Inverse hyperbolic functions

$$\operatorname{arsinh} x = \ln\left(x + \sqrt{x^2+1}\right), \qquad \operatorname{arcosh} x = \ln\left(x + \sqrt{x^2-1}\right)\ (x \geq 1), \qquad \operatorname{artanh} x = \frac{1}{2}\ln\frac{1+x}{1-x}\ (|x| < 1).$$

Derivation of arsinh. Set $x = \sinh y = \frac{1}{2}(e^y - e^{-y})$ and multiply by $2e^y$: $e^{2y} - 2xe^y - 1 = 0$, a quadratic in $u = e^y$. Its roots are $u = x \pm \sqrt{x^2+1}$; only the $+$ root is positive, so $e^y = x + \sqrt{x^2+1}$ and $y = \ln\left(x + \sqrt{x^2+1}\right)$. □

Check: $\operatorname{arsinh} 2 = \ln(2 + \sqrt{5}) = 1.4436$ and $\sinh(1.4436) = 2.000$ ✓. Inverse hyperbolic functions appear in the capacitance of two parallel wires, $C' = \pi\varepsilon/\operatorname{arcosh}(d/2a)$, and in the design of Chebyshev filters.

Common Pitfall — the -1 superscript

$\sin^{-1} x$ means $\arcsin x$, **not** $1/\sin x = \csc x$; yet $\sin^2 x$ means $(\sin x)^2$. Likewise $f^{-1}(x)$ is the inverse function, which is in general **not** $1/f(x)$. Prefer the unambiguous names arcsin, arccos, arctan. Also, $f^{-1}(f(x)) = x$ holds only on the domain on which f was inverted.

Engineering Note — calibration and linearisation

Inverting a sensor characteristic is called **calibration** or **linearisation**. When the forward model has no closed-form inverse (a thermocouple polynomial, the full diode equation with series resistance), the inverse is computed numerically — by a lookup table with interpolation, or by Newton's method (Ch. 22). Either way the forward function must be one-to-one on the measuring range, or the reading is ambiguous.

1.10 Mathematical notation and dimensional consistency

Why notation and dimensions

Mathematics is a language with a compact, precise grammar. Datasheets, standards, textbooks and papers state results as "for all $\varepsilon > 0$ there exists $\delta > 0$ such that…", or "$P \Rightarrow Q$", or with nested sums; misreading a quantifier or the direction of an implication changes the meaning entirely. At the same time, every equation an engineer writes describes physical quantities, and physical quantities carry **dimensions**. Requiring both sides of every equation to have the same

dimensions is the cheapest, fastest error check there is — it catches most algebra slips in seconds, before any numbers are substituted.

Logic and set notation

Symbol	Meaning	Symbol	Meaning
$\forall$	for all	$\exists$	there exists
$\exists!$	there exists exactly one	$\neg P$	not P
$P \Rightarrow Q$	P implies Q	$P \iff Q$	P if and only if Q
$\wedge$, $\vee$	and, or (inclusive)	$:=$ or $\equiv$	is defined as
$\in$, $\notin$	is / is not an element of	$\subseteq$, $\subset$	subset of, proper subset of
$\cup$, $\cap$	union, intersection	$A \setminus B$	elements of A not in B
$\varnothing$	empty set	$A \times B$	Cartesian product (ordered pairs)
$\approx$	approximately equal	$\propto$	proportional to
$\sim$	asymptotically equal / of the order of	$\ll$, $\gg$	much less, much greater than

Set-builder notation describes a set by a property: $\{x \in \mathbb{R} : x^2 < 4\} = (-2, 2)$, read "the set of real x such that $x^2 < 4$". **Cartesian products** build multi-dimensional spaces: $\mathbb{R}^2 = \mathbb{R} \times \mathbb{R}$ is the plane, $\mathbb{R}^3$ is space.

Implication. $P \Rightarrow Q$ says that whenever P is true, Q is true. Then P is **sufficient** for Q and Q is **necessary** for P. The implication is equivalent to its **contrapositive** $\neg Q \Rightarrow \neg P$, but **not** to its **converse** $Q \Rightarrow P$. For example, "if a system is linear and time-invariant, its response to a sinusoid is a sinusoid at the same frequency" is true; the converse is false. "$P \iff Q$" asserts both directions.

Quantifiers. The order matters. "$\forall x \, \exists y : y > x$" (every number has a larger one) is true; "$\exists y \, \forall x : y > x$" (some number is larger than every number) is false. To negate a quantified statement, swap $\forall$ and $\exists$ and negate the inner statement: $\neg(\forall x : P(x)) \iff \exists x : \neg P(x)$. So disproving "all transistors in this batch meet spec" needs only one counter-example.

Proof techniques

Four patterns cover nearly every argument in this book:

- **Direct proof:** assume P, deduce Q (the proof of the triangle inequality in Section 1.1).
- **Contrapositive:** assume $\neg Q$, deduce $\neg P$.
- **Contradiction:** assume the statement false and derive an absurdity (the irrationality of $\sqrt{2}$).
- **Induction:** to prove $P(n)$ for all $n \in \mathbb{N}$, prove $P(1)$ (base case) and $P(n) \Rightarrow P(n+1)$ (inductive step).

Worked Example 1.53 — Proof by induction

Prove $\displaystyle\sum_{k=1}^{n} k = \frac{n(n+1)}{2}$ for all $n \in \mathbb{N}$.

Base case. $n = 1$: LHS $= 1$, RHS $= \frac{1 \cdot 2}{2} = 1$ ✓.

Inductive step. Assume the formula for n. Then

$$\sum_{k=1}^{n+1} k = \frac{n(n+1)}{2} + (n+1) = \frac{(n+1)(n+2)}{2},$$

which is the formula for $n+1$. By induction it holds for all n. □

Check at $n = 100$: 5050 — the sum Gauss is said to have found as a schoolboy by pairing $1 + 100$, $2 + 99$, … .

Sums and products

$$\sum_{k=1}^{n} a_k = a_1 + a_2 + \cdots + a_n, \qquad \prod_{k=1}^{n} a_k = a_1 a_2 \cdots a_n.$$

The index k is a **dummy variable**: $\sum_{k=1}^{n} a_k = \sum_{i=1}^{n} a_i$. Rules that follow from the field axioms:

$$\sum_{k} (c a_k + b_k) = c \sum_{k} a_k + \sum_{k} b_k, \qquad \sum_{k=1}^{n} a_k = \sum_{m=0}^{n-1} a_{m+1} \ \ (\text{shift } m = k-1), \qquad \sum_{k=1}^{n} c = nc.$$

But $\sum a_k b_k \neq \left(\sum a_k\right)\left(\sum b_k\right)$ in general. Useful closed forms:

$$\sum_{k=1}^{n} k = \frac{n(n+1)}{2}, \qquad \sum_{k=1}^{n} k^2 = \frac{n(n+1)(2n+1)}{6}, \qquad \sum_{k=1}^{n} k^3 = \left(\frac{n(n+1)}{2}\right)^2.$$

(Check: $\sum_{k=1}^{10} k^2 = 385 = \frac{10 \cdot 11 \cdot 21}{6}$ ✓.)

Geometric series

For $r \neq 1$,

$$\sum_{k=0}^{n-1} r^k = 1 + r + r^2 + \cdots + r^{n-1} = \frac{1 - r^n}{1 - r},$$

and for $|r| < 1$ the infinite series converges:

$$\sum_{k=0}^{\infty} r^k = \frac{1}{1 - r}.$$

Proof. Let $S = 1 + r + \cdots + r^{n-1}$. Then $rS = r + r^2 + \cdots + r^n$, and subtracting, $S - rS = 1 - r^n$ — all other terms cancel ("telescope"). Divide by $1 - r$. If $|r| < 1$ then $r^n \to 0$ as $n \to \infty$, giving the infinite sum. □

Worked Example 1.54 — Geometric sums in digital systems

(a) Binary full scale. An 8-bit unsigned register holds at most $\sum_{k=0}^{7} 2^k = \dfrac{1 - 2^8}{1 - 2} = 255$.

(b) Echoes. A signal is reflected repeatedly so that each echo has half the amplitude of the previous one. The total of the original plus all echoes is $\sum_{k=0}^{\infty} 0.5^k = \dfrac{1}{1 - 0.5} = 2$ times the original amplitude; the first ten terms already give 1.998.

(c) Feedback. In a loop with forward gain A and feedback β, a signal circulating repeatedly sums to $A \sum_{k=0}^{\infty} (-A\beta)^k = \dfrac{A}{1 + A\beta}$ when $|A\beta| < 1$ — the closed-loop gain of Example 1.9(b) seen as a geometric series.

Check (b): $(1 - 0.5^{10})/0.5 = 1.998047$ ✓.

The geometric series underlies discrete-time systems, the Z-transform (Ch. 17) and the analysis of convergence of iterative algorithms.

Order-of-magnitude notation

Big-O notation states how fast a quantity grows or shrinks: $f(x) = O(g(x))$ as $x \to 0$ means $|f(x)| \leq M|g(x)|$ for some constant M and all small enough x. Thus $\sin x = x + O(x^3)$ and $(1 + x)^n = 1 + nx + O(x^2)$, which makes precise the size of the error in the approximations of Sections 1.2 and 1.6. As $n \to \infty$, Big-O describes algorithm cost: Gaussian elimination needs $O(n^3)$ operations, the FFT $O(n \log n)$ (Ch. 24).

Dimensions and units

Every physical quantity has a **dimension** built from the seven SI base dimensions: M (mass), L (length), T (time), I (electric current), Θ (temperature), N (amount of substance), J (luminous intensity). The dimension of a quantity Q is written $[Q]$. Derived dimensions follow from defining equations:

Quantity	Defining relation	Dimension	SI unit
Charge Q	$Q = It$	$\mathrm{T\,I}$	C
Force F	$F = ma$	$\mathrm{M\,L\,T^{-2}}$	N
Energy W	force × distance	$\mathrm{M\,L^2\,T^{-2}}$	J
Power P	W/t	$\mathrm{M\,L^2\,T^{-3}}$	W
Voltage V	P/I	$\mathrm{M\,L^2\,T^{-3}\,I^{-1}}$	V
Resistance R	V/I	$\mathrm{M\,L^2\,T^{-3}\,I^{-2}}$	Ω
Conductance G	$1/R$	$\mathrm{M^{-1}\,L^{-2}\,T^{3}\,I^{2}}$	S
Capacitance C	Q/V	$\mathrm{M^{-1}\,L^{-2}\,T^{4}\,I^{2}}$	F
Inductance L	$V\,t/I$	$\mathrm{M\,L^2\,T^{-2}\,I^{-2}}$	H
Magnetic flux Φ	$V\,t$	$\mathrm{M\,L^2\,T^{-2}\,I^{-1}}$	Wb
Electric field E	V/length	$\mathrm{M\,L\,T^{-3}\,I^{-1}}$	V/m
Permittivity ε	C·length/area	$\mathrm{M^{-1}\,L^{-3}\,T^{4}\,I^{2}}$	F/m
Permeability μ	L·length/area	$\mathrm{M\,L\,T^{-2}\,I^{-2}}$	H/m
Conductivity σ	G·length/area	$\mathrm{M^{-1}\,L^{-3}\,T^{3}\,I^{2}}$	S/m
Frequency f, ω	cycles or radians per second	$\mathrm{T^{-1}}$	Hz, rad/s

Rules of dimensional consistency

1. Only quantities of the **same dimension** may be added, subtracted, equated or compared.
2. Dimensions **multiply and divide** like algebraic symbols, and powers apply to them: $[x^n] = [x]^n$.
3. The arguments of exp, ln, sin, cos, tanh and of any other function defined by a power series must be **dimensionless**, and so are the values of these functions.
4. Pure numbers (2, π, $\frac{1}{2}$) and angles in radians are dimensionless.

Why rule 3 holds. $e^x = 1 + x + \frac{x^2}{2} + \dots$ adds 1, x and x^2; by rule 1 this is possible only if x is dimensionless. The same argument applies to every function with a power series. □

Worked Example 1.55 — Checking time constants and energy

(a) $[RC] = \mathrm{M\,L^2\,T^{-3}\,I^{-2}} \cdot \mathrm{M^{-1}L^{-2}T^4I^2} = \mathrm{T}$, so $e^{-t/RC}$ has a dimensionless exponent ✓.

(b) $[L/R] = \dfrac{\mathrm{M\,L^2\,T^{-2}\,I^{-2}}}{\mathrm{M\,L^2\,T^{-3}\,I^{-2}}} = \mathrm{T}$ ✓.

(c) $[LC] = \mathrm{T^2}$, so $\omega_0 = 1/\sqrt{LC}$ has dimension $\mathrm{T^{-1}}$ — a frequency ✓.

(d) Capacitor energy $W = \frac{1}{2}CV^2$: $[C][V]^2 = \mathrm{M^{-1}L^{-2}T^4I^2} \cdot \mathrm{M^2L^4T^{-6}I^{-2}} = \mathrm{M\,L^2\,T^{-2}}$, an energy ✓. Numerically $\frac{1}{2}(100\ \mu\mathrm{F})(20\ \mathrm{V})^2 = 0.02\ \mathrm{J}$.

(e) A formula claiming $\tau = R/C$ fails immediately: $[R/C] = \mathrm{M^2L^4T^{-7}I^{-4}} \neq \mathrm{T}$.

Worked Example 1.56 — Checking an electromagnetic formula

(a) Speed of light. $[\mu\varepsilon] = \mathrm{M\,L\,T^{-2}I^{-2}} \cdot \mathrm{M^{-1}L^{-3}T^4I^2} = \mathrm{L^{-2}T^2}$, so $1/\sqrt{\mu_0\varepsilon_0}$ is a speed. Numerically $1/\sqrt{(8.854\times10^{-12})(4\pi\times10^{-7})} = 2.998\times10^8\ \mathrm{m/s}$ ✓.

(b) Skin depth. The claimed formula $\delta = \sqrt{2/(\omega\mu\sigma)}$ should be a length. $[\omega\mu\sigma] = \mathrm{T^{-1}} \cdot \mathrm{M\,L\,T^{-2}I^{-2}} \cdot \mathrm{M^{-1}L^{-3}T^3I^2} = \mathrm{L^{-2}}$, so $[\delta] = \mathrm{L}$ ✓. For copper ($\sigma = 5.8\times10^7\ \mathrm{S/m}$, $\mu = \mu_0$) at 60 Hz, $\delta = 8.53$ mm; at 1 MHz, $\delta = 66\ \mu$m.

Dimensional analysis as a design tool

Dimensional consistency can do more than check formulas: it can predict their form. If a quantity depends only on a known list of others, its formula must be a product of powers with matching dimensions.

Worked Example 1.57 — Predicting the resonance formula

Suppose the resonant angular frequency of an ideal LC circuit depends only on L and C: $\omega_0 = k\,L^aC^b$ with k dimensionless. Find a and b.

Step 1 — dimensions. $\mathrm{T^{-1}} = \left(\mathrm{M\,L^2T^{-2}I^{-2}}\right)^a \left(\mathrm{M^{-1}L^{-2}T^4I^2}\right)^b$.

Step 2 — match exponents. M: $a - b = 0$. L: $2a - 2b = 0$. I: $-2a + 2b = 0$. T: $-2a + 4b = -1$.

Step 3 — solve. $a = b$ and $2a = -1$, so $a = b = -\frac{1}{2}$, giving $\omega_0 = k/\sqrt{LC}$.

The analysis cannot find k (circuit analysis gives $k = 1$), but it pins down the structure. Its systematic form, the Buckingham π theorem, is developed in Ch. 25.

Units, prefixes and conversions

Dimensions say *what kind* of quantity; **units** say *how much*. SI prefixes scale units by powers of 10^3:

Prefix	p	n	μ	m	k	M	G
Factor	10^{-12}	10^{-9}	10^{-6}	10^{-3}	10^3	10^6	10^9

Convert by multiplying by factors equal to one, such as $\frac{10^{-9}\ \mathrm{F}}{1\ \mathrm{nF}}$, so that units cancel algebraically. Prefixes bind to the unit before powers apply: $1\ \mathrm{cm^2} = (10^{-2}\ \mathrm{m})^2 = 10^{-4}\ \mathrm{m^2}$, not $10^{-2}\ \mathrm{m^2}$. Treat units as algebraic symbols throughout a calculation and the final unit appears automatically — if it is not the expected one, there is an error.

Common Pitfall — dimensionless is not unitless in practice

Angles are dimensionless, but radians and degrees are different units: ωt must be in radians for $\sin\omega t$ to be correct with ω in rad/s. Hertz and rad/s have the same dimension $\mathrm{T^{-1}}$ but differ by 2π — a dimensional check cannot catch f written for ω. Likewise decibels are dimensionless but need a stated reference (Section 1.5).

Engineering Note

Dimensional checking cannot detect missing dimensionless factors (2π, $\frac{1}{2}$, $\sqrt{2}$), but it catches the majority of algebra slips in seconds. Make it a habit: check the dimensions of every derived formula before substituting numbers, check limiting cases (what happens as $R \to 0$ or $\omega \to \infty$?), and estimate the order of magnitude of the answer before trusting a calculator.

Summary

Topic	Key result
Number sets	$\mathbb{N} \subset \mathbb{Z} \subset \mathbb{Q} \subset \mathbb{R} \subset \mathbb{C}$; $\mathbb{C}$ is not ordered
Triangle inequality	$\lvert x+y\rvert \le \lvert x\rvert + \lvert y\rvert$, $\big\lvert\lvert x\rvert - \lvert y\rvert\big\rvert \le \lvert x-y\rvert$
Machine epsilon (double)	$\varepsilon_{\text{mach}} = 2^{-52} \approx 2.2\times10^{-16}$

Topic	Key result
Binomial theorem	$(a+b)^n = \sum_{k=0}^{n} \binom{n}{k} a^{n-k} b^k,\ \binom{n}{k} = \dfrac{n!}{k!(n-k)!}$
Binomial approximation	$(1+x)^n \approx 1 + nx,\ \lvert x\rvert \ll 1$, any real n
Completing the square	$ax^2 + bx + c = a\left(x + \frac{b}{2a}\right)^2 + c - \frac{b^2}{4a}$
Quadratic formula	$x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$; stable form $q = -\frac{1}{2}\big(b + \operatorname{sgn}(b)\sqrt{\Delta}\big)$, $x_1 = q/a$, $x_2 = c/q$
Vieta (quadratic)	$x_1 + x_2 = -b/a,\ x_1 x_2 = c/a$
Cramer (2×2)	$x = \dfrac{c_1 b_2 - c_2 b_1}{a_1 b_2 - a_2 b_1},\ y = \dfrac{a_1 c_2 - a_2 c_1}{a_1 b_2 - a_2 b_1}$
AM–GM	$\frac{1}{2}(a+b) \geq \sqrt{ab}$, equality iff $a = b$
Remainder / factor theorem	$p(x) \bmod (x-r) = p(r);\ p(r) = 0 \iff (x-r) \mid p(x)$
Fundamental theorem of algebra	$p(x) = a_n \prod_{i=1}^{n} (x - r_i)$; real coefficients $\Rightarrow$ conjugate pairs
Cover-up rule	$A = \Big[(x-a)R(x)\Big]_{x=a}$
Repeated pole	$A_{m-k} = \dfrac{1}{k!}\dfrac{d^k}{dx^k}\Big[(x-a)^m R(x)\Big]_{x=a}$
Euler's number	$e = \lim_{n\to\infty}(1+1/n)^n = \sum 1/k! = 2.71828\ldots$
Logarithms	$\log(xy) = \log x + \log y,\ \log x^p = p \log x,\ \log_a x = \ln x / \ln a$
First-order transient	$e^{-t/\tau}$; $t_{10\%} = \tau \ln 10$; 10–90 % rise time $= \tau \ln 9 = 2.197\tau$
Decibels	$10 \log_{10}(P_2/P_1) = 20 \log_{10}(V_2/V_1)$; 0 dBm $= 1$ mW
Hyperbolic	$\cosh x = \frac{1}{2}(e^x + e^{-x})$, $\sinh x = \frac{1}{2}(e^x - e^{-x})$, $\cosh^2 x - \sinh^2 x = 1$
Pythagorean identity	$\sin^2\theta + \cos^2\theta = 1,\ 1 + \tan^2\theta = \sec^2\theta$
Compound angle	$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B,\ \sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$
Double angle / power reduction	$\sin 2\theta = 2\sin\theta\cos\theta,\ \cos^2\theta = \frac{1}{2}(1 + \cos 2\theta)$
Product-to-sum	$\cos A \cos B = \frac{1}{2}[\cos(A-B) + \cos(A+B)]$
Harmonic addition	$a\cos\theta + b\sin\theta = \sqrt{a^2+b^2}\cos\big(\theta - \operatorname{atan2}(b,a)\big)$
Law of cosines	$c^2 = a^2 + b^2 - 2ab\cos C$
Polar	$r = \sqrt{x^2+y^2},\ \theta = \operatorname{atan2}(y,x)$
Cylindrical (r,ϕ,z)	$x = r\cos\phi,\ y = r\sin\phi;\ dV = r\,dr\,d\phi\,dz$
Spherical (R,θ,ϕ)	$x = R\sin\theta\cos\phi,\ y = R\sin\theta\sin\phi,\ z = R\cos\theta;\ dV = R^2\sin\theta\,dR\,d\theta\,d\phi$
Even–odd split	$f_e = \frac{1}{2}[f(x) + f(-x)],\ f_o = \frac{1}{2}[f(x) - f(-x)]$
Graph transformation	$A\,f\big(b(x-c)\big) + d$: shift right c, scale by $1/b$ horizontally, A vertically, up d
Inverse of composite	$(f \circ g)^{-1} = g^{-1} \circ f^{-1}$
Inverse hyperbolic	$\operatorname{arsinh} x = \ln\left(x + \sqrt{x^2+1}\right),\ \operatorname{artanh} x = \frac{1}{2}\ln\frac{1+x}{1-x}$
Geometric series	$\sum_{k=0}^{n-1} r^k = \dfrac{1-r^n}{1-r};\ \sum_{k=0}^{\infty} r^k = \dfrac{1}{1-r},\ \lvert r\rvert < 1$
Dimensions	$[V] = \mathrm{M\,L^2T^{-3}I^{-1}}$; $[RC] = [L/R] = \mathrm{T}$; $[LC] = \mathrm{T^2}$; arguments of exp, ln, sin dimensionless

Chapter 2 — Complex Numbers and Engineering Representation

> **Prerequisites:** Ch. 1 (algebra, polynomials, exponentials and logarithms, trigonometric identities, polar coordinates) **Learning outcomes:** After this chapter you can
>
> - move freely between rectangular, polar and exponential forms of a complex number, getting the quadrant of the angle right every time;
> - add, multiply, divide, conjugate and take magnitudes of complex numbers, choosing the form that makes each operation easiest;
> - use Euler's formula to turn trigonometric identities, sums and integrals into algebra with exponentials;
> - compute integer powers and all n-th roots of a complex number, and use roots of unity;
> - interpret complex arithmetic geometrically and describe curves and regions of the complex plane;
> - represent sinusoids as phasors, solve sinusoidal steady-state problems algebraically, and express impedances and transfer functions as complex functions of $j\omega$ or s.

A sinusoidal signal is described by two numbers — an amplitude and a phase. A complex number is also two numbers, and complex multiplication combines magnitudes and angles in exactly the way that linear circuits combine amplitudes and phases. That coincidence, which turns out to be no coincidence at all, is why every alternating-current calculation in electrical engineering, every frequency response, every Fourier and Laplace transform and every digital filter is written in complex numbers.

Historically, complex numbers were not invented to solve $x^2 + 1 = 0$; mathematicians were content to say that equation had no solution. They were forced on sixteenth-century algebraists by the *cubic* formula, which for equations with three perfectly real roots (such as $x^3 - 15x - 4 = 0$, whose roots include $x = 4$) produces intermediate expressions like $\sqrt{-121}$. The square roots of negative numbers cancel at the end, but there is no way to avoid them on the way. The lesson carries straight into engineering: complex numbers are a *computational device* that often lets you reach a real answer by the shortest route. A circuit's voltages are real, its transient responses are real, its measured gains are real — yet the shortest path to all of them runs through $\mathbb{C}$.

This chapter is the mathematical foundation for that path. Sections 2.1–2.3 build the algebra, Sections 2.4–2.6 the exponential machinery that makes it powerful, Section 2.7 the geometry, and Sections 2.8–2.9 show how the whole apparatus becomes the phasor method and the language of impedance and transfer functions. Complex *functions* — differentiation, contour integration and residues — are deferred to Ch. 18.

2.1 Rectangular and polar forms

Why two forms?

An engineer meets complex numbers in two guises. A network analyser reports an impedance as "$40 - j30\ \Omega$" — a resistance and a reactance, the **rectangular** description. An oscilloscope comparing two sinusoids reports "amplitude ratio 0.8, phase $-36.9°$" — a magnitude and an angle, the **polar** description. They are the same complex number seen in two coordinate systems, exactly as a point in the plane can be given by (x, y) or by (r, θ) (Ch. 1, Section 1.7). Fluency means converting between them without thinking and knowing which one a given operation prefers.

Definition and the complex number system

Complex number

A **complex number** is an expression $z = a + jb$ with $a, b \in \mathbb{R}$, where the **imaginary unit** j satisfies $j^2 = -1$. The real number $a = \mathrm{Re}\{z\}$ is the **real part** and the real number $b = \mathrm{Im}\{z\}$ is the **imaginary part** (note: b, not jb). The writing $a + jb$ is the **rectangular** (Cartesian) form. The set of all complex numbers is $\mathbb{C}$.

A number with $b = 0$ is **real**; a number with $a = 0$, $b \neq 0$ is **purely imaginary**.

Equality

Two complex numbers are equal if and only if their real parts are equal **and** their imaginary parts are equal:

$$a + jb = c + jd \iff a = c \ \text{ and } \ b = d.$$

The equality rule is more powerful than it looks: **one complex equation is two real equations.** Many derivations in circuit theory exploit exactly this — a single complex KVL equation delivers both an amplitude condition and a phase condition.

A rigorous construction, for readers who distrust a symbol "whose square is -1": define $\mathbb{C}$ as the set of ordered pairs (a, b) of reals with

$$(a, b) + (c, d) = (a + c,\ b + d), \qquad (a, b) \cdot (c, d) = (ac - bd,\ ad + bc).$$

One checks that these operations obey all the usual laws of arithmetic (commutative, associative, distributive, with $(0, 0)$ and $(1, 0)$ as additive and multiplicative identities). Pairs $(a, 0)$ behave exactly like the real numbers a, and the pair $j = (0, 1)$ satisfies $j \cdot j = (0 \cdot 0 - 1 \cdot 1,\ 0) = (-1, 0) = -1$. Writing $(a, b) = a + jb$ recovers the familiar notation. So complex numbers are nothing more mysterious than points of the plane with a cleverly chosen multiplication rule — the rule is what makes them useful.

Common Pitfall — $\mathbb{C}$ is not ordered

There is no meaningful "$z_1 < z_2$" for complex numbers. Statements such as "$3 + j4 > 2$" are meaningless. Only real quantities derived from complex numbers — magnitudes, real parts, imaginary parts, angles — can be compared. When an engineer says "this impedance is larger", they mean $|Z|$ is larger.

The complex plane and polar coordinates

Plot $z = a + jb$ as the point (a, b), with the real axis horizontal and the imaginary axis vertical. Its distance from the origin and its angle measured anticlockwise from the positive real axis give the **polar form**.

Magnitude, argument, polar form

For $z = a + jb \neq 0$,

$$r = |z| = \sqrt{a^2 + b^2}, \qquad \theta = \arg z = \angle z, \quad \text{where } \cos\theta = \frac{a}{r},\ \sin\theta = \frac{b}{r}.$$

Then

$$z = r(\cos\theta + j\sin\theta), \qquad a = r\cos\theta, \quad b = r\sin\theta.$$

Engineers abbreviate this as $z = r\angle\theta$. The quantity $r \geq 0$ is the **magnitude** (modulus, absolute value) and θ the **argument** (angle, phase). The argument is defined only up to multiples of 2π; the **principal argument** $\operatorname{Arg} z$ is the value in $(-\pi, \pi]$. For $z = 0$ the magnitude is 0 and the argument is undefined.

Both $\cos\theta = a/r$ **and** $\sin\theta = b/r$ are needed to fix θ; either one alone leaves two candidate angles. The ratio $\tan\theta = b/a$ also leaves two candidates, π apart, which is the source of the most common error in this whole subject.

The quadrant problem and atan2

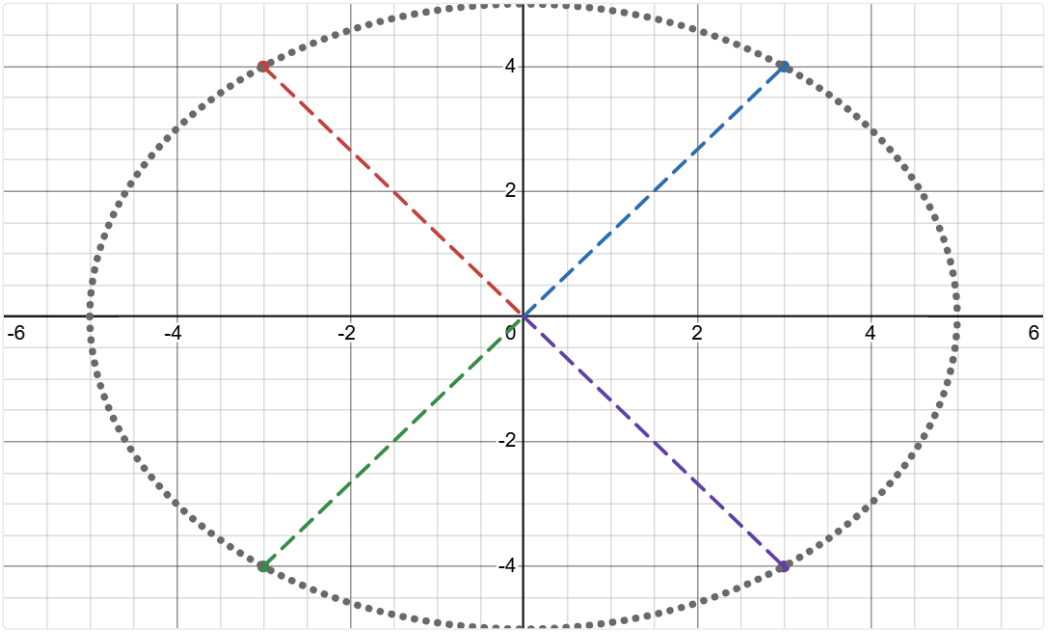
The calculator function arctan returns values in $(-\pi/2, \pi/2)$ — the right half-plane only. It therefore gives the correct argument only when $a > 0$. The correct rule is the two-argument arctangent:

Two-argument arctangent

$$\operatorname{atan2}(b, a) = \begin{cases} \arctan(b/a), & a > 0, \\ \arctan(b/a) + \pi, & a < 0,\ b \geq 0, \\ \arctan(b/a) - \pi, & a < 0,\ b < 0, \\ +\pi/2, & a = 0,\ b > 0, \\ -\pi/2, & a = 0,\ b < 0. \end{cases}$$

It returns $\operatorname{Arg}(a + jb) \in (-\pi, \pi]$. It is available as `atan2(b, a)` in C, Python, MATLAB and spreadsheets (spreadsheets often reverse the argument order — check).

The geometric content is simple: points in the second and third quadrants have arguments of magnitude greater than 90°, and arctan can never return such a value, so a correction of $\pm 180^\circ$ is required there.



The four points $\pm 3 \pm j4$ all have magnitude 5 and $|\tan\theta| = 4/3$, but their arguments are 53.13°, 126.87°, -126.87° and -53.13°. Only the sign pattern of (a, b) distinguishes them.

Degrees and radians

Engineers quote phase angles in degrees ($10\angle -30^\circ$) because instruments do; mathematics and every exponential formula require radians. Convert with $\theta_{\text{rad}} = \theta_{\text{deg}} \cdot \pi/180$. The convention in this book: when an angle carries a degree sign it is in degrees; otherwise it is in radians. Inside an exponent ($e^{j\theta}$, Section 2.4) the angle is **always** in radians.

Worked Example 2.1 — Rectangular to polar

Convert $3+j4$, $-3+j4$, $-1-j$, -2, $j5$ and $-5-j12$ to polar form.

Step 1 — magnitude. $|3+j4| = \sqrt{9+16} = 5$; $|-3+j4| = 5$; $|-1-j| = \sqrt{2} \approx 1.4142$; $|-2| = 2$; $|j5| = 5$; $|-5-j12| = \sqrt{25+144} = 13$.

Step 2 — locate the quadrant, then the angle.

- $3+j4$: first quadrant, $\theta = \arctan\frac{4}{3} = 53.13^\circ$ (0.9273 rad).
- $-3+j4$: second quadrant, $\arctan\frac{4}{-3} = -53.13^\circ$ is wrong; add 180°: $\theta = 126.87^\circ$.
- $-1-j$: third quadrant, $\arctan\frac{-1}{-1} = 45^\circ$ is wrong; subtract 180°: $\theta = -135^\circ = -3\pi/4$.
- -2: negative real axis, $\theta = 180^\circ = \pi$ (principal value $+\pi$, not $-\pi$).
- $j5$: positive imaginary axis, $\theta = 90^\circ$; $\arctan(5/0)$ is undefined, so use the special case.
- $-5-j12$: third quadrant, $\arctan\frac{12}{5} = 67.38^\circ$, so $\theta = 67.38^\circ - 180^\circ = -112.62^\circ$.

z	$\lvert z\rvert$	Arg z
$3+j4$	5	53.13°
$-3+j4$	5	126.87°
$-1-j$	1.4142	-135°
-2	2	180°
$j5$	5	90°
$-5-j12$	13	-112.62°

Check one of them backwards: $13\cos(-112.62^\circ) = 13(-0.3846) = -5.00$ and $13\sin(-112.62^\circ) = 13(-0.9231) = -12.00$. ✓

Worked Example 2.2 — Polar to rectangular

Convert $10\angle -30^\circ$, $25\angle 143.13^\circ$, $4\angle\frac{5\pi}{6}$ and $2\angle 200^\circ$.

Use $a = r\cos\theta$, $b = r\sin\theta$ — no quadrant care is needed in this direction, because cosine and sine carry the signs automatically.

- $10\angle -30^\circ = 10(0.8660) + j10(-0.5) = 8.660 - j5.000$.
- $25\angle 143.13^\circ = 25(-0.8000) + j25(0.6000) = -20.00 + j15.00$.
- $4\angle\frac{5\pi}{6} = 4\left(-\frac{\sqrt{3}}{2}\right) + j4\left(\frac{1}{2}\right) = -2\sqrt{3} + j2 \approx -3.464 + j2.000$.
- $2\angle 200^\circ = 2(-0.9397) + j2(-0.3420) = -1.879 - j0.684$. Note that 200° is not a principal argument; the same number is $2\angle -160^\circ$.

Worked Example 2.3 — Using equality of complex numbers

Find real x and y such that $(x+jy)(2-j) = 7+j4$.

Expand the left side: $(x+jy)(2-j) = 2x - jx + j2y - j^2y = (2x+y) + j(2y-x)$.

Equate real and imaginary parts — one complex equation gives two real ones:

$$2x + y = 7, \qquad -x + 2y = 4.$$

From the second, $x = 2y - 4$; substituting, $4y - 8 + y = 7$, so $y = 3$ and $x = 2$.

Check: $(2+j3)(2-j) = 4 - j2 + j6 - j^2 3 = 4 + 3 + j4 = 7 + j4$. ✓

(Section 2.3 gives a quicker route: $x + jy = (7+j4)/(2-j)$.)

Worked Example 2.4 — An impedance measurement

An impedance analyser reports $|Z| = 50\ \Omega$ and $\angle Z = -36.87^\circ$ for an unknown component at 1 kHz. Find the series resistance and reactance, and say whether the component behaves capacitively or inductively.

$$Z = 50\cos(-36.87^\circ) + j50\sin(-36.87^\circ) = 40.0 - j30.0\ \Omega.$$

The resistance is $R = 40\ \Omega$ and the reactance $X = -30\ \Omega$. A negative reactance is capacitive (Section 2.9: $Z_C = -j/(\omega C)$). If the reactance comes from a pure capacitor, $1/(\omega C) = 30$, so $C = 1/(2\pi \cdot 1000 \cdot 30) = 5.31\ \mu\text{F}$.

Check: $\sqrt{40^2 + 30^2} = 50$ ✓ and $\operatorname{atan2}(-30, 40) = -36.87^\circ$ ✓.

Common Pitfall — the calculator arctangent

A calculator's $\tan^{-1}$ gives $\arctan\frac{-1}{-1} = \arctan 1 = 45^\circ$ for $-1-j$, which is the angle of $1+j$ — the diametrically opposite point. **Always sketch the point first** (or at least note the signs of a and b), or use `atan2`. A phase error of exactly 180° in a circuit result is almost always this mistake: it flips the sign of the entire signal.

Engineering Note — which form do instruments use?

Network and impedance analysers can display either form: "$R + jX$" (rectangular), "$|Z|, \theta$" (polar), or on a Smith chart (a geometric map, Section 2.7). Oscilloscopes and lock-in amplifiers naturally measure magnitude and phase, or the **in-phase** (I) and **quadrature** (Q) components a and b. In digital communications, a received symbol is literally a complex number $I + jQ$, and a constellation diagram is a plot of the complex plane. Every one of these displays is just one of the two forms of this section.

2.2 Complex conjugates

Motivation

Division by a complex number, extracting real and imaginary parts, computing a magnitude without square roots, finding average power in an AC circuit, and proving that a real filter's poles come in mirror-image pairs — all of these rest on one operation: changing the sign of j. Because j and $-j$ are algebraically indistinguishable (both square to -1), replacing every j by $-j$ in a true equation produces another true equation. That symmetry is the complex conjugate.

Complex conjugate

The **complex conjugate** of $z = a + jb = r\angle\theta$ is

$$z^* = a - jb = r\angle(-\theta).$$

Geometrically it is the **reflection of z in the real axis**. Mathematics texts often write $\bar{z}$; this book uses z^*, which matches the conjugate-transpose notation $\mathbf{A}^{\mathsf{H}}$ of linear algebra.

Algebraic properties

Properties of the conjugate

For all $z, z_1, z_2 \in \mathbb{C}$:

(i) $(z^*)^* = z$, (ii) $(z_1 \pm z_2)^* = z_1^* \pm z_2^*$, (iii) $(z_1 z_2)^* = z_1^* z_2^*$, (iv) $\left(\dfrac{z_1}{z_2}\right)^* = \dfrac{z_1^*}{z_2^*}$ $(z_2 \neq 0)$, (v) $(z^n)^* = (z^*)^n$, (vi) $zz^* = a^2 + b^2 = |z|^2$,

Proof sketch. Each is a one-line computation in rectangular form. For (iii), with $z_1 = a + jb$, $z_2 = c + jd$:

$$z_1 z_2 = (ac - bd) + j(ad + bc) \;\Rightarrow\; (z_1 z_2)^* = (ac - bd) - j(ad + bc),$$

$$z_1^* z_2^* = (a - jb)(c - jd) = (ac - bd) - j(ad + bc). \checkmark$$

Property (v) follows from (iii) by induction, (iv) from (iii) applied to $z_1 = (z_1/z_2)\, z_2$, and (vi) from $(a + jb)(a - jb) = a^2 - j^2 b^2 = a^2 + b^2$. For (viii) and (ix), add and subtract $z = a + jb$ and $z^* = a - jb$. □

Property (vi) deserves emphasis: **the product of a number and its conjugate is real and non-negative**. It is the identity behind division (Section 2.3), behind the energy of a signal $\int |x(t)|^2 dt = \int x\, x^*\, dt$, and behind power in circuits.

Conjugate of a rational expression

Let f be built from z and **real** constants by addition, subtraction, multiplication, division and integer powers (for example a polynomial or rational function with real coefficients). Then

$$f(z^*) = \big(f(z)\big)^*.$$

Proof. Properties (ii)–(v) let the conjugate pass through every operation, and a real constant c satisfies $c^* = c$. □

The most important consequence:

Conjugate root theorem

If $p(x) = c_n x^n + \cdots + c_1 x + c_0$ has **real** coefficients and $p(z_0) = 0$, then $p(z_0^*) = 0$. Non-real roots of real polynomials occur in **conjugate pairs**, and a real polynomial of odd degree has at least one real root.

Proof. $p(z_0^*) = \big(p(z_0)\big)^* = 0^* = 0$. Pairing off the non-real roots leaves an odd number of roots to be real when n is odd. □

Each conjugate pair $\alpha \pm j\beta$ combines into a real quadratic factor:

$$\big(x - (\alpha + j\beta)\big)\big(x - (\alpha - j\beta)\big) = (x - \alpha)^2 + \beta^2 = x^2 - 2\alpha x + (\alpha^2 + \beta^2).$$

So every real polynomial factors into real linear and real irreducible quadratic factors — exactly the factors that appear in the partial-fraction decompositions of Ch. 1 and Ch. 14.

Worked Example 2.5 — Basic conjugate manipulations

Let $z = 2 - j3$. Find z^*, zz^*, $\text{Re}\{z\}$ via (viii), and $1/z$.

- $z^* = 2 + j3$.
- $zz^* = (2 - j3)(2 + j3) = 4 + 9 = 13 = |z|^2$, so $|z| = \sqrt{13} \approx 3.606$.
- $\dfrac{z + z^*}{2} = \dfrac{4}{2} = 2$. ✓
- $\dfrac{1}{z} = \dfrac{z^*}{zz^*} = \dfrac{2 + j3}{13} = 0.1538 + j0.2308$.

Check: $(2 - j3)(0.1538 + j0.2308) = 0.3077 + 0.6923 + j(0.4615 - 0.4615) = 1.000$. ✓

Worked Example 2.6 — An equation involving z and z^*

Solve $z + 2z^* = 3 - j4$.

An equation containing both z and z^* is **not** a polynomial equation in z, so substitute $z = x + jy$ and use equality:

$$(x + jy) + 2(x - jy) = 3x - jy = 3 - j4.$$

Real parts: $3x = 3$, so $x = 1$. Imaginary parts: $-y = -4$, so $y = 4$. Hence $z = 1 + j4$.

Check: $(1 + j4) + 2(1 - j4) = 3 - j4$. ✓

Worked Example 2.7 — Completing a factorisation

The real cubic $p(z) = z^3 - 5z^2 + 9z - 5$ has a root $z = 2 + j$. Find the others.

Step 1. Coefficients are real, so $2 - j$ is also a root.

Step 2. The pair gives the real quadratic factor $(z - 2)^2 + 1 = z^2 - 4z + 5$.

Step 3. Divide: $z^3 - 5z^2 + 9z - 5 = (z^2 - 4z + 5)(z - 1)$ — check by expanding: $z^3 - z^2 - 4z^2 + 4z + 5z - 5 = z^3 - 5z^2 + 9z - 5$. ✓

The roots are $1, 2 + j, 2 - j$. Their sum is 5 (the negative of the z^2 coefficient) and their product is $1 \cdot \big((2 + j)(2 - j)\big) = 5$ (the negative of the constant term) — both consistent with Vieta's relations. ✓

Worked Example 2.8 — Unit magnitude and the all-pass property

(a) Show that if $|z| = 1$ then $1/z = z^*$.

From (vi), $zz^* = |z|^2 = 1$, so $z^* = 1/z$. Points on the unit circle are inverted by conjugation — a fact used constantly in discrete-time signal processing, where $z = e^{j\Omega}$ lies on the unit circle (Ch. 17).

(b) Let a be any complex number with $|a| \neq 1$. Show that

$$A(z) = \frac{z - a}{1 - a^* z}$$

satisfies $|A(z)| = 1$ whenever $|z| = 1$.

Step 1. Use $|z| = 1$ to write $1 = zz^*$ in the denominator: $1 - a^* z = zz^* - a^* z = z\,(z^* - a^*)$.

Step 2. Take magnitudes: $|1 - a^* z| = |z|\,|z^* - a^*| = 1 \cdot |(z - a)^*| = |z - a|$, by property (ii) and (vii).

Step 3. Hence $|A(z)| = |z - a| / |z - a| = 1$. □

Numerical check: $a = 0.5 + j0.3$, $z = e^{j1} = 0.5403 + j0.8415$: $z - a = 0.0403 + j0.5415$, $|z - a| = 0.5430$; $a^* z = (0.5 - j0.3)(0.5403 + j0.8415) = 0.5226 + j0.2587$, $1 - a^* z = 0.4774 - j0.2587$, $|1 - a^* z| = 0.5430$. ✓

This $A(z)$ is the **first-order all-pass** section of digital filtering: it changes phase but passes every frequency with unit gain.

Engineering Note — where conjugates appear

- **Power:** with amplitude phasors, complex power is $S = \frac{1}{2}\mathbf{V}\mathbf{I}^*$ (Section 2.9). The conjugate makes the angle of S equal to the voltage–current phase difference.
- **Real signals:** the Fourier transform of a real signal satisfies $X(-\omega) = X(\omega)^*$ (Ch. 16) — a direct consequence of the theorem on conjugates of expressions with real constants.
- **Real systems:** poles and zeros of any circuit built from real R, L, C and controlled sources are real or occur in conjugate pairs, so pole–zero plots are always symmetric about the real axis.
- **Matched filtering and correlation** use $x(t)\,y^*(t)$; **maximum power transfer** requires a load equal to the conjugate of the source impedance (Section 2.9).

Common Pitfall — conjugating only part of an expression

To conjugate $\dfrac{3+j2}{(1-j)\,e^{j\pi/5}}$ you must change the sign of **every** j: $\dfrac{3-j2}{(1+j)\,e^{-j\pi/5}}$. A frequent error is to conjugate the numerator only. Conversely, do **not** conjugate real symbols that merely look complex: if ω, R, L, C are real, then $(R+j\omega L)^* = R - j\omega L$, with ω untouched.

2.3 Complex arithmetic

Motivation

Circuit analysis in the sinusoidal steady state is ordinary DC circuit analysis — Ohm's law, Kirchhoff's laws, series and parallel combination, nodal and mesh equations — carried out with complex numbers instead of real ones (Section 2.9). Every one of those operations reduces to the four arithmetic operations of this section. The arithmetic itself is easy; what takes practice is doing it **reliably** and choosing the form that minimises effort.

The four operations

Rectangular arithmetic

For $z_1 = a + jb$ and $z_2 = c + jd$:

$$\begin{aligned} z_1 \pm z_2 &= (a \pm c) + j(b \pm d), \\ z_1 z_2 &= (ac - bd) + j(ad + bc), \\ \frac{z_1}{z_2} &= \frac{z_1 z_2^*}{z_2 z_2^*} = \frac{(ac+bd) + j(bc-ad)}{c^2 + d^2}, \qquad z_2 \neq 0. \end{aligned}$$

Addition is component-wise — vector addition in the plane. **Multiplication** is ordinary expansion of brackets followed by $j^2 = -1$:

$$(a+jb)(c+jd) = ac + jad + jbc + j^2 bd = (ac - bd) + j(ad + bc).$$

Division uses the conjugate trick: multiplying numerator and denominator by z_2^* makes the denominator the real number $|z_2|^2$, after which division is just scaling. In particular the **reciprocal** is

$$\frac{1}{c+jd} = \frac{c - jd}{c^2 + d^2}, \qquad \text{e.g.} \quad \frac{1}{j} = \frac{-j}{1} = -j.$$

Polar arithmetic

For $z_1 = r_1 \angle \theta_1$ and $z_2 = r_2 \angle \theta_2$:

$$z_1 z_2 = r_1 r_2 \angle(\theta_1 + \theta_2), \qquad \frac{z_1}{z_2} = \frac{r_1}{r_2}\angle(\theta_1 - \theta_2), \qquad \frac{1}{z_2} = \frac{1}{r_2}\angle(-\theta_2).$$

Magnitudes multiply, angles add.

Proof. Multiply the polar forms and use the compound-angle identities of Ch. 1:

$$\begin{aligned} z_1 z_2 &= r_1 r_2 \big[(\cos\theta_1 \cos\theta_2 - \sin\theta_1 \sin\theta_2) + j(\sin\theta_1 \cos\theta_2 + \cos\theta_1 \sin\theta_2)\big] \\ &= r_1 r_2 \big[\cos(\theta_1 + \theta_2) + j \sin(\theta_1 + \theta_2)\big]. \end{aligned}$$

The quotient rule follows by checking that $\frac{r_1}{r_2}\angle(\theta_1 - \theta_2)$ times $r_2 \angle \theta_2$ gives $r_1 \angle \theta_1$. $\square$

This proof is a little laborious; Section 2.5 gives a one-line version using exponentials. Notice that the trigonometric identities and the multiplication rule are *the same fact* in two notations — a theme Section 2.4 makes systematic.

Powers of j

Because $j^2 = -1$, the powers of j cycle with period 4:

$$j^0 = 1, \quad j^1 = j, \quad j^2 = -1, \quad j^3 = -j, \quad j^4 = 1, \quad j^5 = j, \ \ldots$$

so $j^n = j^{\,n \bmod 4}$. Negative powers follow from $1/j = -j$: $j^{-1} = -j$, $j^{-2} = -1$, $j^{-3} = j$. In polar form $j = 1\angle 90^\circ$, and $j^n = 1\angle(90n)^\circ$ — each multiplication by j is a quarter-turn.

Field properties

$\mathbb{C}$ is a field

Addition and multiplication of complex numbers are commutative and associative, multiplication distributes over addition, 0 and 1 are identities, every z has an additive inverse $-z$, and every $z \neq 0$ has a multiplicative inverse $1/z$.

The practical meaning: **every algebraic manipulation you know for real numbers is valid for complex numbers** — expanding brackets, collecting terms, cross-multiplying, solving linear systems by elimination or Cramer's rule, factorising polynomials, the quadratic formula. What does *not* carry over are statements involving order ($<$, $>$) and some rules for multivalued functions such as square roots and logarithms (pitfall below, and Section 2.5).

Magnitude rules and the triangle inequality

Magnitude rules

$$|z_1 z_2| = |z_1|\,|z_2|, \qquad \left|\frac{z_1}{z_2}\right| = \frac{|z_1|}{|z_2|}, \qquad |z^n| = |z|^n, \qquad |\operatorname{Re}\{z\}| \le |z|, \quad |\operatorname{Im}\{z\}| \le |z|.$$

Triangle inequality:

$$|z_1 + z_2| \le |z_1| + |z_2|, \qquad \text{and} \qquad \big||z_1| - |z_2|\big| \le |z_1 - z_2|.$$

Proof of the product rule without polar form. $|z_1 z_2|^2 = (z_1 z_2)(z_1 z_2)^* = z_1 z_1^*\, z_2 z_2^* = |z_1|^2 |z_2|^2$.

Proof of the triangle inequality.

$$\begin{aligned} |z_1 + z_2|^2 &= (z_1 + z_2)(z_1^* + z_2^*) = |z_1|^2 + |z_2|^2 + z_1 z_2^* + z_1^* z_2 \\ &= |z_1|^2 + |z_2|^2 + 2\operatorname{Re}\{z_1 z_2^*\} \\ &\le |z_1|^2 + |z_2|^2 + 2|z_1 z_2^*| = (|z_1| + |z_2|)^2. \end{aligned}$$

Take square roots. Equality holds exactly when $z_1 z_2^*$ is real and non-negative, i.e. when z_1 and z_2 point in the same direction. The reverse inequality follows by applying the triangle inequality to $z_1 = (z_1 - z_2) + z_2$. □

The middle line of that proof is worth remembering on its own:

$$|z_1 + z_2|^2 = |z_1|^2 + |z_2|^2 + 2|z_1||z_2|\cos(\theta_1 - \theta_2),$$

which is the **law of cosines**. When two sinusoids of the same frequency are added (Section 2.8), the amplitude of the sum is given by exactly this formula: maximal ($|z_1| + |z_2|$) when in phase, minimal ($\big||z_1| - |z_2|\big|$) when in antiphase.

Engineering Note — choose the form to suit the operation

Rectangular for sums and differences (series impedances, KCL/KVL, adding phasors), polar for products, quotients, powers and roots (gains, voltage dividers, Ohm's law, cascaded stages). A mixed calculation such as $\dfrac{z_1 z_2}{z_3 + z_4}$ is done by forming $z_3 + z_4$ in rectangular form, converting it to polar, then multiplying and dividing in polar. Numerical packages store complex numbers in rectangular form and convert on demand, so on a computer you simply write the expression; by hand, the choice of form is half the skill.

Worked Example 2.9 — The four operations

Let $z_1 = 3 + j4$ and $z_2 = 1 - j2$.

- $z_1 + z_2 = 4 + j2$; $\quad z_1 - z_2 = 2 + j6$.
- $z_1 z_2 = 3 - j6 + j4 - j^2 8 = 3 + 8 + j(-6 + 4) = 11 - j2$.
- $\dfrac{z_1}{z_2} = \dfrac{(3 + j4)(1 + j2)}{1^2 + 2^2} = \dfrac{3 + j6 + j4 + j^2 8}{5} = \dfrac{-5 + j10}{5} = -1 + j2$.

Check the quotient by multiplying back: $(-1 + j2)(1 - j2) = -1 + j2 + j2 - j^2 4 = 3 + j4$. ✓

Check with polar form: $z_1 = 5\angle 53.13^\circ$, $z_2 = \sqrt{5}\angle -63.43^\circ$. Then $z_1 z_2 = 5\sqrt{5}\angle(-10.30^\circ) = 11.18\angle -10.30^\circ$, and $|11 - j2| = \sqrt{125} = 11.18$, $\operatorname{atan2}(-2, 11) = -10.30^\circ$. ✓ Likewise $z_1/z_2 = \sqrt{5}\angle 116.57^\circ = -1 + j2$. ✓

Worked Example 2.10 — A compound expression

Evaluate $w = \dfrac{(2 + j)(3 - j2)}{1 + j} - j^7$ in rectangular form.

Step 1 — numerator. $(2 + j)(3 - j2) = 6 - j4 + j3 - j^2 2 = 8 - j$.

Step 2 — divide by $1 + j$. $\dfrac{8 - j}{1 + j} = \dfrac{(8 - j)(1 - j)}{2} = \dfrac{8 - j8 - j + j^2}{2} = \dfrac{7 - j9}{2} = 3.5 - j4.5$.

Step 3 — the power of j. $7 \bmod 4 = 3$, so $j^7 = j^3 = -j$, and $-j^7 = +j$.

Step 4. $w = 3.5 - j4.5 + j = 3.5 - j3.5 = 3.5\sqrt{2}\angle -45^\circ \approx 4.950\angle -45^\circ$.

Polar check of Step 2: $|8 - j|/|1 + j| = \sqrt{65}/\sqrt{2} = 5.701$ and $|3.5 - j4.5| = \sqrt{32.5} = 5.701$. ✓

Worked Example 2.11 — A complex linear system

Two coupled loop currents satisfy

$$(3+j4)I_1 - j4\,I_2 = 10, \qquad -j4\,I_1 + (2+j2)I_2 = 0.$$

(This is the form mesh analysis produces for two loops sharing an inductive element.) Solve for I_1 and I_2.

Step 1 — determinant. Cramer's rule works exactly as for real systems:

$$\Delta = (3+j4)(2+j2) - (-j4)(-j4) = (6+j6+j8-8) - (j^2\,16) = (-2+j14) + 16 = 14 + j14.$$

Step 2 — I_1.

$$I_1 = \frac{10(2+j2) - (-j4)(0)}{\Delta} = \frac{20+j20}{14+j14} = \frac{20}{14} = 1.4286\angle 0^\circ.$$

Step 3 — I_2.

$$I_2 = \frac{(3+j4)(0) - (-j4)(10)}{\Delta} = \frac{j40}{14+j14} = \frac{40\angle 90^\circ}{19.799\angle 45^\circ} = 2.0203\angle 45^\circ = 1.4286 + j1.4286.$$

Check the second equation: $-j4(1.4286) + (2+j2)(1.4286+j1.4286) = -j5.714 + (2.857 - 2.857) + j(2.857+2.857) = 0$. ✓

Common Pitfall — $\sqrt{a}\sqrt{b} \neq \sqrt{ab}$ for negative numbers

The rule $\sqrt{a}\sqrt{b} = \sqrt{ab}$ holds for $a, b \geq 0$ but fails otherwise: $\sqrt{-4}\sqrt{-9} = (j2)(j3) = -6$, whereas $\sqrt{(-4)(-9)} = \sqrt{36} = 6$. Square roots of complex numbers are two-valued (Section 2.6), and "laws" that silently pick one value can break. Safe practice: write $\sqrt{-a} = j\sqrt{a}$ for $a > 0$ **first**, then multiply.

Engineering Note — numerical care

Computing $|z| = \sqrt{a^2+b^2}$ naively can overflow or underflow when a or b is very large or very small, even if $|z|$ itself is representable. Library functions (`abs` for complex types, `hypot`) rescale internally. Similarly, robust complex division (Smith's algorithm) divides through by the larger of $|c|, |d|$ before forming $c^2 + d^2$. You rarely need to implement these yourself, but you should know why `abs(z)` is preferred to `sqrt(z.real**2 + z.imag**2)`.

2.4 Euler's formula

Motivation

Polar multiplication says angles **add** when numbers multiply. Exponentials have the same property: $e^x e^y = e^{x+y}$, exponents add when quantities multiply. Euler's formula makes this analogy exact — the angle of a complex number behaves precisely like an imaginary exponent. The payoff is enormous: sinusoids, which are awkward to differentiate, integrate, multiply and add, become exponentials, which are the easiest functions in all of calculus. This single identity underlies phasors, Fourier series and transforms, the Laplace transform, and the solution of every linear differential equation with constant coefficients.

Euler's formula

For every real θ,

$$e^{j\theta} = \cos\theta + j\sin\theta.$$

Before proving it, be clear about what is being claimed. For real x, e^x is defined (Ch. 1, Ch. 4) and has the series $e^x = \sum_{n\geq 0} x^n/n!$. For imaginary arguments $e^{j\theta}$ has no meaning until we *give* it one. There are three equivalent ways to do so, and each gives a different insight.

Derivation 1 — power series

Define e^z for any complex z by the same series that works for real arguments,

$$e^z = \sum_{n=0}^{\infty} \frac{z^n}{n!} = 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \cdots,$$

which converges for every z (Ch. 4, Ch. 18). Put $z = j\theta$ and use the cycle $j^2 = -1$, $j^3 = -j$, $j^4 = 1$:

$$\begin{aligned} e^{j\theta} &= 1 + j\theta + \frac{(j\theta)^2}{2!} + \frac{(j\theta)^3}{3!} + \frac{(j\theta)^4}{4!} + \frac{(j\theta)^5}{5!} + \cdots \\ &= 1 + j\theta - \frac{\theta^2}{2!} - j\frac{\theta^3}{3!} + \frac{\theta^4}{4!} + j\frac{\theta^5}{5!} - \cdots \\ &= \left(1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots\right) + j\left(\theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \cdots\right) \\ &= \cos\theta + j\sin\theta. \end{aligned}$$

The even powers are real and reproduce the Maclaurin series of $\cos\theta$; the odd powers are imaginary and reproduce that of $\sin\theta$. (Rearranging the terms is legitimate because the series converges absolutely.)

Derivation 2 — a differential equation

Any sensible definition of $e^{j\theta}$ should satisfy $\frac{d}{d\theta}e^{j\theta} = je^{j\theta}$ and $e^{j0} = 1$. Let $g(\theta) = \cos\theta + j\sin\theta$. Then

$$g'(\theta) = -\sin\theta + j\cos\theta = j(\cos\theta + j\sin\theta) = j\,g(\theta), \qquad g(0) = 1.$$

So g satisfies the same initial-value problem. To see that the two must coincide, consider $f(\theta) = e^{-j\theta}g(\theta)$. By the product rule $f'(\theta) = -je^{-j\theta}g + e^{-j\theta}jg = 0$, so f is constant, and $f(0) = 1$. Hence $g(\theta) = e^{j\theta}$. (This uniqueness argument is the prototype of the uniqueness theorems for ODEs in Ch. 11.)

Derivation 3 — geometry of motion

Think of $z(\theta) = e^{j\theta}$ as the position of a particle at "time" θ. The equation $z' = jz$ says the velocity is the position rotated by 90° — always perpendicular to the radius — and has the same magnitude as the position. Motion perpendicular to the radius keeps the distance from the origin constant, so the particle moves on the circle $|z| = 1$; with unit speed, after time θ it has travelled arc length θ, i.e. it sits at angle θ radians. That point is $(\cos\theta, \sin\theta)$. This picture explains *why* the angle in $e^{j\theta}$ must be in radians: radians are arc length on the unit circle.

Immediate consequences

Basic properties of $e^{j\theta}$

For real θ, ϕ and integer k:

$$\begin{aligned}
&|e^{j\theta}| = 1, \qquad \angle e^{j\theta} = \theta, \qquad (e^{j\theta})^* = e^{-j\theta} = \frac{1}{e^{j\theta}},\\
&e^{j\theta}e^{j\phi} = e^{j(\theta+\phi)}, \qquad e^{j(\theta+2\pi k)} = e^{j\theta},\\
&e^{j0} = 1, \quad e^{j\pi/2} = j, \quad e^{j\pi} = -1, \quad e^{j3\pi/2} = e^{-j\pi/2} = -j, \quad e^{j2\pi} = 1.
\end{aligned}$$

The modulus follows from $\cos^2\theta + \sin^2\theta = 1$. The addition rule is the polar multiplication theorem of Section 2.3 restated; periodicity follows from that of cosine and sine. The case $e^{j\pi} + 1 = 0$ — linking e, π, j, 1 and 0 — is famous, but the engineer's version is more useful: **multiplying by $e^{j\pi} = -1$ is a 180° phase shift, and multiplying by $e^{j\pi/2} = j$ is a 90° phase advance.**

The inverse Euler formulas

Replace θ by $-\theta$: $e^{-j\theta} = \cos\theta - j\sin\theta$. Adding and subtracting this from Euler's formula isolates the cosine and the sine.

Cosine and sine as exponentials

$$\cos\theta = \frac{e^{j\theta} + e^{-j\theta}}{2} = \mathrm{Re}\{e^{j\theta}\}, \qquad \sin\theta = \frac{e^{j\theta} - e^{-j\theta}}{2j} = \mathrm{Im}\{e^{j\theta}\}.$$

These are the workhorses of signal analysis. They express the two real trigonometric functions as combinations of a **single** kind of function, the complex exponential, which differentiates, integrates and multiplies trivially:

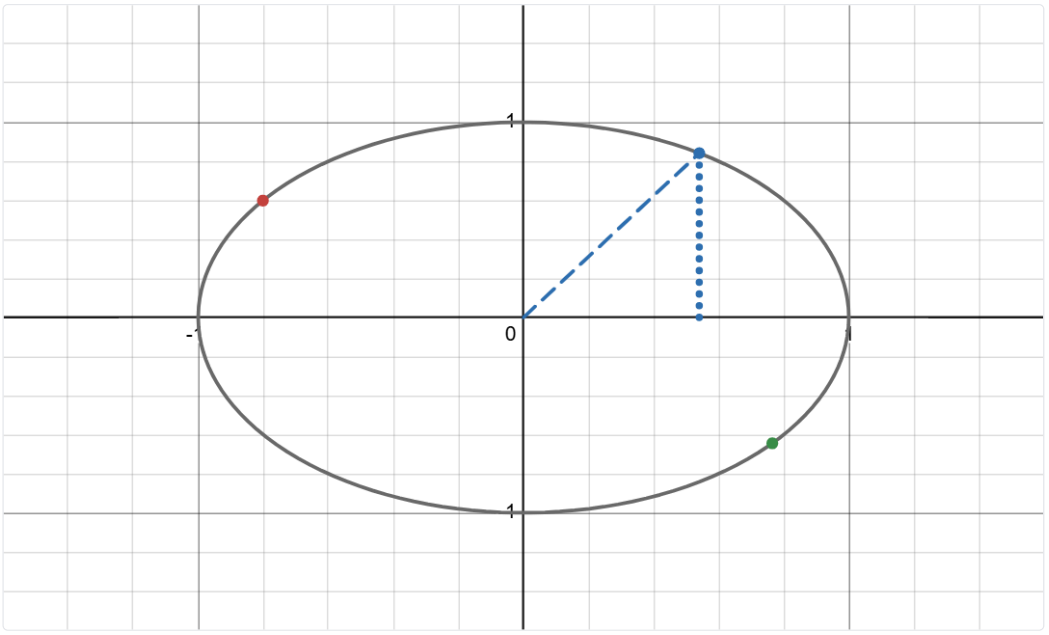
$$\frac{d}{d\theta}e^{ja\theta} = ja\,e^{ja\theta}, \qquad \int e^{ja\theta}\,d\theta = \frac{e^{ja\theta}}{ja} + C\ (a \neq 0), \qquad e^{ja\theta}e^{jb\theta} = e^{j(a+b)\theta}.$$

The general strategy, used again and again in this book, is therefore:

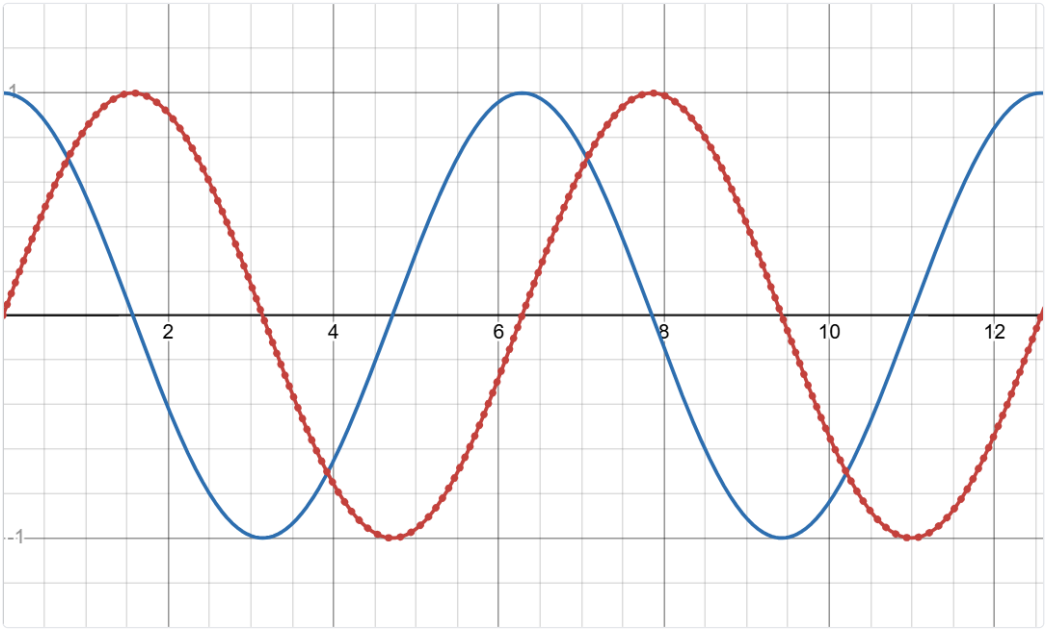
1. Rewrite sines and cosines as exponentials (or as real/imaginary parts of exponentials).
2. Do the algebra or calculus with exponentials.
3. Convert back with Euler's formula, or take a real/imaginary part.

Engineering Note — rotating phasors and negative frequency

As t increases, $e^{j\omega t}$ traces the unit circle anticlockwise at ω rad/s, completing a revolution every $T = 2\pi/\omega$ seconds. Its horizontal projection is $\cos\omega t$ and its vertical projection is $\sin\omega t$. The inverse Euler formula says a real cosine is the average of two **counter-rotating** exponentials, $e^{+j\omega t}$ and $e^{-j\omega t}$, whose imaginary parts cancel. This is the origin of the "negative frequencies" in two-sided spectra (Ch. 15–16): a real signal at 100 Hz has spectral lines at both $+100$ Hz and -100 Hz, each carrying half the amplitude.



Euler's formula places $e^{j\theta}$ on the unit circle at angle θ radians. For $\theta = 1$ the dashed radius and dotted drop line show the real part $\cos 1 = 0.540$ and imaginary part $\sin 1 = 0.841$.



The real part (blue, $\cos\theta$) and imaginary part (red, $\sin\theta$) of $e^{j\theta}$. The sine is the cosine delayed by $\pi/2$ — the dotted curve, $\cos(\theta - \pi/2)$, lies exactly on it — reflecting $\mathrm{Im}\{e^{j\theta}\} = \mathrm{Re}\{e^{j(\theta-\pi/2)}\} = \mathrm{Re}\{-je^{j\theta}\}$.

Trigonometry from exponentials

All the identities of Ch. 1, Section 1.6 can be derived mechanically, which means you never need to memorise more than Euler's formula.

Worked Example 2.12 — Compound-angle formulas

Derive $\cos(A+B)$ and $\sin(A+B)$.

Step 1. $e^{j(A+B)} = e^{jA}e^{jB}$.

Step 2. Expand the right side with Euler's formula:

$$(\cos A + j\sin A)(\cos B + j\sin B) = (\cos A\cos B - \sin A\sin B) + j(\sin A\cos B + \cos A\sin B).$$

Step 3. The left side is $\cos(A+B) + j\sin(A+B)$. Equate real and imaginary parts (one complex equation = two real ones):

$$\cos(A+B) = \cos A\cos B - \sin A\sin B, \qquad \sin(A+B) = \sin A\cos B + \cos A\sin B.$$

Check with $A = 0.4$, $B = 0.9$: $\cos 1.3 = 0.2675$, and $\cos 0.4\cos 0.9 - \sin 0.4\sin 0.9 = 0.9211(0.6216) - 0.3894(0.7833) = 0.5726 - 0.3050 = 0.2675$. ✓

Worked Example 2.13 — Power reduction and the mixer identity

(a) Express $\cos^3\theta$ in terms of cosines of multiple angles (no powers).

$$\cos^3\theta = \left(\frac{e^{j\theta}+e^{-j\theta}}{2}\right)^3 = \frac{1}{8}\left(e^{j3\theta}+3e^{j\theta}+3e^{-j\theta}+e^{-j3\theta}\right)$$
$$= \frac{1}{8}\left(2\cos 3\theta + 6\cos\theta\right) = \frac{3}{4}\cos\theta + \frac{1}{4}\cos 3\theta.$$

Check at $\theta = 0.5$: $\cos^3 0.5 = 0.8776^3 = 0.6759$; $0.75(0.8776) + 0.25\cos 1.5 = 0.6582 + 0.25(0.0707) = 0.6759$. ✓

Engineering reading: passing a pure cosine through a cubic nonlinearity $y = x^3$ produces a fundamental component plus a **third harmonic** of one-third its size — harmonic distortion, computed in one line.

(b) A mixer multiplies a received signal $\cos\omega_1 t$ by a local oscillator $\cos\omega_2 t$. Show what frequencies emerge.

$$\cos\omega_1 t\cos\omega_2 t = \frac{1}{4}\left(e^{j\omega_1 t}+e^{-j\omega_1 t}\right)\left(e^{j\omega_2 t}+e^{-j\omega_2 t}\right) = \frac{1}{2}\cos(\omega_1-\omega_2)t + \frac{1}{2}\cos(\omega_1+\omega_2)t.$$

With $f_1 = 10.7$ MHz and $f_2 = 10.0$ MHz the product contains 0.7 MHz and 20.7 MHz components — the sum and difference frequencies on which every superheterodyne receiver relies.

Worked Example 2.14 — Summing a trigonometric series

Find a closed form for $C_N(\theta) = \sum_{k=0}^{N-1}\cos k\theta$ for θ not a multiple of 2π.

Step 1 — embed in an exponential sum. $C_N = \mathrm{Re}\{S_N\}$ where $S_N = \sum_{k=0}^{N-1} e^{jk\theta}$, a geometric series with ratio $e^{j\theta} \neq 1$:

$$S_N = \frac{1-e^{jN\theta}}{1-e^{j\theta}}.$$

Step 2 — factor out half-angles (a standard trick that turns $1-e^{jx}$ into a sine):

$$1-e^{jx} = e^{jx/2}\left(e^{-jx/2}-e^{jx/2}\right) = -2j\,e^{jx/2}\sin\frac{x}{2}.$$

Applying this to numerator and denominator:

$$S_N = \frac{e^{jN\theta/2}\sin(N\theta/2)}{e^{j\theta/2}\sin(\theta/2)} = e^{j(N-1)\theta/2}\,\frac{\sin(N\theta/2)}{\sin(\theta/2)}.$$

Step 3 — take the real part.

$$\sum_{k=0}^{N-1}\cos k\theta = \cos\left(\frac{(N-1)\theta}{2}\right)\frac{\sin(N\theta/2)}{\sin(\theta/2)}.$$

Check with $N=5$, $\theta = 0.3$: the direct sum is $1+0.9553+0.8253+0.6216+0.3624 = 3.7646$; the formula gives $\cos(0.6)\,\sin(0.75)/\sin(0.15) = 0.8253\times 0.6816/0.1494 = 3.7646$. ✓

The ratio $\sin(N\theta/2)/\sin(\theta/2)$ is the **Dirichlet kernel**; it describes the beam pattern of an N-element antenna array and the frequency response of an N-point moving-average filter.

Worked Example 2.15 — An integral via exponentials

Evaluate $I = \int_0^\infty e^{-2t}\cos 3t\,dt$.

Step 1. $\cos 3t = \mathrm{Re}\{e^{j3t}\}$, and since e^{-2t} is real and integration is linear, $I = \mathrm{Re}\left\{\int_0^\infty e^{(-2+j3)t}dt\right\}$.

Step 2. For $a = -2+j3$, $\int_0^\infty e^{at}dt = \left[\frac{e^{at}}{a}\right]_0^\infty = 0 - \frac{1}{a} = \frac{1}{2-j3}$, because $|e^{at}| = e^{-2t}\to 0$.

Step 3. $\dfrac{1}{2-j3} = \dfrac{2+j3}{13}$, so $I = \dfrac{2}{13} \approx 0.1538$.

As a bonus the imaginary part gives $\int_0^\infty e^{-2t}\sin 3t\,dt = \frac{3}{13}$ for free. Compare with the alternative — integrating by parts twice (Ch. 5). This calculation is, in fact, the Laplace transform of $\cos 3t$ evaluated at $s = 2$ (Ch. 14): $\mathcal{L}\{\cos\omega t\} = s/(s^2+\omega^2) = 2/13$. ✓

Common Pitfall — degrees inside an exponent

e^{j30} means $e^{j\cdot 30\ \mathrm{rad}}$, which is $\cos 30 + j\sin 30 = 0.154 - j0.988$, not $0.866 + j0.5$. The notation $1\angle 30^\circ$ may use degrees; the exponential $e^{j\pi/6}$ must use radians. Calculators set to degree mode will happily give wrong answers to complex-exponential calculations.

Common Pitfall — $\cos\theta \neq e^{j\theta}$

A cosine is the **real part** of $e^{j\theta}$, not equal to it. Replacing $\cos\omega t$ by $e^{j\omega t}$ in a calculation is legitimate only if every operation that follows is **linear with real coefficients** (addition, multiplication by real constants, differentiation, integration), so that "take the real part" can be postponed to the end. Products of two signals do not satisfy this: $\mathrm{Re}\{z_1\}\,\mathrm{Re}\{z_2\} \neq \mathrm{Re}\{z_1 z_2\}$ in general. This is why power calculations need the conjugate formula $\frac{1}{2}\mathrm{Re}\{\mathbf{V}\mathbf{I}^*\}$ rather than $\mathrm{Re}\{\mathbf{V}\mathbf{I}\}$ (Section 2.9).

2.5 Exponential representation

Motivation

Combining the polar form of Section 2.1 with Euler's formula gives the most compact and most powerful way to write a complex number. In exponential form the rules for multiplication, division, powers and roots are simply the laws of exponents you already know, and a complex number can be fed directly into calculus. It is also the form in which signals are written: a damped oscillation, a growing instability and a pure tone are all e^{st} for different complex s.

Exponential form

Every non-zero complex number can be written

$$z = re^{j\theta} = r(\cos\theta + j\sin\theta) = r\angle\theta, \qquad r = |z| > 0,\ \theta = \arg z.$$

The notation $r\angle\theta$ is engineering shorthand for $re^{j\theta}$. Angles written with $\angle$ are often in degrees; inside $e^{j\theta}$ they must be in radians.

Polar arithmetic from the laws of exponents

Exponential-form arithmetic

$$z_1 z_2 = r_1 r_2\, e^{j(\theta_1+\theta_2)}, \quad \frac{z_1}{z_2} = \frac{r_1}{r_2}\, e^{j(\theta_1-\theta_2)},$$
$$z^* = r\, e^{-j\theta}, \qquad \frac{1}{z} = \frac{1}{r}\, e^{-j\theta}, \qquad z^n = r^n e^{jn\theta}\ (n \in \mathbb{Z}).$$

Proof. $z_1 z_2 = r_1 e^{j\theta_1} r_2 e^{j\theta_2} = r_1 r_2 e^{j\theta_1} e^{j\theta_2} = r_1 r_2 e^{j(\theta_1+\theta_2)}$, using $e^{j\theta_1}e^{j\theta_2} = e^{j(\theta_1+\theta_2)}$ from Section 2.4. The others follow similarly. □

Compare this one-line proof with the trigonometric proof in Section 2.3: the exponential notation has absorbed the compound-angle identities.

An important special case: since $|e^{j\alpha}| = 1$, multiplying by $e^{j\alpha}$ changes only the angle. $e^{j\alpha}$ **is a pure rotation (phase shift) by** α, and a general multiplier $Ae^{j\alpha}$ is a scaling by A combined with a rotation by α. Every linear time-invariant system acting on a sinusoid does exactly this (Section 2.9).

Worked Example 2.16 — Products and quotients in exponential form

Evaluate $w = \dfrac{(2e^{j\pi/3})(6e^{-j\pi/6})}{3e^{j\pi/2}}$ and give it in rectangular form.

Magnitude: $|w| = \dfrac{2\cdot 6}{3} = 4.$

Angle: $\angle w = \dfrac{\pi}{3} - \dfrac{\pi}{6} - \dfrac{\pi}{2} = \dfrac{2\pi - \pi - 3\pi}{6} = -\dfrac{\pi}{3}.$

Rectangular: $w = 4e^{-j\pi/3} = 4\left(\frac{1}{2} - j\frac{\sqrt{3}}{2}\right) = 2 - j2\sqrt{3} \approx 2 - j3.464.$

Check by direct rectangular computation: $2e^{j\pi/3} = 1 + j1.732$, $6e^{-j\pi/6} = 5.196 - j3$, their product is $5.196 + 5.196 + j(9-3) = 10.392 + j6$; dividing by $3e^{j\pi/2} = j3$ gives $(10.392 + j6)/(j3) = 2 - j3.464$. ✓

Worked Example 2.17 — A sum in exponential form

Evaluate $w = 4e^{j\pi/6} + 3e^{-j\pi/3}$.

Exponential form has no addition rule, so convert to rectangular:

$$4e^{j\pi/6} = 3.464 + j2.000, \qquad 3e^{-j\pi/3} = 1.500 - j2.598, \qquad w = 4.964 - j0.598.$$

Then $|w| = \sqrt{4.964^2 + 0.598^2} = 5.000$ and $\angle w = \mathrm{atan2}(-0.598, 4.964) = -6.87^\circ$.

Geometric check: the two terms point at $+30^\circ$ and -60°, which are 90° apart, so they form the legs of a right triangle: $|w| = \sqrt{4^2 + 3^2} = 5$ ✓, and w lies $\arctan\frac{3}{4} = 36.87^\circ$ clockwise of the $4e^{j\pi/6}$ term: $30^\circ - 36.87^\circ = -6.87^\circ$. ✓

The complex exponential function

For a general complex exponent $z = \sigma + j\omega$, the law $e^{a+b} = e^a e^b$ (which holds for the series definition) gives

Exponential of a complex number

$$e^{\sigma+j\omega} = e^{\sigma}e^{j\omega} = e^{\sigma}(\cos\omega + j\sin\omega), \qquad |e^{z}| = e^{\mathrm{Re}\{z\}}, \quad \angle e^{z} = \mathrm{Im}\{z\}.$$

Moreover $e^{z} \neq 0$ for every z, and $e^{z+j2\pi k} = e^{z}$ for every integer k: the complex exponential is **periodic with period** $j2\pi$.

So the real part of the exponent controls the **size** and the imaginary part the **angle**. This splitting is the key to the Laplace variable $s = \sigma + j\omega$ (Ch. 14). Replace σ, ω by $\sigma t, \omega t$:

$$e^{st} = e^{\sigma t}e^{j\omega t}, \qquad \mathrm{Re}\{e^{st}\} = e^{\sigma t}\cos\omega t.$$

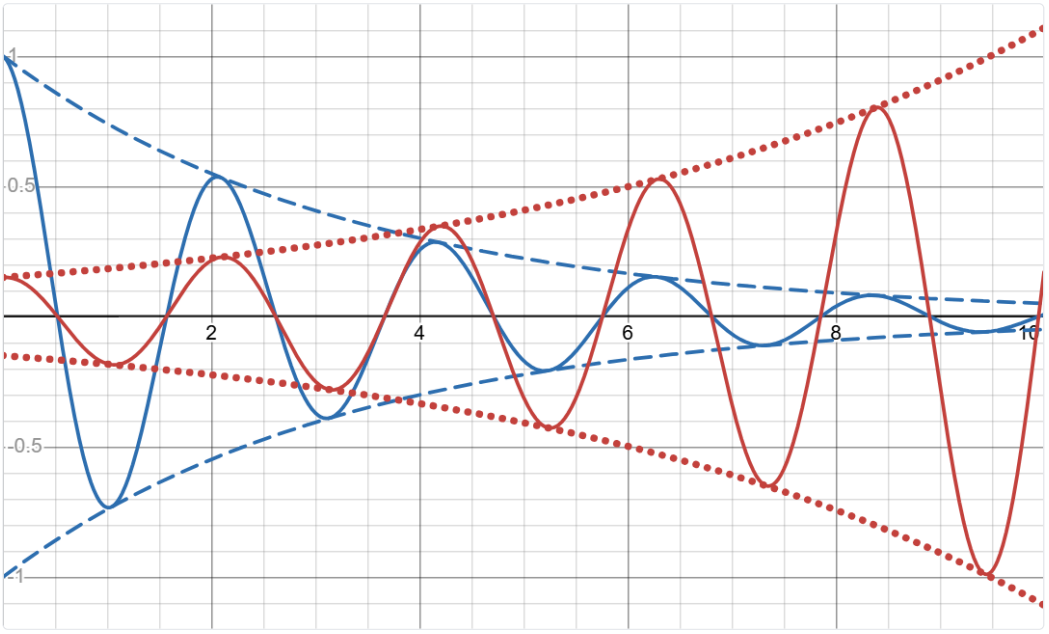
The single expression e^{st} covers every elementary signal shape:

s	$\mathrm{Re}\{e^{st}\}$	**Behaviour**
0	1	constant (DC)
$\sigma < 0$ real	$e^{\sigma t}$	exponential decay
$\sigma > 0$ real	$e^{\sigma t}$	exponential growth
$j\omega$	$\cos\omega t$	steady oscillation
$\sigma + j\omega, \sigma < 0$	$e^{\sigma t}\cos\omega t$	damped oscillation
$\sigma + j\omega, \sigma > 0$	$e^{\sigma t}\cos\omega t$	growing oscillation (instability)

More generally, a damped sinusoid with arbitrary amplitude and phase is

$$A\,e^{\sigma t}\cos(\omega t + \phi) = \mathrm{Re}\left\{Ae^{j\phi}\,e^{(\sigma+j\omega)t}\right\},$$

a complex constant $Ae^{j\phi}$ (which will be called a phasor in Section 2.8) times a complex exponential.



$\mathrm{Re}\{e^{st}\}$ for $s = -0.3 + j3$ (blue, decaying inside its envelope $\pm e^{-0.3t}$) and $0.15\,\mathrm{Re}\{e^{st}\}$ for $s = 0.2 + j3$ (red, growing inside $\pm 0.15e^{0.2t}$). The imaginary part of s sets the oscillation rate; the real part sets the envelope.

Worked Example 2.18 — Evaluating e^{z} and writing a signal as $\mathrm{Re}\{Ae^{st}\}$

(a) Evaluate e^{1+j2}.

$$e^{1+j2} = e^{1}(\cos 2 + j\sin 2) = 2.7183(-0.4161 + j0.9093) = -1.1312 + j2.4717.$$

Its magnitude is $e^{1} = 2.718$ and its angle 2 rad $= 114.6^{\circ}$ — read straight off the exponent.

(b) Write $x(t) = 3e^{-2t}\cos(5t - 40^{\circ})$ in the form $\mathrm{Re}\{Ae^{st}\}$.

Match to $\mathrm{Re}\{Ae^{j\phi}e^{(\sigma+j\omega)t}\}$: $A = 3\angle -40^{\circ} = 2.298 - j1.928$ and $s = -2 + j5\ \mathrm{s}^{-1}$. So

$$x(t) = \mathrm{Re}\left\{(2.298 - j1.928)\,e^{(-2+j5)t}\right\}.$$

Check at $t = 0$: $\mathrm{Re}\{A\} = 2.298$ and $3\cos(-40^{\circ}) = 2.298$. ✓

(c) Solve $e^{z} = -2$. Write $z = x + jy$; then $e^{x}e^{jy} = 2e^{j\pi}$. Equating magnitudes, $e^{x} = 2$, so $x = \ln 2$; equating angles (up to 2π), $y = \pi + 2\pi k$. Hence $z = \ln 2 + j(2k+1)\pi$, $k \in \mathbb{Z}$ — infinitely many solutions, because e^{z} is periodic.

The complex logarithm

Part (c) shows that inverting the exponential is ambiguous. Solving $e^w = z$ for $z = re^{j\theta} \neq 0$ in general gives $w = \ln r + j(\theta + 2\pi k)$.

Complex logarithm

For $z \neq 0$, the **logarithm** is the multivalued expression

$$\log z = \ln|z| + j(\operatorname{Arg} z + 2\pi k), \qquad k \in \mathbb{Z},$$

and the **principal logarithm** is the single value

$$\operatorname{Log} z = \ln|z| + j \operatorname{Arg} z, \qquad -\pi < \operatorname{Arg} z \leq \pi.$$

The real part of a logarithm is the log of the magnitude; the imaginary part is the angle. In engineering this is exactly the content of a Bode plot: $\ln H = \ln|H| + j\angle H$, so plotting $\ln|H|$ (or $20\log_{10}|H|$, in dB) and $\angle H$ is plotting the real and imaginary parts of $\ln H$, and the gains and phases of cascaded stages add because logarithms turn products into sums.

Complex powers

For $z \neq 0$ and complex c, define $z^c = e^{c \log z}$. This is multivalued in general (single-valued when c is an integer, n-valued when $c = 1/n$ — the n-th roots of Section 2.6). The **principal value** uses $\operatorname{Log} z$.

Worked Example 2.19 — Logarithms and complex powers

(a) $\operatorname{Log}(-3 + j4)$. Here $|z| = 5$ and $\operatorname{Arg} z = 126.87^\circ = 2.2143$ rad, so

$$\operatorname{Log}(-3 + j4) = \ln 5 + j2.2143 = 1.6094 + j2.2143.$$

Check: $e^{1.6094} e^{j2.2143} = 5(\cos 2.2143 + j \sin 2.2143) = 5(-0.6 + j0.8) = -3 + j4$. ✓

(b) j^j. Since $\log j = j(\pi/2 + 2\pi k)$,

$$j^j = e^{j \log j} = e^{j \cdot j(\pi/2 + 2\pi k)} = e^{-\pi/2 - 2\pi k}.$$

Every value is **real**; the principal value ($k = 0$) is $e^{-\pi/2} = 0.2079$.

(c) Principal value of $(1 + j)^j$. $\operatorname{Log}(1 + j) = \ln\sqrt{2} + j\pi/4 = 0.3466 + j0.7854$. Then

$$(1 + j)^j = e^{j(0.3466 + j0.7854)} = e^{-0.7854} e^{j0.3466} = 0.4559(0.9405 + j0.3397) = 0.4288 + j0.1549.$$

Common Pitfall — logarithm laws with complex numbers

The rule $\operatorname{Log}(z_1 z_2) = \operatorname{Log} z_1 + \operatorname{Log} z_2$ can fail for principal values, because the sum of two principal arguments may fall outside $(-\pi, \pi]$. Example: $z_1 = z_2 = -1$ gives $\operatorname{Log}(1) = 0$ but $\operatorname{Log}(-1) + \operatorname{Log}(-1) = j2\pi$. The identity holds **modulo** $j2\pi$. In phase calculations this appears as the familiar "phase wrapping": a phase computed by adding contributions may differ from the instrument's principal value by a multiple of 360°, and both are correct.

Hyperbolic functions and complex arguments

Replacing θ by jx in the inverse Euler formulas links trigonometric and hyperbolic functions:

$$\cos(jx) = \frac{e^{-x} + e^{x}}{2} = \cosh x, \qquad \sin(jx) = \frac{e^{-x} - e^{x}}{2j} = j \sinh x.$$

Combined with the compound-angle formula this gives the real and imaginary parts of the sine and cosine of any complex number:

$$\sin(x + jy) = \sin x \cosh y + j \cos x \sinh y, \qquad \cos(x + jy) = \cos x \cosh y - j \sin x \sinh y.$$

For example $\sin(\pi/2 + j1) = \cosh 1 = 1.5431$ — a sine can exceed 1 when its argument is complex. These formulas appear in transmission-line theory, where the voltage along a lossy line involves $\cosh(\gamma\ell)$ and $\sinh(\gamma\ell)$ with a complex propagation constant $\gamma = \alpha + j\beta$, and in waveguides below cut-off, where a "sinusoidal" field becomes an exponentially decaying one.

Engineering Note — the exponential form in software

Numerical libraries provide `exp`, `log`, `abs` and `angle` / `arg` for complex arguments, and they return **principal** values. When a quantity is built up by multiplying many complex factors (a cascade of filter stages, a long chain of transmission-line sections), it is often more robust to accumulate $\ln|H|$ and $\angle H$ separately — adding logarithms of magnitudes and adding (unwrapped) phases — than to multiply complex numbers directly, which can overflow or lose track of full turns.

2.6 Roots and powers of complex numbers

Motivation

Raising a complex number to a high power by repeated rectangular multiplication is tedious and error-prone; in exponential form it is a single step. The inverse problem — finding all solutions of $w^n = z$ — is even more important in engineering, because the poles of standard filter families, the frequencies of a discrete Fourier transform, the phases of a polyphase power system and the symbols of a phase-shift-keyed modulator are all n-th roots of some complex number. The central fact is that a non-zero complex number has exactly n distinct n-th roots, arranged symmetrically on a circle.

Integer powers: De Moivre's theorem

De Moivre's theorem

For every integer n (positive, zero or negative) and real θ,

$$(\cos\theta + j\sin\theta)^n = \cos n\theta + j\sin n\theta, \qquad \text{equivalently} \qquad (re^{j\theta})^n = r^n e^{jn\theta}.$$

Proof. For $n \geq 0$, by induction: the case $n = 0$ is $1 = 1$. If true for n, then

$$(\cos\theta + j\sin\theta)^{n+1} = (\cos n\theta + j\sin n\theta)(\cos\theta + j\sin\theta) = \cos(n+1)\theta + j\sin(n+1)\theta$$

by the polar multiplication rule (angles add). For negative $n = -m$, $(\cos\theta + j\sin\theta)^{-m} = 1/(\cos m\theta + j\sin m\theta) = \cos m\theta - j\sin m\theta = \cos(-m\theta) + j\sin(-m\theta)$, using $1/e^{j\phi} = e^{-j\phi}$. With exponentials the whole theorem is just $(e^{j\theta})^n = e^{jn\theta}$. $\square$

Recipe for z^n: convert to polar, raise the magnitude to the n-th power, multiply the angle by n, reduce the angle to the principal range if desired, convert back.

Worked Example 2.20 — High powers

(a) $(1+j)^8$. Here $1 + j = \sqrt{2}\,e^{j\pi/4}$, so $(1+j)^8 = (\sqrt{2})^8 e^{j2\pi} = 16$.

Check: $(1+j)^2 = 2j$, so $(1+j)^8 = (2j)^4 = 16j^4 = 16$. ✓

(b) $(1 + j\sqrt{3})^{10}$. Here $1 + j\sqrt{3} = 2e^{j\pi/3}$, so

$$(1+j\sqrt{3})^{10} = 2^{10}e^{j10\pi/3} = 1024\,e^{j(10\pi/3 - 4\pi)} = 1024\,e^{-j2\pi/3} = 1024\left(-\tfrac{1}{2} - j\tfrac{\sqrt{3}}{2}\right) = -512 - j886.8.$$

Expanding by the binomial theorem would have required eleven terms.

(c) A negative power: $(1 - j\sqrt{3})^{-4}$. With $1 - j\sqrt{3} = 2e^{-j\pi/3}$,

$$(1-j\sqrt{3})^{-4} = 2^{-4}e^{j4\pi/3} = \tfrac{1}{16}\left(-\tfrac{1}{2} - j\tfrac{\sqrt{3}}{2}\right) = -0.03125 - j0.05413.$$

Multiple-angle formulas

Expanding the left side of De Moivre's theorem with the binomial theorem and equating real and imaginary parts produces formulas for $\cos n\theta$ and $\sin n\theta$ as polynomials in $\cos\theta$ and $\sin\theta$ — the reverse of the power-reduction of Example 2.13.

Worked Example 2.21 — Triple-angle formulas

Write $c = \cos\theta$, $s = \sin\theta$. Then

$$(c + js)^3 = c^3 + 3c^2(js) + 3c(js)^2 + (js)^3 = (c^3 - 3cs^2) + j(3c^2 s - s^3).$$

By De Moivre this equals $\cos 3\theta + j\sin 3\theta$. Equate parts and use $s^2 = 1 - c^2$, $c^2 = 1 - s^2$:

$$\cos 3\theta = c^3 - 3c(1-c^2) = 4\cos^3\theta - 3\cos\theta, \qquad \sin 3\theta = 3(1-s^2)s - s^3 = 3\sin\theta - 4\sin^3\theta.$$

Check at $\theta = 0.7$: $4\cos^3 0.7 - 3\cos 0.7 = -0.5048$ and $\cos 2.1 = -0.5048$. ✓

The polynomial $T_3(x) = 4x^3 - 3x$ with $\cos 3\theta = T_3(\cos\theta)$ is a **Chebyshev polynomial**; the family T_n defined by $\cos n\theta = T_n(\cos\theta)$ is the basis of Chebyshev filter design.

n-th roots

n-th roots of a complex number

Let $z = re^{j\theta} \neq 0$ and $n \geq 1$ an integer. The equation $w^n = z$ has exactly n distinct solutions

$$w_k = r^{1/n}\exp\left(j\,\frac{\theta + 2\pi k}{n}\right), \qquad k = 0, 1, \ldots, n-1,$$

where $r^{1/n}$ is the ordinary positive real root. They lie on the circle $|w| = r^{1/n}$, equally spaced at angular intervals of $2\pi/n$, forming the vertices of a regular n-gon.

Proof. Write the unknown as $w = \rho e^{j\phi}$. Then $w^n = \rho^n e^{jn\phi}$, and $w^n = z$ requires equal magnitudes and angles equal up to multiples of 2π:

$$\rho^n = r \;\Rightarrow\; \rho = r^{1/n}; \qquad n\phi = \theta + 2\pi k \;\Rightarrow\; \phi = \frac{\theta + 2\pi k}{n}, \quad k \in \mathbb{Z}.$$

Values of k that differ by a multiple of n give angles differing by a multiple of 2π — the same point. So exactly the n values $k = 0, \dots, n-1$ give distinct roots. □

The crucial step is keeping the "$+2\pi k$" **before** dividing by n. Adding 2π to θ does not change z, but adding $2\pi/n$ to the root's angle does change the root — that is where the extra roots come from. The root with $k = 0$ and principal θ is the **principal root**.

Recipe for the n-th roots of z: (1) write $z = re^{j\theta}$; (2) the first root is $r^{1/n}e^{j\theta/n}$; (3) the others follow by repeatedly rotating by $2\pi/n$ (i.e. multiplying by $e^{j2\pi/n}$).

Worked Example 2.22 — Cube roots of $8j$

Solve $w^3 = 8j$.

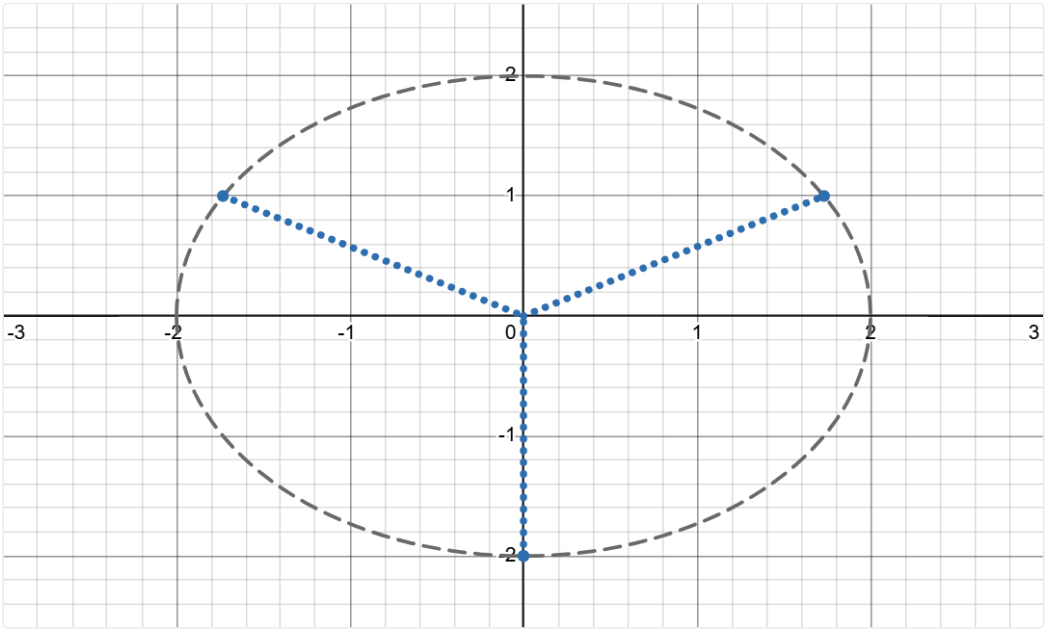
Step 1. $8j = 8e^{j\pi/2}$, so $r^{1/3} = 2$ and the angles are $\frac{\pi/2 + 2\pi k}{3} = \frac{\pi}{6} + \frac{2\pi k}{3}$.

Step 2.

$$w_0 = 2e^{j\pi/6} = \sqrt{3} + j, \qquad w_1 = 2e^{j5\pi/6} = -\sqrt{3} + j, \qquad w_2 = 2e^{j3\pi/2} = -2j.$$

Check w_2: $(-2j)^3 = -8j^3 = -8(-j) = 8j$. ✓ And w_0: $(\sqrt{3}+j)^2 = 3 + 2\sqrt{3}j - 1 = 2 + j2\sqrt{3}$; times $(\sqrt{3}+j)$ gives $2\sqrt{3} + j2 + j6 - 2\sqrt{3} = 8j$. ✓

Structural check: the roots of $w^3 - 8j = 0$ sum to zero (the coefficient of w^2 is zero): $\sqrt{3} + j - \sqrt{3} + j - 2j = 0$. ✓



The three cube roots of $8j$ lie on the circle of radius 2, 120° apart, starting at 30° (one-third of the angle 90° of $8j$).

Square roots in rectangular form

For square roots it is sometimes quicker to avoid polar form. Seek $w = x + jy$ with $w^2 = a + jb$: equating parts of $x^2 - y^2 + j2xy = a + jb$ gives $x^2 - y^2 = a$, $2xy = b$, and taking magnitudes gives $x^2 + y^2 = r = \sqrt{a^2 + b^2}$. Adding and subtracting:

Square root of $a + jb$

$$\sqrt{a + jb} = \pm\left(\sqrt{\frac{r + a}{2}} + j\,\operatorname{sgn}(b)\sqrt{\frac{r - a}{2}}\right), \qquad r = \sqrt{a^2 + b^2},$$

with $\operatorname{sgn}(b) = 1$ if $b \geq 0$ and -1 if $b < 0$ (the sign makes $2xy$ have the sign of b).

Worked Example 2.23 — A quadratic with complex coefficients

Solve $z^2 - (3+j)z + (4+j3) = 0$.

Step 1 — discriminant. The quadratic formula is valid in $\mathbb{C}$ (it is pure field algebra):

$$D = (3+j)^2 - 4(4+j3) = (9+j6-1) - 16 - j12 = -8 - j6.$$

Step 2 — square root of D. $a=-8, b=-6, r=10$: $\sqrt{(10-8)/2}=1$, $\sqrt{(10+8)/2}=3$, and $b<0$, so $\sqrt{D} = \pm(1-j3)$. *Check:* $(1-j3)^2 = 1 - j6 - 9 = -8-j6$. ✓

Step 3 — roots.

$$z = \frac{(3+j) \pm (1-j3)}{2}: \qquad z_1 = \frac{4-j2}{2} = 2-j, \qquad z_2 = \frac{2+j4}{2} = 1+j2.$$

Check with Vieta: $z_1+z_2 = 3+j$ ✓ and $z_1 z_2 = (2-j)(1+j2) = 2+j4-j+2 = 4+j3$. ✓

Note that the roots are **not** conjugates of each other: the conjugate root theorem needs real coefficients.

Roots of unity

Roots of unity

The n solutions of $w^n = 1$ are the **n-th roots of unity**

$$W^k = e^{j2\pi k/n}, \qquad k = 0, 1, \ldots, n-1, \qquad W = e^{j2\pi/n}.$$

W is the **primitive** n-th root of unity; the others are its powers.

The n-th roots of any z are the principal root multiplied by each root of unity: $w_k = w_0 W^k$. Roots of unity therefore carry all the "rotational" structure of root-finding.

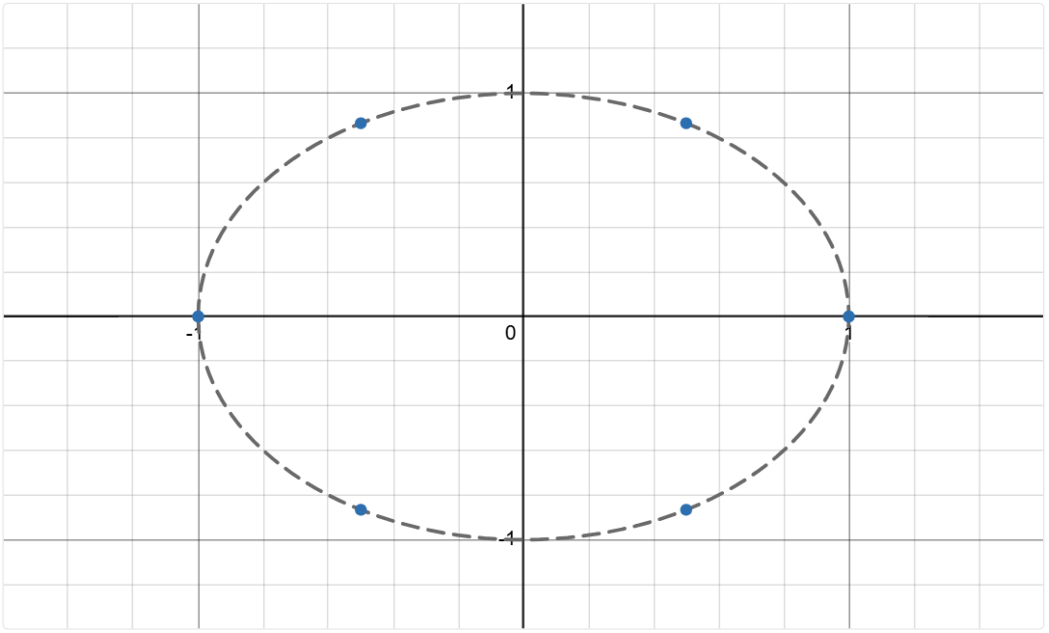
Sums of roots of unity

For $n \geq 2$,

$$\sum_{k=0}^{n-1} W^k = 0, \qquad \text{and more generally} \qquad \sum_{k=0}^{n-1} W^{mk} = \begin{cases} n, & m \equiv 0 \pmod{n}, \\ 0, & \text{otherwise.} \end{cases}$$

Proof. If m is a multiple of n, every term is $W^{mk} = e^{j2\pi mk/n} = 1$ and the sum is n. Otherwise $W^m \neq 1$ and the geometric series gives $\dfrac{1-W^{mn}}{1-W^m} = \dfrac{1-1}{1-W^m} = 0$, since $W^{mn} = (W^n)^m = 1$. □

Geometrically: the roots are the vertices of a regular polygon centred at the origin, and arrows from the centre to the vertices of a regular polygon balance out. The second form is the **orthogonality relation** of the discrete Fourier transform (Ch. 16, Ch. 24), where $W_N = e^{-j2\pi/N}$ is called the twiddle factor; it is what allows the DFT to be inverted.



The six sixth roots of unity, $e^{j2\pi k/6}$, form a regular hexagon on the unit circle; their sum is zero.

Engineering Note — three-phase power and PSK

The cube roots of unity 1, $a = e^{j2\pi/3}$, $a^2 = e^{-j2\pi/3}$ describe the 120° spacing of a balanced three-phase supply. Because $1 + a + a^2 = 0$, the three phase voltages (or balanced load currents) sum to zero at every instant, so the neutral conductor of a balanced system carries no current. Power engineers use the operator "a" throughout symmetrical-component analysis of faults. In digital communications, M-ary phase-shift keying transmits one of the M-th roots of unity (scaled) per symbol: QPSK uses $e^{j(\pi/4 + k\pi/2)}$, the four fourth roots of -1.

Factoring polynomials with roots

Worked Example 2.24 — Factoring $z^4 + 1$ over the reals

Step 1 — roots. $z^4 = -1 = e^{j\pi}$ gives $z_k = e^{j(\pi + 2\pi k)/4}$, i.e. $e^{\pm j\pi/4}$ and $e^{\pm j3\pi/4}$, or $\frac{\pm 1 \pm j}{\sqrt{2}}$.

Step 2 — pair conjugates. For a pair $e^{\pm j\alpha}$ the real quadratic factor is $z^2 - 2\cos\alpha\, z + 1$:

$$\alpha = \tfrac{\pi}{4}: \; z^2 - \sqrt{2}z + 1, \qquad \alpha = \tfrac{3\pi}{4}: \; z^2 + \sqrt{2}z + 1.$$

Step 3. $z^4 + 1 = (z^2 - \sqrt{2}z + 1)(z^2 + \sqrt{2}z + 1)$. *Check:* the product is $(z^2+1)^2 - 2z^2 = z^4 + 2z^2 + 1 - 2z^2 = z^4 + 1$. ✓

Such factorisations are needed when integrating rational functions by partial fractions (Ch. 5) and when building filters from second-order sections.

Worked Example 2.25 — Butterworth filter poles

An n-th order Butterworth low-pass filter with cut-off 1 rad/s has $|H(j\omega)|^2 = \dfrac{1}{1 + \omega^{2n}}$. Its poles are the left-half-plane roots of $1 + (-s^2)^n = 0$, obtained by substituting $\omega^2 = -s^2$ (since $s = j\omega$). Find the third-order Butterworth polynomial.

Step 1. For $n = 3$: $1 + (-s^2)^3 = 1 - s^6 = 0$, so $s^6 = 1$: the sixth roots of unity, $s_k = e^{jk\pi/3}$.

Step 2 — keep the stable ones. The roots with $\mathrm{Re}\{s\} < 0$ are $k = 2, 3, 4$: $e^{j2\pi/3} = -\frac{1}{2} + j\frac{\sqrt{3}}{2}$, -1, and $e^{j4\pi/3} = -\frac{1}{2} - j\frac{\sqrt{3}}{2}$. (The right-half-plane roots belong to $H(-s)$, the mirror factor of $|H|^2 = H(s)H(-s)$.)

Step 3 — multiply out. The conjugate pair gives $s^2 + s + 1$ (since $-2\cos(2\pi/3) = 1$), and

$$B_3(s) = (s+1)(s^2 + s + 1) = s^3 + 2s^2 + 2s + 1, \qquad H(s) = \frac{1}{s^3 + 2s^2 + 2s + 1}.$$

Check at $\omega = 1$: $B_3(j) = -j - 2 + 2j + 1 = -1 + j$, so $|H(j1)|^2 = 1/|-1+j|^2 = 1/2$, matching $1/(1+1^6)$. ✓ The poles lie on the unit circle at 120°, 180° and 240° — evenly spaced by $\pi/n = 60^\circ$, the defining geometry of the Butterworth family.

Common Pitfall — keeping only the principal root

A calculator's $\sqrt[n]{z}$, or `z**(1/n)` in software, returns only the principal root ($k = 0$). Equations such as $w^4 = -16$ have four roots ($\sqrt{2}(\pm 1 \pm j)$); forgetting the other three loses poles of filters, branches of a root locus, or valid solutions of a characteristic equation. Always write "$+2\pi k$" before dividing the angle by n.

Common Pitfall — $(z^{1/n})^n$ versus $(z^n)^{1/n}$

$(z^{1/n})^n = z$ for every root, but $(z^n)^{1/n}$ need not return z: $\left((-1)^2\right)^{1/2} = 1^{1/2}$ has principal value 1, not -1. Fractional powers do not commute with integer powers once principal values are used, for the same reason the logarithm laws fail (Section 2.5).

2.7 Complex plane and geometric interpretation

Motivation

Many engineering judgements are made by looking at the complex plane rather than by computing: whether a system is stable (where are its poles?), how much phase margin a feedback loop has (how close does the Nyquist curve pass to -1?), whether an antenna is matched (where does its reflection coefficient sit on the Smith chart?), how noisy a received constellation is (how spread are the points?). Each of these is a geometric statement about complex numbers. This section collects the dictionary between algebra and geometry so that such pictures can be read fluently.

Complex numbers as vectors

Complex (Argand) plane

The **complex plane** identifies $z = x + jy$ with the point (x, y), or with the vector from the origin to that point. The horizontal axis is the **real axis**, the vertical axis the **imaginary axis**. The magnitude $|z|$ is the length of the vector and $\arg z$ its direction.

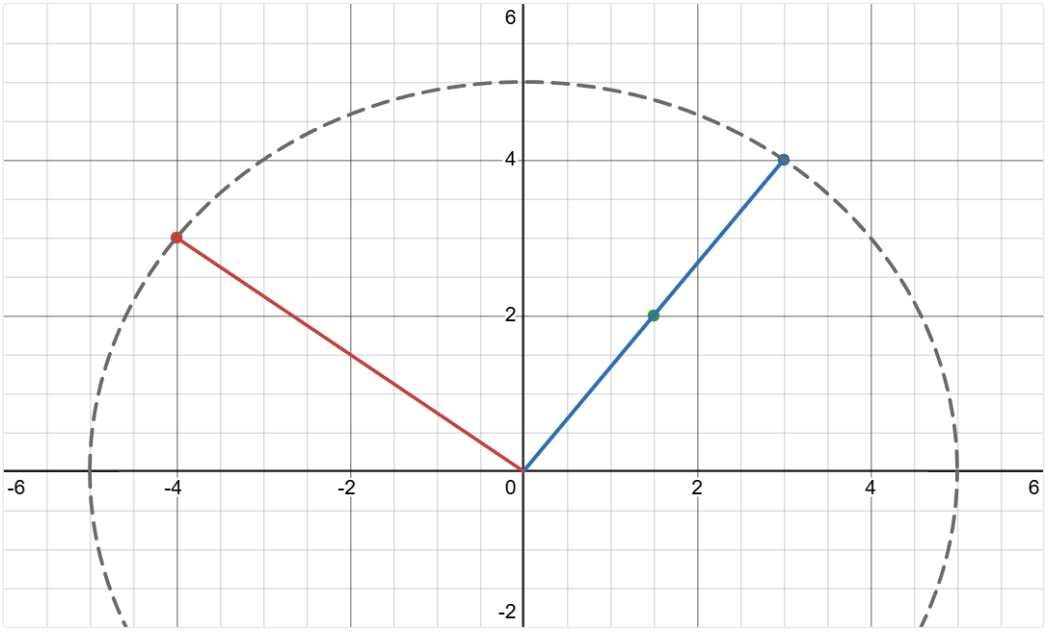
Under this identification addition, subtraction and real scaling of complex numbers are exactly vector addition, subtraction and scaling in $\mathbb{R}^2$. What the plane adds to $\mathbb{R}^2$ is **multiplication**, which has no counterpart for ordinary 2-D vectors and which is a rotation-plus-scaling.

Geometric meaning of the operations

Operation	Geometric effect
$z + w$	translation of z by the vector w (parallelogram rule)
$z - w$	vector from w to z
$\lvert z - w \rvert$	distance between the points z and w
$\arg(z - w)$	direction of the segment from w to z
kz, $k > 0$ real	scaling by k about the origin
$-z$	rotation by 180° (point reflection in the origin)
jz	rotation by $+90^\circ$ (anticlockwise)
$e^{j\alpha}z$	rotation by α about the origin
$(re^{j\alpha})z$	scaling by r combined with rotation by α (a "spiral similarity")
z^*	reflection in the real axis
$1/z$	$\frac{1}{r}e^{-j\theta}$: inversion in the unit circle ($r \to 1/r$) followed by reflection in the real axis
$w_0 + e^{j\alpha}(z - w_0)$	rotation by α about the point w_0

The last entry is built from simpler ones: translate w_0 to the origin, rotate, translate back. Composite geometric transformations are obtained by composing complex functions.

Why multiplication by j is a quarter-turn, without polar form: $j(x + jy) = -y + jx$, and the map $(x, y) \mapsto (-y, x)$ is the standard 90° rotation matrix $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ of linear algebra (Ch. 9). More generally, multiplication by $a + jb$ is the linear map with matrix $\begin{pmatrix} a & -b \\ b & a \end{pmatrix}$, which is r times a rotation matrix.



Multiplying by j rotates $z = 3 + j4$ by 90° to $-4 + j3$; both lie on the circle $|z| = 5$. Multiplying by the real number 0.5 only shrinks it.

Worked Example 2.26 — Completing an equilateral triangle

Two vertices of an equilateral triangle are 0 and $4 + j2$. Find the third vertex.

Idea. The third vertex is obtained by rotating the side vector $4 + j2$ by $\pm 60^\circ$ about 0.

Step 1. $e^{j\pi/3} = \frac{1}{2} + j\frac{\sqrt{3}}{2} = 0.5 + j0.8660$.

Step 2. $(4 + j2)(0.5 + j0.866) = 2 + j3.464 + j1 - 1.732 = 0.268 + j4.464$.

Step 3. The other orientation: $(4 + j2)(0.5 - j0.866) = 2 - j3.464 + j1 + 1.732 = 3.732 - j2.464$.

Check the first solution: its distance from 0 is $\sqrt{0.268^2 + 4.464^2} = 4.472 = \sqrt{20} = |4 + j2|$, and its distance from $4 + j2$ is $|-3.732 + j2.464| = \sqrt{13.93 + 6.07} = \sqrt{20}$. ✓ All three sides equal.

The same idea computes the line-to-line voltages of a three-phase system (Section 2.8), whose phasors form an equilateral triangle.

Distances, midpoints and centroids

Distances between points are magnitudes of differences, $|z_1 - z_2|$. The midpoint of the segment from z_1 to z_2 is $\frac{1}{2}(z_1 + z_2)$, and the point dividing it in ratio $t : (1-t)$ is $(1-t)z_1 + tz_2$, $0 \le t \le 1$ — the **parametric equation of a segment**. The centroid of points $z_1, \dots, z_n$ is their average $\frac{1}{n}\sum z_k$; for instance the centroid of the triangle $1 + j2$, $5 - j$, $3 + j4$ is $\frac{1}{3}(9 + j5) = 3 + j1.667$. In a received constellation, the centroid of many noisy samples estimates the transmitted symbol.

Curves and regions

Simple equations and inequalities in z describe the curves and regions that recur in engineering. Here $z = x + jy$.

Standard loci

Equation	Locus
$\lvert z - z_0\rvert = R$	circle, centre z_0, radius R
$\lvert z - z_0\rvert < R$	open disc (interior of the circle)
$\lvert z - z_1\rvert = \lvert z - z_2\rvert$	perpendicular bisector of the segment $z_1 z_2$
$\lvert z - z_1\rvert = k\lvert z - z_2\rvert$, $k > 0$, $k \neq 1$	a circle (circle of Apollonius)
$\arg(z - z_0) = \alpha$	ray from z_0 at angle α (excluding z_0)
$\mathrm{Re}\{z\} = c$, $\mathrm{Im}\{z\} = c$	vertical / horizontal line
$\mathrm{Re}\{z\} < 0$	open left half-plane
$\alpha < \arg z < \beta$	open sector (wedge)
$z = z_0 + Re^{jt}$, $0 \le t < 2\pi$	parametric form of the circle $\lvert z - z_0\rvert = R$

To identify an unfamiliar locus, the reliable method is to substitute $z = x + jy$, square any magnitudes (using $|w|^2 = ww^*$ or simply $|a + jb|^2 = a^2 + b^2$), and recognise the resulting real equation in x and y.

Worked Example 2.27 — A half-plane

Describe $\{z : |z - 1| \le |z + 1|\}$.

Geometric reading. Points no farther from 1 than from -1. The boundary $|z - 1| = |z + 1|$ is the set of points equidistant from ± 1: the perpendicular bisector, which is the imaginary axis. Testing $z = 2$: $|1| \le |3|$ holds, so the region is the side containing 2.

Algebraic confirmation. Both sides are non-negative, so square: $(x-1)^2 + y^2 \le (x+1)^2 + y^2 \iff -2x \le 2x \iff x \ge 0$.

The region is the closed right half-plane $\mathrm{Re}\{z\} \ge 0$. ✓

Worked Example 2.28 — A circle of Apollonius

Identify the locus $|z - j| = 2|z + 1|$.

Step 1 — substitute and square.

$$x^2 + (y-1)^2 = 4\left[(x+1)^2 + y^2\right].$$

Step 2 — expand and collect. $x^2 + y^2 - 2y + 1 = 4x^2 + 8x + 4 + 4y^2$, so $3x^2 + 3y^2 + 8x + 2y + 3 = 0$, i.e.

$$x^2 + y^2 + \tfrac{8}{3}x + \tfrac{2}{3}y + 1 = 0.$$

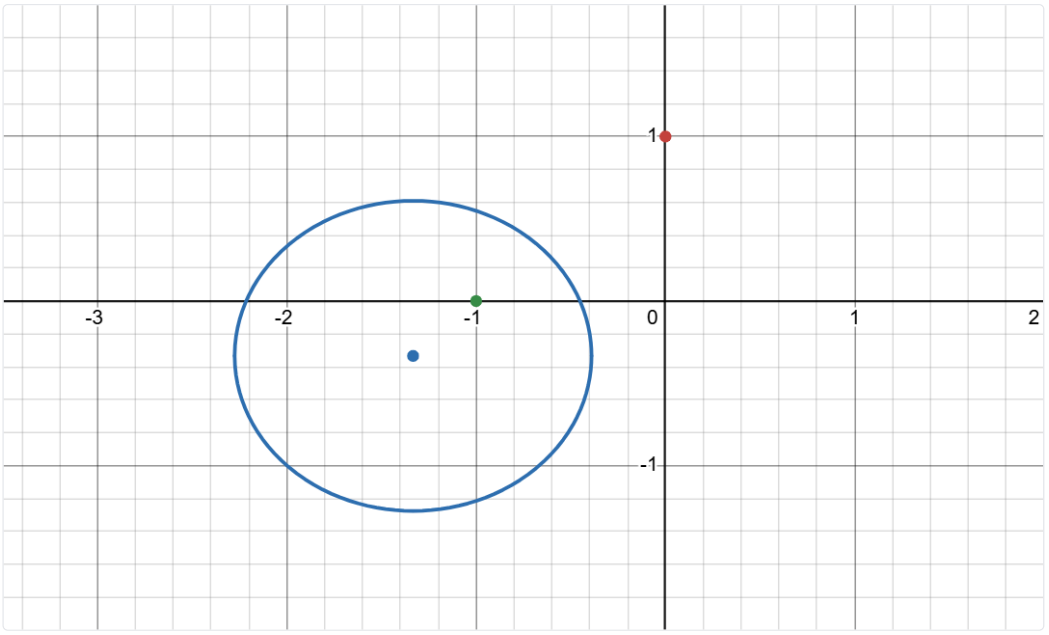
Step 3 — complete the square.

$$\left(x + \tfrac{4}{3}\right)^2 + \left(y + \tfrac{1}{3}\right)^2 = \tfrac{16}{9} + \tfrac{1}{9} - 1 = \tfrac{8}{9}.$$

A circle with centre $-\frac{4}{3} - j\frac{1}{3}$ and radius $\sqrt{8}/3 \approx 0.943$.

Check a point: the rightmost point of the circle is $z = -\frac{4}{3} + 0.943 - j\frac{1}{3} = -0.391 - j0.333$. Then $|z - j| = |-0.391 - j1.333| = 1.389$ and $|z + 1| = |0.609 - j0.333| = 0.694$; ratio 2.00. ✓

The circle encloses -1 (the point the ratio favours) but not j. Circles of this kind are the constant-gain contours of a single-pole, single-zero system: $|z - j|/|z + 1|$ is the magnitude of $(z - j)/(z + 1)$.



The locus $|z - j| = 2|z + 1|$ is a circle around -1; every point on it is twice as far from j as from -1.

Mappings: what $1/z$ does to lines

The map $w = 1/z$ is a good first example of a complex function viewed as a transformation of the plane. Its key property — lines and circles map to lines and circles — is the basis of the Smith chart.

Worked Example 2.29 — Image of a line under inversion

Show that $w = 1/z$ maps the vertical line $\mathrm{Re}\{z\} = 1$ onto the circle $|w - \frac{1}{2}| = \frac{1}{2}$ (minus the origin).

Step 1 — parametrise the line. $z = 1 + jy$, $y \in \mathbb{R}$.

Step 2 — compute w.

$$w = \frac{1}{1+jy} = \frac{1-jy}{1+y^2}, \qquad u = \mathrm{Re}\{w\} = \frac{1}{1+y^2}, \quad v = \mathrm{Im}\{w\} = \frac{-y}{1+y^2}.$$

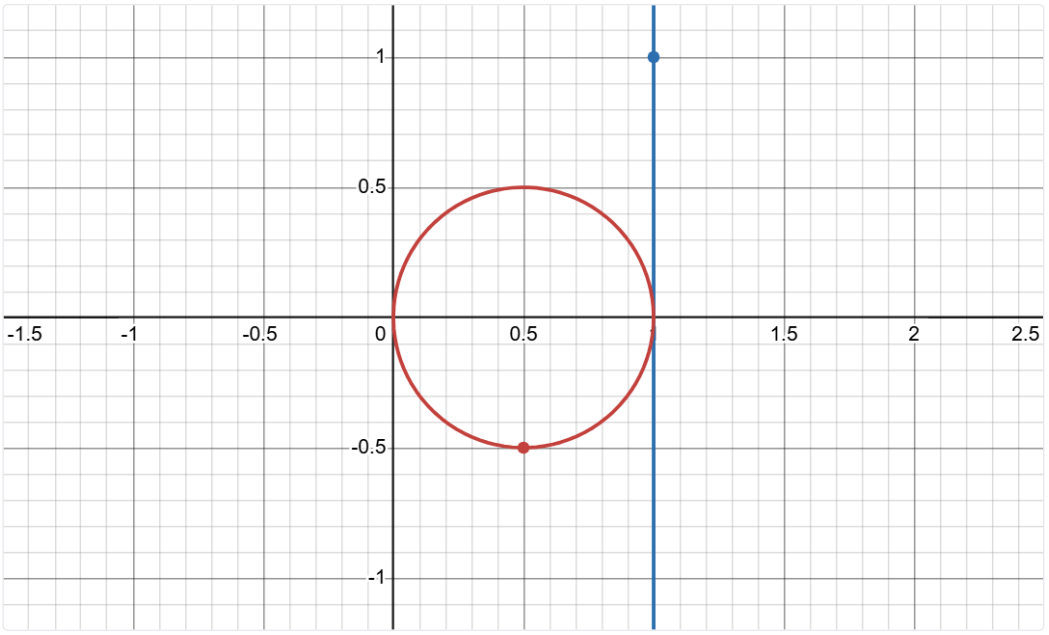
Step 3 — eliminate y. $u^2 + v^2 = \dfrac{1+y^2}{(1+y^2)^2} = \dfrac{1}{1+y^2} = u$, so $u^2 - u + v^2 = 0$, i.e.

$$\left(u - \tfrac{1}{2}\right)^2 + v^2 = \tfrac{1}{4}.$$

As $y \to \pm\infty$, $w \to 0$, which is approached but never reached.

Check: $y = 1$ gives $w = \frac{1-j}{2}$, and $|w - \frac{1}{2}| = |-j/2| = \frac{1}{2}$. ✓

Engineering reading: the line $\mathrm{Re}\{Z\} = 1\ \Omega$ is "all impedances with 1 Ω resistance". Its image under $Y = 1/Z$ shows that the corresponding admittances fill a circle in the admittance plane — exactly the constant-resistance circles of impedance/admittance charts.



Inversion $w = 1/z$ maps the vertical line $\mathrm{Re}\{z\} = 1$ (blue) onto the circle of diameter 1 through the origin (red). The point $1 + j$ maps to $\frac{1}{2} - j\frac{1}{2}$: inversion also reflects in the real axis.

Engineering Note — the Smith chart and stability regions

Smith chart. The reflection coefficient of a load Z_L on a line of characteristic impedance Z_0 is $\Gamma = \dfrac{z-1}{z+1}$ with $z = Z_L/Z_0$. This map (a **bilinear** or Möbius transformation, studied in Ch. 18) sends the entire right half-plane $\mathrm{Re}\{z\} \geq 0$ — every passive load — into the unit disc $|\Gamma| \leq 1$. A matched load $z = 1$ lands at the centre $\Gamma = 0$; any pure reactance $z = jx$ lands on the rim $|\Gamma| = 1$ (total reflection). For example $z = 1 + j$ gives $\Gamma = \dfrac{j}{2+j} = 0.2 + j0.4$, $|\Gamma| = 0.447$. The Smith chart is the unit disc with the images of the lines $\mathrm{Re}\{z\} = \text{const}$ and $\mathrm{Im}\{z\} = \text{const}$ drawn on it — all circles, by the line-to-circle property.

Stability. A continuous-time linear time-invariant system is stable when every pole of its transfer function lies in the open left half-plane $\mathrm{Re}\{s\} < 0$; a discrete-time system is stable when every pole lies inside the unit circle $|z| < 1$ (Ch. 14, 17). Lines of constant damping ratio are rays $\arg s = \pm(\pi - \cos^{-1}\zeta)$; contours of constant settling time are vertical lines $\mathrm{Re}\{s\} = -\sigma$. Root locus, Nyquist and pole–zero plots are all geometry in this plane.

Common Pitfall — reading "arg" loci

The equation $\arg(z - z_0) = \alpha$ describes a **ray**, not a full line: the opposite ray has argument $\alpha \pm \pi$. Likewise $\arg\left(\frac{z-z_1}{z-z_2}\right) = \alpha$ is an **arc** of a circle through z_1 and z_2, not the whole circle (the other arc has argument $\alpha - \pi$). Squaring or taking tangents of an argument equation silently adds the missing pieces, so check candidate points against the original equation.

2.8 Applications to AC circuits and phasors

Motivation

A linear circuit driven by a sinusoidal source is governed by a linear differential equation. Solving it directly — guessing $A\cos\omega t + B\sin\omega t$, substituting, and grinding through trigonometric identities — is laborious even for a single loop and impractical for a network. The **phasor method** replaces the differential equation by an algebraic equation in complex numbers. It rests on three facts already established: a sinusoid is the real part of a complex exponential (Section 2.4), complex arithmetic follows all the ordinary rules (Section 2.3), and differentiating $e^{j\omega t}$ merely multiplies it by $j\omega$.

The method applies to the **sinusoidal steady state**: the response that remains after transients have died out, when every voltage and current is a sinusoid at the source frequency ω. For a stable linear time-invariant circuit, such a steady state always exists and differs from the input only in amplitude and phase. Transients are the subject of Ch. 11–12 and the Laplace transform (Ch. 14).

Sinusoids as real parts

A sinusoid is specified by an amplitude $V_m > 0$, an angular frequency ω and a phase ϕ (Ch. 3 treats these in detail). By Euler's formula

$$v(t) = V_m\cos(\omega t + \phi) = \mathrm{Re}\left\{V_m e^{j(\omega t+\phi)}\right\} = \mathrm{Re}\left\{\left(V_m e^{j\phi}\right)e^{j\omega t}\right\}.$$

The factor $e^{j\omega t}$ is common to every signal in the circuit. All the information that distinguishes one signal from another is in the complex constant $V_m e^{j\phi}$.

Phasor

The **phasor** of the sinusoid $v(t) = V_m \cos(\omega t + \phi)$ is the complex constant

$$\mathbf{V} = V_m e^{j\phi} = V_m \angle \phi.$$

The sinusoid is recovered by

$$v(t) = \operatorname{Re}\left\{\mathbf{V} e^{j\omega t}\right\}.$$

The magnitude of the phasor is the amplitude; its angle is the phase. The phasor does not contain ω — the frequency is a shared, separately remembered parameter.

Conventions. This book uses **amplitude (peak) phasors** and the **cosine reference**. A sine is first converted to a cosine: $V_m \sin(\omega t + \phi) = V_m \cos(\omega t + \phi - 90^\circ)$, so its phasor is $V_m \angle(\phi - 90^\circ) = -jV_m e^{j\phi}$. A negative amplitude is absorbed into the phase: $-V_m \cos(\omega t + \phi) = V_m \cos(\omega t + \phi \pm 180^\circ)$. Power-systems texts commonly use **RMS phasors** with $|\mathbf{V}| = V_m/\sqrt{2}$; for example the UK mains is "230 V" RMS, a peak of $230\sqrt{2} = 325.3$ V. Every formula in this section holds for either convention, except power formulas, which lose the factor $\frac{1}{2}$ with RMS phasors (Section 2.9). State which convention you are using.

The phasor transform is one-to-one and linear

Uniqueness of phasors

Let $\mathbf{A}, \mathbf{B}$ be complex constants and $\omega \neq 0$. If

$$\operatorname{Re}\{\mathbf{A} e^{j\omega t}\} = \operatorname{Re}\{\mathbf{B} e^{j\omega t}\} \quad \text{for all } t,$$

then $\mathbf{A} = \mathbf{B}$.

Proof. Put $\mathbf{C} = \mathbf{A} - \mathbf{B} = c_1 + jc_2$; we have $\operatorname{Re}\{\mathbf{C} e^{j\omega t}\} = c_1 \cos \omega t - c_2 \sin \omega t = 0$ for all t. At $t = 0$ this gives $c_1 = 0$; at $\omega t = \pi/2$ it gives $-c_2 = 0$. So $\mathbf{C} = 0$. □

This theorem is what licenses the method: if two sinusoidal expressions at the same frequency are equal for all time, their phasors are equal, and conversely. Combined with the following rules, it converts any linear constant-coefficient relation between same-frequency sinusoids into the same relation between phasors.

Phasor properties

Let $x(t) \leftrightarrow \mathbf{X}$ and $y(t) \leftrightarrow \mathbf{Y}$ be sinusoids at a common frequency ω. Then:

- **Linearity:** $a\,x(t) + b\,y(t) \;\leftrightarrow\; a\mathbf{X} + b\mathbf{Y}$ for real constants a, b.
- **Differentiation:** $\dfrac{dx}{dt} \;\leftrightarrow\; j\omega\mathbf{X}$, and $\dfrac{d^n x}{dt^n} \;\leftrightarrow\; (j\omega)^n \mathbf{X}$.
- **Integration** (the zero-mean, steady-state antiderivative): $\displaystyle\int x\,dt \;\leftrightarrow\; \frac{\mathbf{X}}{j\omega}$.
- **Time delay:** $x(t - \tau) \;\leftrightarrow\; e^{-j\omega\tau}\mathbf{X}$.

Proof of the differentiation rule. The real part commutes with differentiation with respect to the real variable t, so

$$\frac{d}{dt}\operatorname{Re}\{\mathbf{X} e^{j\omega t}\} = \operatorname{Re}\left\{\mathbf{X}\frac{d}{dt}e^{j\omega t}\right\} = \operatorname{Re}\{(j\omega\mathbf{X}) e^{j\omega t}\}.$$

Linearity follows because Re is additive and commutes with multiplication by **real** constants. The delay rule: $\operatorname{Re}\{\mathbf{X} e^{j\omega(t-\tau)}\} = \operatorname{Re}\{(\mathbf{X} e^{-j\omega\tau}) e^{j\omega t}\}$. □

In words: **differentiation multiplies the amplitude by ω and advances the phase by** 90°, since $j\omega = \omega \angle 90^\circ$. Check directly: $\frac{d}{dt}\cos \omega t = -\omega \sin \omega t = \omega \cos(\omega t + 90^\circ)$. ✓ A delay of τ seconds is a phase lag of $\omega\tau$ radians.

The method

1. Convert every source to a cosine and write its phasor.
2. Replace every d/dt by $j\omega$ (equivalently, replace each circuit element by its impedance — Section 2.9).
3. Solve the resulting **algebraic** equations with complex arithmetic.
4. Convert each phasor answer back: $\mathbf{X} = X_m \angle \phi \;\Rightarrow\; x(t) = X_m \cos(\omega t + \phi)$.

Worked Example 2.30 — Adding sinusoids

Express $v(t) = 10\cos(\omega t + 30^\circ) + 5\cos(\omega t - 45^\circ)$ as a single sinusoid.

Step 1 — phasors in rectangular form (addition needs rectangular):

$$\begin{aligned} 10\angle 30^\circ &= 8.660 + j5.000 \\ 5\angle -45^\circ &= 3.536 - j3.536 \\ \text{sum} &= 12.196 + j1.464 \end{aligned}$$

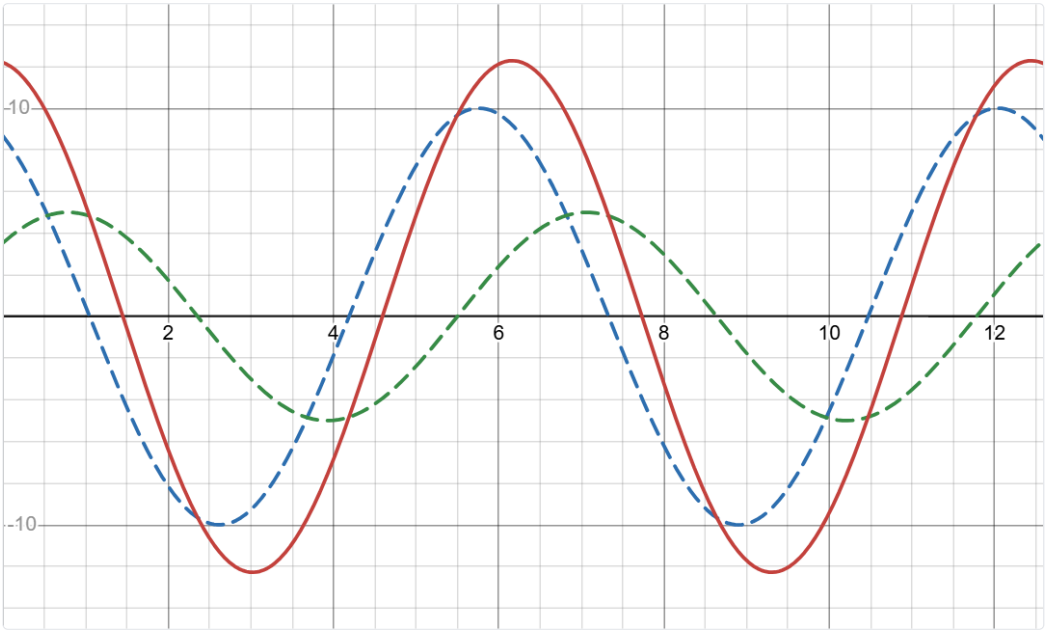
Step 2 — back to polar. $\sqrt{12.196^2 + 1.464^2} = 12.28$; $\operatorname{atan2}(1.464, 12.196) = 6.85^\circ$.

Step 3.

$$v(t) = 12.28\cos(\omega t + 6.85^\circ).$$

Checks. At $t = 0$: $10\cos 30^\circ + 5\cos 45^\circ = 8.660 + 3.536 = 12.196$ and $12.28\cos 6.85^\circ = 12.196$. ✓ Law of cosines (Section 2.3): $\sqrt{100 + 25 + 2(10)(5)\cos 75^\circ} = \sqrt{150.88} = 12.28$. ✓

Note $12.28 < 10 + 5$: same-frequency sinusoids add as **vectors**, not as amplitudes.



The sum (red) of $10\cos(x + 30^\circ)$ (blue) and $5\cos(x - 45^\circ)$ (green) is again a sinusoid of the same frequency, with amplitude 12.28 and phase 6.85° — exactly as the phasor sum predicts.

Worked Example 2.31 — Mixing sines and cosines

Express $v(t) = 4\sin\omega t - 3\cos(\omega t + 60^\circ)$ as a single cosine.

Step 1 — cosine reference. $4\sin\omega t = 4\cos(\omega t - 90^\circ) \leftrightarrow 4\angle -90^\circ = -j4$. The second term has phasor $3\angle 60^\circ = 1.500 + j2.598$.

Step 2 — subtract. $\mathbf{V} = -j4 - (1.500 + j2.598) = -1.500 - j6.598$.

Step 3 — polar. $|\mathbf{V}| = \sqrt{2.25 + 43.53} = 6.766$. The point is in the **third quadrant**, so $\angle\mathbf{V} = \arctan\frac{6.598}{1.5} - 180^\circ = 77.19^\circ - 180^\circ = -102.81^\circ$.

$$v(t) = 6.766\cos(\omega t - 102.81^\circ).$$

Check at $t = 0$: $0 - 3\cos 60^\circ = -1.5$ and $6.766\cos(-102.81^\circ) = -1.500$. ✓ At $\omega t = 90^\circ$: $4 - 3\cos 150^\circ = 4 + 2.598 = 6.598$, and $6.766\cos(-12.81^\circ) = 6.598$. ✓

Worked Example 2.32 — A first-order differential equation

A series RL circuit with $R = 30\ \Omega$, $L = 0.1$ H is driven by $v(t) = 100\cos 400t$ V. Its current obeys

$$L\frac{di}{dt} + Ri = v(t).$$

Find the steady-state current, then the complete response for $i(0) = 0$.

Step 1 — phasor equation. With $\mathbf{V} = 100\angle 0^\circ$ and $d/dt \to j\omega = j400$:

$$(j\omega L + R)\mathbf{I} = \mathbf{V} \;\Rightarrow\; \mathbf{I} = \frac{100}{30 + j40} = \frac{100\angle 0^\circ}{50\angle 53.13^\circ} = 2\angle -53.13^\circ \text{ A}.$$

Step 2 — back to time. $i_{ss}(t) = 2\cos(400t - 53.13^\circ)$ A.

Step 3 — verify by substitution. In rectangular form $\mathbf{I} = 1.2 - j1.6$, i.e. $i_{ss} = 1.2\cos 400t + 1.6\sin 400t$. Then

$$L\frac{di_{ss}}{dt} = 0.1(-480\sin 400t + 640\cos 400t) = 64\cos 400t - 48\sin 400t,$$

$$Ri_{ss} = 36\cos 400t + 48\sin 400t,$$

and the sum is $100\cos 400t$. ✓ The phasor method did in one division what substitution did in several lines.

Step 4 — complete response. The homogeneous solution of $Li' + Ri = 0$ is $Ke^{-(R/L)t} = Ke^{-300t}$ (Ch. 11). Then $i(0) = 1.2 + K = 0$ gives $K = -1.2$:

$$i(t) = 2\cos(400t - 53.13^\circ) - 1.2\,e^{-300t} \text{ A}.$$

The transient decays with time constant $L/R = 3.33$ ms; after about five time constants only the phasor solution remains.

Worked Example 2.33 — A second-order differential equation

Find the steady-state solution of

$$\frac{d^2v}{dt^2} + 3\frac{dv}{dt} + 2v = 10\cos 2t.$$

Step 1. With $\omega = 2$, $d/dt \to j2$ and $d^2/dt^2 \to (j2)^2 = -4$:

$$(-4 + j6 + 2)\mathbf{V} = 10 \;\Rightarrow\; \mathbf{V} = \frac{10}{-2 + j6}.$$

Step 2. $\mathbf{V} = \dfrac{10(-2 - j6)}{4 + 36} = -0.5 - j1.5 = 1.581\angle -108.43^\circ$ (third quadrant).

Step 3. $v_{ss}(t) = 1.581\cos(2t - 108.43^\circ)$.

Check (rectangular): $v_{ss} = -0.5\cos 2t + 1.5\sin 2t$, $v' = \sin 2t + 3\cos 2t$, $v'' = 2\cos 2t - 6\sin 2t$. Then $v'' + 3v' + 2v = (2 + 9 - 1)\cos 2t + (-6 + 3 + 3)\sin 2t = 10\cos 2t$. ✓

The complex number $(j\omega)^2 + 3(j\omega) + 2$ is the characteristic polynomial $p(s) = s^2 + 3s + 2$ evaluated at $s = j\omega$. In general the steady-state response of $p(D)y = x$ to $X_m\cos\omega t$ has phasor $X_m/p(j\omega)$ — the frequency response $H(j\omega) = 1/p(j\omega)$ of Section 2.9.

Phasor diagrams

Drawing phasors as arrows in the complex plane shows phase relationships at a glance. The whole diagram rotates anticlockwise at ω rad/s ($\mathbf{V}e^{j\omega t}$), and the instantaneous value of each signal is the projection of its rotating arrow onto the real axis. Relative angles never change, so the frozen diagram at $t = 0$ carries all the information.

A phasor at a larger angle **leads**: its peaks occur earlier in time. If $\mathbf{V} = V_m\angle\phi_v$ and $\mathbf{I} = I_m\angle\phi_i$, the voltage leads the current by $\phi_v - \phi_i$ (a negative value means it lags). For a capacitor, $i = C\,dv/dt$ gives $\mathbf{I} = j\omega C\mathbf{V}$, so the current **leads** the voltage by 90°; for an inductor, $\mathbf{V} = j\omega L\mathbf{I}$, so the current **lags** by 90°. (The mnemonic "ELI the ICE man": voltage E before current I in an inductor L; current before voltage in a capacitor C.)

Worked Example 2.34 — Three-phase line voltages

A balanced three-phase supply has phase voltages (RMS phasors) $\mathbf{V}_a = V\angle 0^\circ$, $\mathbf{V}_b = V\angle -120^\circ$, $\mathbf{V}_c = V\angle 120^\circ$. Find the line voltage $\mathbf{V}_{ab} = \mathbf{V}_a - \mathbf{V}_b$.

Step 1. $\mathbf{V}_{ab} = V\left(1 - e^{-j2\pi/3}\right) = V\left(1 + \frac{1}{2} + j\frac{\sqrt{3}}{2}\right) = V\left(\frac{3}{2} + j\frac{\sqrt{3}}{2}\right)$.

Step 2. $\left|\frac{3}{2} + j\frac{\sqrt{3}}{2}\right| = \sqrt{\frac{9}{4} + \frac{3}{4}} = \sqrt{3}$ and the angle is $\arctan\frac{1}{\sqrt{3}} = 30^\circ$:

$$\mathbf{V}_{ab} = \sqrt{3}\,V\angle 30^\circ.$$

With $V = 230$ V the line voltage is $\sqrt{3} \times 230 = 398.4$ V, quoted as the familiar "400 V" three-phase supply. Geometrically, the tips of $\mathbf{V}_a$, $\mathbf{V}_b$, $\mathbf{V}_c$ form an equilateral triangle and the line voltages are its sides (compare Example 2.26). Also $\mathbf{V}_a + \mathbf{V}_b + \mathbf{V}_c = V(1 + a^2 + a) = 0$ (Section 2.6). ✓

Common Pitfall — different frequencies

Phasors only combine signals of the **same** frequency. $\cos\omega_1 t + \cos\omega_2 t$ with $\omega_1 \neq \omega_2$ cannot be written as one phasor, because the factor $e^{j\omega t}$ is no longer common. For a circuit driven at several frequencies (or by a periodic non-sinusoidal waveform), solve a separate phasor problem at each frequency and **add the time-domain results** (superposition) — the basis of Fourier-series circuit analysis (Ch. 15).

Common Pitfall — mixing phasor and time domains

Expressions such as "$i(t) = 2\angle -53.13°$" or "$\mathbf{I} = 2\cos(400t - 53.13°)$" are category errors: a phasor is a time-independent complex number, a signal is a real function of time. Keep the arrow $\leftrightarrow$ between them and convert explicitly. Likewise, never multiply two phasors and expect the phasor of the product of the signals — the product of two sinusoids at ω contains frequencies 0 and 2ω (Example 2.13b).

Engineering Note — what phasors buy you

Every DC circuit-analysis technique — nodal and mesh analysis, superposition, source transformation, Thévenin and Norton equivalents — carries over unchanged to the sinusoidal steady state with resistances replaced by complex impedances and real sources by phasors. A network of fifty components at one frequency becomes a complex linear system $\mathbf{Y}\mathbf{v} = \mathbf{i}$, solved by the same Gaussian elimination as a real one (Ch. 8). This is precisely what circuit simulators do in "AC analysis" mode, sweeping ω and solving one complex linear system per frequency.

2.9 Complex impedance and transfer functions

Motivation

Section 2.8 converted differential equations into algebra one equation at a time. Engineers go one step further and attach the conversion to the **components**: each resistor, inductor and capacitor is assigned a complex number, its impedance, and the circuit is then analysed exactly like a resistive network. The ratio of an output phasor to an input phasor, viewed as a function of frequency, is the **frequency response**; extended to the complex variable s it becomes the **transfer function**, the central object of circuit theory, filtering and control. Both are nothing but complex-valued functions evaluated with the arithmetic of this chapter.

Impedance and admittance

Impedance and admittance

For a linear two-terminal element or network in sinusoidal steady state at angular frequency ω, with terminal voltage phasor $\mathbf{V}$ and current phasor $\mathbf{I}$ (passive sign convention), the **impedance** is

$$Z(j\omega) = \frac{\mathbf{V}}{\mathbf{I}} = R + jX \quad [\Omega],$$

and the **admittance** is

$$Y(j\omega) = \frac{1}{Z} = \frac{\mathbf{I}}{\mathbf{V}} = G + jB \quad [\mathrm{S}].$$

$R = \mathrm{Re}\{Z\}$ is the **resistance**, $X = \mathrm{Im}\{Z\}$ the **reactance**, G the **conductance** and B the **susceptance**. $X > 0$ is called inductive, $X < 0$ capacitive.

In polar form $Z = |Z|\angle\theta_Z$, Ohm's law $\mathbf{V} = Z\mathbf{I}$ says two things at once: the voltage amplitude is $|Z|$ times the current amplitude, and the voltage leads the current by θ_Z. Impedance is a complex number, **not** a phasor: it does not represent a sinusoid, it relates two of them.

Note that $G \neq 1/R$ in general. From $Y = 1/(R + jX) = (R - jX)/(R^2 + X^2)$,

$$G = \frac{R}{R^2 + X^2}, \qquad B = \frac{-X}{R^2 + X^2}.$$

For example $Z = 30 + j40\ \Omega$ gives $Y = (30 - j40)/2500 = 0.012 - j0.016$ S: the conductance is 0.012 S, not $1/30 = 0.0333$ S.

Element impedances

Apply the phasor differentiation rule ($d/dt \leftrightarrow j\omega$) to each element law:

Element	Time-domain law	Phasor law	Impedance	$\angle Z$
Resistor	$v = Ri$	$\mathbf{V} = R\mathbf{I}$	$Z_R = R$	$0°$
Inductor	$v = L\dfrac{di}{dt}$	$\mathbf{V} = j\omega L\,\mathbf{I}$	$Z_L = j\omega L$	$+90°$
Capacitor	$i = C\dfrac{dv}{dt}$	$\mathbf{I} = j\omega C\,\mathbf{V}$	$Z_C = \dfrac{1}{j\omega C} = -\dfrac{j}{\omega C}$	$-90°$

The inductive reactance $X_L = \omega L$ rises with frequency (an inductor is a short circuit at DC and an open circuit at very high frequency); the capacitive reactance $X_C = -1/(\omega C)$ has magnitude falling with frequency (open at DC, short at high frequency). Dimensional check: ωL has units $\mathrm{s}^{-1}\cdot\mathrm{H} = \mathrm{s}^{-1}\cdot\Omega\,\mathrm{s} = \Omega$, and $1/(\omega C)$ has units $1/(\mathrm{s}^{-1}\cdot\mathrm{F}) = \mathrm{s}/(\mathrm{A\,s/V}) = \Omega$. ✓

Combining impedances

Because KVL and KCL are linear relations with real (± 1) coefficients, they hold for phasors (Section 2.8). Hence impedances combine exactly as resistances do:

Series, parallel and divider rules

$$Z_{\text{series}} = Z_1 + Z_2 + \cdots, \qquad \frac{1}{Z_{\text{par}}} = \frac{1}{Z_1} + \frac{1}{Z_2} + \cdots \quad \left(Z_{\text{par}} = \frac{Z_1 Z_2}{Z_1 + Z_2} \text{ for two}\right),$$

$$\mathbf{V}_2 = \frac{Z_2}{Z_1 + Z_2}\mathbf{V} \quad \text{(voltage divider)}, \qquad \mathbf{I}_2 = \frac{Z_1}{Z_1 + Z_2}\mathbf{I} \quad \text{(current divider)}.$$

Admittances add in parallel: $Y_{\text{par}} = Y_1 + Y_2 + \cdots$.

Worked Example 2.35 — Series RL: current and power

$R = 30\ \Omega$, $L = 0.1$ H, source $v(t) = 100\cos 400t$ V (the circuit of Example 2.32). Find $i(t)$ and the power drawn.

Impedance. $X_L = \omega L = 400(0.1) = 40\ \Omega$, so $Z = 30 + j40 = 50\angle 53.13^\circ\ \Omega$.

Current. $\mathbf{I} = \mathbf{V}/Z = \dfrac{100\angle 0^\circ}{50\angle 53.13^\circ} = 2\angle -53.13^\circ$ A, so $i(t) = 2\cos(400t - 53.13^\circ)$ A — the same as Example 2.32, now with no differential equation in sight. The current lags the voltage by 53.13° (inductive).

Power (formulas derived below). $S = \tfrac{1}{2}\mathbf{V}\mathbf{I}^* = \tfrac{1}{2}(100)(2)\angle 53.13^\circ = 100\angle 53.13^\circ = 60 + j80$. Average power $P = 60$ W, reactive power $Q = 80$ var.

Check: $P = \tfrac{1}{2}|\mathbf{I}|^2 R = \tfrac{1}{2}(4)(30) = 60$ W ✓ and $Q = \tfrac{1}{2}|\mathbf{I}|^2 X_L = \tfrac{1}{2}(4)(40) = 80$ var. ✓ Only the resistor dissipates power.

Worked Example 2.36 — A series–parallel network

At $\omega = 1000$ rad/s, a $10\ \Omega$ resistor is in series with the parallel combination of a $20\ \Omega$ resistor and a $50\ \mu$F capacitor. A source $\mathbf{V} = 100\angle 0^\circ$ V drives the network. Find the input impedance, the source current and the voltage across the parallel part.

Step 1 — capacitor. $Z_C = \dfrac{1}{j(1000)(50\times 10^{-6})} = \dfrac{1}{j0.05} = -j20\ \Omega$.

Step 2 — parallel part.

$$Z_p = \frac{20(-j20)}{20 - j20} = \frac{-j400}{20 - j20} = \frac{-j400(20 + j20)}{800} = \frac{8000 - j8000}{800} = 10 - j10\ \Omega.$$

Step 3 — total. $Z = 10 + (10 - j10) = 20 - j10 = 22.36\angle -26.57^\circ\ \Omega$ (capacitive).

Step 4 — current. $\mathbf{I} = \dfrac{100}{22.36\angle -26.57^\circ} = 4.472\angle 26.57^\circ$ A: the current **leads** the voltage, as expected of a capacitive load.

Step 5 — divider. $\mathbf{V}_p = Z_p\mathbf{I} = (14.14\angle -45^\circ)(4.472\angle 26.57^\circ) = 63.25\angle -18.43^\circ = 60 - j20$ V.

Check by KVL: the series resistor drops $10\mathbf{I} = 44.72\angle 26.57^\circ = 40 + j20$ V, and $(40 + j20) + (60 - j20) = 100$. ✓ Note that $|\mathbf{V}_p| + |10\mathbf{I}| = 63.25 + 44.72 = 107.97 > 100$: voltage **magnitudes** around a loop need not sum to the source magnitude — only the phasors do.

Resonance

Worked Example 2.37 — Series RLC resonance, bandwidth and Q

A series RLC circuit has $R = 10\ \Omega$, $L = 10$ mH, $C = 1\ \mu$F. Its impedance is

$$Z(j\omega) = R + j\left(\omega L - \frac{1}{\omega C}\right).$$

Resonance. The reactance vanishes when $\omega L = 1/(\omega C)$, i.e. at

$$\omega_0 = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{10^{-2}\cdot 10^{-6}}} = 10^4 \text{ rad/s} \quad (f_0 = 1.592 \text{ kHz}).$$

There $Z = R = 10\ \Omega$: purely resistive and minimal in magnitude, so the current for a given voltage is maximal and in phase with it.

Off resonance. At $\omega = 2\times 10^4$: $\omega L = 200$, $1/(\omega C) = 50$, $Z = 10 + j150 = 150.3\angle 86.19^\circ\ \Omega$ — strongly inductive, and the current is 15 times smaller than at resonance.

Half-power frequencies. The power $\tfrac{1}{2}|\mathbf{I}|^2 R$ falls to half its peak when $|Z| = \sqrt{2}R$, i.e. when the reactance equals $\pm R$: $\omega L - \dfrac{1}{\omega C} = \pm R$. Multiplying by ω/L gives $\omega^2 \mp \frac{R}{L}\omega - \omega_0^2 = 0$, whose positive roots are

$$\omega_{1,2} = \mp\frac{R}{2L} + \sqrt{\left(\frac{R}{2L}\right)^2 + \omega_0^2} = \mp 500 + \sqrt{500^2 + 10^8} = 9512.5,\ 10512.5 \text{ rad/s}.$$

Bandwidth $\Delta\omega = \omega_2 - \omega_1 = R/L = 1000$ rad/s, and **quality factor** $Q = \omega_0/\Delta\omega = \omega_0 L/R = 10$.

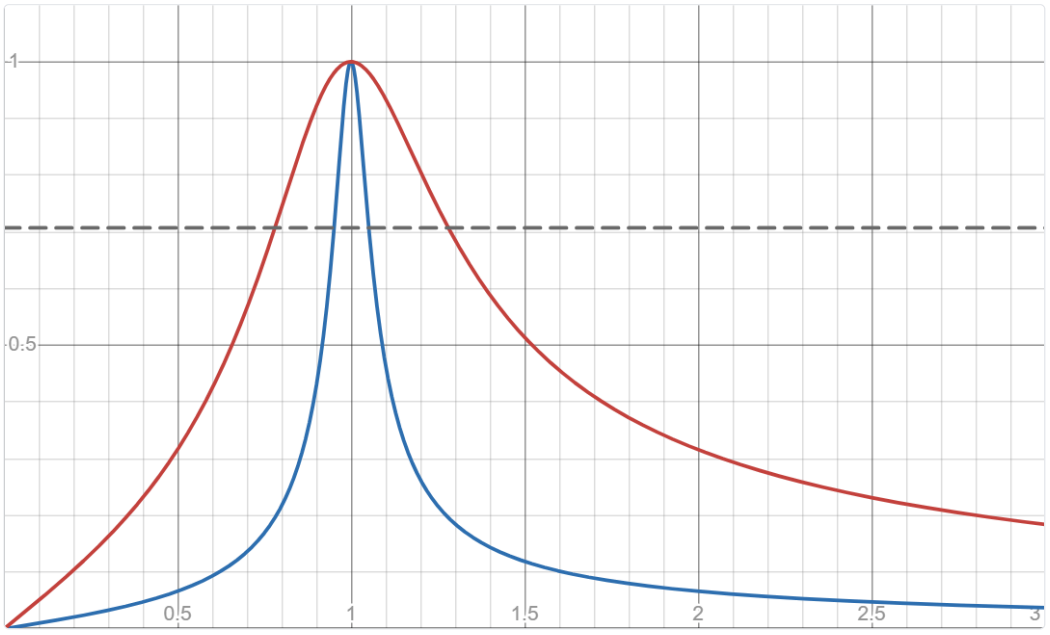
Check at $\omega_1 = 9512.5$: $\omega_1 L = 95.125$, $1/(\omega_1 C) = 105.125$, reactance $-10.00\ \Omega = -R$. ✓

Voltage magnification. At resonance, with source amplitude V, $|\mathbf{I}| = V/R$ and the capacitor voltage is $|\mathbf{V}_C| = \dfrac{V}{R\,\omega_0 C} = QV = 10V$: the capacitor sees ten times the source voltage — a design hazard and the basis of tuned circuits.

Normalising $x = \omega/\omega_0$, the current relative to its peak is

$$\frac{|\mathbf{I}(j\omega)|}{|\mathbf{I}|_{\max}} = \frac{R}{|Z|} = \frac{1}{\sqrt{1 + Q^2\left(x - \dfrac{1}{x}\right)^2}},$$

which shows that the sharpness of the peak depends only on Q.



Normalised series-RLC current $R/|Z|$ against $x = \omega/\omega_0$ for $Q = 10$ (blue, narrow) and $Q = 2$ (red, broad). The dashed line marks the half-power level $1/\sqrt{2}$; its intersections give the bandwidth ω_0/Q.

Complex power

Average and complex power

With amplitude phasors $\mathbf{V} = V_m\angle\phi_v$ and $\mathbf{I} = I_m\angle\phi_i$, the instantaneous power $p(t) = v(t)i(t)$ has average

$$P = \frac{1}{T}\int_0^T p(t)\,dt = \tfrac{1}{2}V_m I_m\cos(\phi_v - \phi_i) = \operatorname{Re}\{S\}, \qquad S = \tfrac{1}{2}\mathbf{V}\mathbf{I}^* = P + jQ.$$

S is the **complex power** [VA], P the **average (real) power** [W], $Q = \tfrac{1}{2}V_m I_m\sin(\phi_v - \phi_i)$ the **reactive power** [var], $|S|$ the **apparent power** and $\cos(\phi_v - \phi_i)$ the **power factor**. For a load Z: $S = \tfrac{1}{2}|\mathbf{I}|^2 Z$, so $P = \tfrac{1}{2}|\mathbf{I}|^2 R$ and $Q = \tfrac{1}{2}|\mathbf{I}|^2 X$. With RMS phasors, drop the factor $\tfrac{1}{2}$: $S = \mathbf{V}_{\text{rms}}\mathbf{I}_{\text{rms}}^*$.

Derivation. Using the product-to-sum identity (Example 2.13b),

$$p(t) = V_m I_m\cos(\omega t + \phi_v)\cos(\omega t + \phi_i) = \tfrac{1}{2}V_m I_m\left[\cos(\phi_v - \phi_i) + \cos(2\omega t + \phi_v + \phi_i)\right].$$

The second term oscillates at 2ω and averages to zero over a period, leaving $P = \tfrac{1}{2}V_m I_m\cos(\phi_v - \phi_i)$. Since $\mathbf{V}\mathbf{I}^* = V_m I_m\angle(\phi_v - \phi_i)$, this is $\operatorname{Re}\{\tfrac{1}{2}\mathbf{V}\mathbf{I}^*\}$. The conjugate is essential: it makes the angle of S the *difference* of phases, the only thing that physically matters. For $S = \tfrac{1}{2}\mathbf{V}\mathbf{I}^*$ with $\mathbf{V} = Z\mathbf{I}$: $S = \tfrac{1}{2}Z\mathbf{I}\mathbf{I}^* = \tfrac{1}{2}|\mathbf{I}|^2 Z$. □

Worked Example 2.38 — Power factor and its correction

A 50 Hz, 230 V (RMS) supply feeds a load $Z = 30 + j40\ \Omega$. Find P, Q and the power factor, then the parallel capacitor that raises the power factor to 1.

Step 1 — current (RMS phasors). $\mathbf{I} = \dfrac{230\angle 0^\circ}{50\angle 53.13^\circ} = 4.6\angle -53.13^\circ$ A.

Step 2 — power. $S = \mathbf{V}\mathbf{I}^* = 230(4.6)\angle 53.13^\circ = 1058\angle 53.13^\circ = 634.8 + j846.4$ VA. So $P = 634.8$ W, $Q = 846.4$ var (inductive), power factor $\cos 53.13^\circ = 0.6$ lagging. *Check:* $|\mathbf{I}|^2 R = 21.16(30) = 634.8$ W ✓, $|\mathbf{I}|^2 X = 21.16(40) = 846.4$ var. ✓

Step 3 — correction. A parallel capacitor draws $S_C = \mathbf{V}\mathbf{I}_C^*$ with $\mathbf{I}_C = j\omega C\mathbf{V}$, so $S_C = \mathbf{V}(-j\omega C\mathbf{V}^*) = -j\omega C|\mathbf{V}|^2$: purely negative reactive power. To cancel Q:

$$\omega C|\mathbf{V}|^2 = 846.4 \;\Rightarrow\; C = \frac{846.4}{(2\pi\cdot 50)(230^2)} = 50.9\ \mu\text{F}.$$

The supply then delivers the same 634.8 W with current $634.8/230 = 2.76$ A instead of 4.6 A, reducing the resistive losses in the supply cables by a factor $0.6^2 = 0.36$.

Maximum power transfer

A source with phasor $\mathbf{V}_s$ and internal impedance $Z_s = R_s + jX_s$ delivers the greatest average power to a load Z_L when

$$Z_L = Z_s^* = R_s - jX_s, \qquad P_{\max} = \frac{|\mathbf{V}_s|^2}{8R_s} \text{ (amplitude phasor)}.$$

Proof sketch. $P = \tfrac{1}{2}|\mathbf{I}|^2 R_L = \dfrac{\tfrac{1}{2}|\mathbf{V}_s|^2 R_L}{(R_s+R_L)^2 + (X_s+X_L)^2}$. For any R_L the denominator is smallest when $X_L = -X_s$; then $P = \tfrac{1}{2}|\mathbf{V}_s|^2 R_L/(R_s+R_L)^2$, maximised over R_L at $R_L = R_s$ (set the derivative to zero, Ch. 4). □ For example $Z_s = 50 + j30\ \Omega$ and $|\mathbf{V}_s| = 10$ V give $Z_L = 50 - j30\ \Omega$, current $10/100 = 0.1$ A, and $P_{\max} = \tfrac{1}{2}(0.1)^2(50) = 0.25$ W $= 100/(8\cdot 50)$. ✓ This **conjugate match** is the target of every RF matching network.

Frequency response and transfer functions

Frequency response

For a stable linear time-invariant circuit with sinusoidal input $x(t) = X_m\cos(\omega t + \phi_x) \leftrightarrow \mathbf{X}$ and steady-state output $\mathbf{Y}$, the **frequency response** is

$$H(j\omega) = \frac{\mathbf{Y}}{\mathbf{X}}.$$

The steady-state output is then

$$y(t) = |H(j\omega)|\, X_m \cos\big(\omega t + \phi_x + \angle H(j\omega)\big).$$

$|H(j\omega)|$ is the **gain** (often quoted as $20\log_{10}|H|$ dB) and $\angle H(j\omega)$ the **phase shift**.

So an LTI system acts on a sinusoid by **one complex multiplication**: scale by $|H|$, rotate by $\angle H$. H is computed from the circuit by impedance methods, or from the governing differential equation by $d/dt \to j\omega$ (Example 2.33).

Transfer function, poles and zeros

When $H(j\omega)$ is a ratio of polynomials in $j\omega$, replacing $j\omega$ by the complex variable $s = \sigma + j\omega$ gives the **transfer function**

$$H(s) = \frac{N(s)}{D(s)} = K\,\frac{(s-z_1)(s-z_2)\cdots(s-z_m)}{(s-p_1)(s-p_2)\cdots(s-p_n)}.$$

The roots z_i of N are the **zeros** and the roots p_i of D the **poles**. For real circuits N and D have real coefficients, so poles and zeros are real or occur in conjugate pairs (Section 2.2). In terms of impedances, each element is assigned $Z_R = R$, $Z_L = sL$, $Z_C = 1/(sC)$.

The interpretation of $H(s)$ for complex s — the response to e^{st} — is developed with the Laplace transform in Ch. 14. Here what matters is that the factored form turns the evaluation of gain and phase into geometry.

Gain and phase from poles and zeros

At $s = j\omega$,

$$|H(j\omega)| = |K|\,\frac{\prod_i |j\omega - z_i|}{\prod_k |j\omega - p_k|}, \qquad \angle H(j\omega) = \angle K + \sum_i \angle(j\omega - z_i) - \sum_k \angle(j\omega - p_k).$$

Each factor $j\omega - z_i$ is the vector from the zero z_i to the point $j\omega$ on the imaginary axis.

Proof. Magnitudes of products and quotients multiply and divide, angles add and subtract (Section 2.3). □ As ω moves up the imaginary axis, the gain rises near zeros and peaks near poles that lie close to the axis — the geometric explanation of resonance.

Worked Example 2.39 — RC low-pass filter

A series resistor R feeds an output taken across a capacitor C. Find $H(j\omega) = \mathbf{V}_{\text{out}}/\mathbf{V}_{\text{in}}$, its gain and phase, and its pole.

Step 1 — divider.

$$H(j\omega) = \frac{Z_C}{R + Z_C} = \frac{1/(j\omega C)}{R + 1/(j\omega C)} = \frac{1}{1 + j\omega RC}, \qquad H(s) = \frac{1}{1+sRC}.$$

Step 2 — polar form.

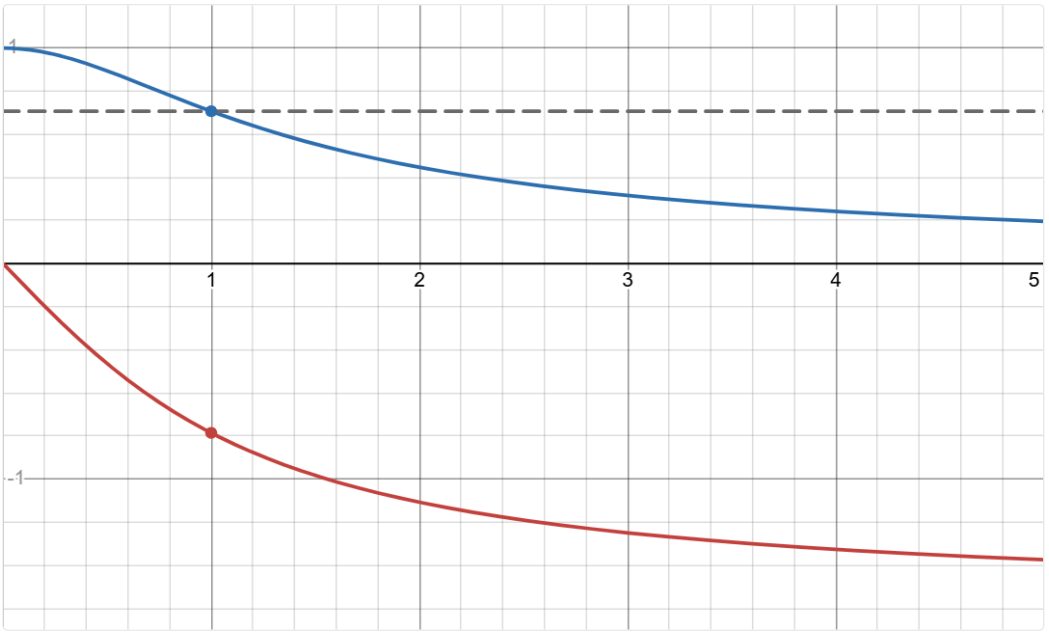
$$|H(j\omega)| = \frac{1}{\sqrt{1 + (\omega RC)^2}}, \qquad \angle H(j\omega) = -\arctan(\omega RC).$$

(The denominator $1 + j\omega RC$ is in the first quadrant, so arctan is safe here.)

Step 3 — cut-off. At $\omega_c = 1/(RC)$: $|H| = 1/\sqrt{2} = 0.7071$, i.e. $20\log_{10} 0.7071 = -3.01$ dB, and $\angle H = -45°$. With $R = 1$ kΩ, $C = 1$ μF: $\omega_c = 1000$ rad/s, $f_c = 159.2$ Hz.

Step 4 — a specific input. For $v_{\text{in}} = 10\cos 2000t$ V, $\omega RC = 2$: $H = 1/(1+j2) = 0.4472\angle -63.43°$ (-6.99 dB), so $v_{\text{out}} = 4.472\cos(2000t - 63.43°)$ V.

Step 5 — pole. $D(s) = 1 + sRC = 0$ at $s = -1/(RC) = -1000$ s^{-1}, on the negative real axis (left half-plane: stable). Geometrically, $|H(j\omega)| = \omega_c/|j\omega + \omega_c|$ is ω_c divided by the distance from the pole to $j\omega$; that distance is $\sqrt{2}\,\omega_c$ when $\omega = \omega_c$, which is where the -3 dB point comes from.



RC low-pass response against normalised frequency $x = \omega RC$: magnitude $|H|$ (blue) and phase $\angle H$ in radians (red), tending to $-\pi/2$. Both shapes follow directly from the polar form of $1/(1 + jx)$.

Worked Example 2.40 — Gain and phase from a pole–zero plot

Evaluate the gain and phase of

$$H(s) = \frac{10(s+1)}{(s+2)(s+10)}$$

at $\omega = 2$ rad/s.

Step 1 — poles and zeros. Zero at -1; poles at -2 and -10; $K = 10$.

Step 2 — vectors to $j2$.

$$\begin{aligned} j2 - (-1) &= 1 + j2 = 2.236\angle 63.43^\circ, \\ j2 - (-2) &= 2 + j2 = 2.828\angle 45.00^\circ, \\ j2 - (-10) &= 10 + j2 = 10.198\angle 11.31^\circ. \end{aligned}$$

Step 3 — combine.

$$|H(j2)| = \frac{10 \times 2.236}{2.828 \times 10.198} = 0.7752 \ (-2.21 \text{ dB}), \qquad \angle H(j2) = 63.43^\circ - 45.00^\circ - 11.31^\circ = 7.12^\circ.$$

Check by direct rectangular evaluation: $(2 + j2)(10 + j2) = 20 + j4 + j20 - 4 = 16 + j24$, and $\dfrac{10(1 + j2)}{16 + j24} = \dfrac{10(1 + j2)(16 - j24)}{832} = \dfrac{10(64 + j8)}{832} = 0.7692 + j0.0962$, whose magnitude is 0.7752 and angle 7.13°. ✓ (The last-digit difference is rounding in the angles.)

Common Pitfall — phase of a factor in the left half of its plane

When a factor such as $j\omega - p$ or $1 - \omega^2 LC + j\omega RC$ has a **negative real part**, its angle exceeds 90°, and $\arctan(\text{Im}/\text{Re})$ is off by 180° (Section 2.1). Second-order denominators $1 - (\omega/\omega_0)^2 + j \cdot (\dots)$ change quadrant at $\omega = \omega_0$, which is why a naive formula makes the phase of a resonant filter jump from -90° to $+90^\circ$ instead of continuing smoothly to -180°. Use `atan2` and then unwrap.

Engineering Note — from here to Bode, filters and control

Bode plots are $20 \log_{10} |H(j\omega)|$ and $\angle H(j\omega)$ against $\log \omega$. Because the log of a product is the sum of logs (Section 2.5), each pole and zero contributes an independent, easily sketched term, and the total is their sum. Filter design chooses pole and zero locations (Butterworth on a circle, Example 2.25; Chebyshev on an ellipse); feedback-loop stability margins are read from $|H|$ and $\angle H$ near the crossover frequency. The mathematics needed is exactly this chapter plus logarithms; the design methods belong to circuits and control texts.

Summary

Topic	Key formula
Rectangular form	$z = a + jb, a = \text{Re}\{z\}, b = \text{Im}\{z\}, j^2 = -1$
Rectangular ↔ polar	$\lvert z\rvert = \sqrt{a^2 + b^2}, \angle z = \text{atan2}(b, a); a = r\cos\theta, b = r\sin\theta$
Equality	$a + jb = c + jd \iff a = c,\ b = d$ (one complex equation = two real equations)

Topic	Key formula
Conjugate	$z^* = a - jb = re^{-j\theta}$; $zz^* = \lvert z\rvert^2$; $\operatorname{Re}\{z\} = \frac{z+z^*}{2}$, $\operatorname{Im}\{z\} = \frac{z-z^*}{2j}$
Conjugate roots	real coefficients $\Rightarrow$ non-real roots in pairs $\alpha \pm j\beta$, factor $x^2 - 2\alpha x + \alpha^2 + \beta^2$
Product	$(a+jb)(c+jd) = (ac-bd) + j(ad+bc)$; $r_1\angle\theta_1 \cdot r_2\angle\theta_2 = r_1 r_2 \angle(\theta_1+\theta_2)$
Division	$\frac{z_1}{z_2} = \frac{z_1 z_2^*}{\lvert z_2\rvert^2} = \frac{r_1}{r_2}\angle(\theta_1 - \theta_2)$
Powers of j	$j^n = j^{\,n \bmod 4}$; $1/j = -j$
Triangle inequality	$\lvert z_1 + z_2\rvert \le \lvert z_1\rvert + \lvert z_2\rvert$; $\lvert z_1+z_2\rvert^2 = \lvert z_1\rvert^2 + \lvert z_2\rvert^2 + 2\operatorname{Re}\{z_1 z_2^*\}$
Euler	$e^{j\theta} = \cos\theta + j\sin\theta$; $e^{j\pi} = -1$, $e^{j\pi/2} = j$
Inverse Euler	$\cos\theta = \frac{e^{j\theta}+e^{-j\theta}}{2}$, $\sin\theta = \frac{e^{j\theta}-e^{-j\theta}}{2j}$
Exponential form	$z = re^{j\theta}$; $z_1 z_2 = r_1 r_2 e^{j(\theta_1+\theta_2)}$
Complex exponential	$e^{\sigma+j\omega} = e^\sigma(\cos\omega + j\sin\omega)$, $\lvert e^z\rvert = e^{\operatorname{Re}\{z\}}$, period $j2\pi$
Logarithm	$\operatorname{Log} z = \ln\lvert z\rvert + j\operatorname{Arg} z$; $\log z = \operatorname{Log} z + j2\pi k$
Complex power of z	$z^c = e^{c\log z}$ (multivalued; principal value uses Log)
De Moivre	$(re^{j\theta})^n = r^n e^{jn\theta}$, $n \in \mathbb{Z}$
n-th roots	$w_k = r^{1/n} e^{j(\theta+2\pi k)/n}$, $k = 0, \dots, n-1$
Square root	$\sqrt{a+jb} = \pm\left(\sqrt{\frac{r+a}{2}} + j\,\operatorname{sgn}(b)\sqrt{\frac{r-a}{2}}\right)$
Roots of unity	$W = e^{j2\pi/n}$; $\sum_{k=0}^{n-1} W^{mk} = n$ if $n \mid m$, else 0
Rotation	multiply by $e^{j\alpha}$; by j for $+90^\circ$; about w_0: $w_0 + e^{j\alpha}(z - w_0)$
Circle	$\lvert z - z_0\rvert = R$; Apollonius $\lvert z - z_1\rvert = k\lvert z - z_2\rvert$
Phasor	$V_m\cos(\omega t + \phi) \leftrightarrow V_m\angle\phi$; $v(t) = \operatorname{Re}\{\mathbf{V}e^{j\omega t}\}$
Phasor calculus	$\frac{d}{dt} \leftrightarrow j\omega$, $\int dt \leftrightarrow \frac{1}{j\omega}$, delay $\tau \leftrightarrow e^{-j\omega\tau}$
Impedances	$Z_R = R$, $Z_L = j\omega L$, $Z_C = \dfrac{1}{j\omega C}$; series add, admittances add in parallel
Series RLC	$\omega_0 = 1/\sqrt{LC}$, $Q = \omega_0 L/R$, bandwidth R/L
Complex power	$S = \frac{1}{2}\mathbf{V}\mathbf{I}^* = P + jQ = \frac{1}{2}\lvert\mathbf{I}\rvert^2 Z$ (amplitude); $S = \mathbf{V}\mathbf{I}^*$ (RMS)
Max power transfer	$Z_L = Z_s^*$, $P_{\max} = \lvert\mathbf{V}_s\rvert^2/(8R_s)$ (amplitude)
Frequency response	$y(t) = \lvert H\rvert X_m\cos(\omega t + \phi_x + \angle H)$
Pole–zero evaluation	$\lvert H\rvert = \lvert K\rvert\frac{\prod\lvert j\omega - z_i\rvert}{\prod\lvert j\omega - p_k\rvert}$, $\angle H = \angle K + \sum\angle(j\omega - z_i) - \sum\angle(j\omega - p_k)$
RC low-pass	$H = \dfrac{1}{1 + j\omega RC}$, $\lvert H\rvert = \dfrac{1}{\sqrt{1+(\omega RC)^2}}$, $\angle H = -\arctan\omega RC$

Chapter 3 — Trigonometry and Periodic Functions

> **Prerequisites:** Ch. 1 (functions, graphs, basic trigonometric ratios), Ch. 2 (Euler's formula, phasors) **Learning outcomes:** After this chapter you can
>
> - measure angles in radians, degrees and revolutions, convert between them, and explain why calculus insists on radians;
> - read amplitude, offset, frequency and phase directly from a sinusoidal expression or graph, and convert any $a\cos\omega t + b\sin\omega t$ into amplitude–phase form;
> - compute phase differences, time delays and leads/lags between sinusoids, and add same-frequency sinusoids exactly;
> - decide whether a sum of sinusoids (continuous or discrete-time) is periodic and find its fundamental period;
> - use the compound-angle, power-reduction and product-to-sum identities to move between products, powers and harmonics;
> - describe periodic waveforms (square, triangle, sawtooth, rectified sine) by formula, symmetry, mean and RMS, and explain how they are built from harmonics.

Almost every quantity an electrical engineer measures either *is* a sinusoid or is analysed as a sum of sinusoids. The mains supply is a 50 Hz or 60 Hz sinusoid; a radio carrier is a sinusoid whose amplitude, frequency or phase is nudged to carry information; the steady-state response of any linear circuit to a sinusoid is another sinusoid of the same frequency; and a distorted current drawn by a rectifier is described by the list of sinusoidal *harmonics* it contains. Trigonometry is the language of all of this.

This chapter builds the working fluency that later chapters assume. It is not a chapter on triangle-solving: the emphasis is on the circular functions as *functions of time*, on the three numbers (amplitude, frequency, phase) that describe a sinusoid, on the identities that convert products and powers of sinusoids into sums of sinusoids, and on the idea that a periodic waveform is a superposition of harmonically related sinusoids. The full theory of that last idea — Fourier series, convergence and spectra — is developed in Ch. 15; here we build the intuition and the algebra that make Ch. 15 easy to read.

Throughout, t is time in seconds, ω is angular frequency in rad/s, f is frequency in Hz, and j is the imaginary unit.

3.1 Angular measurement

Why angle measure needs care

An angle measures *rotation*: how far a ray has turned about a point. In electrical engineering, rotation appears literally (the shaft of a motor or generator, the rotor position read by an encoder, the bearing of an antenna) and figuratively (the phase of a sinusoid, which is the angle of a rotating phasor). Getting the *unit* of angle right is the single most common source of numerical error in trigonometric calculations, because the same number — say 1.5 — is a modest angle in radians, a tiny angle in degrees and an enormous one in revolutions, and a calculator or software library will silently accept any of them.

Units of angle

Radian

Let a circle of radius r be centred at the vertex of an angle, and let s be the length of arc the angle cuts off. The angle in **radians** is

$$\theta = \frac{s}{r}.$$

Because it is a ratio of two lengths, the radian is dimensionless: $[\theta] = 1$. One radian is the angle that cuts off an arc equal to the radius.

A full turn cuts off the whole circumference $2\pi r$, so one revolution is 2π rad. All other units are defined by dividing the full turn into a conventional number of parts:

Unit	Full turn	Right angle	Typical use
radian (rad)	$2\pi \approx 6.2832$	$\pi/2$	all of calculus, ωt, software libraries
degree (°)	360	90	phase on datasheets and phasor diagrams
revolution (rev, turn)	1	$1/4$	shaft speed (rpm), encoder counts
gradian (gon)	400	100	surveying; a trap on some calculators
milliradian (mrad)	≈ 6283	≈ 1571	small pointing errors, optics

The conversion rules follow from equating full turns:

$$\theta_{\text{deg}} = \frac{180}{\pi}\,\theta_{\text{rad}}, \qquad \theta_{\text{rad}} = \frac{\pi}{180}\,\theta_{\text{deg}}, \qquad \theta_{\text{rev}} = \frac{\theta_{\text{rad}}}{2\pi}.$$

A useful anchor is $1\text{ rad} \approx 57.296^\circ$ and $1^\circ \approx 0.017453\text{ rad}$.

Worked Example 3.1 — Unit conversions

(a) Convert 2.5 rad to degrees. (b) Convert 37° to radians. (c) A shaft turns through 1350°. How many revolutions is that, and what angle in $[0^\circ, 360^\circ)$ does it end at?

(a) $\theta = 2.5 \times 180/\pi = 143.24^\circ$.

(b) $\theta = 37 \times \pi/180 = 0.6458$ rad.

(c) $1350/360 = 3.75$ rev. Three whole turns (1080°) bring the shaft back to where it started, leaving $1350 - 1080 = 270^\circ$. The final position is 270° (equivalently $3\pi/2$ rad, or -90°).

Check: $143.24^\circ / 57.296 = 2.500$; $0.6458 \times 57.296 = 37.00^\circ$.

Arc length, sector area and angular speed

The radian definition gives three formulas with no conversion factors — which is precisely why radians are the natural unit:

$$s = r\theta, \qquad A_{\text{sector}} = \tfrac{1}{2} r^2 \theta, \qquad v = r\,\Omega,$$

where $\Omega = d\theta/dt$ is the angular speed in rad/s and v the linear speed of a point at radius r. The sector area follows by proportion: the sector is the fraction $\theta/(2\pi)$ of the disc of area πr^2, so $A = \frac{\theta}{2\pi}\pi r^2 = \frac{1}{2} r^2 \theta$. If θ were in degrees each formula would acquire a factor $\pi/180$.

Shaft speeds are usually quoted in revolutions per minute (rpm). Since one revolution is 2π rad and one minute is 60 s,

$$\Omega\ [\text{rad/s}] = \frac{2\pi}{60}\, N\ [\text{rpm}] \approx 0.10472\, N.$$

Worked Example 3.2 — Encoder resolution and tip speed

An incremental encoder on a motor shaft gives 2048 counts per revolution. The shaft drives a pulley of radius $r = 40$ mm and runs at $N = 3000$ rpm.

(a) What angle does one count represent, in degrees and in milliradians? (b) What arc length of belt passes per count? (c) What is the belt speed?

(a) One count is $1/2048$ rev, i.e. $360/2048 = 0.17578^\circ$, or $2\pi/2048 = 3.0680 \times 10^{-3}$ rad $= 3.068$ mrad.

(b) $s = r\theta = 0.040 \times 3.0680 \times 10^{-3} = 1.227 \times 10^{-4}$ m $= 0.1227$ mm.

(c) $\Omega = 2\pi \times 3000/60 = 314.16$ rad/s, so $v = r\Omega = 0.040 \times 314.16 = 12.57$ m/s.

Check: At 3000 rpm the shaft makes 50 rev/s; the circumference is $2\pi(0.04) = 0.2513$ m; $50 \times 0.2513 = 12.57$ m/s. ✓

Electrical and mechanical degrees

In a rotating machine with p pole *pairs*, the magnetic field pattern repeats p times around the air gap. One mechanical revolution therefore carries the generated voltage through p complete electrical cycles. Engineers distinguish

$$\theta_e = p\,\theta_m, \qquad \omega_e = p\,\Omega_m,$$

where the subscript e denotes *electrical* angle/frequency and m *mechanical*. A four-pole machine ($p = 2$) running at 1500 rpm has $\Omega_m = 157.08$ rad/s and produces $\omega_e = 314.16$ rad/s, i.e. $f = 50$ Hz. Phase angles of voltages and currents are always electrical angles.

Engineering Note — Which "degree" is on the datasheet?

Motor-control datasheets quote commutation angles in electrical degrees; encoder datasheets quote resolution in mechanical counts. Mixing them up in a field-oriented controller for a p-pole-pair motor produces a commutation error multiplied by p, which shows up as a motor that vibrates, runs hot, or will not start.

The circular functions on the unit circle

The six trigonometric functions are defined for *any* real angle, not only acute angles of right triangles, by placing the angle in standard position (vertex at the origin, initial ray along the positive x-axis, positive angles anticlockwise) and reading off the point where the terminal ray meets the unit circle.

Circular functions

Let the terminal ray of the angle θ (in radians) meet the unit circle $x^2 + y^2 = 1$ at $P = (x, y)$. Then

$$\cos\theta = x, \qquad \sin\theta = y, \qquad \tan\theta = \frac{y}{x}\ (x \neq 0),$$

$$\sec\theta = \frac{1}{x}, \qquad \csc\theta = \frac{1}{y}, \qquad \cot\theta = \frac{x}{y}.$$

For a point at distance r from the origin, $(x, y) = (r\cos\theta,\ r\sin\theta)$.

Several facts follow at once from the picture:

- **Range.** $-1 \le \cos\theta \le 1$ and $-1 \le \sin\theta \le 1$, because P lies on the unit circle.
- **Pythagorean identity.** $\cos^2\theta + \sin^2\theta = 1$, because $x^2 + y^2 = 1$.

- **Periodicity.** Adding 2π to θ returns P to the same point, so $\sin(\theta+2\pi)=\sin\theta$ and $\cos(\theta+2\pi)=\cos\theta$. The tangent repeats after only π, because $\theta+\pi$ sends P to $-P$ and $(-y)/(-x)=y/x$.
- **Symmetry.** Reflecting in the x-axis replaces θ by $-\theta$ and y by $-y$: $\cos(-\theta)=\cos\theta$ (cosine is *even*), $\sin(-\theta)=-\sin\theta$ (sine is *odd*).
- **Complementarity.** Reflecting in the line $y=x$ swaps x and y and sends θ to $\pi/2-\theta$: $\sin(\pi/2-\theta)=\cos\theta$, $\cos(\pi/2-\theta)=\sin\theta$.

The signs of sin and cos in each quadrant follow from the signs of y and x:

Quadrant	θ range	$\sin\theta$	$\cos\theta$	$\tan\theta$
I	$0<\theta<\pi/2$	$+$	$+$	$+$
II	$\pi/2<\theta<\pi$	$+$	$-$	$-$
III	$\pi<\theta<3\pi/2$	$-$	$-$	$+$
IV	$3\pi/2<\theta<2\pi$	$-$	$+$	$-$

Special angles and reference angles

The values at multiples of 30° and 45° come from the equilateral triangle (halved) and the isosceles right triangle, and are worth knowing without a calculator:

θ	0	$\pi/6$ (30°)	$\pi/4$ (45°)	$\pi/3$ (60°)	$\pi/2$ (90°)
$\sin\theta$	0	$1/2$	$\sqrt{2}/2$	$\sqrt{3}/2$	1
$\cos\theta$	1	$\sqrt{3}/2$	$\sqrt{2}/2$	$1/2$	0
$\tan\theta$	0	$1/\sqrt{3}$	1	$\sqrt{3}$	undefined

For any other quadrant, the **reference angle** $\theta_r\in[0,\pi/2]$ is the acute angle between the terminal ray and the x-axis. Then $|\sin\theta|=\sin\theta_r$, $|\cos\theta|=\cos\theta_r$, and the sign comes from the quadrant table. For example, $\theta=240^\circ$ lies in quadrant III with $\theta_r=60^\circ$, so $\sin 240^\circ=-\sqrt{3}/2$ and $\cos 240^\circ=-1/2$. These two numbers reappear constantly in three-phase work, where phases are 0°, -120° and -240° (equivalently $+120^\circ$).

Inverse functions and the quadrant problem

Because sin, cos and tan are periodic they are not one-to-one, so their inverses are defined by restricting the domain to a **principal branch**:

Principal inverse trigonometric functions

$$\begin{aligned}\arcsin x &\in [-\pi/2,\ \pi/2], && -1\le x\le 1,\\ \arccos x &\in [0,\ \pi], && -1\le x\le 1,\\ \arctan x &\in (-\pi/2,\ \pi/2), && x\in\mathbb{R}.\end{aligned}$$

Each returns the *one* angle in its range with the given sine, cosine or tangent. Every other solution differs by the symmetries above: $\sin\theta=s$ has solutions $\theta=\arcsin s+2\pi k$ and $\theta=\pi-\arcsin s+2\pi k$; $\cos\theta=c$ has $\theta=\pm\arccos c+2\pi k$; $\tan\theta=t$ has $\theta=\arctan t+\pi k$.

The engineering problem is usually: *given the coordinates (x,y) of a point (or the real and imaginary parts of a phasor), find its angle.* The ratio y/x loses the signs of x and y separately, so $\arctan(y/x)$ cannot distinguish $(1,1)$ from $(-1,-1)$. The two-argument arctangent fixes this.

Two-argument arctangent

For $(x,y)\neq(0,0)$, $\operatorname{atan2}(y,x)$ is the unique $\theta\in(-\pi,\pi]$ with $\cos\theta=x/\sqrt{x^2+y^2}$ and $\sin\theta=y/\sqrt{x^2+y^2}$. In terms of arctan:

$$\operatorname{atan2}(y,x)=\begin{cases}\arctan(y/x), & x>0,\\ \arctan(y/x)+\pi, & x<0,\ y\ge 0,\\ \arctan(y/x)-\pi, & x<0,\ y<0,\\ +\pi/2, & x=0,\ y>0,\\ -\pi/2, & x=0,\ y<0.\end{cases}$$

Worked Example 3.3 — Solving trigonometric equations on a full period

(a) Find all $\theta\in[0,2\pi)$ with $\sin\theta=-0.5$. (b) Find the angle of the point $(-4,-3)$. (c) Solve $\cos(2\theta)=0.3$ for $\theta\in[0,2\pi)$.

(a) $\arcsin(-0.5)=-\pi/6$. The two families are $\theta=-\pi/6+2\pi k$ and $\theta=\pi-(-\pi/6)+2\pi k=7\pi/6+2\pi k$. In $[0,2\pi)$: $\theta=7\pi/6$ (210°) and $\theta=11\pi/6$ (330°). Both are in quadrants III and IV, where sine is negative. ✓

(b) $\arctan(-3/-4)=\arctan(0.75)=36.87^\circ$ — a first-quadrant answer for a third-quadrant point. Since $x<0,\ y<0$: $\operatorname{atan2}(-3,-4)=36.87^\circ-180^\circ=-143.13^\circ$ (or 216.87°). Check: $5\cos(-143.13^\circ)=-4.00$, $5\sin(-143.13^\circ)=-3.00$. ✓

(c) Let $u=2\theta$; as θ ranges over $[0,2\pi)$, u ranges over $[0,4\pi)$ — *two* full turns, so expect four solutions. $\arccos 0.3=1.2661$ rad. Solutions $u=\pm1.2661+2\pi k$ in $[0,4\pi)$: $u=1.2661,\ 5.0171,\ 7.5493,\ 11.3003$. Dividing by 2: $\theta=0.6331,\ 2.5086,\ 3.7746,\ 5.6502$ rad.

Check: $\cos(2\times 2.5086)=\cos(5.0171)=0.300$. ✓

Common Pitfall — Calculator and library angle modes

`sin(30)` is -0.988 in radian mode and 0.5 in degree mode. Every mainstream programming library (C `math.h`, Python `math`, NumPy, MATLAB `sin`) works in radians; MATLAB's `sind`, `cosd` and spreadsheet `RADIANS()` exist precisely because people forget. A second trap is `atan` vs `atan2`: using `atan(y/x)` to compute the phase of a phasor gives an answer off by exactly 180° whenever the real part is negative.

Why calculus insists on radians

The decisive reason for radians is the limit

$$\lim_{\theta \to 0} \frac{\sin\theta}{\theta} = 1 \qquad (\theta \text{ in radians}).$$

Proof sketch. For $0 < \theta < \pi/2$ draw the unit circle, the point $P = (\cos\theta, \sin\theta)$ and the point $Q = (1, \tan\theta)$ on the tangent line $x = 1$. The triangle OAP (with $A = (1,0)$), the sector OAP and the triangle OAQ are nested, so their areas satisfy

$$\tfrac{1}{2}\sin\theta \;\le\; \tfrac{1}{2}\theta \;\le\; \tfrac{1}{2}\tan\theta.$$

The middle term uses the radian sector-area formula $\tfrac{1}{2}r^2\theta$. Dividing by $\tfrac{1}{2}\sin\theta > 0$ and taking reciprocals gives $\cos\theta \le \dfrac{\sin\theta}{\theta} \le 1$. As $\theta \to 0^+$, $\cos\theta \to 1$, and the squeeze gives the limit; evenness of $\sin\theta/\theta$ covers $\theta \to 0^-$. $\square$

This limit is exactly what makes $\dfrac{d}{d\theta}\sin\theta = \cos\theta$ (derived in Ch. 4). If θ were measured in degrees, every derivative would carry a factor $\pi/180$: $\frac{d}{d\theta^\circ}\sin\theta^\circ = \frac{\pi}{180}\cos\theta^\circ$. The exponential form $e^{j\theta} = \cos\theta + j\sin\theta$ of Ch. 2 likewise holds only with θ in radians.

Small-angle approximations

The limit above says $\sin\theta \approx \theta$ for small θ. Combined with the Taylor series (developed in Ch. 4)

$$\sin\theta = \theta - \frac{\theta^3}{6} + \cdots, \qquad \cos\theta = 1 - \frac{\theta^2}{2} + \cdots, \qquad \tan\theta = \theta + \frac{\theta^3}{3} + \cdots,$$

we have the working approximations $\sin\theta \approx \tan\theta \approx \theta$ and $\cos\theta \approx 1 - \theta^2/2$, with relative error of $\sin\theta \approx \theta$ about $\theta^2/6$.

Worked Example 3.4 — How small is "small"?

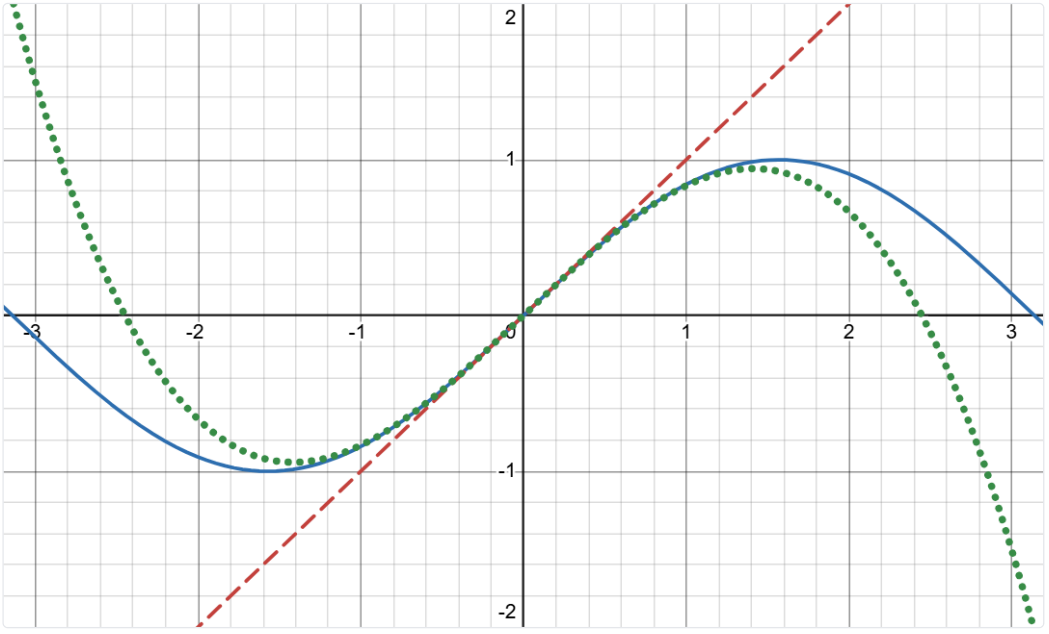
For what angle is the relative error of $\sin\theta \approx \theta$ equal to 1%? Evaluate the approximation at $\theta = 0.1$ rad and at 10°.

Solution. Relative error $\approx \theta^2/6 = 0.01$ gives $\theta \approx \sqrt{0.06} = 0.245$ rad $\approx 14^\circ$.

At $\theta = 0.1$: $\sin 0.1 = 0.099833$, error $0.1 - 0.099833 = 1.67 \times 10^{-4}$, relative error 0.167%, matching $\theta^2/6 = 0.00167$. ✓

At $10^\circ = 0.17453$ rad: $\sin 10^\circ = 0.17365$; relative error $(0.17453 - 0.17365)/0.17365 = 0.51\%$; prediction $0.17453^2/6 = 0.51\%$. ✓

So the approximation is good to about 1 % up to roughly 14°, which is why it is used freely for small phase errors, small pointing errors and small-signal analysis of phase-locked loops.



sin x (blue) with its linear approximation x (red) and cubic approximation $x - x^3/6$ (green): both hug the sine near the origin and peel away for larger angles.

3.2 Sinusoidal functions

Motivation

A sinusoid is the only periodic waveform whose shape survives every linear, time-invariant operation: scaling it, delaying it, differentiating it, integrating it, or adding it to another sinusoid of the same frequency all produce a sinusoid of the same frequency. Resistors scale, capacitors and inductors differentiate or integrate, transmission lines delay — so in a linear circuit driven by a sinusoid, *every* voltage and current is a sinusoid of the source frequency, differing only in amplitude and phase. That is the mathematical reason why AC analysis, phasors (Ch. 2) and frequency response (Ch. 14, Ch. 16) all reduce to the bookkeeping of two numbers per signal.

The general sinusoid

Sinusoid

A **sinusoid** (sinusoidal function of time) is any function of the form

$$x(t) = A\cos(\omega t + \phi) + C,$$

with

- **amplitude** (peak value) $A > 0$, in the units of x;
- **angular frequency** $\omega > 0$, in rad/s;
- **phase** (phase angle, initial phase) ϕ, in rad or degrees, conventionally reduced to $(-\pi, \pi]$;
- **offset** (DC component, mean value) C, in the units of x.

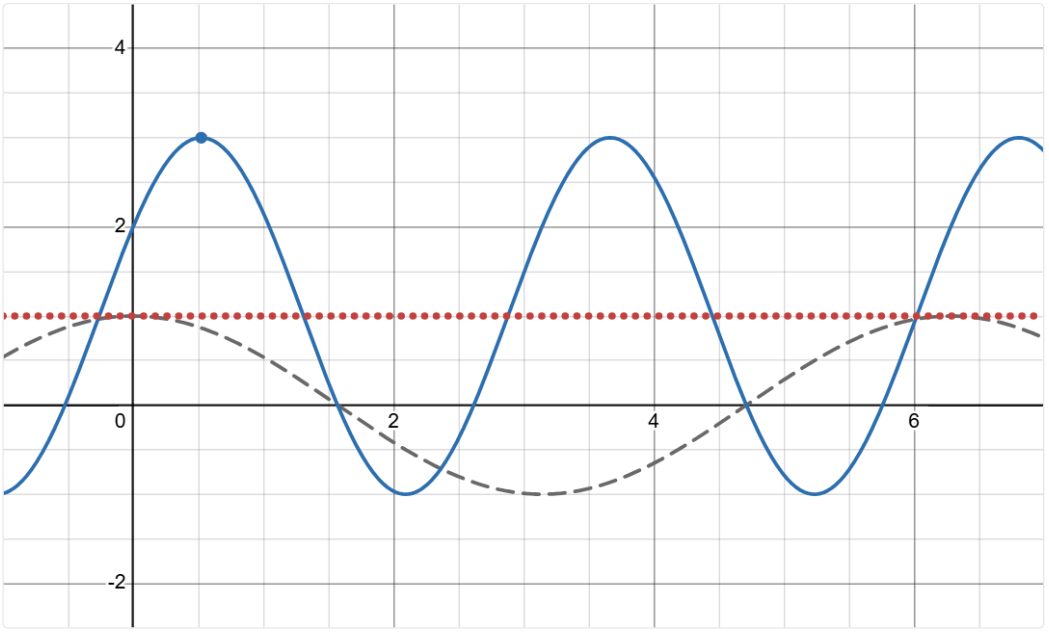
The quantity $\Theta(t) = \omega t + \phi$ is the **instantaneous phase** (total phase angle) at time t; $\phi = \Theta(0)$.

The electrical-engineering convention is to use the **cosine** as the reference sinusoid, because $\cos(\omega t + \phi) = \mathrm{Re}\{e^{j(\omega t + \phi)}\}$ connects directly to the phasor $Ae^{j\phi}$. Many physics and mathematics texts use sin as the reference; both describe the same family of functions, and you must convert before comparing phases (§3.3).

The four parameters act on the graph of $\cos t$ as elementary transformations (Ch. 1):

Parameter	Effect on the graph of $\cos t$
A	vertical stretch: peaks at $C \pm A$
C	vertical shift: the waveform oscillates about the line $x = C$
ω	horizontal compression by the factor ω: one cycle takes $2\pi/\omega$ seconds
ϕ	horizontal shift by $-\phi/\omega$: the peak that $\cos t$ has at $t = 0$ moves to $t = -\phi/\omega$

Note that the horizontal shift is ϕ/ω, **not** ϕ: writing $\cos(\omega t + \phi) = \cos\big(\omega(t + \phi/\omega)\big)$ shows that the graph is shifted left by ϕ/ω seconds. A positive phase moves the waveform *earlier* in time.



The reference $\cos t$ (grey) and $1 + 2\cos(2t - \pi/3)$ (blue): amplitude 2, offset 1 (red line), angular frequency 2 so the period halves to π, and a phase of $-\pi/3$ that delays the first peak to $t = \pi/6$.

Elementary properties

For $x(t) = A\cos(\omega t + \phi) + C$:

- **Extremes.** Maximum $C + A$ where $\omega t + \phi = 2\pi k$; minimum $C - A$ where $\omega t + \phi = \pi + 2\pi k$.

- **Peak-to-peak value.** $x_{pp} = 2A$.
- **Crossings of the mean.** $x = C$ where $\omega t + \phi = \pi/2 + \pi k$, i.e. twice per cycle, a quarter-cycle after each extreme.
- **Period.** $T = 2\pi/\omega$ (§3.4).
- **Boundedness and smoothness.** x is bounded and infinitely differentiable; all of its derivatives are sinusoids of the same frequency.

Converting between sine and cosine and normalising the phase

Because the sine curve is the cosine curve delayed by a quarter cycle, every sinusoid can be written in the cosine reference with a positive amplitude. The conversion rules, read off the unit circle, are:

$$\begin{aligned} \sin\theta &= \cos(\theta - \tfrac{\pi}{2}), & -\sin\theta &= \cos(\theta + \tfrac{\pi}{2}), \\ -\cos\theta &= \cos(\theta \pm \pi), & \cos\theta &= \sin(\theta + \tfrac{\pi}{2}). \end{aligned}$$

In degrees: $\sin\theta = \cos(\theta - 90^\circ)$, $-\sin\theta = \cos(\theta + 90^\circ)$, $-\cos\theta = \cos(\theta \pm 180^\circ)$. A negative amplitude is absorbed into the phase as $\pm 180^\circ$, chosen so that the resulting phase lands in $(-180^\circ, 180^\circ]$.

Standard (canonical) form

A sinusoid is in **standard form** when written $A\cos(\omega t + \phi) + C$ with $A > 0$, $\omega > 0$ and $-\pi < \phi \le \pi$. In standard form the parameters are unique, so two sinusoids are equal if and only if their standard-form parameters agree.

A negative frequency can likewise be removed, using evenness of cosine: $\cos(-\omega t + \phi) = \cos(\omega t - \phi)$.

Worked Example 3.5 — Reading parameters and putting a sinusoid into standard form

Write each signal in standard form and state amplitude, angular frequency, frequency, phase and offset.

(a) $v(t) = -170\sin(377t + 20^\circ)$ V. (b) $i(t) = 5 - 3\cos(2000\pi t - 60^\circ)$ mA. (c) $x(t) = 4\sin(-50t + 0.3)$.

(a) $-\sin\theta = \cos(\theta + 90^\circ)$, so $v = 170\cos(377t + 110^\circ)$ V. Amplitude 170 V, $\omega = 377$ rad/s, $f = 377/2\pi = 60.0$ Hz, phase $+110^\circ$, offset 0. (This is a 120 V RMS, 60 Hz supply: $170/\sqrt{2} = 120.2$ V.)

(b) $-\cos\theta = \cos(\theta + 180^\circ)$: $-3\cos(2000\pi t - 60^\circ) = 3\cos(2000\pi t + 120^\circ)$. So $i = 5 + 3\cos(2000\pi t + 120^\circ)$ mA: amplitude 3 mA, $\omega = 2000\pi = 6283$ rad/s, $f = 1$ kHz, phase 120°, offset 5 mA. The current never reverses: it swings between 2 mA and 8 mA.

(c) Sine is odd: $4\sin(-50t + 0.3) = -4\sin(50t - 0.3) = 4\cos(50t - 0.3 + \pi/2) = 4\cos(50t + 1.2708)$. Amplitude 4, $\omega = 50$ rad/s, $f = 7.958$ Hz, phase 1.2708 rad $= 72.8^\circ$.

Check (c) at $t = 0.01$: original $4\sin(-0.5 + 0.3) = 4\sin(-0.2) = -0.7947$; standard form $4\cos(0.5 + 1.2708) = 4\cos(1.7708) = -0.7947$. ✓

Amplitude–phase form: combining $a\cos\omega t + b\sin\omega t$

Solutions of differential equations (Ch. 11, Ch. 12) and Fourier series (Ch. 15) naturally come out as $a\cos\omega t + b\sin\omega t$. For interpretation we want a single sinusoid.

Amplitude–phase form

For real a, b not both zero,

$$a\cos\omega t + b\sin\omega t = R\cos(\omega t - \alpha), \qquad R = \sqrt{a^2 + b^2}, \quad \alpha = \operatorname{atan2}(b, a).$$

Equivalently $a\cos\omega t + b\sin\omega t = R\cos(\omega t + \phi)$ with $\phi = -\alpha = \operatorname{atan2}(-b, a)$. Conversely, $R\cos(\omega t + \phi) = a\cos\omega t + b\sin\omega t$ with $a = R\cos\phi$, $b = -R\sin\phi$.

Derivation 1 (compound angle). Expand the right-hand side with $\cos(X - Y) = \cos X\cos Y + \sin X\sin Y$ (proved in §3.6):

$$R\cos(\omega t - \alpha) = R\cos\alpha\,\cos\omega t + R\sin\alpha\,\sin\omega t.$$

This equals $a\cos\omega t + b\sin\omega t$ for all t if and only if $R\cos\alpha = a$ and $R\sin\alpha = b$ (compare values at $t = 0$ and at $\omega t = \pi/2$). These say that (a, b) is the point with polar coordinates (R, α), so $R = \sqrt{a^2 + b^2}$ and $\alpha = \operatorname{atan2}(b, a)$.

Derivation 2 (phasor). Since $\cos\omega t = \operatorname{Re}\{e^{j\omega t}\}$ and $\sin\omega t = \operatorname{Re}\{-je^{j\omega t}\}$,

$$a\cos\omega t + b\sin\omega t = \operatorname{Re}\{(a - jb)e^{j\omega t}\}.$$

The phasor is $a - jb = Re^{-j\alpha}$, so the sum is $\operatorname{Re}\{Re^{j(\omega t - \alpha)}\} = R\cos(\omega t - \alpha)$. The phasor route makes the sign of the phase automatic: **the sine coefficient enters the phasor with a minus sign.**

Worked Example 3.6 — Amplitude–phase conversions

(a) $3\cos\omega t + 4\sin\omega t$. (b) $5\cos\omega t - 12\sin\omega t$. (c) $-2\sqrt{3}\cos\omega t - 2\sin\omega t$.

(a) $R = \sqrt{9+16} = 5$, $\alpha = \operatorname{atan2}(4,3) = 53.13°$: $3\cos\omega t + 4\sin\omega t = 5\cos(\omega t - 53.13°)$.

(b) $R = \sqrt{25+144} = 13$, $\alpha = \operatorname{atan2}(-12,5) = -67.38°$: $5\cos\omega t - 12\sin\omega t = 13\cos(\omega t + 67.38°)$.

(c) $R = \sqrt{12+4} = 4$. Here $a<0, b<0$, so the point is in quadrant III: $\alpha = \operatorname{atan2}(-2,-2\sqrt{3}) = -150°$. Hence $-2\sqrt{3}\cos\omega t - 2\sin\omega t = 4\cos(\omega t + 150°)$.

Check (c): $4\cos(\omega t + 150°) = 4\cos 150°\cos\omega t - 4\sin 150°\sin\omega t = 4(-0.8660)\cos\omega t - 4(0.5)\sin\omega t = -3.464\cos\omega t - 2\sin\omega t$. ✓ A naive $\arctan(b/a) = \arctan(1/\sqrt{3}) = 30°$ would have given $4\cos(\omega t - 30°)$ — the negative of the correct answer.

Derivatives and integrals of sinusoids

Using $\frac{d}{dt}\cos(\omega t+\phi) = -\omega\sin(\omega t+\phi)$ and the conversion rule $-\sin\theta = \cos(\theta+\pi/2)$:

$$\frac{d}{dt}\big[A\cos(\omega t+\phi)\big] = \omega A\cos\big(\omega t+\phi+\tfrac{\pi}{2}\big), \qquad \int A\cos(\omega t+\phi)\,dt = \frac{A}{\omega}\cos\big(\omega t+\phi-\tfrac{\pi}{2}\big) + K.$$

Differentiation multiplies the amplitude by ω and advances the phase by $90°$; integration divides by ω and retards the phase by $90°$. In phasor language these are multiplication and division by $j\omega$, since $j = e^{j\pi/2}$. Differentiating twice gives back the original sinusoid times $-\omega^2$, so every sinusoid of angular frequency ω (without offset) satisfies

$$\ddot{x} + \omega^2 x = 0,$$

the equation of simple harmonic motion (§3.5).

Worked Example 3.7 — Capacitor current from capacitor voltage

A $C = 1\ \mu$F capacitor has $v(t) = 10\cos(1000t + 30°)$ V. Find $i(t) = C\,dv/dt$ and state which leads.

Solution. $dv/dt = 1000 \times 10\cos(1000t + 30° + 90°) = 10^4\cos(1000t + 120°)$ V/s. So $i = 10^{-6} \times 10^4\cos(1000t + 120°) = 10\cos(1000t + 120°)$ mA.

The current phase ($120°$) exceeds the voltage phase ($30°$) by $90°$: **current leads voltage by** $90°$ in a capacitor. The amplitude ratio $V/I = 10/0.01 = 1000\ \Omega = 1/(\omega C)$ is the capacitive reactance. ✓

Mean, RMS and related measures

The **mean** (average) of a periodic function over one period T is $\bar{x} = \frac{1}{T}\int_0^T x\,dt$, and the **root-mean-square** value is $X_{\text{rms}} = \sqrt{\frac{1}{T}\int_0^T x^2\,dt}$. RMS matters because the average power delivered to a resistor is $\overline{v^2}/R = V_{\text{rms}}^2/R$: the RMS value is the DC value that would deliver the same power. The general theory of mean and RMS values belongs to Ch. 5; here we need the sinusoidal case.

Mean and RMS of a sinusoid

Over any whole number of periods,

$$\overline{\cos(\omega t+\phi)} = 0, \qquad \overline{\cos^2(\omega t+\phi)} = \tfrac{1}{2}.$$

Hence for $x = A\cos(\omega t+\phi) + C$:

$$\bar{x} = C, \qquad X_{\text{rms}} = \sqrt{C^2 + \tfrac{1}{2}A^2}.$$

For a pure sinusoid ($C = 0$), $X_{\text{rms}} = A/\sqrt{2} \approx 0.7071A$.

Proof. The integral of $\cos(\omega t+\phi)$ over one period is $\frac{1}{\omega}[\sin(\omega t+\phi)]_0^T = \frac{1}{\omega}[\sin(2\pi+\phi) - \sin\phi] = 0$. For the square, use the power-reduction identity $\cos^2\theta = \frac{1}{2}(1+\cos 2\theta)$ (§3.6): the constant $\frac{1}{2}$ averages to $\frac{1}{2}$ and $\cos 2\theta$ averages to 0. Then

$$\overline{x^2} = \overline{C^2 + 2AC\cos(\cdot) + A^2\cos^2(\cdot)} = C^2 + 0 + \tfrac{1}{2}A^2. \qquad \square$$

There is a neat way to see $\overline{\cos^2} = \frac{1}{2}$ without any identity: $\cos^2$ and $\sin^2$ have the same graph shifted by a quarter period, so they have the same average over a full period; and they add to 1. Each must average $\frac{1}{2}$.

Two further ratios describe waveform shape and are printed on meter datasheets:

$$\text{crest factor} = \frac{X_{\text{peak}}}{X_{\text{rms}}}, \qquad \text{form factor} = \frac{X_{\text{rms}}}{\overline{|x|}}.$$

For a pure sinusoid, the rectified average is $\overline{|A\cos\omega t|} = 2A/\pi$ (computed in §3.8), so crest factor $= \sqrt{2} \approx 1.414$ and form factor $= \dfrac{A/\sqrt{2}}{2A/\pi} = \dfrac{\pi}{2\sqrt{2}} \approx 1.1107$.

Worked Example 3.8 — Mains voltage and a biased sinusoid

(a) A 230 V (RMS), 50 Hz supply: what is the peak voltage, the peak-to-peak voltage, and the instantaneous voltage 3 ms after a positive peak? (b) A sensor output is $v(t) = 2 + 3\sin(100t)$ V. Find its mean, its RMS value and the power it would deliver to a 50 Ω resistor.

(a) $V_p = \sqrt{2} \times 230 = 325.3$ V; $V_{pp} = 650.5$ V. With the peak at $t = 0$, $v = 325.3\cos(2\pi \cdot 50\,t)$. At $t = 3$ ms: $\omega t = 2\pi(50)(0.003) = 0.9425$ rad $= 54°$, so $v = 325.3\cos 54° = 191.2$ V.

(b) Mean $= 2$ V. RMS $= \sqrt{2^2 + 3^2/2} = \sqrt{8.5} = 2.915$ V. Power $= V_{\text{rms}}^2/R = 8.5/50 = 0.170$ W. Note that the DC and AC powers simply add: $2^2/50 + (3/\sqrt{2})^2/50 = 0.08 + 0.09 = 0.17$ W — a first glimpse of the orthogonality result of §3.7.

Worked Example 3.9 — Recovering a sinusoid from two observations

An oscilloscope shows a sinusoid with a maximum of 7 V at $t = 2$ ms and the next minimum of -1 V at $t = 7$ ms. Write it in standard form.

Offset and amplitude. $C = \frac{7+(-1)}{2} = 3$ V, $A = \frac{7-(-1)}{2} = 4$ V.

Frequency. A maximum and the next minimum are half a period apart: $T/2 = 5$ ms, so $T = 10$ ms, $f = 100$ Hz, $\omega = 200\pi = 628.3$ rad/s.

Phase. A maximum occurs where $\omega t + \phi = 0 \pmod{2\pi}$: $\phi = -\omega(0.002) = -0.4\pi$ rad $= -72°$.

Result. $v(t) = 3 + 4\cos(200\pi t - 0.4\pi)$ V.

Check: at $t = 7$ ms, $200\pi(0.007) - 0.4\pi = 1.0\pi$, $\cos\pi = -1$, $v = 3 - 4 = -1$ V. ✓

Common Pitfall — Peak, peak-to-peak or RMS?

"10 V AC" is ambiguous. Function generators often display peak-to-peak (into a matched load!), multimeters display RMS, and the formula $A\cos(\omega t + \phi)$ uses peak. Convert explicitly: $V_{pp} = 2V_p = 2\sqrt{2}\,V_{\text{rms}} \approx 2.83\,V_{\text{rms}}$. Also note that the $1/\sqrt{2}$ rule is for *sinusoids only*: an "average-responding, RMS-calibrated" meter multiplies the rectified average by 1.1107 and is wrong for every non-sinusoidal waveform.

3.3 Phase and phase difference

Motivation

Amplitude tells you *how big* a sinusoid is; phase tells you *when* it peaks. In a single isolated signal the phase is arbitrary — it depends only on where you chose $t = 0$. What carries physical meaning is the **phase difference** between two sinusoids of the same frequency: the angle by which the current in a motor lags its voltage (which fixes the power factor), the phase shift through an amplifier (which decides whether a feedback loop oscillates), the phase between the three lines of a power system, or the phase between signals at two antennas (which steers a beam). This section makes "leads", "lags" and "phase difference" precise and shows how to compute them without sign errors.

Phase of a single sinusoid

For $x(t) = A\cos(\omega t + \phi)$ the phase ϕ is the instantaneous phase at $t = 0$. Moving the time origin by t_0 (that is, writing $t = t' + t_0$) changes the phase to $\phi + \omega t_0$ but leaves the waveform itself untouched. Hence:

- the phase of one sinusoid is meaningful only relative to a stated time reference (or a reference signal);
- phases are defined modulo 2π (360°), and are normally reported in the principal interval $(-180°, 180°]$ — this reduction is called **phase wrapping**.

Phase difference, lead and lag

Phase difference, lead, lag

Let $x_1(t) = A_1\cos(\omega t + \phi_1)$ and $x_2(t) = A_2\cos(\omega t + \phi_2)$ have the **same** angular frequency ω and be written in standard form ($A_1, A_2 > 0$, both cosines). The **phase difference** of x_1 relative to x_2 is

$$\Delta\phi = \phi_1 - \phi_2, \qquad \text{reduced to } (-\pi, \pi].$$

If $0 < \Delta\phi < \pi$, x_1 **leads** x_2 by $\Delta\phi$; if $-\pi < \Delta\phi < 0$, x_1 **lags** x_2 by $|\Delta\phi|$. The signals are **in phase** if $\Delta\phi = 0$, in **quadrature** if $\Delta\phi = \pm\pi/2$, and in **antiphase** (phase opposition) if $\Delta\phi = \pi$.

"Leads" means *happens earlier*: if x_1 leads x_2 by $\Delta\phi$, each feature of x_1 (peak, upward zero crossing) occurs $\Delta\phi/\omega$ seconds before the corresponding feature of x_2. Indeed

$$x_1(t) = A_1\cos\big(\omega t + \phi_2 + \Delta\phi\big) = \frac{A_1}{A_2}\,x_2\!\left(t + \frac{\Delta\phi}{\omega}\right),$$

so x_1 is a scaled copy of x_2 advanced by $\Delta\phi/\omega$.

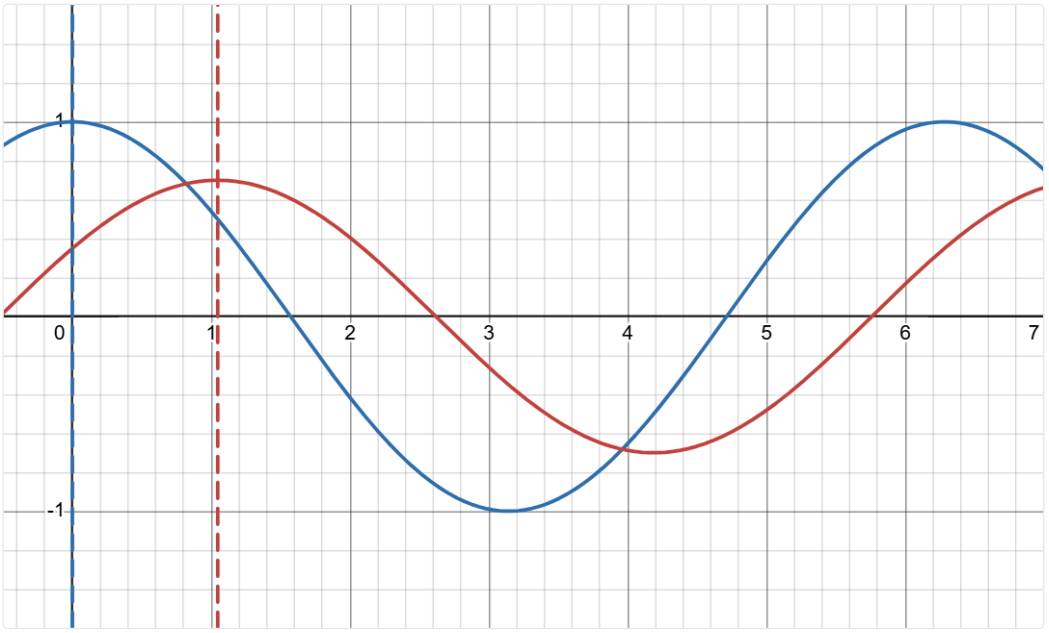
The restriction to $(-\pi, \pi]$ matters: a lead of 270° is the same physical relationship as a lag of 90°, and engineers always quote the smaller one. A phase difference of exactly 180° is neither a lead nor a lag.

Phase difference as time delay

For two sinusoids of the same frequency f (period T), a phase difference $\Delta\phi$ corresponds to a time shift

$$\Delta t = \frac{\Delta\phi}{\omega} = \frac{\Delta\phi}{2\pi f} = \frac{\Delta\phi_{\text{deg}}}{360^\circ}\,T.$$

Conversely a pure time delay τ produces a phase lag $\omega\tau$, which grows linearly with frequency.



$\cos t$ (blue) leads $0.7\cos(t-\pi/3)$ (red) by 60°: every red peak arrives $\pi/3$ rad of ωt after the corresponding blue peak (dashed lines).

Worked Example 3.10 — Comparing phases written in different forms

$v(t) = 10\sin(\omega t + 30^\circ)$ V and $i(t) = -2\cos(\omega t - 20^\circ)$ A. Find the phase of i relative to v.

Step 1 — convert both to standard cosine form. $v = 10\cos(\omega t + 30^\circ - 90^\circ) = 10\cos(\omega t - 60^\circ)$. $i = 2\cos(\omega t - 20^\circ + 180^\circ) = 2\cos(\omega t + 160^\circ)$.

Step 2 — subtract. $\Delta\phi = \phi_i - \phi_v = 160^\circ - (-60^\circ) = 220^\circ$.

Step 3 — wrap. $220^\circ - 360^\circ = -140^\circ$. So i **lags** v **by** 140° (equivalently, v leads i by 140°).

Check. Comparing the original expressions directly (30° vs -20°, "v leads by 50°") is wrong on two counts: one is a sine and the other a cosine, and i has a negative amplitude. Numerically, v has a positive peak at $\omega t = 60^\circ$; i has a positive peak at $\omega t = -160^\circ \equiv 200^\circ$, which is 140° later. ✓

Worked Example 3.11 — From phase to time and back

(a) Two 50 Hz voltages differ in phase by 36°. What is the time between their peaks? (b) A coaxial cable delays a signal by 5 ns per metre. What phase lag does 2 m of cable introduce at 10 MHz, at 100 MHz and at 150 MHz? (c) An RC low-pass filter with $R = 1\ \text{k}\Omega$, $C = 100$ nF has output phase $-\arctan(\omega RC)$ relative to its input. At 1 kHz, what are the phase lag and the corresponding time delay?

(a) $T = 20$ ms; $\Delta t = (36/360)\times 20 = 2$ ms.

(b) $\tau = 10$ ns. Lag $= 360^\circ f\tau$: at 10 MHz, 36°; at 100 MHz, 360° (indistinguishable from 0°!); at 150 MHz, $540^\circ \equiv 180^\circ$.

(c) $\omega RC = 2\pi(1000)(1000)(10^{-7}) = 0.6283$. Lag $= \arctan 0.6283 = 32.14^\circ$. Delay $= \frac{32.14}{360}\times 1\text{ ms} = 89.3\ \mu\text{s}$.

Interpretation. Part (b) shows that a measured phase cannot distinguish delays that differ by whole periods; part (c) shows that the phase lag of a filter, unlike that of a cable, is *not* proportional to frequency, so different frequencies are delayed by different amounts.

Common Pitfall — Phase ambiguity

A phase measurement determines a time delay only modulo one period. Phase meters, network analysers and FFT routines report a wrapped phase in $(-180^\circ, 180^\circ]$; to recover total delay you must *unwrap* — track the phase continuously as frequency is swept and add 360° at each jump. NumPy's `unwrap` and MATLAB's `unwrap` do exactly this, assuming that consecutive samples differ by less than 180°.

Adding sinusoids of the same frequency

The sum of two sinusoids of the same frequency is a sinusoid of that frequency. The cleanest proof uses phasors (Ch. 2):

$$A_1\cos(\omega t + \phi_1) + A_2\cos(\omega t + \phi_2) = \text{Re}\left\{(A_1 e^{j\phi_1} + A_2 e^{j\phi_2})e^{j\omega t}\right\} = R\cos(\omega t + \psi),$$

where $Re^{j\psi} = A_1 e^{j\phi_1} + A_2 e^{j\phi_2}$. Writing out real and imaginary parts gives explicit formulas:

Sum of two same-frequency sinusoids

$$R^2 = A_1^2 + A_2^2 + 2A_1A_2\cos(\phi_1 - \phi_2), \qquad \psi = \operatorname{atan2}\left(A_1\sin\phi_1 + A_2\sin\phi_2,\ A_1\cos\phi_1 + A_2\cos\phi_2\right).$$

The magnitude formula is the law of cosines applied to the phasor triangle. It shows that the resultant amplitude depends only on the *phase difference*: it ranges from $A_1 + A_2$ (in phase, **constructive** interference) down to $|A_1 - A_2|$ (antiphase, **destructive** interference), and equals $\sqrt{A_1^2 + A_2^2}$ in quadrature.

Worked Example 3.12 — Adding two currents at a node

Two branch currents enter a node: $i_1 = 10\cos(\omega t + 30^\circ)$ A and $i_2 = 6\cos(\omega t - 45^\circ)$ A. Find $i_1 + i_2$.

Rectangular components. $10\angle 30^\circ = 8.660 + j5.000$; $6\angle -45^\circ = 4.243 - j4.243$. Sum: $12.903 + j0.757$.

Polar. $R = \sqrt{12.903^2 + 0.757^2} = 12.925$; $\psi = \operatorname{atan2}(0.757, 12.903) = 3.36^\circ$.

Result. $i_1 + i_2 = 12.93\cos(\omega t + 3.36^\circ)$ A.

Check with the law of cosines: $R^2 = 100 + 36 + 120\cos 75^\circ = 136 + 31.06 = 167.06$, $R = 12.925$. ✓ Also at $\omega t = 0.3$ rad the original sum evaluates to 12.103 and the result to 12.103. ✓ Note that the resultant (12.9 A) is less than the arithmetic sum (16 A) — an ammeter reading RMS values on each branch does *not* add.

Three-phase sets

A **balanced three-phase set** consists of three sinusoids of equal amplitude and frequency displaced by 120°:

$$v_a = V\cos\omega t, \qquad v_b = V\cos(\omega t - 120^\circ), \qquad v_c = V\cos(\omega t + 120^\circ).$$

Balanced sets sum to zero

$v_a + v_b + v_c = 0$ for all t. More generally, for any integer $N \geq 2$, $\displaystyle\sum_{k=0}^{N-1}\cos\left(\omega t + \phi - \frac{2\pi k}{N}\right) = 0$.

Proof. The phasor sum is $V\sum_{k=0}^{N-1} e^{-j2\pi k/N}$, a geometric series with ratio $r = e^{-j2\pi/N} \neq 1$: it equals $V\frac{1-r^N}{1-r} = 0$ because $r^N = e^{-j2\pi} = 1$. (These are the N-th roots of unity of Ch. 2, which sum to zero.) □

This is why a balanced three-phase load needs no neutral return current.

Worked Example 3.13 — Line-to-line voltage

With v_a and v_b as above, find the line-to-line voltage $v_{ab} = v_a - v_b$.

Phasors. $V\angle 0^\circ - V\angle -120^\circ = V\left[1 - \left(-\tfrac{1}{2} - j\tfrac{\sqrt{3}}{2}\right)\right] = V\left(\tfrac{3}{2} + j\tfrac{\sqrt{3}}{2}\right)$.

Magnitude $V\sqrt{9/4 + 3/4} = \sqrt{3}\,V$; angle $\arctan\left(\frac{\sqrt{3}/2}{3/2}\right) = 30^\circ$.

Result. $v_{ab} = \sqrt{3}\,V\cos(\omega t + 30^\circ)$: the line voltage is $\sqrt{3}$ times the phase voltage and leads v_a by 30°. For a 230 V phase supply, the line voltage is $\sqrt{3} \times 230 = 398 \approx 400$ V.

Measuring phase: zero crossings and Lissajous figures

Two practical measurement methods follow directly from the definitions.

Zero-crossing timing. Measure the time Δt between corresponding upward zero crossings of the two signals and the period T; then $|\Delta\phi| = 360^\circ\,\Delta t/T$. The signal whose crossing comes first leads.

Lissajous (X–Y) method. Apply $x = X\sin\omega t$ to the horizontal input of an oscilloscope and $y = Y\sin(\omega t + \phi)$ to the vertical. Eliminating t gives an ellipse:

$$\frac{x^2}{X^2} - \frac{2xy\cos\phi}{XY} + \frac{y^2}{Y^2} = \sin^2\phi.$$

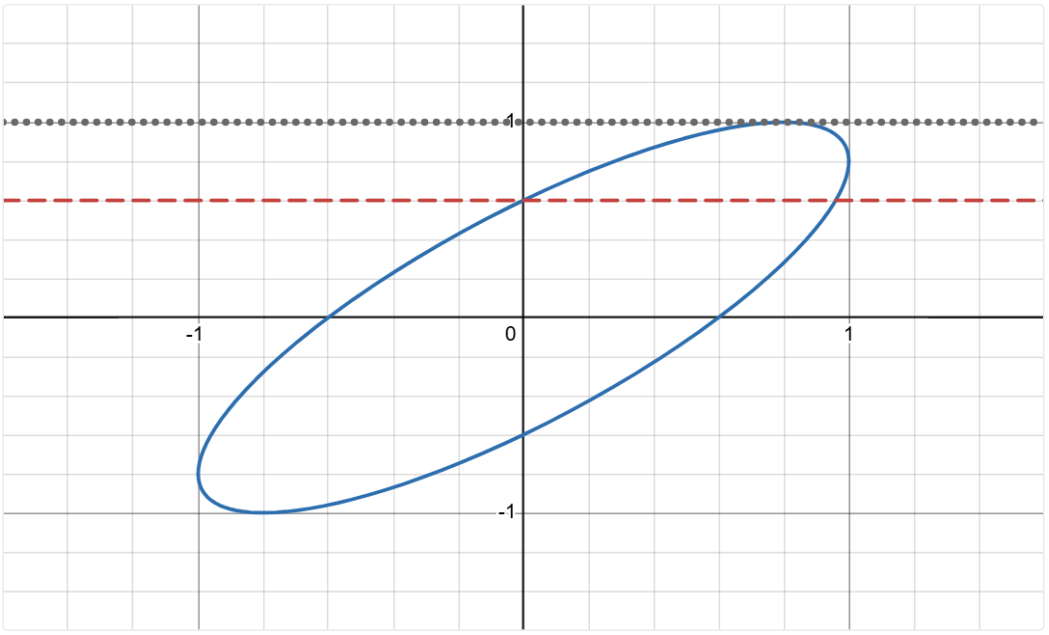
Derivation. Write $s = \sin\omega t = x/X$ and expand $y/Y = s\cos\phi + \cos\omega t\,\sin\phi$, so $\cos\omega t\,\sin\phi = y/Y - (x/X)\cos\phi$. Squaring and using $\cos^2\omega t = 1 - x^2/X^2$:

$$\left(1 - \frac{x^2}{X^2}\right)\sin^2\phi = \frac{y^2}{Y^2} - \frac{2xy}{XY}\cos\phi + \frac{x^2}{X^2}\cos^2\phi,$$

which rearranges to the ellipse equation. Setting $x = 0$ gives $y = \pm Y|\sin\phi|$. Hence

$$|\sin\phi| = \frac{y_0}{Y},$$

where y_0 is the height at which the ellipse crosses the vertical axis and Y is its maximum height. The ellipse collapses to a line of positive slope at $\phi = 0$, to a line of negative slope at $\phi = 180^\circ$, and becomes an axis-aligned ellipse at $\phi = \pm 90^\circ$. The sign of ϕ (lead or lag) cannot be read from a static picture; the tilt distinguishes $|\phi| < 90^\circ$ (major axis in quadrants I/III) from $|\phi| > 90^\circ$ (quadrants II/IV).



Lissajous ellipse for equal amplitudes and $\phi = 36.87°$: it crosses the vertical axis at $y_0 = 0.6$ (red), its maximum height is $Y = 1$ (grey), and $\sin\phi = 0.6$.

Worked Example 3.14 — Reading a Lissajous figure

An X–Y display shows an ellipse tilted into quadrants I and III, with maximum height 5.0 divisions and vertical-axis intercepts at ± 3.0 divisions. Find the magnitude of the phase difference.

Solution. $|\sin\phi| = 3.0/5.0 = 0.6$, so $|\phi| = \arcsin 0.6 = 36.87°$ or $180° - 36.87° = 143.13°$. The tilt into quadrants I/III means $|\phi| < 90°$: $|\phi| = 36.9°$.

Check: at $x = 0$ we have $\sin\omega t = 0$, $\cos\omega t = \pm 1$, so $y = \pm Y \sin\phi = \pm 5(0.6) = \pm 3$. ✓

Engineering Note — Phase in feedback and power systems

Two phase numbers dominate EE practice. In power systems the **power factor** $\cos\Delta\phi$ (with $\Delta\phi$ the voltage–current phase difference) sets how much of the volt-amperes delivered is real power: $P = V_{\text{rms}} I_{\text{rms}} \cos\Delta\phi$ — a consequence of the product-to-sum identity in §3.6. In feedback amplifiers the **phase margin** is $180°$ plus the loop phase at the frequency where loop gain is 1; when the loop phase reaches $-180°$ negative feedback has become positive feedback and the circuit oscillates. Both are phase *differences* of same-frequency sinusoids.

3.4 Period, frequency, and angular frequency

Motivation

"How often does it repeat?" is the first question asked of any signal. The answer comes in three interchangeable currencies — period in seconds, frequency in hertz, angular frequency in radians per second — and each is natural in a different place: the oscilloscope shows periods, the spectrum analyser and the datasheet show hertz, and every formula derived from calculus or phasors uses rad/s. A factor of 2π lost between them is the most common numerical error in circuit and signal calculations. Beyond single sinusoids, we need to know when a *combination* of sinusoids repeats, because that decides whether Fourier series (Ch. 15) or Fourier transforms (Ch. 16) is the right tool, and how sampled (discrete-time) sinusoids differ from continuous ones.

Periodic functions

Periodic function, fundamental period

A function $x(t)$ defined for all real t is **periodic** with period $T > 0$ if

$$x(t + T) = x(t) \qquad \text{for all } t.$$

If T is a period then so is kT for every positive integer k. The smallest positive period, when one exists, is the **fundamental period** T_0; its reciprocal $f_0 = 1/T_0$ is the **fundamental frequency** and $\omega_0 = 2\pi f_0$ the **fundamental angular frequency**.

A constant function satisfies $x(t + T) = x(t)$ for every $T > 0$ and so has no smallest period; by convention it is periodic with any period but has no fundamental period. (Its "frequency" is zero, which is why a constant is called the DC component.)

Period, frequency and angular frequency of a sinusoid

For $x(t) = A\cos(\omega t + \phi)$, the cosine repeats when its argument advances by 2π. Solving $\omega(t + T) + \phi = \omega t + \phi + 2\pi$ gives

$$T = \frac{2\pi}{\omega}, \qquad f = \frac{1}{T} = \frac{\omega}{2\pi}, \qquad \omega = 2\pi f = \frac{2\pi}{T}.$$

Quantity	Symbol	Unit	Meaning
period	T	s	time for one cycle
frequency	f	$\text{Hz} = \text{s}^{-1}$ (cycles per second)	cycles per unit time
angular frequency	ω	rad/s	rate of change of phase, $\omega = d\Theta/dt$

Dimensionally $[f] = [\omega] = \text{T}^{-1}$; the radian is dimensionless, so the unit "rad/s" is formally s^{-1} as well. This is exactly why a factor of 2π is never caught by a dimensional check — you must track it by keeping the units "Hz" and "rad/s" distinct in your working. The product ωt is dimensionless, as the argument of any function like cos must be.

Worked Example 3.15 — Conversions in practice

(a) North American mains has $\omega = 377$ rad/s: find f and T. (b) A Wi-Fi carrier is at 2.4 GHz: find T and ω. (c) A scope shows 4 complete cycles across 10 divisions at 50 μs/div: find f and ω.

(a) $f = 377/2\pi = 60.0$ Hz, $T = 1/60 = 16.67$ ms.

(b) $T = 1/(2.4 \times 10^9) = 416.7$ ps, $\omega = 2\pi \times 2.4 \times 10^9 = 1.508 \times 10^{10}$ rad/s.

(c) 10 divisions $= 500$ μs contains 4 periods, so $T = 125$ μs, $f = 8$ kHz, $\omega = 5.027 \times 10^4$ rad/s.

Time scaling and related functions

If $x(t)$ has fundamental period T_0, then $x(at)$ with $a > 0$ has fundamental period T_0/a: compressing time by a multiplies all frequencies by a. Several functions built from sinusoids have periods *shorter* than the sinusoid they come from:

Function	Fundamental period	Reason
$\cos(\omega t + \phi)$	$2\pi/\omega$	definition
$\tan \omega t$	π/ω	$\tan(\theta + \pi) = \tan\theta$
$\lvert\cos \omega t\rvert$	π/ω	full-wave rectification removes the sign
$\cos^2 \omega t$	π/ω	$\cos^2\theta = \frac{1}{2} + \frac{1}{2}\cos 2\theta$
$\cos \omega t \, \sin \omega t$	π/ω	$= \frac{1}{2}\sin 2\omega t$

The full-wave-rectifier entry is the reason the ripple on a 50 Hz full-wave rectifier's output is at 100 Hz.

When is a sum of sinusoids periodic?

Periodicity of a sum

Let x_1 and x_2 be periodic with fundamental periods T_1 and T_2.

1. If $T_1/T_2 = p/q$ is **rational**, with p, q coprime positive integers, then $x_1 + x_2$ is periodic with period $T = qT_1 = pT_2$ (the least common multiple of T_1 and T_2). Equivalently, the common frequency is the greatest common divisor of f_1 and f_2.
2. For sums of sinusoids, if T_1/T_2 is **irrational**, $x_1 + x_2$ is **not** periodic.

In case 1, T is the fundamental period of the sum unless cancellations occur (for example $x_2 = -x_1$); for a sum of sinusoids with nonzero amplitudes and distinct frequencies the fundamental frequency is exactly $\gcd(f_1, f_2)$.

Proof of 1. qT_1 is a whole number of periods of x_1, and $pT_2 = qT_1$ is a whole number of periods of x_2, so both terms, hence their sum, repeat after T.

Proof of 2 (for $\cos \omega_1 t + \cos \omega_2 t$). The sum equals its maximum value 2 at $t = 0$. It equals 2 at any other time t only if both cosines equal 1, i.e. $\omega_1 t = 2\pi m$ and $\omega_2 t = 2\pi n$ for integers m, n with $t \neq 0$. Dividing, $\omega_1/\omega_2 = m/n$ would be rational — contradiction. So the value 2 is attained only at $t = 0$. A periodic function attains each of its values infinitely often (at $t, t + T, t + 2T, \ldots$), so the sum is not periodic. □

Such sums are called **almost periodic** (or quasi-periodic): they come arbitrarily close to repeating but never do exactly. In practice, any measured frequency ratio is rational to within instrument precision, but the theoretical distinction matters: Fourier *series* need exact periodicity, whereas the Fourier *transform* (Ch. 16) handles any combination of frequencies.

Worked Example 3.16 — Fundamental periods of combinations

Find the fundamental period, or show none exists.

(a) $x(t) = \sin 3t + \cos 4.5t$. (b) $v(t) = \cos(100\pi t) + 0.2\cos(300\pi t) + 0.1\cos(500\pi t)$. (c) $y(t) = \cos t + \cos\sqrt{2}\,t$. (d) $p(t) = \cos^2(100\pi t)$.

(a) $\omega_1 = 3$, $\omega_2 = 4.5$; ratio $3/4.5 = 2/3$, rational. The common angular frequency is $\gcd(3, 4.5) = 1.5$ rad/s ($3 = 2 \times 1.5$, $4.5 = 3 \times 1.5$). So $T_0 = 2\pi/1.5 = 4\pi/3 \approx 4.189$ s. Check: in $4\pi/3$ s the first term completes $3 \times \frac{4\pi}{3}/2\pi = 2$ cycles and the second $4.5 \times \frac{4\pi}{3}/2\pi = 3$ cycles. ✓

(b) Frequencies 50, 150, 250 Hz; gcd $= 50$ Hz, so $T_0 = 20$ ms. This is a 50 Hz waveform with 3rd and 5th harmonic distortion (§3.5, §3.7).

(c) $1/\sqrt{2}$ is irrational: **not periodic**.

(d) $\cos^2(100\pi t) = \frac{1}{2} + \frac{1}{2}\cos(200\pi t)$: fundamental period $2\pi/(200\pi) = 10$ ms — half the 20 ms period of $\cos(100\pi t)$. This is the instantaneous power in a resistor fed from 50 Hz: it pulses at 100 Hz.

Spatial periodicity: wavelength and wavenumber

Signals on transmission lines, in waveguides and in free space vary in both time and position. A sinusoidal wave travelling in the $+z$ direction is

$$u(z,t) = A\cos(\omega t - kz + \phi).$$

At a fixed position it is a sinusoid in time with angular frequency ω; at a fixed instant it is a sinusoid in space with **wavenumber** (spatial angular frequency) k in rad/m and spatial period, the **wavelength**,

$$\lambda = \frac{2\pi}{k}.$$

A point of constant phase satisfies $\omega t - kz = \text{const}$, so it moves at the **phase velocity** $v_p = dz/dt = \omega/k$. Combining,

$$v_p = \frac{\omega}{k} = f\lambda, \qquad \lambda = \frac{v_p}{f}.$$

The sign convention is worth memorising: $\omega t - kz$ travels towards $+z$; $\omega t + kz$ travels towards $-z$.

Worked Example 3.17 — Wavelengths and electrical length

(a) Find the free-space wavelength ($v_p = c = 3.00\times10^8$ m/s) at 50 Hz and at 2.4 GHz. (b) A PCB trace has $v_p = 0.5c$. How long is a trace that is a quarter-wavelength at 2.4 GHz, and what phase shift does a 10 mm trace introduce at that frequency?

(a) At 50 Hz: $\lambda = 3\times10^8/50 = 6000$ km. At 2.4 GHz: $\lambda = 0.125$ m $= 12.5$ cm.

(b) On the trace $\lambda = 0.5\times12.5 = 6.25$ cm, so $\lambda/4 = 15.6$ mm. A 10 mm trace has $kz = 2\pi(10/62.5) = 1.005$ rad $= 57.6^\circ$ of phase lag.

Interpretation. A circuit is "electrically small" — phase differences across it negligible, lumped-element analysis valid — when its dimensions are a small fraction of λ. Mains wiring is tiny compared with 6000 km; a 10 mm PCB trace at 2.4 GHz is not small at all.

Discrete-time sinusoids

When a sinusoid $\cos(\omega t + \phi)$ is sampled every T_s seconds, the samples are

$$x[n] = \cos(\omega n T_s + \phi) = \cos(\Omega n + \phi), \qquad \Omega = \omega T_s = 2\pi\frac{f}{f_s},$$

where $f_s = 1/T_s$ is the sampling rate and Ω is the **digital (normalised) angular frequency** in rad/sample. Discrete-time sinusoids behave differently from continuous ones in two important ways.

Periodicity of a discrete-time sinusoid

$x[n] = \cos(\Omega n + \phi)$ is periodic in n if and only if $\Omega/(2\pi)$ is rational. If $\Omega/(2\pi) = m/N$ in lowest terms ($N > 0$), the fundamental period is N samples.

Proof. $x[n+N] = x[n]$ for all n requires $\Omega N = 2\pi m$ for some integer m, i.e. $\Omega/2\pi = m/N$. The smallest such positive N is the denominator in lowest terms. □

Frequency ambiguity (aliasing)

$\cos\big((\Omega + 2\pi k)n + \phi\big) = \cos(\Omega n + \phi)$ for every integer k, and $\cos(-\Omega n - \phi) = \cos(\Omega n + \phi)$. Hence discrete-time frequencies are only distinguishable within $0 \le \Omega \le \pi$; in terms of the original analogue frequency, tones at f and $|f - k f_s|$ produce identical samples.

The highest distinguishable frequency, $\Omega = \pi$ (i.e. $f = f_s/2$), is the **Nyquist frequency**; sampling theory proper is in Ch. 16–17.

Worked Example 3.18 — Periods and aliases of sampled sinusoids

(a) Find the fundamental periods of $\cos(\pi n/6)$, $\cos(3\pi n/8)$ and $\cos(0.5n)$. (b) A 1 kHz tone and a 7 kHz tone are each sampled at $f_s = 8$ kHz. Compare the samples.

(a) $\frac{\pi/6}{2\pi} = \frac{1}{12}$: period 12 samples. $\frac{3\pi/8}{2\pi} = \frac{3}{16}$: period 16 samples (it completes 3 cycles of the underlying cosine in 16 samples). $\frac{0.5}{2\pi} = \frac{1}{4\pi}$ is irrational: **not periodic**, even though the continuous-time $\cos(0.5t)$ is periodic with period 4π.

(b) $\Omega_1 = 2\pi(1/8) = \pi/4$; $\Omega_2 = 2\pi(7/8) = 7\pi/4 = 2\pi - \pi/4$. Since $\cos(7\pi n/4) = \cos(2\pi n - \pi n/4) = \cos(\pi n/4)$, the two sample sequences are **identical**: the 7 kHz tone aliases to 1 kHz ($|7-8| = 1$ kHz). Both have period 8 samples.

Check: computing $\cos(2\pi\cdot 7000\,n/8000)$ and $\cos(2\pi\cdot 1000\,n/8000)$ for $n = 0,\dots,11$ gives identical values to machine precision. ✓

Common Pitfall — Hz versus rad/s in formulas

Reactance is $X_C = 1/(\omega C) = 1/(2\pi f C)$, not $1/(fC)$; a resonant frequency $\omega_0 = 1/\sqrt{LC}$ is in rad/s, so $f_0 = 1/(2\pi\sqrt{LC})$; filter "corner frequencies" on datasheets are usually in Hz while transfer functions $H(j\omega)$ use rad/s. Because the radian is dimensionless, no unit check will catch a missing 2π — always label which one a number is.

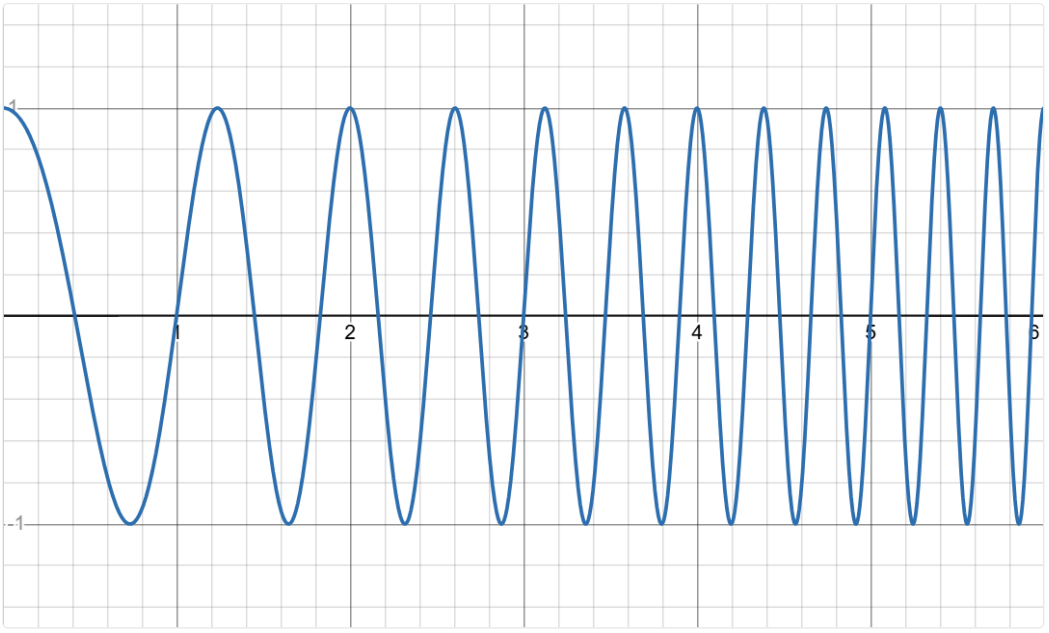
Instantaneous frequency

When the phase of a signal is not a linear function of time — as in frequency modulation or a radar "chirp" — we generalise frequency to the rate of change of phase.

Instantaneous angular frequency

For $x(t) = A\cos\Theta(t)$, the **instantaneous angular frequency** is $\omega_i(t) = \dfrac{d\Theta}{dt}$ and the instantaneous frequency is $f_i(t) = \dfrac{1}{2\pi}\dfrac{d\Theta}{dt}$.

For a pure sinusoid $\Theta = \omega t + \phi$ and $\omega_i = \omega$, as it should. For the linear chirp $\Theta(t) = 2\pi\left(f_0 t + \tfrac{1}{2}\beta t^2\right)$, $f_i(t) = f_0 + \beta t$: the frequency sweeps linearly at β Hz/s. With $f_0 = 1$ kHz and $\beta = 10$ kHz/s, at $t = 0.5$ s the instantaneous frequency is $1 + 10(0.5) = 6$ kHz. Note that the "frequency" of a chirp is *not* the coefficient of t inside the cosine at a given instant: writing $\cos(2\pi f(t)\,t)$ with $f(t) = f_0 + \beta t$ would give $f_i = f_0 + 2\beta t$, twice the intended sweep rate.



A linear chirp $\cos\left(2\pi(0.5t + 0.25t^2)\right)$: the instantaneous frequency $0.5 + 0.5t$ Hz rises steadily, so the oscillations crowd together as t increases.

3.5 Harmonic functions

Two meanings of "harmonic"

The word *harmonic* carries two related meanings in engineering mathematics, and this section is about both:

1. A **harmonic function of time** (a *harmonic oscillation*) is a sinusoid $A\cos(\omega t + \phi)$ — the motion of an ideal mass on a spring, the voltage across an ideal LC tank, the projection of a uniformly rotating vector. It is characterised as the solution of the simple-harmonic equation $\ddot{x} + \omega^2 x = 0$.
2. The **harmonics** of a periodic signal with fundamental frequency f_0 are the sinusoids at the integer multiples $n f_0$. A distorted 50 Hz current "contains a 5th harmonic" if it has a 250 Hz sinusoidal component.

(A third, unrelated, meaning — a function of several variables satisfying Laplace's equation $\nabla^2 u = 0$ — appears in Ch. 13 and Ch. 18. The shared word comes from the fact that Laplace's equation in a disc is solved by sums of $r^n\cos n\phi$ — harmonics again.)

Simple harmonic motion

Simple harmonic oscillator

A quantity $x(t)$ undergoes **simple harmonic motion** (SHM) with natural angular frequency $\omega_0 > 0$ if

$$\ddot{x} + \omega_0^2 x = 0.$$

The acceleration is proportional to the displacement and directed back towards zero.

Solutions of the simple-harmonic equation

Every solution of $\ddot{x} + \omega_0^2 x = 0$ can be written in each of the equivalent forms

$$x(t) = c_1\cos\omega_0 t + c_2\sin\omega_0 t = A\cos(\omega_0 t + \phi) = \operatorname{Re}\{\mathbf{X}e^{j\omega_0 t}\},$$

with $\mathbf{X} = Ae^{j\phi} = c_1 - jc_2$. Given initial values $x(0) = x_0$ and $\dot{x}(0) = v_0$,

$$c_1 = x_0, \quad c_2 = \frac{v_0}{\omega_0}, \qquad A = \sqrt{x_0^2 + \left(\frac{v_0}{\omega_0}\right)^2}, \quad \phi = \operatorname{atan2}\!\left(-\frac{v_0}{\omega_0},\, x_0\right).$$

Derivation. *That these are solutions* follows from §3.2: differentiating $A\cos(\omega_0 t+\phi)$ twice multiplies it by $-\omega_0^2$. *That they are all the solutions* follows from an energy argument. Suppose x is any solution and let $y = x - (c_1\cos\omega_0 t + c_2\sin\omega_0 t)$ with $c_1 = x(0)$, $c_2 = \dot x(0)/\omega_0$. Then y solves the same equation with $y(0) = \dot y(0) = 0$. Multiply $\ddot y + \omega_0^2 y = 0$ by $\dot y$:

$$\frac{d}{dt}\left[\tfrac12 \dot y^2 + \tfrac12\omega_0^2 y^2\right] = \dot y\,\ddot y + \omega_0^2 y\,\dot y = 0.$$

So $E = \frac12\dot y^2 + \frac12\omega_0^2 y^2$ is constant; it is zero at $t=0$, hence zero for all t, so $y \equiv 0$. The initial-value formulas come from $x(0)=c_1$, $\dot x(0) = \omega_0 c_2$ and the amplitude–phase conversion of §3.2. The general theory of such equations is in Ch. 11–12. □

The quantity E in the proof is (up to a constant factor) the physical energy, which in SHM sloshes between two forms — kinetic and potential, or electric and magnetic — while its total stays fixed.

> **Worked Example 3.19 — Fitting initial conditions**
>
> Solve $\ddot x + 9x = 0$ with $x(0) = 2$, $\dot x(0) = -6$ and write the answer in amplitude–phase form.
>
> **Solution.** $\omega_0 = 3$. $c_1 = 2$, $c_2 = -6/3 = -2$, so $x = 2\cos 3t - 2\sin 3t$. Amplitude $A = \sqrt{4+4} = 2\sqrt2 = 2.828$; phase $\phi = \operatorname{atan2}(2,2) = 45^\circ$. $x(t) = 2\sqrt2\cos(3t + 45^\circ)$.
>
> **Check:** $x(0) = 2\sqrt2\cos 45^\circ = 2$ ✓; $\dot x(0) = -3(2\sqrt2)\sin 45^\circ = -6$ ✓.

The LC tank: an electrical harmonic oscillator

For an ideal inductor L connected across an ideal capacitor C, the capacitor voltage v and the current i (taken as the current leaving the capacitor's positive plate and flowing through L) satisfy $i = -C\,\dot v$ and $v = L\,\dot i$. Eliminating i:

$$\ddot v + \frac{1}{LC}v = 0, \qquad \omega_0 = \frac{1}{\sqrt{LC}}, \qquad f_0 = \frac{1}{2\pi\sqrt{LC}}.$$

The stored energy $W = \frac12 C v^2 + \frac12 L i^2$ is constant. With $v = V\cos(\omega_0 t+\phi)$, the capacitor energy is $\frac12 CV^2\cos^2(\cdot) = \frac14 CV^2[1+\cos(2\omega_0 t + 2\phi)]$: **each stored energy oscillates at twice the natural frequency**, the two oscillating parts cancelling exactly.

> **Worked Example 3.20 — Free oscillation of an LC tank**
>
> $L = 10$ mH, $C = 100$ nF. At $t=0$ the capacitor voltage is 5 V and the current through the inductor is $i(0) = 20$ mA (so $C\dot v(0) = -20$ mA). Find $v(t)$, the peak voltage, and verify energy conservation.
>
> **Natural frequency.** $\omega_0 = 1/\sqrt{10^{-2}\times 10^{-7}} = 1/\sqrt{10^{-9}} = 31\,623$ rad/s; $f_0 = 5.033$ kHz.
>
> **Initial slope.** $\dot v(0) = -0.020/10^{-7} = -2.0\times10^5$ V/s, so $v_0/\omega_0 = -6.325$ V.
>
> **Amplitude and phase.** $V = \sqrt{5^2 + 6.325^2} = \sqrt{65} = 8.062$ V; $\phi = \operatorname{atan2}(6.325, 5) = 51.67^\circ$.
>
> **Result.** $v(t) = 8.062\cos(31\,623\,t + 51.67^\circ)$ V.
>
> **Energy check.** Initially $\frac12(10^{-7})(25) + \frac12(10^{-2})(0.02)^2 = 1.25 + 2.00 = 3.25$ μJ. At a voltage peak the current is zero and $W = \frac12(10^{-7})(65) = 3.25$ μJ. ✓

The rotating phasor picture

Euler's formula gives a geometric picture of every harmonic oscillation. The complex number $\mathbf{X}e^{j\omega t} = Ae^{j(\omega t+\phi)}$ moves anticlockwise around a circle of radius A, completing one revolution every $T = 2\pi/\omega$ seconds. Its projection on the real axis is $A\cos(\omega t+\phi)$ and on the imaginary axis $A\sin(\omega t+\phi)$:

- **amplitude** = radius of the circle,
- **angular frequency** = angular speed of rotation,
- **phase** = angle of the vector at $t=0$,
- **phase difference** between two same-frequency signals = the fixed angle between their rotating vectors.

Since both vectors rotate at the same rate, the angle between them never changes; this is why a phasor diagram can be drawn as a static picture "frozen" at $t=0$.

A real cosine can also be written as the sum of *two* counter-rotating vectors:

$$A\cos(\omega t+\phi) = \frac{A}{2}e^{j(\omega t+\phi)} + \frac{A}{2}e^{-j(\omega t+\phi)}.$$

The second term rotates clockwise — it has *negative frequency* $-\omega$. The imaginary parts cancel and the real parts add. This two-sided view is the basis of the complex Fourier series (Ch. 15) and the Fourier transform (Ch. 16), in which every real sinusoid appears as a pair of spectral lines at $\pm\omega$ with conjugate complex amplitudes $\frac{A}{2}e^{\pm j\phi}$.

Damped harmonic oscillations

Real oscillators lose energy. Adding a resistance to the LC tank, or friction to the spring, gives the damped equation

$$\ddot x + 2\alpha\dot x + \omega_0^2 x = 0, \qquad \alpha > 0,$$

whose solution for light damping ($\alpha < \omega_0$) is derived in Ch. 12:

Underdamped oscillation

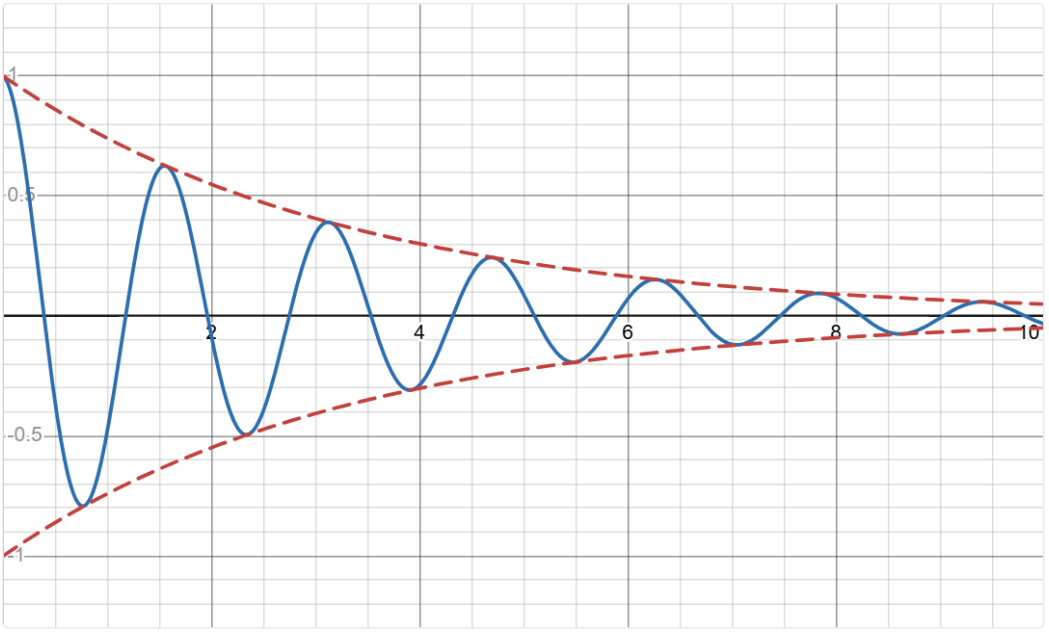
For $0 < \alpha < \omega_0$ every solution has the form

$$x(t) = A e^{-\alpha t}\cos(\omega_d t + \phi), \qquad \omega_d = \sqrt{\omega_0^2 - \alpha^2}.$$

It is a sinusoid of angular frequency ω_d (the **damped natural frequency**) whose amplitude decays inside the **envelope** $\pm A e^{-\alpha t}$. The **quality factor** is $Q = \omega_0/(2\alpha)$.

The verification is a direct (if tedious) differentiation; more elegantly, $x = \operatorname{Re}\{\mathbf{X} e^{st}\}$ with $s = -\alpha + j\omega_d$, and s is a root of $s^2 + 2\alpha s + \omega_0^2 = 0$.

Such a signal is **not periodic** — it never repeats exactly — but its zero crossings are evenly spaced, half a *pseudo-period* $T_d = 2\pi/\omega_d$ apart, and the ratio of successive peaks is the constant $e^{-\alpha T_d}$. The natural logarithm of that ratio, $\delta = \alpha T_d$, is the **logarithmic decrement**, a standard way to measure damping from an oscilloscope trace.



An underdamped oscillation $e^{-0.3t}\cos 4t$ (blue) confined within its exponential envelope $\pm e^{-0.3t}$ (red).

Worked Example 3.21 — Ringing of a series RLC circuit

A series RLC circuit with $R = 20\ \Omega$, $L = 10$ mH, $C = 100$ nF rings after a disturbance. For a series circuit $\alpha = R/(2L)$ and $\omega_0 = 1/\sqrt{LC}$. Find ω_d, Q, the logarithmic decrement, and the fraction of the initial amplitude left after 10 cycles.

Parameters. $\alpha = 20/(0.02) = 1000\ \text{s}^{-1}$; $\omega_0 = 31\,623$ rad/s; $\omega_d = \sqrt{31\,623^2 - 1000^2} = 31\,607$ rad/s (only 0.05 % below ω_0).

Quality factor. $Q = 31\,623/2000 = 15.8$.

Decrement. $T_d = 2\pi/\omega_d = 198.8\ \mu$s; $\delta = \alpha T_d = 0.1988$, so each peak is $e^{-0.1988} = 0.820$ of the previous one.

After 10 cycles. $e^{-10\delta} = e^{-1.988} = 0.137$: about 14 % of the initial amplitude remains.

Check: a useful rule of thumb is that the amplitude falls by $e^{-\pi} \approx 4.3\%$ in Q cycles; here $Q \approx 16$ cycles gives $e^{-16\times 0.1988} = e^{-3.14}$. ✓

Harmonics of a fundamental

Harmonics

Given a fundamental frequency f_0 (angular frequency ω_0), the **n-th harmonic** is a sinusoid at $n f_0$, $n = 1, 2, 3, \ldots$:

$$h_n(t) = A_n \cos(n\omega_0 t + \phi_n).$$

The 1st harmonic is the fundamental itself; n is the **harmonic number** (harmonic order). Harmonics with even n are **even harmonics**, those with odd n **odd harmonics**. A component at a frequency that is not an integer multiple of f_0 is an **interharmonic**; one at f_0/m is a **subharmonic**.

Musicians call the n-th harmonic the $(n-1)$-th *overtone*; engineers almost always count harmonics, so the "3rd harmonic" of 50 Hz is 150 Hz.

A sum of harmonics is periodic with the fundamental period

Any finite sum

$$x(t) = A_0 + \sum_{n=1}^{N} A_n \cos(n\omega_0 t + \phi_n)$$

is periodic with period $T_0 = 2\pi/\omega_0$. If $A_1 \neq 0$ it is the fundamental period; in general the fundamental period is T_0/g, where g is the greatest common divisor of the harmonic numbers n with $A_n \neq 0$.

Proof. In time T_0 the n-th harmonic advances its phase by $n\omega_0 T_0 = 2\pi n$, a whole number of cycles, so every term repeats. The statement about g follows from §3.4: the frequencies present are multiples of $g f_0$ and their greatest common divisor is exactly $g f_0$. □

So, for example, $\cos 2\omega_0 t + \cos 4\omega_0 t$ repeats every $T_0/2$: it "contains only even harmonics of f_0", but is better described as the 1st and 2nd harmonics of $2f_0$.

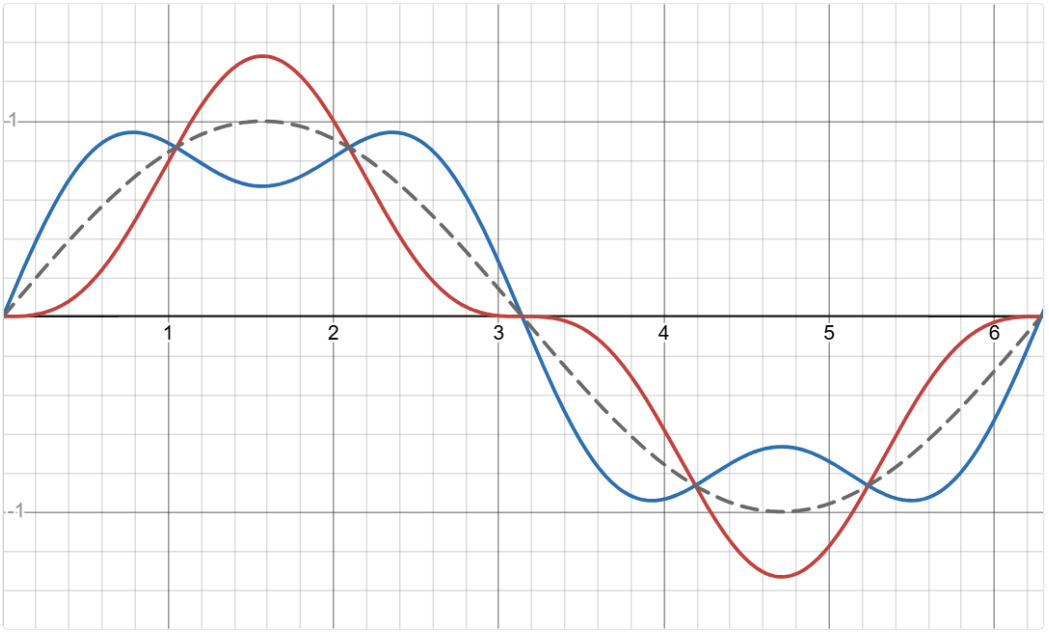
Worked Example 3.22 — Identifying harmonics

A power-quality analyser on a 60 Hz feeder reports components at 60, 180, 300, 420, 540 and 210 Hz. Classify each.

Solution. $180/60 = 3$, $300/60 = 5$, $420/60 = 7$, $540/60 = 9$: the 3rd, 5th, 7th and 9th harmonics (all odd — typical of loads with half-wave symmetric current, §3.8). $210/60 = 3.5$ is not an integer: an **interharmonic**, often produced by variable-frequency drives or arc furnaces, and not part of the 60 Hz harmonic series.

Harmonic content versus waveform shape

The amplitudes A_n determine the *power* in each harmonic (§3.7) but the phases ϕ_n strongly affect the *shape*. Adding a third harmonic of amplitude $\frac{1}{3}$ to a fundamental gives a flattened, nearly square top if the third harmonic is in the right phase, and a peaked waveform if it is inverted:



Fundamental plus a one-third-amplitude third harmonic: in phase (blue) the peaks flatten towards a square wave; inverted (red) the peaks sharpen. Both have exactly the same RMS value.

Engineering Note — Harmonics in power systems and RF

In power systems, nonlinear loads (rectifiers, switch-mode supplies, LED drivers) draw currents rich in odd harmonics; standards such as IEC 61000-3-2 limit each harmonic current by order. In RF systems, a power amplifier driven at f_0 radiates harmonics at $2f_0, 3f_0, \ldots$, which regulations require to be filtered. In both cases the engineer works with the *list* of harmonic amplitudes, which is why the rest of this chapter develops the algebra of harmonics.

3.6 Trigonometric expansions

Motivation

Linear systems are analysed one frequency at a time, so the natural currency of signal analysis is the *sum* of sinusoids. But physics keeps handing us *products* and *powers*: instantaneous power is the product $v(t)\,i(t)$; a mixer multiplies two signals; a diode or transistor responds to v^2, v^3, …; a modulator multiplies a carrier by a message. Trigonometric identities are the dictionary that translates products and powers back into sums, and the frequencies that appear in those sums are exactly the frequencies a spectrum analyser will show. This section collects the identities, derives them all from one source — Euler's formula — and shows how to apply them systematically.

The master method: Euler's formula

From $e^{j\theta} = \cos\theta + j\sin\theta$ (Ch. 2) and its conjugate,

$$\cos\theta = \frac{e^{j\theta} + e^{-j\theta}}{2}, \qquad \sin\theta = \frac{e^{j\theta} - e^{-j\theta}}{2j}.$$

Every identity in this section can be proved by (i) replacing each cos and sin by these exponentials, (ii) multiplying out using $e^{ja}e^{jb} = e^{j(a+b)}$, and (iii) regrouping conjugate pairs back into cosines and sines. Products of exponentials *add* their exponents, which is the whole reason products of sinusoids become sinusoids at sum and difference frequencies.

Compound-angle formulas

Compound-angle (addition) formulas

$$\begin{aligned}\cos(A \pm B) &= \cos A\cos B \mp \sin A\sin B,\\ \sin(A \pm B) &= \sin A\cos B \pm \cos A\sin B,\\ \tan(A \pm B) &= \frac{\tan A \pm \tan B}{1 \mp \tan A\tan B}.\end{aligned}$$

Proof. $e^{j(A+B)} = e^{jA}e^{jB}$. Expand both sides:

$$\cos(A+B) + j\sin(A+B) = (\cos A + j\sin A)(\cos B + j\sin B) = (\cos A\cos B - \sin A\sin B) + j(\sin A\cos B + \cos A\sin B).$$

Equating real and imaginary parts gives the $+$ formulas; replacing B by $-B$ and using evenness of cos and oddness of sin gives the $-$ formulas. Dividing the sine formula by the cosine formula, then numerator and denominator by $\cos A\cos B$, gives the tangent formula. $\square$

A purely geometric proof (rotating a unit vector by A and then by B) is also standard; the rotation view is worth keeping in mind because it says that the compound-angle formula *is* the rule for multiplying by the rotation matrix $\begin{pmatrix}\cos B & -\sin B\\ \sin B & \cos B\end{pmatrix}$ of Ch. 9.

Worked Example 3.23 — Exact values from compound angles

Find exact values of $\sin 75^\circ$, $\cos 15^\circ$ and $\tan 75^\circ$.

Solution. $75^\circ = 45^\circ + 30^\circ$:

$$\sin 75^\circ = \sin 45^\circ\cos 30^\circ + \cos 45^\circ\sin 30^\circ = \frac{\sqrt{2}}{2}\cdot\frac{\sqrt{3}}{2} + \frac{\sqrt{2}}{2}\cdot\frac{1}{2} = \frac{\sqrt{6}+\sqrt{2}}{4}.$$

$\cos 15^\circ = \cos(90^\circ - 75^\circ) = \sin 75^\circ = \dfrac{\sqrt{6}+\sqrt{2}}{4}$.

$$\tan 75^\circ = \frac{\tan 45^\circ + \tan 30^\circ}{1 - \tan 45^\circ\tan 30^\circ} = \frac{1 + 1/\sqrt{3}}{1 - 1/\sqrt{3}} = \frac{\sqrt{3}+1}{\sqrt{3}-1} = 2 + \sqrt{3}.$$

Check: $(\sqrt{6}+\sqrt{2})/4 = 0.965926 = \sin 75^\circ$; $2+\sqrt{3} = 3.73205 = \tan 75^\circ$. ✓

Double-angle, half-angle and power-reduction formulas

Setting $B = A$ in the compound-angle formulas:

$$\sin 2A = 2\sin A\cos A, \qquad \cos 2A = \cos^2 A - \sin^2 A = 2\cos^2 A - 1 = 1 - 2\sin^2 A, \qquad \tan 2A = \frac{2\tan A}{1 - \tan^2 A}.$$

Solving the two alternative forms of $\cos 2A$ for the squares gives the **power-reduction** formulas, which convert a square (a "power") into a constant plus a second harmonic:

$$\cos^2 A = \frac{1 + \cos 2A}{2}, \qquad \sin^2 A = \frac{1 - \cos 2A}{2}, \qquad \sin A\cos A = \frac{\sin 2A}{2}.$$

Replacing A by $A/2$ gives the **half-angle** formulas $\cos\frac{A}{2} = \pm\sqrt{\frac{1+\cos A}{2}}$, $\sin\frac{A}{2} = \pm\sqrt{\frac{1-\cos A}{2}}$, with the sign fixed by the quadrant of $A/2$, and

$$\tan\frac{A}{2} = \frac{\sin A}{1 + \cos A} = \frac{1 - \cos A}{\sin A}.$$

The **tangent half-angle substitution** $u = \tan(A/2)$ expresses everything rationally,

$$\sin A = \frac{2u}{1+u^2}, \qquad \cos A = \frac{1-u^2}{1+u^2},$$

which turns any rational function of $\sin A$ and $\cos A$ into a rational function of u — a standard integration technique (Ch. 5) and, in signal processing, the origin of the bilinear transform (Ch. 17).

Applying the double-angle formula twice gives triple angles:

$$\cos 3A = 4\cos^3 A - 3\cos A, \qquad \sin 3A = 3\sin A - 4\sin^3 A,$$

and inverting these gives the cubic power-reduction formulas

$$\cos^3 A = \frac{3\cos A + \cos 3A}{4}, \qquad \sin^3 A = \frac{3\sin A - \sin 3A}{4}.$$

These are the identities that explain harmonic distortion. If a device has a cubic term in its transfer characteristic, a pure input $\cos \omega t$ produces $\cos^3 \omega t$, which contains a component at 3ω (§3.7).

Worked Example 3.24 — Reducing a fourth power

Express $\sin^4 \theta$ as a sum of cosines of multiple angles, and deduce its average value.

Solution. Square the power-reduction formula:

$$\sin^4 \theta = \left(\frac{1 - \cos 2\theta}{2}\right)^2 = \frac{1 - 2\cos 2\theta + \cos^2 2\theta}{4}.$$

Reduce $\cos^2 2\theta = \frac{1+\cos 4\theta}{2}$:

$$\sin^4 \theta = \frac{1}{4} - \frac{1}{2}\cos 2\theta + \frac{1 + \cos 4\theta}{8} = \frac{3}{8} - \frac{1}{2}\cos 2\theta + \frac{1}{8}\cos 4\theta.$$

The cosine terms average to zero over a period, so $\overline{\sin^4 \theta} = 3/8$.

Check: at $\theta = \pi/2$: LHS $= 1$; RHS $= \frac{3}{8} + \frac{1}{2} + \frac{1}{8} = 1$ ✓. At $\theta = \pi/4$: LHS $= \frac{1}{4}$; RHS $= \frac{3}{8} - 0 - \frac{1}{8} = \frac{1}{4}$ ✓. A numerical comparison at 50 points agrees to 10^{-16}.

Powers of cosine in general

Harmonic expansion of $\cos^n \theta$

For a positive integer n,

$$\cos^n \theta = \frac{1}{2^n} \sum_{k=0}^{n} \binom{n}{k} \cos\big((n - 2k)\theta\big).$$

Grouping the terms k and $n - k$ (which give equal cosines), $\cos^n \theta$ contains only the harmonics $n,\ n-2,\ n-4, \ldots$ — all odd if n is odd, and all even (including a constant) if n is even. The constant term for even n is $\binom{n}{n/2}/2^n$.

Proof. By the binomial theorem,

$$\cos^n \theta = \frac{(e^{j\theta} + e^{-j\theta})^n}{2^n} = \frac{1}{2^n}\sum_{k=0}^{n} \binom{n}{k} e^{j(n-k)\theta} e^{-jk\theta} = \frac{1}{2^n}\sum_{k=0}^{n} \binom{n}{k} e^{j(n-2k)\theta}.$$

The left side is real, so it equals the real part of the right, which replaces each exponential by a cosine. □

The same argument with $(e^{j\theta} - e^{-j\theta})^n/(2j)^n$ handles $\sin^n \theta$: odd powers of sine give sines of odd multiples, even powers give cosines of even multiples.

Multiple angles and Chebyshev polynomials

Going the other way, De Moivre's theorem $(\cos\theta + j\sin\theta)^n = \cos n\theta + j \sin n\theta$ (Ch. 2) expresses $\cos n\theta$ as a polynomial in $\cos\theta$.

Chebyshev polynomials

For each $n \geq 0$ there is a polynomial T_n of degree n with

$$\cos n\theta = T_n(\cos\theta).$$

They satisfy $T_0(x) = 1$, $T_1(x) = x$ and the recurrence

$$T_{n+1}(x) = 2x\,T_n(x) - T_{n-1}(x),$$

giving $T_2 = 2x^2 - 1$, $T_3 = 4x^3 - 3x$, $T_4 = 8x^4 - 8x^2 + 1$, $T_5 = 16x^5 - 20x^3 + 5x$.

Proof of the recurrence. Add the compound-angle formulas $\cos(n+1)\theta = \cos n\theta\cos\theta - \sin n\theta \sin\theta$ and $\cos(n-1)\theta = \cos n\theta\cos\theta + \sin n\theta\sin\theta$:

$$\cos(n+1)\theta + \cos(n-1)\theta = 2\cos\theta\cos n\theta.$$

With $x = \cos\theta$ this is $T_{n+1}(x) + T_{n-1}(x) = 2xT_n(x)$. Since T_0 and T_1 are polynomials, induction shows every T_n is a polynomial of degree n with leading coefficient 2^{n-1} $(n \geq 1)$. □

Because $|T_n(x)| = |\cos n\theta| \leq 1$ on $-1 \leq x \leq 1$ while growing rapidly outside, Chebyshev polynomials are the basis of Chebyshev filters (equal-ripple passband) and of near-optimal polynomial approximation (Ch. 22).

Worked Example 3.25 — Two directions: $\cos 5\theta$ and $\cos^5\theta$

(a) Express $\cos 5\theta$ as a polynomial in $c = \cos\theta$. (b) Express $\cos^5\theta$ as a sum of harmonics.

(a) From the recurrence: $T_4 = 2x(4x^3 - 3x) - (2x^2 - 1) = 8x^4 - 8x^2 + 1$, then $T_5 = 2x(8x^4 - 8x^2 + 1) - (4x^3 - 3x) = 16x^5 - 20x^3 + 5x$. So $\cos 5\theta = 16c^5 - 20c^3 + 5c$.

(b) With $n = 5$: $\binom{5}{0}, \dots, \binom{5}{5} = 1, 5, 10, 10, 5, 1$ multiply $\cos 5\theta, \cos 3\theta, \cos\theta, \cos(-\theta), \cos(-3\theta), \cos(-5\theta)$. Pairing:

$$\cos^5\theta = \frac{1}{32}\big(2\cos 5\theta + 10\cos 3\theta + 20\cos\theta\big) = \frac{10\cos\theta + 5\cos 3\theta + \cos 5\theta}{16}.$$

Consistency check. Substitute (b)'s $\cos 5\theta = 16\cos^5\theta - 5\cos 3\theta - 10\cos\theta$ and $\cos 3\theta = 4c^3 - 3c$: $16c^5 - 20c^3 + 15c - 10c = 16c^5 - 20c^3 + 5c$, agreeing with (a). ✓ At $\theta = 0$ both sides of (b) equal $16/16 = 1$. ✓

Product-to-sum and sum-to-product formulas

Adding and subtracting the compound-angle formulas in pairs gives:

Product-to-sum formulas

$$\begin{aligned}
\cos A\cos B &= \tfrac{1}{2}\big[\cos(A-B) + \cos(A+B)\big],\\
\sin A\sin B &= \tfrac{1}{2}\big[\cos(A-B) - \cos(A+B)\big],\\
\sin A\cos B &= \tfrac{1}{2}\big[\sin(A+B) + \sin(A-B)\big].
\end{aligned}$$

For example, the first comes from adding $\cos(A-B) = \cos A\cos B + \sin A\sin B$ and $\cos(A+B) = \cos A\cos B - \sin A\sin B$. Applied to signals, $A = \omega_1 t$ and $B = \omega_2 t$: **the product of two sinusoids is the sum of two sinusoids at the sum and difference frequencies, each with half the product amplitude.** This single fact underlies mixing, modulation, demodulation and the computation of average power.

Setting $A = (P+Q)/2$, $B = (P-Q)/2$ reverses the formulas:

Sum-to-product formulas

$$\begin{aligned}
\cos P + \cos Q &= 2\cos\tfrac{P+Q}{2}\cos\tfrac{P-Q}{2}, & \cos P - \cos Q &= -2\sin\tfrac{P+Q}{2}\sin\tfrac{P-Q}{2},\\
\sin P + \sin Q &= 2\sin\tfrac{P+Q}{2}\cos\tfrac{P-Q}{2}, & \sin P - \sin Q &= 2\cos\tfrac{P+Q}{2}\sin\tfrac{P-Q}{2}.
\end{aligned}$$

Sum-to-product is the tool for equations (a product is zero iff a factor is) and for the beat phenomenon (§3.7).

Worked Example 3.26 — Instantaneous and average power

A load has $v(t) = 325\cos\omega t$ V and $i(t) = 10\cos(\omega t - 30^\circ)$ A. Find the instantaneous power $p(t) = v\,i$, its average, and the frequency at which it pulsates.

Solution. Product-to-sum with $A = \omega t$, $B = \omega t - 30^\circ$:

$$p(t) = 3250\cdot\tfrac{1}{2}\big[\cos 30^\circ + \cos(2\omega t - 30^\circ)\big] = 1407 + 1625\cos(2\omega t - 30^\circ)\ \text{W}.$$

The average (real) power is $P = 1407$ W and $p(t)$ pulsates at **twice** the supply frequency with amplitude 1625 W. Because $1625 > 1407$, p is briefly negative each half-cycle: energy flows back from the load's reactive part to the source.

General result. For $v = V_m\cos(\omega t + \phi_v)$, $i = I_m\cos(\omega t + \phi_i)$:

$$P = \overline{p} = \tfrac{1}{2}V_m I_m\cos(\phi_v - \phi_i) = V_{\text{rms}}I_{\text{rms}}\cos(\phi_v - \phi_i),$$

the power-factor formula quoted in §3.3. Check: $\frac{325}{\sqrt{2}}\cdot\frac{10}{\sqrt{2}}\cos 30^\circ = 1625\times 0.8660 = 1407$ W. ✓

Worked Example 3.27 — Solving an equation with sum-to-product

Solve $\sin 3x + \sin x = \cos x$ on $[0, \pi]$.

Solution. $\sin 3x + \sin x = 2\sin 2x\cos x$. The equation becomes $2\sin 2x\cos x - \cos x = 0$, i.e. $\cos x\,(2\sin 2x - 1) = 0$.

- $\cos x = 0$: $x = \pi/2$.
- $\sin 2x = \tfrac{1}{2}$: $2x = \pi/6$ or $5\pi/6$ (within $[0, 2\pi]$), so $x = \pi/12$ or $5\pi/12$.

Solutions: $x = \pi/12,\ 5\pi/12,\ \pi/2$.

Check $x = \pi/12 = 15^\circ$: $\sin 45^\circ + \sin 15^\circ = 0.7071 + 0.2588 = 0.9659 = \cos 15^\circ$. ✓

Sums of sinusoids with phases in arithmetic progression

A sum that appears in antenna arrays, multi-tap filters and the discrete Fourier transform is

$$S = \sum_{k=0}^{N-1} e^{jk\delta}.$$

Geometric phasor sum

For δ not a multiple of 2π,

$$\sum_{k=0}^{N-1} e^{jk\delta} = e^{j(N-1)\delta/2}\,\frac{\sin(N\delta/2)}{\sin(\delta/2)},$$

and consequently

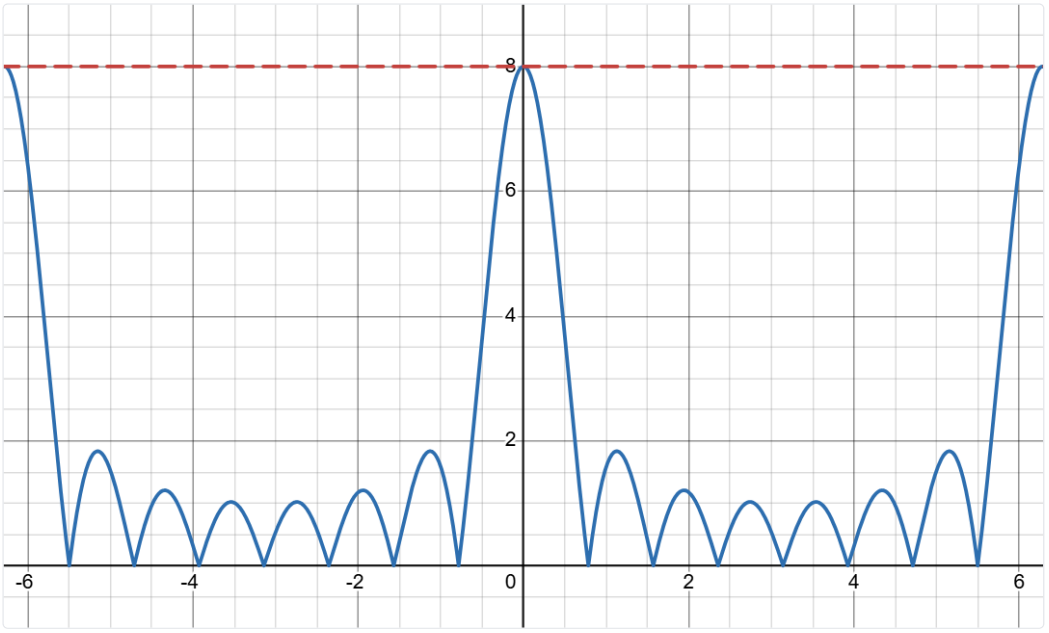
$$\sum_{k=0}^{N-1} \cos(\theta + k\delta) = \frac{\sin(N\delta/2)}{\sin(\delta/2)}\cos\!\Big(\theta + \frac{(N-1)\delta}{2}\Big).$$

Proof. The geometric-series formula gives $S = \dfrac{e^{jN\delta}-1}{e^{j\delta}-1}$. Factor $e^{jN\delta/2}$ from the numerator and $e^{j\delta/2}$ from the denominator:

$$S = \frac{e^{jN\delta/2}\big(e^{jN\delta/2} - e^{-jN\delta/2}\big)}{e^{j\delta/2}\big(e^{j\delta/2} - e^{-j\delta/2}\big)} = e^{j(N-1)\delta/2}\,\frac{2j\sin(N\delta/2)}{2j\sin(\delta/2)}.$$

For the cosine sum, multiply by $e^{j\theta}$ and take real parts. $\square$

The magnitude $|S| = |\sin(N\delta/2)/\sin(\delta/2)|$ equals N at $\delta = 0$ (all phasors aligned) and vanishes when $N\delta/2$ is a nonzero multiple of π (phasors spread evenly round a full circle, as in the three-phase theorem of §3.3).



The array factor $|\sin(N\delta/2)/\sin(\delta/2)|$ for $N = 8$ against the inter-element phase δ: a main lobe of height $N = 8$ at $\delta = 0$, nulls at multiples of $\delta = 2\pi/8$, and smaller side lobes between them.

Worked Example 3.28 — Eight-element array

Eight equal antenna elements are fed with a progressive phase δ between neighbours. Find the magnitude of the combined phasor (relative to one element) for $\delta = 0^\circ$, 10° and 45°.

Solution. $|S| = |\sin(4\delta)/\sin(\delta/2)|$.

- $\delta = 0$: limit $= N = 8$ (full coherent addition).
- $\delta = 10^\circ$: $\sin 40^\circ / \sin 5^\circ = 0.6428/0.08716 = 7.375$.
- $\delta = 45^\circ$: $\sin 180^\circ = 0$: complete cancellation — the eight phasors are spaced 45° apart round the full circle.

Check for $\delta = 10^\circ$: summing $\cos(10^\circ k)$ and $\sin(10^\circ k)$ for $k = 0..7$ directly gives 6.041 and 4.230, magnitude $\sqrt{6.041^2 + 4.230^2} = 7.375$. ✓

Series expansions

The circular functions also have power-series expansions, valid for every real (indeed complex) θ:

$$\sin\theta = \sum_{m=0}^{\infty} \frac{(-1)^m \theta^{2m+1}}{(2m+1)!}, \qquad \cos\theta = \sum_{m=0}^{\infty} \frac{(-1)^m \theta^{2m}}{(2m)!}.$$

They are derived as Maclaurin series in Ch. 4; substituting them into $e^{j\theta} = \sum (j\theta)^k/k!$ and separating even and odd powers is one standard proof of Euler's formula. For computation they converge quickly only for small $|\theta|$, so libraries first reduce the argument into $[-\pi/4, \pi/4]$ using periodicity and the identities above, then apply a short polynomial — a direct engineering use of this section.

Common Pitfall — Squaring away the sign

Half-angle formulas involve a square root, and solving $\sin^2 x = k$ or $\cos 2x = c$ yields *all* sign choices; check which roots are genuine. Conversely, identities like $\sqrt{1-\cos^2\theta} = \sin\theta$ are only true where $\sin\theta \geq 0$. In an algorithm that computes $\sin\phi$ from $\cos\phi$, the lost sign is a lost lead/lag distinction — exactly the error that a power meter makes if it computes reactive power as $\sqrt{S^2 - P^2}$ instead of $V_{\text{rms}} I_{\text{rms}} \sin\Delta\phi$.

3.7 Harmonic relationships

Motivation

Section 3.5 introduced harmonics as sinusoids at integer multiples of a fundamental; §3.6 supplied the identities that turn products and powers into sums. This section puts the two together and answers the questions engineers actually ask about collections of sinusoids:

- How do the powers of several sinusoids combine? (Orthogonality.)
- Where do harmonics come from, and how big are they? (Nonlinearity.)
- What new frequencies appear when two signals pass through the same nonlinear device or are multiplied? (Intermodulation, mixing, modulation.)
- What does the sum of two *nearly* equal frequencies look like? (Beats.)
- How is "how distorted" quantified? (Total harmonic distortion.)
- How do harmonics behave in three-phase systems? (Phase sequence of harmonics.)

Orthogonality of harmonics

Orthogonality relations

Let $\omega_0 = 2\pi/T_0$ and let m, n be non-negative integers. Over one period,

$$\int_0^{T_0} \cos m\omega_0 t \, \cos n\omega_0 t \, dt = \begin{cases} 0, & m \neq n, \\ T_0/2, & m = n \geq 1, \\ T_0, & m = n = 0, \end{cases}$$

$$\int_0^{T_0} \sin m\omega_0 t \, \sin n\omega_0 t \, dt = \begin{cases} 0, & m \neq n, \\ T_0/2, & m = n \geq 1, \end{cases}$$

$$\int_0^{T_0} \sin m\omega_0 t \, \cos n\omega_0 t \, dt = 0 \quad \text{for all } m, n.$$

The same results hold over any interval of length T_0.

Proof. By product-to-sum, $\cos m\omega_0 t \cos n\omega_0 t = \tfrac{1}{2}[\cos(m-n)\omega_0 t + \cos(m+n)\omega_0 t]$. A cosine $\cos k\omega_0 t$ with integer $k \neq 0$ completes exactly $|k|$ cycles in T_0, so its integral is zero; for $k = 0$ it is the constant 1 with integral T_0. If $m \neq n$ both $m-n$ and $m+n$ are nonzero and the integral vanishes. If $m = n \geq 1$, only $\cos 0 = 1$ survives, giving $\tfrac{1}{2}T_0$; if $m = n = 0$ the integrand is 1. The sine–sine case is identical with $\tfrac{1}{2}[\cos(m-n)\omega_0 t - \cos(m+n)\omega_0 t]$. For sine–cosine, $\tfrac{1}{2}[\sin(m+n)\omega_0 t + \sin(m-n)\omega_0 t]$ integrates to zero in every case (including $\sin 0 = 0$). □

In the language of Ch. 9, the functions $1, \cos\omega_0 t, \sin\omega_0 t, \cos 2\omega_0 t, \ldots$ are mutually **orthogonal** with respect to the inner product $\langle x, y\rangle = \int_0^{T_0} x(t)y(t)\,dt$. That is the structural fact behind Fourier series: it is what lets us *extract* each harmonic's coefficient from a waveform by a single integral (§3.8, Ch. 15).

In complex form the relations are even more compact:

$$\frac{1}{T_0}\int_0^{T_0} e^{jm\omega_0 t}\, e^{-jn\omega_0 t}\, dt = \begin{cases} 1, & m = n, \\ 0, & m \neq n. \end{cases}$$

Power of a sum of harmonics

Mean-square value of a harmonic sum

If $x(t) = A_0 + \sum_{n=1}^{N} A_n \cos(n\omega_0 t + \phi_n)$, then

$$\overline{x^2} = \frac{1}{T_0}\int_0^{T_0} x^2\, dt = A_0^2 + \sum_{n=1}^{N} \frac{A_n^2}{2}, \qquad X_{\text{rms}} = \sqrt{A_0^2 + \sum_{n=1}^{N} \left(\frac{A_n}{\sqrt{2}}\right)^2}.$$

The mean-square value — the average power in a 1 Ω resistor — is the **sum of the powers of the individual harmonics**, independent of their phases.

Proof. Squaring x produces squared terms and cross terms. Each cross term $2A_m A_n \cos(m\omega_0 t + \phi_m)\cos(n\omega_0 t + \phi_n)$ with $m \neq n$ is, after expanding the phases with the compound-angle formula, a combination of the orthogonal products above, so it averages to zero; the cross terms with the constant average to zero because each harmonic does. Each squared harmonic averages to $A_n^2/2$ (§3.2). □

This is the finite version of **Parseval's theorem** (Ch. 15). Two warnings: the result needs *distinct* frequencies (two components at the same frequency must first be combined with phasors, §3.3, because their cross term does *not* vanish); and it concerns power, not peak value — the peak of x depends strongly on the phases (recall the two waveforms in §3.5 with identical RMS but different peaks).

Worked Example 3.29 — RMS of a multi-harmonic waveform

Find the RMS value of $v(t) = 10 + 8\cos\omega t + 6\cos(3\omega t + 40^\circ)$ V and the average power it delivers to $R = 5\ \Omega$.

Solution. $V_{\text{rms}}^2 = 10^2 + \frac{8^2}{2} + \frac{6^2}{2} = 100 + 32 + 18 = 150\ \text{V}^2$, so $V_{\text{rms}} = 12.25$ V. Power $= 150/5 = 30$ W, of which 20 W is DC, 6.4 W fundamental, 3.6 W third harmonic. The 40° phase plays no role.

Check: numerical averaging of v^2 over a period on 200 000 points gives $V_{\text{rms}} = 12.2474$ V. ✓

Nonlinearity generates harmonics

A linear system cannot create new frequencies. A nonlinear one — a diode, a transistor driven hard, a saturating transformer core, an amplifier clipping at its supply rails — can and does. Many weakly nonlinear devices are well modelled by a polynomial (the first few terms of a Taylor expansion about the operating point, Ch. 4):

$$y = a_1 x + a_2 x^2 + a_3 x^3.$$

Drive it with $x = A\cos\omega t$ and reduce the powers with §3.6:

$$x^2 = \frac{A^2}{2} + \frac{A^2}{2}\cos 2\omega t, \qquad x^3 = \frac{3A^3}{4}\cos\omega t + \frac{A^3}{4}\cos 3\omega t.$$

Harmonics from a cubic nonlinearity

For $y = a_1 x + a_2 x^2 + a_3 x^3$ and $x = A\cos\omega t$,

$$y = \underbrace{\frac{a_2 A^2}{2}}_{\text{DC}} + \underbrace{\left(a_1 A + \frac{3a_3 A^3}{4}\right)}_{\text{fundamental}}\cos\omega t + \underbrace{\frac{a_2 A^2}{2}}_{\text{2nd}}\cos 2\omega t + \underbrace{\frac{a_3 A^3}{4}}_{\text{3rd}}\cos 3\omega t.$$

Four features generalise to higher-order polynomials:

1. A term x^k produces harmonics up to the k-th, of the same parity as k (the $\cos^n$ theorem of §3.6).
2. **Even-order terms** produce even harmonics and a **DC shift** — the principle of rectification and of envelope detection.
3. **Odd-order terms** produce odd harmonics and also change the fundamental: if $a_3 < 0$ (a compressive, saturating device) the fundamental gain falls as A grows — **gain compression**.
4. The k-th harmonic grows as A^k: halving the drive level (a 6 dB reduction) lowers the fundamental by 6 dB, the 2nd harmonic by 12 dB and the 3rd by 18 dB, so *relative to the fundamental* the 2nd harmonic improves by 6 dB and the 3rd by 12 dB. Plotting harmonic levels against drive level on log axes gives straight lines of slope k — the basis of intercept-point specifications.

A device with odd symmetry, $y(-x) = -y(x)$ (a symmetric clipper, a push–pull amplifier), has $a_2 = a_4 = \cdots = 0$ and generates **only odd harmonics**; this is the waveform-symmetry result of §3.8 seen from the device side.

Worked Example 3.30 — Harmonic distortion of a weakly nonlinear amplifier

An amplifier has $y = x + 0.1x^2 + 0.05x^3$ (volts) and is driven by $x = 2\cos\omega t$ V. Find each output component and the second- and third-harmonic distortion relative to the output fundamental.

Solution. With $A = 2$, $a_1 = 1$, $a_2 = 0.1$, $a_3 = 0.05$:

- DC: $a_2 A^2/2 = 0.1(4)/2 = 0.20$ V,
- fundamental: $a_1 A + \frac{3}{4}a_3 A^3 = 2 + \frac{3}{4}(0.05)(8) = 2.30$ V,
- 2nd harmonic: $a_2 A^2/2 = 0.20$ V,
- 3rd harmonic: $a_3 A^3/4 = 0.05(8)/4 = 0.10$ V.

$\text{HD}_2 = 0.20/2.30 = 8.7\%$, $\text{HD}_3 = 0.10/2.30 = 4.3\%$.

Check: at $\omega t = 0$, $x = 2$ and $y = 2 + 0.4 + 0.4 = 2.8$; the harmonic sum gives $0.2 + 2.3 + 0.2 + 0.1 = 2.8$. ✓ Numerical projection onto $\cos n\omega t$ also returns $0.2,\ 2.3,\ 0.2,\ 0.1$.

Two tones in a nonlinearity: intermodulation

Now drive the same nonlinearity with two tones, $x = A\cos\omega_1 t + A\cos\omega_2 t$. The square term gives, by product-to-sum,

$$x^2 = A^2 + \frac{A^2}{2}\cos 2\omega_1 t + \frac{A^2}{2}\cos 2\omega_2 t + A^2\cos(\omega_1 + \omega_2)t + A^2\cos(\omega_1 - \omega_2)t.$$

Besides the harmonics $2\omega_1$, $2\omega_2$ there are new **intermodulation (IM) products** at $\omega_1 \pm \omega_2$. The cube term, expanded the same way, produces components at

$$\omega_1,\ \omega_2,\ 3\omega_1,\ 3\omega_2,\ 2\omega_1 \pm \omega_2,\ 2\omega_2 \pm \omega_1.$$

In general an order-k nonlinearity produces every frequency $|p\omega_1 + q\omega_2|$ with integers p, q satisfying $|p| + |q| \le k$ and of the same parity as k. The **order** of a product is $|p| + |q|$.

Worked Example 3.31 — Third-order intermodulation

Two equal carriers at $f_1 = 100$ MHz and $f_2 = 101$ MHz pass through an amplifier with second- and third-order nonlinearity. List the output frequencies and identify those that fall near the original band.

Second order ($|p| + |q| = 2$): $2f_1 = 200$, $2f_2 = 202$, $f_1 + f_2 = 201$, $f_2 - f_1 = 1$ MHz, plus DC.

Third order ($|p| + |q| = 3$): $3f_1 = 300$, $3f_2 = 303$, $2f_1 + f_2 = 301$, $2f_2 + f_1 = 302$, $2f_1 - f_2 = 99$, $2f_2 - f_1 = 102$ MHz, plus contributions at f_1 and f_2 themselves.

Interpretation. Every second-order product and every harmonic lies far outside a 99–102 MHz band and can be filtered out. The **third-order IM products at 99 MHz and 102 MHz** sit right next to the wanted signals, cannot be filtered, and land on neighbouring channels. This is why RF amplifiers and mixers are specified by their third-order intercept point rather than by their harmonic distortion.

Mixing and modulation

A **mixer** multiplies two signals. With product-to-sum,

$$\cos\omega_1 t \cdot \cos\omega_2 t = \tfrac{1}{2}\cos(\omega_1 - \omega_2)t + \tfrac{1}{2}\cos(\omega_1 + \omega_2)t,$$

so multiplication *shifts* frequencies: a signal at ω_1 mixed with a local oscillator at ω_2 reappears at the **difference** (intermediate) frequency $|\omega_1 - \omega_2|$ and the **sum** frequency $\omega_1 + \omega_2$. A filter then keeps the one that is wanted. This is the superheterodyne principle behind essentially every radio receiver.

Amplitude modulation is mixing of a carrier with $(1 + \text{message})$:

$$s(t) = A_c\big[1 + m\cos\omega_m t\big]\cos\omega_c t = A_c\cos\omega_c t + \frac{mA_c}{2}\cos(\omega_c - \omega_m)t + \frac{mA_c}{2}\cos(\omega_c + \omega_m)t.$$

The spectrum is a carrier with two **sidebands** at $\omega_c \pm \omega_m$; $0 < m \le 1$ is the **modulation index**.

Worked Example 3.32 — Spectrum and power of an AM signal

A 1 MHz carrier of amplitude 10 V is amplitude-modulated by a 5 kHz tone with $m = 0.5$. Find the spectral components and the fraction of the total power in the sidebands.

Components. Carrier: 1000 kHz, 10 V. Sidebands: 995 kHz and 1005 kHz, each $mA_c/2 = 2.5$ V.

Power (into 1 Ω, using orthogonality): carrier $10^2/2 = 50$ W; each sideband $2.5^2/2 = 3.125$ W; total 56.25 W. Sideband fraction $6.25/56.25 = 11.1\%$.

General formula. Sideband fraction $= \dfrac{m^2/2}{1 + m^2/2}$; at $m = 0.5$ this is $0.125/1.125 = 11.1\%$ ✓, and even at $m = 1$ only one third of the power carries information — the reason for suppressed-carrier and single-sideband systems.

Beats

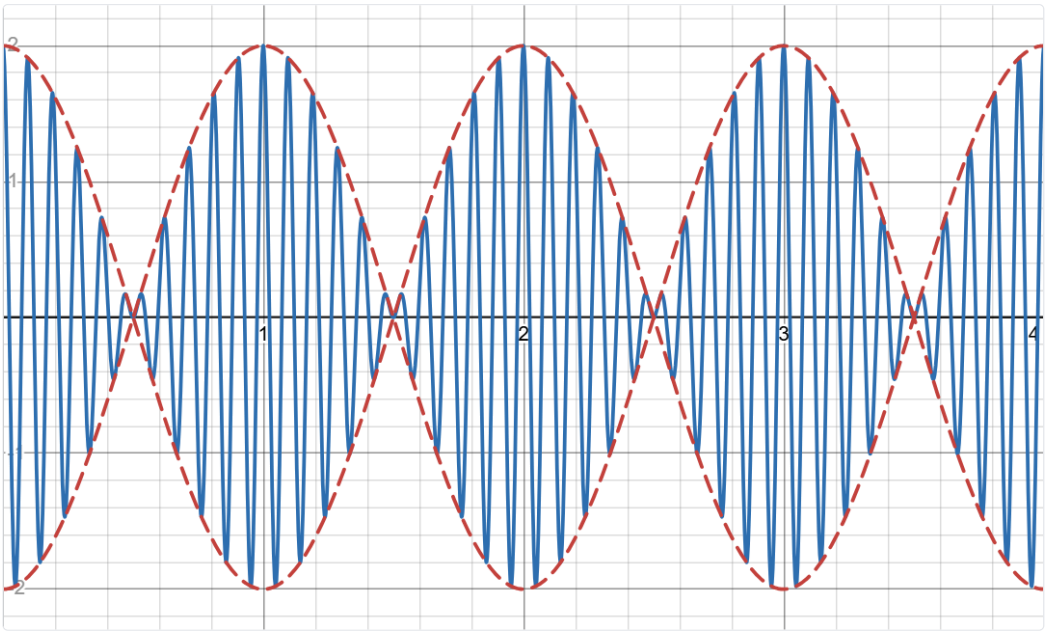
The sum of two equal-amplitude sinusoids at *close* frequencies is best understood through sum-to-product:

$$\cos\omega_1 t + \cos\omega_2 t = 2\cos\left(\frac{\omega_1 - \omega_2}{2}t\right)\cos\left(\frac{\omega_1 + \omega_2}{2}t\right).$$

When $|\omega_1 - \omega_2| \ll \omega_1$, this is a fast oscillation at the **average** frequency $\bar\omega = (\omega_1 + \omega_2)/2$, whose amplitude is modulated by the slow envelope $|2\cos(\Delta\omega\, t/2)|$, with $\Delta\omega = \omega_1 - \omega_2$. The envelope magnitude peaks twice per cycle of $\cos(\Delta\omega t/2)$, so the loudness (or the reading of an envelope detector) pulses at the **beat frequency**

$$f_{\text{beat}} = |f_1 - f_2|.$$

Physically: the two phasors rotate at slightly different speeds; once per beat period they line up (constructive, amplitude $2A$) and once they oppose (destructive, amplitude 0).



Beats: $\cos(2\pi\,10t) + \cos(2\pi\,11t)$ (blue) inside the envelope $\pm 2\cos(\pi t)$ (red). The envelope magnitude peaks once per second, the beat frequency $|11 - 10| = 1$ Hz.

Worked Example 3.33 — Tuning by beats, and the difference with AM

(a) A reference tone at 440 Hz and a slightly sharp tone at 444 Hz sound together. What is heard? (b) Compare $\cos\omega_1 t + \cos\omega_2 t$ with the AM signal of Example 3.32. Why do they look similar?

(a) A 442 Hz tone whose loudness pulses $|444 - 440| = 4$ times per second. Adjusting until the beats slow to zero brings the tones into unison — the classical way to tune an instrument, and the principle of a *zero-beat* frequency comparison.

(b) By sum-to-product, the beat signal is a product $2\cos(\Delta\omega t/2)\cos\bar{\omega}t$: a carrier at $\bar{\omega}$ multiplied by a sinusoid at $\Delta\omega/2$. That is AM with *suppressed* carrier (double-sideband suppressed carrier, DSB-SC): two sidebands at $\bar{\omega} \pm \Delta\omega/2$ and no component at $\bar{\omega}$ itself. The "envelope" crosses zero and the fast oscillation flips sign there, unlike true AM with $m < 1$, whose envelope $1 + m\cos\omega_m t$ stays positive.

Total harmonic distortion

Total harmonic distortion

For a periodic signal with fundamental RMS amplitude X_1 and harmonic RMS amplitudes $X_2, X_3, \ldots$,

$$\mathrm{THD} = \frac{\sqrt{X_2^2 + X_3^2 + X_4^2 + \cdots}}{X_1}.$$

It is often quoted in percent or in dB ($20\log_{10}$ THD). By orthogonality the total RMS value is $X_{\mathrm{rms}} = X_1\sqrt{1 + \mathrm{THD}^2}$ when there is no DC component.

(Some instruments normalise by the total RMS instead of the fundamental — "THD-R" or THD+N — so state which definition is used.)

Worked Example 3.34 — THD of a rectifier load current

A single-phase rectifier draws a 50 Hz current with RMS harmonic content $I_1 = 10$ A, $I_3 = 3$ A, $I_5 = 2$ A, $I_7 = 1$ A. Find the THD, the total RMS current, and the RMS current a meter responding only to the fundamental would read.

Solution. $\mathrm{THD} = \sqrt{9 + 4 + 1}/10 = \sqrt{14}/10 = 37.4\%$. $I_{\mathrm{rms}} = \sqrt{100 + 9 + 4 + 1} = \sqrt{114} = 10.68$ A $= 10\sqrt{1 + 0.374^2}$ ✓. A fundamental-only meter reads 10 A, under-reading the heating current by 6.4 %.

Engineering consequence. The harmonic currents carry no average power with a sinusoidal supply voltage (by orthogonality, $V_1 I_n \cos(\cdot)$ averages to zero for $n \neq 1$), yet they heat cables and transformers. The *true* power factor therefore drops below $\cos\Delta\phi_1$ by the factor $1/\sqrt{1 + \mathrm{THD}^2}$.

Harmonics in three-phase systems

Take a balanced set of identical, distorted phase currents, each a copy of the previous one delayed by one-third of a period: $i_b(t) = i_a(t - T_0/3)$, $i_c(t) = i_a(t - 2T_0/3)$. A delay of $T_0/3$ shifts the n-th harmonic by $n\omega_0 T_0/3 = n \cdot 120^\circ$. So the n-th harmonics of the three phases have phases 0°, $-120^\circ n$ and $-240^\circ n$, which reduce as follows:

Harmonic n	Phases (mod 360°)	Sequence	Sum of the three phases
$1, 4, 7, \ldots$ $(n = 3k + 1)$	$0^\circ, -120^\circ, +120^\circ$	positive (abc)	0
$2, 5, 8, \ldots$ $(n = 3k + 2)$	$0^\circ, +120^\circ, -120^\circ$	negative (acb)	0
$3, 6, 9, \ldots$ $(n = 3k)$	$0^\circ, 0^\circ, 0^\circ$	zero (in phase)	$3\times$ one phase

Triplen harmonics

In a balanced three-phase set, the harmonics of order $3, 6, 9, \ldots$ (**triplens**) are in phase in all three lines. They do not cancel in the neutral: the neutral current at each triplen frequency is three times the per-phase value. All other harmonics form balanced sets (positive or negative sequence) and sum to zero.

Worked Example 3.35 — Neutral current from single-phase loads

A four-wire 50 Hz system feeds three identical banks of switch-mode supplies, one per phase. Each phase current has $I_1 = 20$ A, $I_3 = 12$ A, $I_5 = 6$ A (RMS). Find the RMS neutral current.

Solution. Fundamentals and 5th harmonics form balanced sets and cancel in the neutral. The 3rd harmonics add in phase: $I_N = 3 \times 12 = 36$ A at 150 Hz.

Comparison. Each phase carries $\sqrt{400 + 144 + 36} = 24.1$ A RMS; the neutral carries 36 A — **more than any phase conductor**, although the load is "balanced". This is why neutral conductors in buildings full of computers are oversized, and why transformers feeding such loads use a delta winding, in which triplen currents circulate instead of reaching the supply.

Engineering Note — Thinking in harmonics

A good habit when meeting any nonlinear or time-varying operation is to ask "what does it do to a single sinusoid?" and then "what does it do to two?". Squaring doubles frequencies and creates DC; cubing triples them and creates $2f_1 - f_2$; multiplying shifts; rectifying (§3.8) creates all even harmonics. Once you know the frequencies a device produces, filter design, channel planning and EMC compliance become bookkeeping.

3.8 Periodic function representation

Motivation

Real periodic signals are rarely pure sinusoids: a clock is a square wave, a switching converter's inductor current is a triangle, a scanning circuit produces a sawtooth, a rectifier delivers humps of sine. We need to (i) write such waveforms down unambiguously, (ii) compute their mean and RMS values, (iii) recognise their symmetries, and (iv) express them as sums of harmonics so that the sinusoidal machinery of the previous sections — phasors, filtering, power by orthogonality — can be applied to them. Items (i)–(iii) are completed here; item (iv) is introduced here and developed fully as Fourier series in Ch. 15.

Defining a periodic function from one period

A periodic function is completely determined by its values on any interval of length T (one period). The standard way to specify it is to give a formula on, say, $0 \le t < T$ (or $-T/2 \le t < T/2$) and then declare the **periodic extension**

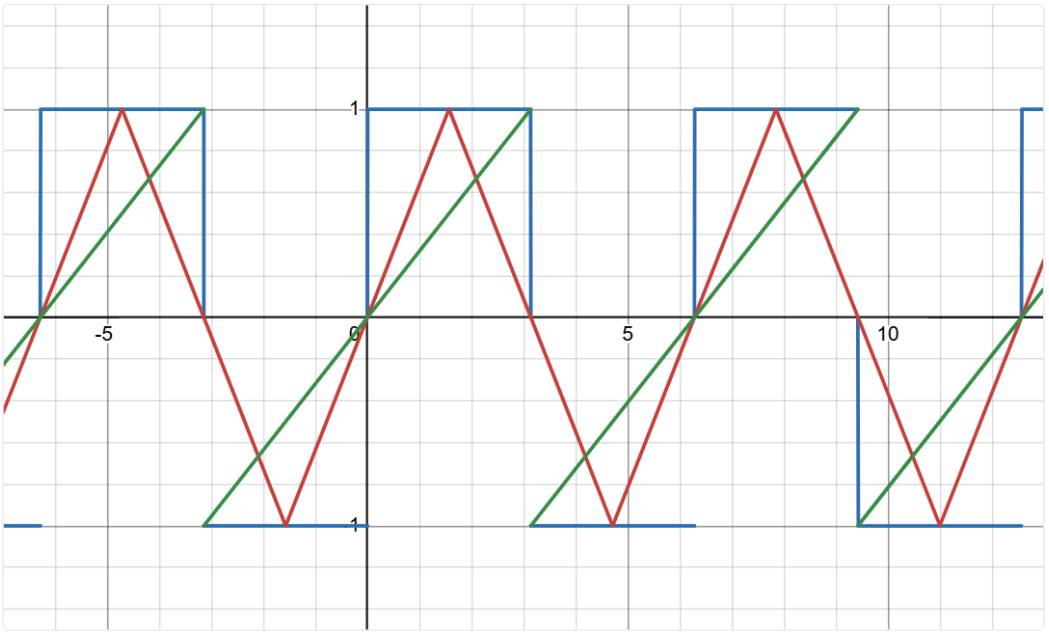
$$x(t + kT) = x(t), \qquad k \in \mathbb{Z}.$$

To evaluate the extension at an arbitrary t, reduce t into the base interval with the floor function: $t \mapsto t - T\lfloor t/T \rfloor \in [0, T)$, which is what `mod(t, T)` computes for $T > 0$.

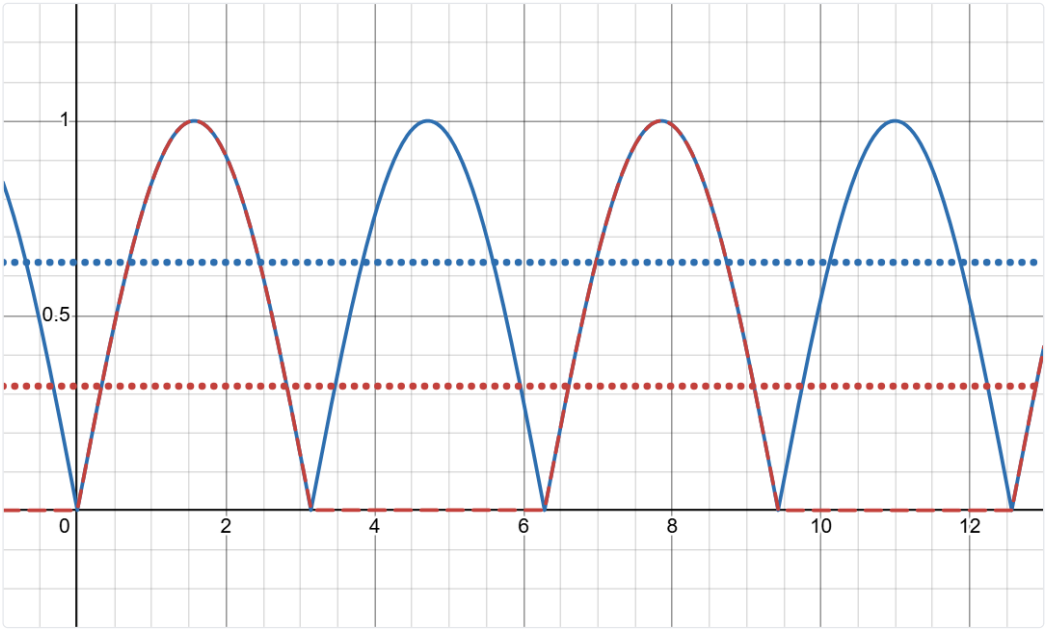
The common engineering waveforms, with amplitude A, period T and $\omega_0 = 2\pi/T$:

Waveform	One period	Closed form for all t
square wave ($\pm A$)	A on $(0, T/2)$, $-A$ on $(T/2, T)$	$A\,\mathrm{sgn}(\sin \omega_0 t)$
sawtooth ($-A$ to A)	$2At/T$ on $(-T/2, T/2)$	$2A\left(\frac{t}{T} - \left\lfloor \frac{t}{T} + \frac{1}{2} \right\rfloor\right)$
triangle ($\pm A$)	linear between $-A$ and A	$\frac{2A}{\pi} \arcsin(\sin \omega_0 t)$
full-wave rectified sine	$A\lvert\sin \omega_0 t\rvert$	$A\lvert\sin \omega_0 t\rvert$ (period $T/2$)
half-wave rectified sine	$A \sin \omega_0 t$ on $(0, T/2)$, 0 on $(T/2, T)$	$\frac{A}{2}\left(\sin \omega_0 t + \lvert\sin \omega_0 t\rvert\right)$
pulse train, duty cycle D	A on $(0, DT)$, 0 on (DT, T)	$A \cdot \mathbf{1}\left[\mathrm{mod}(t, T) < DT\right]$

The triangle-wave formula works because $\arcsin(\sin\theta)$ equals θ on $[-\pi/2, \pi/2]$ and folds back linearly outside it — an application of the principal branch of §3.1.



Three standard waveforms of period 2π and amplitude 1: square (blue), triangle (red) and sawtooth (green), all generated from closed-form expressions.



Full-wave (blue) and half-wave (red, dashed) rectified sines with their mean values $2/\pi$ and $1/\pi$ (dotted). The full-wave output repeats every π — twice the input frequency.

Worked Example 3.36 — Evaluating a periodic extension

A sawtooth generator produces a waveform of amplitude 5 V and period 2 ms that rises linearly from -5 V to $+5$ V. Find its value at $t = 3.7$ ms and at $t = -0.3$ ms.

Solution. $x(t) = 10\big(t/T - \lfloor t/T + \tfrac{1}{2}\rfloor\big)$ V with $T = 2$ ms.

- $t = 3.7$ ms: $t/T = 1.85$, $\lfloor 2.35\rfloor = 2$, so $x = 10(1.85 - 2) = -1.5$ V.
- $t = -0.3$ ms: $t/T = -0.15$, $\lfloor 0.35\rfloor = 0$, so $x = 10(-0.15) = -1.5$ V.

Check: the two times differ by 4 ms $= 2T$, so the values must agree. ✓ Note that $\lfloor\cdot\rfloor$ rounds *down* for negative arguments ($\lfloor -0.65\rfloor = -1$), which is why the floor form handles negative t correctly where truncation would not.

Mean and RMS of standard waveforms

Using $\bar{x} = \frac{1}{T}\int_0^T x\,dt$ and $X_{\text{rms}}^2 = \frac{1}{T}\int_0^T x^2\,dt$ (Ch. 5):

Waveform (amplitude A)	Mean	RMS	Crest factor
sine	0	$A/\sqrt{2}$	$\sqrt{2} = 1.414$
square ($\pm A$)	0	A	1

Waveform (amplitude A)	Mean	RMS	Crest factor
triangle or sawtooth ($\pm A$)	0	$A/\sqrt{3}$	$\sqrt{3} = 1.732$
full-wave rectified sine	$2A/\pi$	$A/\sqrt{2}$	$\sqrt{2}$
half-wave rectified sine	A/π	$A/2$	2
pulse train, 0 to A, duty D	DA	$A\sqrt{D}$	$1/\sqrt{D}$

Derivations. *Full-wave mean:* over one hump, $\frac{1}{\pi}\int_0^{\pi} A\sin\theta\,d\theta = \frac{A}{\pi}[-\cos\theta]_0^{\pi} = \frac{2A}{\pi}$. *Full-wave RMS:* $|\sin|^2 = \sin^2$, so the RMS is that of the sine. *Half-wave:* the waveform equals the sine on half the period and zero on the other half, so its mean is half the full-wave mean, A/π, and its mean square is half of $A^2/2$, giving RMS $A/2$. *Sawtooth:* on $(-T/2, T/2)$, $x = 2At/T$, so

$$X_{\text{rms}}^2 = \frac{1}{T}\int_{-T/2}^{T/2} \frac{4A^2t^2}{T^2}\,dt = \frac{4A^2}{T^3}\cdot\frac{2}{3}\left(\frac{T}{2}\right)^3 = \frac{A^2}{3}.$$

The triangle wave consists of the same linear ramps rearranged in time, so it has the same RMS. *Pulse train:* $x^2 = A^2$ for a fraction D of the time, so $X_{\text{rms}}^2 = DA^2$.

Worked Example 3.37 — Rectifier and PWM levels

(a) A half-wave rectifier fed from 230 V RMS mains (peak 325 V) drives a resistive load. What DC voltmeter and true-RMS voltmeter readings are expected across the load? (b) A PWM output switches between 0 and 5 V at 25 % duty cycle. Find its mean and RMS, and the power delivered to a 10 Ω heater.

(a) Mean $= 325/\pi = 103.5$ V. RMS $= 325/2 = 162.5$ V.

(b) Mean $= 0.25 \times 5 = 1.25$ V. RMS $= 5\sqrt{0.25} = 2.5$ V. Power $= 2.5^2/10 = 0.625$ W — which is $D \times 5^2/10$, as it must be, and *not* $1.25^2/10 = 0.156$ W. Heating depends on the RMS value, not the mean.

Symmetry

Symmetries of a waveform constrain which harmonics it can contain, often halving the work of analysis and giving an instant sanity check.

Even, odd and half-wave symmetry

A periodic function x with period T is

- **even** if $x(-t) = x(t)$ (mirror symmetry about $t = 0$);
- **odd** if $x(-t) = -x(t)$ (point symmetry about the origin);
- **half-wave symmetric** if $x(t + T/2) = -x(t)$ (the second half-cycle is the first one inverted).

Every function splits uniquely into even and odd parts,

$$x(t) = x_e(t) + x_o(t), \qquad x_e(t) = \frac{x(t) + x(-t)}{2}, \qquad x_o(t) = \frac{x(t) - x(-t)}{2}.$$

Symmetry and harmonic content

For a periodic function written as a sum of harmonics $a_0 + \sum_{n\ge1}(a_n\cos n\omega_0 t + b_n \sin n\omega_0 t)$:

1. If x is **even**, all $b_n = 0$: only cosines (and possibly DC) appear.
2. If x is **odd**, $a_0 = 0$ and all $a_n = 0$: only sines appear.
3. If x has **half-wave symmetry**, $a_0 = 0$ and all **even** harmonics vanish: only odd harmonics appear.

Shifting the time origin changes even/odd symmetry but not half-wave symmetry, so property 3 is the more robust one.

Proof of 3. If $x(t + T/2) = -x(t)$, then the mean over a period is minus itself, so $a_0 = 0$. For the n-th harmonic coefficient (formula below), split $\int_0^T$ into $\int_0^{T/2} + \int_{T/2}^{T}$ and substitute $t = \tau + T/2$ in the second:

$$\int_{T/2}^{T} x(t)\cos n\omega_0 t\,dt = \int_0^{T/2} x(\tau + \tfrac{T}{2})\cos(n\omega_0\tau + n\pi)\,d\tau = (-1)^{n+1}\int_0^{T/2} x(\tau)\cos n\omega_0\tau\,d\tau.$$

So $a_n \propto \left(1 + (-1)^{n+1}\right)\int_0^{T/2} x\cos n\omega_0 t\,dt$, which is zero for even n; the same holds for b_n. Properties 1 and 2 follow because cos is even, sin is odd, and the integral over a symmetric interval of an odd function is zero. □

Worked Example 3.38 — Predicting harmonic content from symmetry

Without computing any integrals, state which harmonics can appear in: (a) the square wave $A\,\mathrm{sgn}(\sin\omega_0 t)$; (b) the triangle wave; (c) the sawtooth; (d) the full-wave rectified sine $A|\sin\omega_0 t|$ (period T of the *original* sine); (e) the half-wave rectified sine.

- **(a)** Odd and half-wave symmetric: only sines of odd harmonics.
- **(b)** $\frac{2A}{\pi}\arcsin(\sin\omega_0 t)$ is odd and half-wave symmetric: only sines of odd harmonics.
- **(c)** Odd but *not* half-wave symmetric: sines of all harmonics.
- **(d)** Even, and it repeats every $T/2$, so in terms of ω_0 it contains a DC term and only **even** harmonics $2\omega_0, 4\omega_0, \ldots$, all cosines. (Its own fundamental is $2\omega_0$.)
- **(e)** Neither even nor odd and not half-wave symmetric. But $\frac{A}{2}(\sin\omega_0 t + |\sin\omega_0 t|)$ shows it is half a sine plus half of (d): DC, the fundamental $\sin\omega_0 t$, and even cosine harmonics — and **no odd harmonics other than the fundamental**.

These predictions are confirmed by the expansions in the summary table below and by numerical projection.

Representing a periodic function by harmonics

The orthogonality relations of §3.7 suggest how a periodic function might be built from harmonics. *Suppose* that

$$x(t) = a_0 + \sum_{n=1}^{\infty}\left(a_n\cos n\omega_0 t + b_n\sin n\omega_0 t\right).$$

Multiply both sides by $\cos m\omega_0 t$ and integrate over a period. By orthogonality every term on the right vanishes except the $n=m$ cosine term, which contributes $a_m T/2$. Doing the same with $\sin m\omega_0 t$ and with 1 gives:

Harmonic (Fourier) coefficients

If x has a harmonic representation as above, its coefficients are

$$a_0 = \frac{1}{T}\int_0^T x(t)\,dt, \qquad a_n = \frac{2}{T}\int_0^T x(t)\cos n\omega_0 t\,dt, \qquad b_n = \frac{2}{T}\int_0^T x(t)\sin n\omega_0 t\,dt.$$

In amplitude–phase form (§3.2) the n-th harmonic is $A_n\cos(n\omega_0 t+\phi_n)$ with $A_n=\sqrt{a_n^2+b_n^2}$ and $\phi_n = \operatorname{atan2}(-b_n, a_n)$. In complex form, $x(t)=\sum_{n=-\infty}^{\infty} c_n e^{jn\omega_0 t}$ with $c_n = \frac{1}{T}\int_0^T x(t)e^{-jn\omega_0 t}\,dt$, $c_0 = a_0$ and $c_{\pm n} = \frac{1}{2}(a_n \mp jb_n)$ for $n\ge 1$.

Each coefficient is a *correlation*: a_n measures how much x "looks like" $\cos n\omega_0 t$. The questions of *which* functions have such representations, in what sense the infinite series converges, and what happens at discontinuities (the Gibbs phenomenon) are the subject of Ch. 15. For all the waveforms in this section the series converges to $x(t)$ at every point of continuity, and to the midpoint of the jump at a discontinuity.

Worked Example 3.39 — Harmonics of a square wave

Find the harmonic representation of the square wave $x = A$ on $(0, T/2)$, $x = -A$ on $(T/2, T)$, its THD, and check Parseval's relation.

Symmetry first. Odd and half-wave symmetric, so $a_0 = a_n = 0$ and only odd-n sines appear.

Coefficients. Directly from the definition:

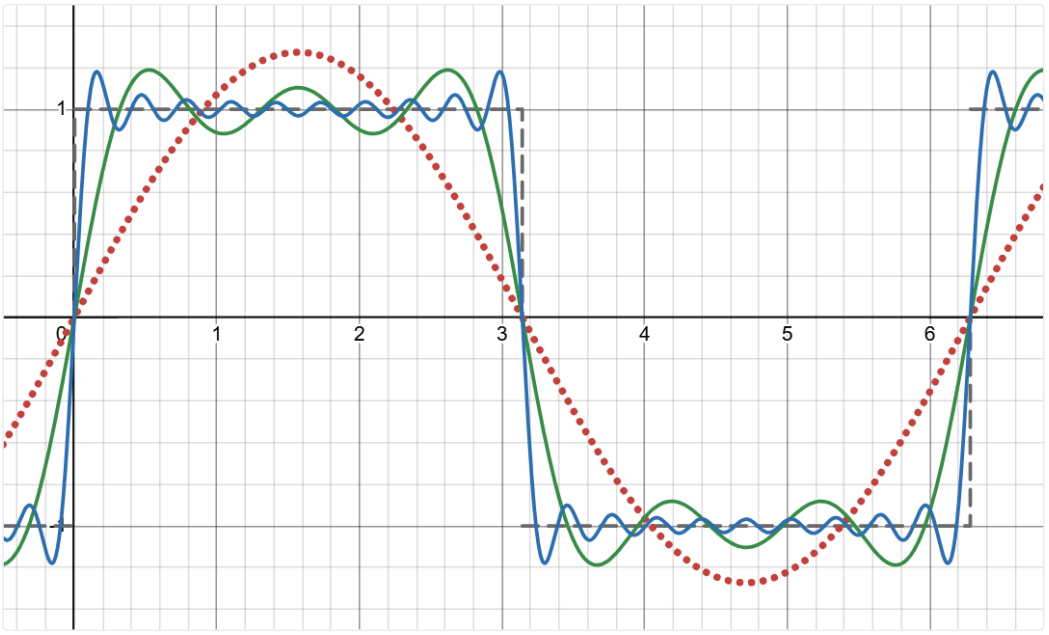
$$b_n = \frac{2}{T}\left[\int_0^{T/2} A\sin n\omega_0 t\,dt - \int_{T/2}^{T} A\sin n\omega_0 t\,dt\right] = \frac{2A}{T}\cdot\frac{1}{n\omega_0}\left[(1-\cos n\pi) - (\cos n\pi - \cos 2n\pi)\right] = \frac{2A}{n\pi}\left(1-(-1)^n\right).$$

So $b_n = \dfrac{4A}{n\pi}$ for odd n and 0 for even n:

$$x(t) = \frac{4A}{\pi}\left(\sin\omega_0 t + \frac{1}{3}\sin 3\omega_0 t + \frac{1}{5}\sin 5\omega_0 t + \cdots\right).$$

THD. The fundamental has RMS $\frac{4A}{\pi\sqrt{2}} = 0.9003A$; the total RMS is A. So $\mathrm{THD} = \sqrt{A^2 - 0.8106A^2}/(0.9003A) = \sqrt{\pi^2/8 - 1} = 48.3\%$.

Parseval check. $\sum_{n\ \text{odd}} \frac{1}{2}\left(\frac{4A}{n\pi}\right)^2 = \frac{8A^2}{\pi^2}\sum_{n\ \text{odd}}\frac{1}{n^2} = \frac{8A^2}{\pi^2}\cdot\frac{\pi^2}{8} = A^2 = X_{\mathrm{rms}}^2$ ✓, using the classical sum $1+\frac{1}{9}+\frac{1}{25}+\cdots = \pi^2/8$ (itself provable from this very example in Ch. 15). Numerical projection gives $b_1 = 1.2732A = 4A/\pi$, $b_3 = 0.4244A$, $b_5 = 0.2546A$. ✓



Building a square wave (grey) from harmonics: the fundamental alone (red), the sum through the 5th harmonic (green), and through the 19th (blue). The ripple narrows toward the jumps but its overshoot stays near 9 % of the jump — the Gibbs phenomenon of Ch. 15.

Worked Example 3.40 — Harmonics of a full-wave rectified sine

Find the DC and the first two nonzero harmonics of $x(t) = A|\sin \omega_0 t|$, and interpret for a full-wave rectifier fed at 50 Hz.

Symmetry. Even with period $T/2$: only DC and cosines at $2\omega_0, 4\omega_0, \dots$ (Example 3.38d).

DC. $a_0 = 2A/\pi$ (computed above).

Harmonics. By evenness and the $T/2$ periodicity, $a_n = \frac{2}{T}\int_0^T A|\sin \omega_0 t| \cos n\omega_0 t\, dt = \frac{2A}{\pi}\int_0^\pi \sin\theta \cos n\theta\, d\theta$ for even n (with $\theta = \omega_0 t$, using that the two half-periods contribute equally). Product-to-sum: $\sin\theta\cos n\theta = \frac{1}{2}[\sin(n+1)\theta - \sin(n-1)\theta]$, and $\int_0^\pi \sin k\theta\, d\theta = \frac{1-\cos k\pi}{k} = \frac{2}{k}$ for odd k. With n even, $n \pm 1$ are odd:

$$a_n = \frac{2A}{\pi}\cdot\frac{1}{2}\left[\frac{2}{n+1} - \frac{2}{n-1}\right] = \frac{2A}{\pi}\cdot\frac{-2}{n^2-1} = -\frac{4A}{\pi(n^2-1)}.$$

So $a_2 = -\frac{4A}{3\pi} = -0.4244A$ and $a_4 = -\frac{4A}{15\pi} = -0.0849A$:

$$A|\sin \omega_0 t| = \frac{2A}{\pi} - \frac{4A}{3\pi}\cos 2\omega_0 t - \frac{4A}{15\pi}\cos 4\omega_0 t - \cdots$$

Interpretation. From a 50 Hz supply the rectifier output is DC ($0.637A$) plus a dominant 100 Hz ripple of amplitude $0.424A$ and a 200 Hz component one-fifth as large. A smoothing filter is designed against the 100 Hz term.

Check: numerical projection gives $a_2 = -0.42441A$, $a_4 = -0.08488A$, $a_6 = -0.03638A$ $(= -4A/35\pi)$. ✓

Effect of time shift, scaling and smoothness on the harmonics

Three general rules let you reuse known expansions:

- **Time shift.** If $x(t)$ has harmonics $A_n\cos(n\omega_0 t + \phi_n)$, then $x(t - t_0)$ has harmonics $A_n\cos(n\omega_0 t + \phi_n - n\omega_0 t_0)$: amplitudes are unchanged; the n-th phase shifts by $-n\omega_0 t_0$ — proportional to n, the "linear phase" of a pure delay seen in §3.3. Example: the square wave shifted by $T/4$ becomes even, and its expansion becomes $\frac{4A}{\pi}\left(\cos\omega_0 t - \frac{1}{3}\cos 3\omega_0 t + \frac{1}{5}\cos 5\omega_0 t - \cdots\right)$.
- **Amplitude scaling and offset.** $\alpha x(t) + \beta$ multiplies every harmonic by α and adds β to the DC term. A 0-to-A square wave is $\frac{A}{2} + \frac{1}{2}(\pm A$ square wave$)$.
- **Smoothness and decay.** The smoother the waveform, the faster the harmonic amplitudes decay with n. A waveform with jumps (square, sawtooth) has $A_n \sim 1/n$; a continuous waveform with corners (triangle, rectified sine) has $A_n \sim 1/n^2$; each further continuous derivative buys another factor of $1/n$. Precise statements are in Ch. 15.

Waveform	Harmonic expansion	Decay
square $\pm A$	$\frac{4A}{\pi}\sum_{n\ \text{odd}}\frac{\sin n\omega_0 t}{n}$	$1/n$
sawtooth $-A$ to A	$\frac{2A}{\pi}\sum_{n\ge 1}\frac{(-1)^{n+1}\sin n\omega_0 t}{n}$	$1/n$
triangle $\pm A$ (odd, peak at $T/4$)	$\frac{8A}{\pi^2}\sum_{n\ \text{odd}}\frac{(-1)^{(n-1)/2}\sin n\omega_0 t}{n^2}$	$1/n^2$
full-wave $A\lvert\sin \omega_0 t\rvert$	$\frac{2A}{\pi} - \frac{4A}{\pi}\sum_{k\ge 1}\frac{\cos 2k\omega_0 t}{4k^2-1}$	$1/n^2$

Waveform	Harmonic expansion	Decay
half-wave rectified	$\frac{A}{\pi}+\frac{A}{2}\sin\omega_0 t-\frac{2A}{\pi}\sum_{k\geq 1}\frac{\cos 2k\omega_0 t}{4k^2-1}$	$1/n^2$

Engineering Note — Rise time, bandwidth and EMI

The $1/n$ decay of a square wave means that a digital clock edge contains significant energy at many harmonics of the clock frequency; a 100 MHz clock with fast edges produces radiated emissions at 300, 500, 700 MHz and beyond. Slowing the edges (rounding the corners) converts the spectrum to $1/n^2$ decay above a frequency of roughly $1/(\pi t_r)$, where t_r is the rise time — a standard EMC design rule. Conversely, an oscilloscope or channel that passes only the first few harmonics turns a square wave into the rippled shape in the partial-sum graph above.

Common Pitfall — Which fundamental?

When a waveform has a hidden shorter period (such as $|\sin\omega_0 t|$, whose period is $T/2$), state whether harmonic numbers refer to the original ω_0 or to the waveform's own fundamental $2\omega_0$. "The 2nd harmonic of the rectifier output" is ambiguous: it is 200 Hz if counted from the 100 Hz ripple, and 100 Hz if counted from the 50 Hz supply. Power-system practice counts from the supply frequency.

Summary

Topic	Key formulas
Angle units	$\theta_{\text{rad}}=s/r$; π rad $=180^\circ$; $\Omega=2\pi N/60$ (rpm); $\theta_e=p\,\theta_m$
Arc, sector	$s=r\theta$; $A=\frac{1}{2}r^2\theta$; $v=r\Omega$
Fundamental limit	$\lim_{\theta\to 0}\sin\theta/\theta=1$ (radians); $\sin\theta\approx\theta$, $\cos\theta\approx 1-\theta^2/2$
Quadrant-safe angle	$\operatorname{atan2}(y,x)\in(-\pi,\pi]$
General sinusoid	$x=A\cos(\omega t+\phi)+C$; shift $=-\phi/\omega$
Sine/cosine conversion	$\sin\theta=\cos(\theta-90^\circ)$; $-\cos\theta=\cos(\theta\pm 180^\circ)$
Amplitude–phase form	$a\cos\omega t+b\sin\omega t=R\cos(\omega t-\alpha)$, $R=\sqrt{a^2+b^2}$, $\alpha=\operatorname{atan2}(b,a)$
Derivative / integral	$\frac{d}{dt}$: $\times\omega$, $+90^\circ$; $\int dt$: $\div\omega$, -90°
Mean, RMS of sinusoid	$\bar{x}=C$; $X_{\text{rms}}=\sqrt{C^2+A^2/2}$; pure sine $A/\sqrt{2}$
Phase difference	$\Delta\phi=\phi_1-\phi_2\in(-180^\circ,180^\circ]$; $\Delta t=\Delta\phi/\omega$
Same-frequency sum	$R^2=A_1^2+A_2^2+2A_1A_2\cos(\phi_1-\phi_2)$
Three-phase	$\sum_{k=0}^{2}\cos(\omega t-120^\circ k)=0$; $V_{LL}=\sqrt{3}V_{ph}\angle 30^\circ$
Lissajous	$\lvert\sin\phi\rvert=y_0/Y$
Period, frequency	$T=2\pi/\omega=1/f$; $\omega=2\pi f$
Sum periodicity	periodic iff f_1/f_2 rational; $f_0=\gcd(f_1,f_2)$
Waves	$\cos(\omega t-kz)$; $\lambda=2\pi/k=v_p/f$; $v_p=\omega/k$
Discrete sinusoid	$\Omega=\omega T_s$; periodic iff $\Omega/2\pi=m/N$; $\Omega\equiv\Omega+2\pi$
Instantaneous frequency	$\omega_i=d\Theta/dt$
SHM	$\ddot{x}+\omega_0^2x=0\Rightarrow x=A\cos(\omega_0 t+\phi)$; $A=\sqrt{x_0^2+(v_0/\omega_0)^2}$
LC tank	$\omega_0=1/\sqrt{LC}$
Damped oscillation	$Ae^{-\alpha t}\cos(\omega_d t+\phi)$, $\omega_d=\sqrt{\omega_0^2-\alpha^2}$, $Q=\omega_0/2\alpha$
Compound angle	$\cos(A\pm B)=\cos A\cos B\mp\sin A\sin B$; $\sin(A\pm B)=\sin A\cos B\pm\cos A\sin B$
Power reduction	$\cos^2 A=\frac{1+\cos 2A}{2}$; $\sin^2 A=\frac{1-\cos 2A}{2}$; $\cos^3 A=\frac{3\cos A+\cos 3A}{4}$
Powers of cosine	$\cos^n\theta=2^{-n}\sum_k\binom{n}{k}\cos(n-2k)\theta$
Chebyshev	$\cos n\theta=T_n(\cos\theta)$, $T_{n+1}=2xT_n-T_{n-1}$
Product-to-sum	$\cos A\cos B=\frac{1}{2}[\cos(A-B)+\cos(A+B)]$
Sum-to-product	$\cos P+\cos Q=2\cos\frac{P+Q}{2}\cos\frac{P-Q}{2}$
Phasor-array sum	$\left\lvert\sum_{k=0}^{N-1}e^{jk\delta}\right\rvert=\lvert\sin(N\delta/2)/\sin(\delta/2)\rvert$
Average power	$P=V_{\text{rms}}I_{\text{rms}}\cos(\phi_v-\phi_i)$
Orthogonality	$\frac{2}{T}\int_0^T\cos m\omega_0 t\cos n\omega_0 t\,dt=\delta_{mn}$ $(m,n\geq 1)$
Power of harmonic sum	$X_{\text{rms}}^2=A_0^2+\sum A_n^2/2$
Cubic nonlinearity	$x^3\to\frac{3A^3}{4}\cos\omega t+\frac{A^3}{4}\cos 3\omega t$
IM products	$\lvert pf_1+qf_2\rvert$, order $\lvert p\rvert+\lvert q\rvert$; IM3 at $2f_1-f_2$, $2f_2-f_1$
Beats	$f_{\text{beat}}=\lvert f_1-f_2\rvert$
AM	$A_c(1+m\cos\omega_m t)\cos\omega_c t$: sidebands $mA_c/2$ at $\omega_c\pm\omega_m$

Topic	Key formulas
THD	$\sqrt{\sum_{n\geq 2} X_n^2}/X_1$
Triplens	harmonics $3k$ are zero-sequence: neutral current $= 3\times$ per phase
Standard waveform RMS	square A; triangle/sawtooth $A/\sqrt{3}$; half-wave $A/2$; pulse $A\sqrt{D}$
Symmetry	even → cosines; odd → sines; half-wave → odd harmonics only
Harmonic coefficients	$a_0 = \bar{x}$; $a_n, b_n = \frac{2}{T}\int_0^T x\,\{\cos,\sin\}\,n\omega_0 t\,dt$
Square wave	$\frac{4A}{\pi}\sum_{n\ \text{odd}} \frac{\sin n\omega_0 t}{n}$; THD 48.3%

Part II — Calculus

Chapter 4 — Differential Calculus

> **Prerequisites:** Ch. 1 (functions, algebra, inequalities), Ch. 2 (complex exponentials, j), Ch. 3 (trigonometric identities, radians) **Learning outcomes:** After this chapter you can
>
> - evaluate limits (algebraically, with the squeeze theorem, with L'Hôpital's rule and with series) and decide whether a function is continuous;
> - differentiate any elementary function using the definition, the product, quotient and chain rules, implicit and logarithmic differentiation;
> - compute partial and higher-order derivatives and use them to describe how a quantity responds to each of its inputs;
> - build Taylor and Maclaurin polynomials, bound their error, and use them to linearize nonlinear devices around an operating point;
> - solve rate-of-change and related-rates problems and locate optimal design values with first- and second-derivative tests;
> - quantify how component tolerances propagate to circuit performance with absolute and relative sensitivities.

Electrical engineering is built on rates. Current is the rate at which charge passes a point, $i = dq/dt$. The voltage across an inductor is proportional to the rate of change of its current, $v = L\,di/dt$; the current into a capacitor is proportional to the rate of change of its voltage, $i = C\,dv/dt$. A transistor amplifier works because a small change in input voltage produces a larger change in output current, and that ratio is a derivative (the transconductance). Designing a filter that tolerates 5 % resistors is a question about derivatives too. Differential calculus is the mathematics of *how fast* and *how sensitive*. This chapter develops it from limits, the idea underneath every derivative, through to engineering optimization and sensitivity analysis.

Throughout, angles are in **radians** unless stated otherwise. Every derivative formula for trigonometric functions in this chapter depends on that.

4.1 Limits and continuity

Why limits?

Suppose a charge meter reports $q(t)$, the charge that has passed a cross-section of a wire. Over an interval $[t, t+\Delta t]$ the *average* current is

$$\bar{i} = \frac{q(t+\Delta t) - q(t)}{\Delta t}.$$

The *instantaneous* current at time t is what this ratio approaches as Δt shrinks to zero. We cannot simply set $\Delta t = 0$, because that gives $0/0$. We need a precise way to say what a quantity *approaches* without ever reaching the forbidden point. That is the limit. Limits also make precise what "a capacitor voltage cannot jump" means (continuity), what a filter does "at very high frequency" (limits at infinity), and when an equation must have a root (the intermediate value theorem).

Definition of a limit

Informally, $\lim_{x \to a} f(x) = L$ means that $f(x)$ can be made as close to L as we like by taking x close enough to a (but not equal to a). The value $f(a)$ itself, or whether it exists, is irrelevant.

Limit (ε–δ)

Let f be defined on an open interval containing a, except possibly at a. We write

$$\lim_{x \to a} f(x) = L$$

if for every $\varepsilon > 0$ there exists $\delta > 0$ such that

$$0 < |x - a| < \delta \quad \Longrightarrow \quad |f(x) - L| < \varepsilon.$$

Read it as a game. An adversary names a tolerance ε on the output. You must reply with a tolerance δ on the input that guarantees the output stays within ε of L. If you can always win, the limit is L. This is the same logic as a specification: "the output must be within ± 1 mV (that is ε), so how tightly must the input be held (that is δ)?"

Worked Example 4.1 — An ε–δ proof

Prove that $\lim_{x \to 2} (3x + 1) = 7$.

Step 1 (scratch work). We need $|(3x+1) - 7| < \varepsilon$, i.e. $|3x - 6| = 3|x - 2| < \varepsilon$, i.e. $|x - 2| < \varepsilon/3$.

Step 2 (choose δ). Take $\delta = \varepsilon/3$.

Step 3 (verify). If $0 < |x - 2| < \delta$ then $|(3x+1) - 7| = 3|x-2| < 3\delta = \varepsilon$. ■

Check. With $\varepsilon = 0.03$, $\delta = 0.01$: $x = 2.009$ gives $3x + 1 = 7.027$, which is within 0.03 of 7. ✓

Nobody evaluates practical limits this way. The definition matters because every limit law below is proved from it, and because it pins down exactly what "approaches" means when intuition fails.

One-sided limits

The **right-hand limit** $\lim_{x \to a^+} f(x)$ only lets x approach from above ($x > a$); the **left-hand limit** $\lim_{x \to a^-} f(x)$ only from below. The two-sided limit exists if and only if both one-sided limits exist and are equal.

The unit step $u(t)$ (equal to 0 for $t<0$ and 1 for $t>0$) has $\lim_{t\to 0^-}u(t)=0$ and $\lim_{t\to 0^+}u(t)=1$. These differ, so $\lim_{t\to 0}u(t)$ does not exist. Circuit analysts use one-sided limits constantly: $v_C(0^-)$ is the capacitor voltage just before a switch operates and $v_C(0^+)$ the value just after. The principle that a capacitor voltage is continuous, $v_C(0^+)=v_C(0^-)$, is a statement about one-sided limits.

Limit laws

Limit laws

If $\lim_{x\to a}f(x)=L$ and $\lim_{x\to a}g(x)=M$ (both finite), then

$$\lim_{x\to a}[f(x)\pm g(x)]=L\pm M,\quad \lim_{x\to a}[c\,f(x)]=cL,$$
$$\lim_{x\to a}[f(x)\,g(x)]=LM,\qquad \lim_{x\to a}\frac{f(x)}{g(x)}=\frac{L}{M}\quad (M\neq 0),$$

and $\lim_{x\to a}[f(x)]^n=L^n$ for any positive integer n.

Proof sketch of the sum law. Given ε, choose δ_1 so that $|f-L|<\varepsilon/2$ and δ_2 so that $|g-M|<\varepsilon/2$. With $\delta=\min(\delta_1,\delta_2)$, the triangle inequality gives $|(f+g)-(L+M)|\le|f-L|+|g-M|<\varepsilon$. The product law uses $fg-LM=f(g-M)+M(f-L)$ in the same way.

Because polynomials are built from sums and products of x and constants, the laws give $\lim_{x\to a}p(x)=p(a)$ for every polynomial, and $\lim_{x\to a}p(x)/q(x)=p(a)/q(a)$ for rational functions whenever $q(a)\neq 0$. The interesting cases are the ones where direct substitution gives an **indeterminate form** such as $0/0$ or ∞/∞.

Worked Example 4.2 — Removing a $0/0$ by factoring

Evaluate $\displaystyle\lim_{x\to 2}\frac{x^2-4}{x-2}$ and $\displaystyle\lim_{h\to 0}\frac{\sqrt{9+h}-3}{h}$.

First limit. Substitution gives $0/0$. Factor: $\dfrac{(x-2)(x+2)}{x-2}=x+2$ for $x\neq 2$. Since the limit ignores the point $x=2$ itself, the limit is $\lim_{x\to 2}(x+2)=4$.

Second limit. Multiply by the conjugate:

$$\frac{\sqrt{9+h}-3}{h}\cdot\frac{\sqrt{9+h}+3}{\sqrt{9+h}+3}=\frac{(9+h)-9}{h(\sqrt{9+h}+3)}=\frac{1}{\sqrt{9+h}+3}\longrightarrow\frac{1}{6}.$$

Numerical check. $h=10^{-4}$: $(\sqrt{9.0001}-3)/10^{-4}=0.166666\ldots\checkmark$. (This second limit is the derivative of $\sqrt{x}$ at $x=9$; see §4.2.)

The squeeze theorem and the fundamental trigonometric limit

Squeeze (sandwich) theorem

If $g(x)\le f(x)\le h(x)$ for all x near a (except possibly at a) and $\lim_{x\to a}g(x)=\lim_{x\to a}h(x)=L$, then $\lim_{x\to a}f(x)=L$.

The most important application in this book is

$$\lim_{x\to 0}\frac{\sin x}{x}=1.$$

Proof. For $0<x<\pi/2$, draw the unit circle with an angle x. The triangle with vertices $(0,0)$, $(1,0)$, $(\cos x,\sin x)$ has area $\tfrac12\sin x$; the circular sector has area $\tfrac12 x$; the larger right triangle with legs 1 and $\tan x$ has area $\tfrac12\tan x$. These regions are nested, so

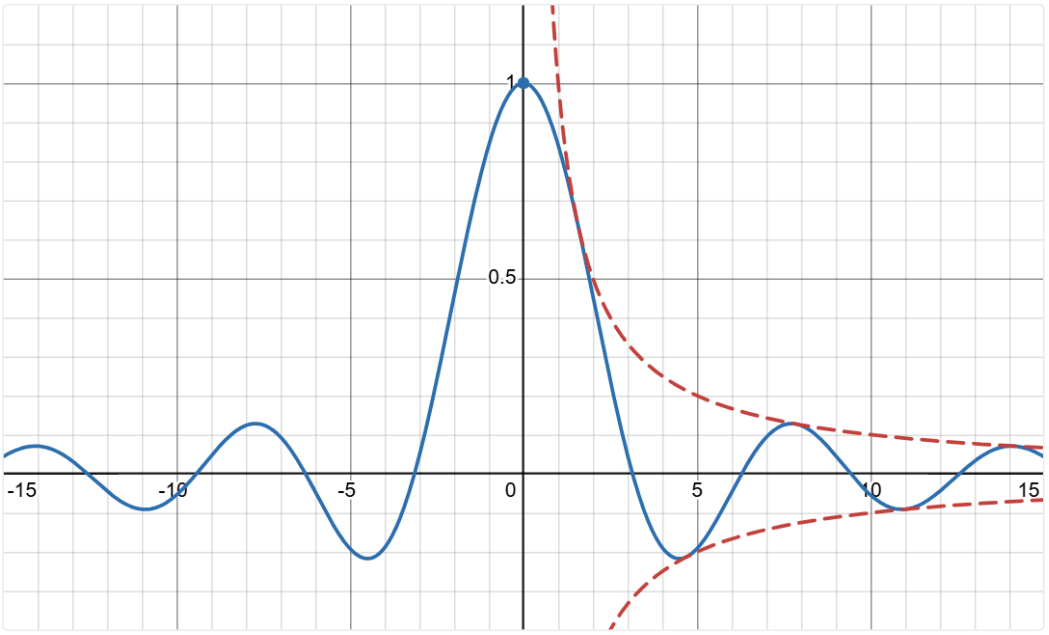
$$\tfrac12\sin x\le\tfrac12 x\le\tfrac12\tan x\quad\Longrightarrow\quad\cos x\le\frac{\sin x}{x}\le 1.$$

As $x\to 0^+$, $\cos x\to 1$, so the squeeze theorem gives the right-hand limit 1. Because $\sin x/x$ is an even function, the left-hand limit is also 1. $\blacksquare$

A consequence used repeatedly below:

$$\lim_{x\to 0}\frac{1-\cos x}{x}=\lim_{x\to 0}\frac{\sin^2 x}{x(1+\cos x)}=\lim_{x\to 0}\frac{\sin x}{x}\cdot\frac{\sin x}{1+\cos x}=1\cdot 0=0,$$

and in the same way $\lim_{x\to 0}(1-\cos x)/x^2=\tfrac12$.



The sinc-type function $\sin x/x$ is undefined at $x=0$ but tends to 1 there; for large x it is squeezed between $\pm 1/x$ and so tends to 0.

Engineering Note — the sinc function

The function $\operatorname{sinc}(x) = \sin(\pi x)/(\pi x)$ (with $\operatorname{sinc}(0)=1$ by the limit above) is the Fourier transform of a rectangular pulse (Ch. 16) and the ideal interpolation kernel in sampling theory. Defining $\operatorname{sinc}(0)=1$ is not a convention pulled from the air; it is the unique value that makes the function continuous.

Worked Example 4.3 — Trigonometric limits

Evaluate (a) $\displaystyle\lim_{x\to 0}\frac{\sin 3x}{x}$, (b) $\displaystyle\lim_{x\to 0}\frac{\tan 5x}{\sin 2x}$, (c) $\displaystyle\lim_{x\to 0}\frac{1-\cos 4x}{x^2}$.

(a) Write $\dfrac{\sin 3x}{x} = 3\cdot\dfrac{\sin 3x}{3x}$. With $u = 3x \to 0$, the limit is $3\cdot 1 = 3$.

(b) $\dfrac{\tan 5x}{\sin 2x} = \dfrac{\sin 5x}{5x}\cdot\dfrac{2x}{\sin 2x}\cdot\dfrac{1}{\cos 5x}\cdot\dfrac{5}{2} \to 1\cdot 1\cdot 1\cdot\tfrac{5}{2} = \tfrac{5}{2}$.

(c) With $u = 4x$, $\dfrac{1-\cos u}{x^2} = 16\,\dfrac{1-\cos u}{u^2} \to 16\cdot\tfrac{1}{2} = 8$.

Numerical check at $x = 10^{-3}$: (a) 2.9999955, (b) 2.50002, (c) 7.99999. ✓

Limits at infinity and infinite limits

$\lim_{x\to\infty} f(x) = L$ means $f(x)$ can be made arbitrarily close to L by taking x large enough; the line $y = L$ is then a **horizontal asymptote**. $\lim_{x\to a} f(x) = \infty$ means $f(x)$ exceeds any bound as $x \to a$; the line $x = a$ is then a **vertical asymptote**. "$=\infty$" here is shorthand for a particular way of *not* having a finite limit.

For rational functions, divide numerator and denominator by the highest power of x in the denominator. The useful facts are

$$\lim_{x\to\infty}\frac{1}{x^p} = 0\ (p>0), \qquad \lim_{x\to\infty} x^n e^{-x} = 0\ (\text{any } n), \qquad \lim_{x\to\infty}\frac{\ln x}{x^p} = 0\ (p>0).$$

In words: exponentials beat powers, and powers beat logarithms. We prove the last two with L'Hôpital's rule in §4.2.

The number e is itself a limit:

$$e = \lim_{n\to\infty}\left(1+\frac{1}{n}\right)^n = 2.718281828\ldots, \qquad \text{and more generally} \qquad \lim_{n\to\infty}\left(1+\frac{x}{n}\right)^n = e^x.$$

Worked Example 4.4 — Asymptotic behaviour of a transfer function

A first-order low-pass filter has magnitude response

$$|H(\omega)| = \frac{1}{\sqrt{1 + (\omega/\omega_c)^2}}.$$

Find $\lim_{\omega \to 0} |H|$, $\lim_{\omega \to \infty} |H|$, and $\lim_{\omega \to \infty} \omega\,|H(\omega)|$.

Low frequency. Direct substitution: $|H(0)| = 1$. The function is continuous, so the limit is 1 (the filter passes DC).

High frequency. The denominator grows without bound, so $|H| \to 0$.

The product. Divide inside the root by ω^2:

$$\omega |H| = \frac{\omega}{\sqrt{1 + \omega^2/\omega_c^2}} = \frac{1}{\sqrt{1/\omega^2 + 1/\omega_c^2}} \longrightarrow \omega_c.$$

So for $\omega \gg \omega_c$, $|H| \approx \omega_c/\omega$: the response falls in proportion to $1/\omega$, which is -20 dB per decade on a Bode plot.

Check. $\omega = 1000\,\omega_c$: $\omega|H|/\omega_c = 1000/\sqrt{1 + 10^6} = 0.9999995$. ✓

Continuity

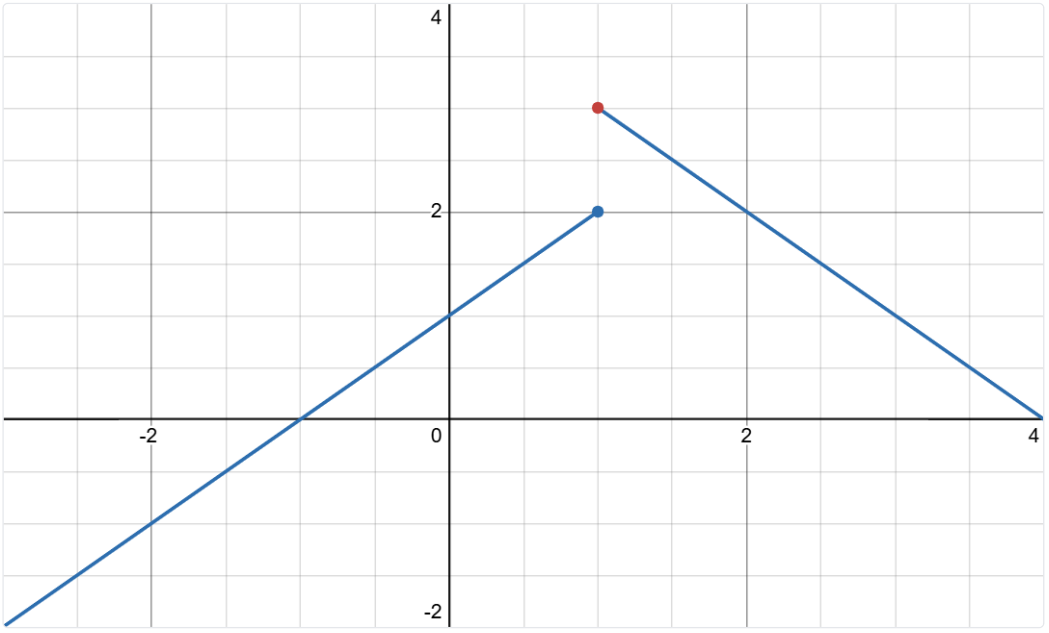
Continuity

f is **continuous at** a if (i) $f(a)$ is defined, (ii) $\lim_{x \to a} f(x)$ exists, and (iii) $\lim_{x \to a} f(x) = f(a)$. f is continuous on an interval if it is continuous at every point of it (using one-sided limits at closed endpoints).

Sums, products, quotients (where the denominator is nonzero) and compositions of continuous functions are continuous. Polynomials, rational functions (on their domains), e^x, $\ln x$ ($x > 0$), $\sin x$, $\cos x$, and $\sqrt{x}$ ($x \geq 0$) are all continuous. So nearly every formula you meet is continuous wherever it is defined, and the action is at the points where it is not.

Types of discontinuity:

Type	What fails	Example
Removable	limit exists but $\neq f(a)$ or $f(a)$ undefined	$\sin x / x$ at 0
Jump	one-sided limits exist but differ	$u(t)$ at 0; a switched source
Infinite	function unbounded near a	$1/(x-1)$ at $x = 1$; an undamped resonance $1/(\omega_0^2 - \omega^2)$
Oscillatory	no limit, no blow-up	$\sin(1/x)$ at 0



A jump discontinuity at $x = 1$: the left-hand limit is 2 and the right-hand limit is 3, so no choice of $f(1)$ can make the function continuous there.

Worked Example 4.5 — Choosing a constant for continuity

For what value of k is

$$f(x) = \begin{cases} \dfrac{e^{2x} - 1}{x}, & x \neq 0 \\ k, & x = 0 \end{cases}$$

continuous at 0?

We need $k = \lim_{x \to 0} (e^{2x} - 1)/x$. With $u = 2x$, this is $2 \lim_{u \to 0} (e^u - 1)/u$. The limit $\lim_{u \to 0} (e^u - 1)/u = 1$ is the defining property of e (it says that the slope of e^u at $u = 0$ is 1; see §4.2). Hence $k = 2$.

Check. $x = 10^{-5}$: $(e^{2 \times 10^{-5}} - 1)/10^{-5} = 2.00002$. ✓

Two theorems about continuous functions

Intermediate value theorem (IVT)

If f is continuous on $[a, b]$ and N lies strictly between $f(a)$ and $f(b)$, then there is at least one $c \in (a, b)$ with $f(c) = N$. In particular, if $f(a)$ and $f(b)$ have opposite signs, f has a root in (a, b).

Extreme value theorem (EVT)

If f is continuous on a closed, bounded interval $[a, b]$, then f attains an absolute maximum and an absolute minimum on $[a, b]$.

The IVT is the basis of the **bisection method** for solving equations (Ch. 22): if $f(a) f(b) < 0$, evaluate f at the midpoint and keep whichever half still has a sign change. Each step halves the interval, so n steps shrink an interval of length L to $L/2^n$. The EVT guarantees that the optimization problems of §4.10 have answers when the design variable lives on a closed interval.

Worked Example 4.6 — Bracketing a root

Show that $x^3 - x - 1 = 0$ has a root in $(1, 2)$ and locate it to within 0.1.

$f(x) = x^3 - x - 1$ is a polynomial, hence continuous. $f(1) = -1 < 0$ and $f(2) = 5 > 0$, so by the IVT there is a root in $(1, 2)$.

Bisection: $f(1.5) = 0.875 > 0 \Rightarrow (1, 1.5)$; $f(1.25) = -0.297 < 0 \Rightarrow (1.25, 1.5)$; $f(1.375) = 0.224 > 0 \Rightarrow (1.25, 1.375)$; $f(1.3125) = -0.0515 < 0 \Rightarrow (1.3125, 1.375)$. The interval now has length $0.0625 < 0.1$; the root is 1.34 ± 0.03.

Check. The root to 9 digits is 1.324717957, inside the final bracket. ✓

Common Pitfall — the IVT needs continuity on the whole interval

$f(x) = 1/x$ has $f(-1) = -1$ and $f(1) = 1$, yet there is no root in $(-1, 1)$. The IVT does not apply because f is discontinuous at 0. A numerical root finder that brackets a sign change across a pole will happily "converge" to the pole. Always check for singularities (for example, poles of a transfer function) inside a bracket.

Engineering Note — continuity of state variables

In a circuit with finite voltages and currents, capacitor voltages and inductor currents are continuous functions of time. The reason is that $i = C\,dv/dt$ is finite, so v cannot jump (a jump would need infinite current); dually for $v = L\,di/dt$. This continuity, $v_C(0^+) = v_C(0^-)$ and $i_L(0^+) = i_L(0^-)$, supplies the initial conditions for every switched-circuit problem in Ch. 11 and Ch. 12. Currents through capacitors and voltages across inductors are *not* state variables and may jump.

4.2 Derivatives and differentiation rules

The derivative as a limit

Derivative

The **derivative** of f at x is

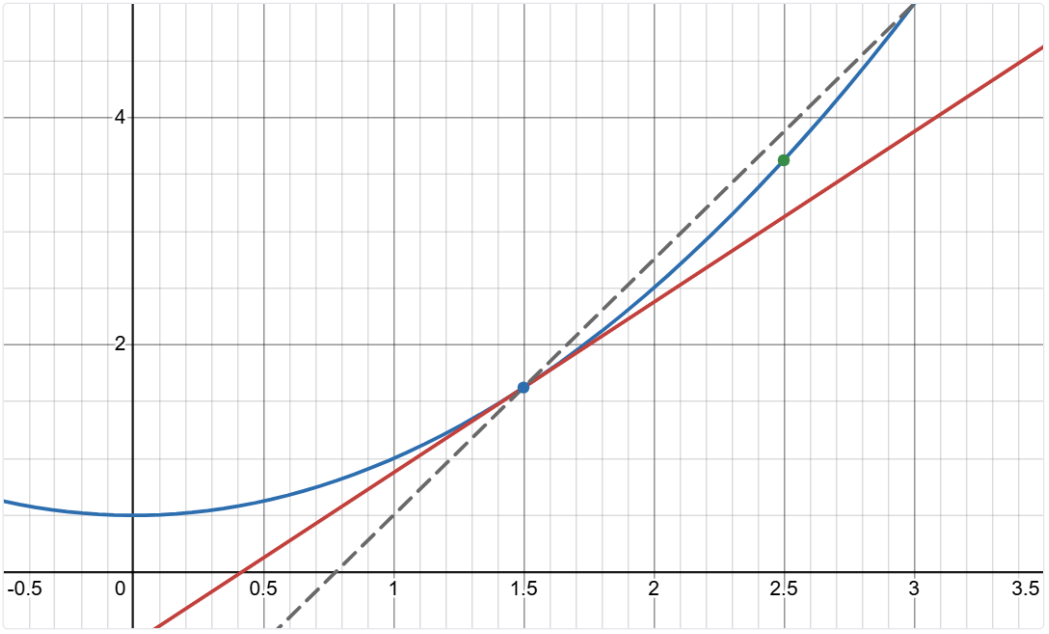
$$f'(x) = \lim_{h \to 0} \frac{f(x + h) - f(x)}{h},$$

provided the limit exists; f is then **differentiable** at x. Equivalent notations: $f'(x)$, $\dfrac{df}{dx}$, $\dfrac{d}{dx} f(x)$, $Df(x)$, and $\dot{f}$ when the variable is time.

The **difference quotient** $\frac{f(x+h) - f(x)}{h}$ is the slope of the secant line through $(x, f(x))$ and $(x + h, f(x + h))$. As $h \to 0$ the secant rotates into the **tangent line**, whose equation at $x = a$ is

$$y = f(a) + f'(a)(x - a).$$

Physically the derivative is an **instantaneous rate of change**, with units of (units of f)/(units of x). If q is in coulombs and t in seconds, dq/dt is in C/s = A.



The curve $y = \tfrac{1}{2}x^2 + \tfrac{1}{2}$, its tangent at $x = 1.5$ (slope 1.5), and a secant through $x = 1.5$ and $x = 2.5$ (slope 2). As the second point slides toward the first, the secant slope tends to the tangent slope.

Worked Example 4.7 — Derivatives from first principles

Find $f'(x)$ from the definition for (a) $f(x) = x^2$, (b) $f(x) = 1/x$, (c) $f(x) = \sqrt{x}$.

(a) $\dfrac{(x+h)^2 - x^2}{h} = \dfrac{2xh + h^2}{h} = 2x + h \to 2x$.

(b) $\dfrac{1}{h}\left(\dfrac{1}{x+h} - \dfrac{1}{x}\right) = \dfrac{x - (x+h)}{h\,x(x+h)} = \dfrac{-1}{x(x+h)} \to -\dfrac{1}{x^2}$.

(c) Rationalize as in Example 4.2: $\dfrac{\sqrt{x+h} - \sqrt{x}}{h} = \dfrac{1}{\sqrt{x+h} + \sqrt{x}} \to \dfrac{1}{2\sqrt{x}}$ (for $x > 0$). At $x = 9$ this is $1/6$, the limit computed in Example 4.2.

All three agree with the power rule $\frac{d}{dx}x^n = nx^{n-1}$ for $n = 2, -1, \tfrac{1}{2}$.

Differentiability and continuity

Differentiable implies continuous

If f is differentiable at a, then f is continuous at a.

Proof. $f(a+h) - f(a) = \dfrac{f(a+h) - f(a)}{h} \cdot h \to f'(a) \cdot 0 = 0$. ∎

The converse is false. $f(x) = |x|$ is continuous at 0, but its difference quotient $|h|/h$ is $+1$ for $h > 0$ and -1 for $h < 0$, so the one-sided limits disagree and $f'(0)$ does not exist. Graphically, a **corner** (or a vertical tangent, as for $x^{1/3}$ at 0, or a cusp) blocks differentiability. An ideal diode's i–v characteristic and the output of a full-wave rectifier $|\sin \omega t|$ both have corners. At a corner the left and right derivatives, defined with one-sided limits, exist but differ.

Derivatives of the basic functions

Powers. For a positive integer n, the binomial theorem gives $(x+h)^n = x^n + nx^{n-1}h + \binom{n}{2}x^{n-2}h^2 + \cdots$, so

$$\frac{(x+h)^n - x^n}{h} = nx^{n-1} + \binom{n}{2}x^{n-2}h + \cdots + h^{n-1} \to nx^{n-1}.$$

The rule $\frac{d}{dx}x^r = rx^{r-1}$ holds for every real r (for $x > 0$); we prove the general case with logarithmic differentiation in §4.3.

Sine and cosine. Using $\sin(x+h) = \sin x \cos h + \cos x \sin h$,

$$\frac{\sin(x+h) - \sin x}{h} = \sin x\,\frac{\cos h - 1}{h} + \cos x\,\frac{\sin h}{h} \;\longrightarrow\; \sin x \cdot 0 + \cos x \cdot 1 = \cos x.$$

A similar computation gives $\frac{d}{dx}\cos x = -\sin x$. Both rely on the two trigonometric limits from §4.1, which in turn rely on measuring x in radians.

Exponential. $\dfrac{e^{x+h} - e^x}{h} = e^x\,\dfrac{e^h - 1}{h} \to e^x$, because e is precisely the base for which $\lim_{h\to 0}(e^h - 1)/h = 1$. The exponential is the function equal to its own derivative, which is why it solves every first-order linear circuit.

Logarithm. From $\ln(x+h) - \ln x = \ln(1 + h/x)$ and the substitution $n = x/h$,

$$\frac{\ln(1+h/x)}{h} = \frac{1}{x}\ln\left(1+\frac{1}{n}\right)^{n} \to \frac{1}{x}\ln e = \frac{1}{x}.$$

The differentiation rules

Rules of differentiation

If f and g are differentiable and c is a constant:

$$\begin{aligned}
&\text{Linearity:} && (cf \pm g)' = cf' \pm g' \\
&\text{Product rule:} && (fg)' = f'g + fg' \\
&\text{Quotient rule:} && \left(\frac{f}{g}\right)' = \frac{f'g - fg'}{g^2} \quad (g \neq 0) \\
&\text{Power rule:} && (x^r)' = r x^{r-1}
\end{aligned}$$

Proof of the product rule. Add and subtract $f(x+h)g(x)$:

$$\frac{f(x+h)g(x+h) - f(x)g(x)}{h} = f(x+h)\frac{g(x+h)-g(x)}{h} + g(x)\frac{f(x+h)-f(x)}{h}.$$

As $h \to 0$, $f(x+h) \to f(x)$ (differentiable implies continuous), and the two quotients tend to g' and f'. $\blacksquare$

Quotient rule. Write $f = (f/g)\,g$ and apply the product rule: $f' = (f/g)'g + (f/g)g'$. Solve for $(f/g)'$.

A useful mnemonic for the product rule is in differentials: $d(fg) = g\,df + f\,dg$. If f and g each change by a small amount, the product changes by "each one's change times the other". For a capacitor with charge $q = Cv$ whose capacitance *and* voltage vary, this gives $i = \dot q = \dot C v + C\dot v$ (see §4.9).

Table of standard derivatives

$f(x)$	$f'(x)$	$f(x)$	$f'(x)$
x^r	$r x^{r-1}$	e^{ax}	$a e^{ax}$
a^x	$a^x \ln a$	$\ln\lvert x\rvert$	$1/x$
$\log_a x$	$1/(x \ln a)$	$\sin x$	$\cos x$
$\cos x$	$-\sin x$	$\tan x$	$\sec^2 x = 1 + \tan^2 x$
$\cot x$	$-\csc^2 x$	$\sec x$	$\sec x \tan x$
$\arcsin x$	$1/\sqrt{1-x^2}$	$\arccos x$	$-1/\sqrt{1-x^2}$
$\arctan x$	$1/(1+x^2)$	$\sinh x$	$\cosh x$
$\cosh x$	$\sinh x$	$\tanh x$	$\operatorname{sech}^2 x = 1 - \tanh^2 x$

The inverse-trigonometric entries follow from the inverse-function rule in §4.3. The hyperbolic ones follow from $\sinh x = (e^x - e^{-x})/2$, $\cosh x = (e^x + e^{-x})/2$.

Complex exponentials. For a real variable t and a complex constant s, $\frac{d}{dt}e^{st} = s e^{st}$. The proof is identical to the real case (or follows by differentiating $e^{\sigma t}\cos\omega t$ and $e^{\sigma t}\sin\omega t$ separately). With $s = j\omega$:

$$\frac{d}{dt}e^{j\omega t} = j\omega\, e^{j\omega t}.$$

This single line is why **differentiation becomes multiplication by $j\omega$** in phasor analysis (Ch. 2) and multiplication by s in the Laplace domain (Ch. 14). An inductor's $v = L\,di/dt$ becomes $V = j\omega L\, I$, giving the impedance $j\omega L$.

Worked Example 4.8 — Product and quotient rules: power into a load

A source of EMF V and internal resistance R_s drives a load R_L. The load power is

$$P(R_L) = \frac{V^2 R_L}{(R_s + R_L)^2}.$$

Find dP/dR_L.

Quotient rule with numerator $N = V^2 R_L$ ($N' = V^2$) and denominator $D = (R_s + R_L)^2$ ($D' = 2(R_s + R_L)$), by the chain rule of §4.3 or by expanding):

$$\frac{dP}{dR_L} = \frac{V^2(R_s+R_L)^2 - V^2 R_L \cdot 2(R_s+R_L)}{(R_s+R_L)^4} = \frac{V^2\left[(R_s+R_L) - 2R_L\right]}{(R_s+R_L)^3} = \frac{V^2(R_s - R_L)}{(R_s+R_L)^3}.$$

Interpretation. The derivative is positive for $R_L < R_s$ and negative for $R_L > R_s$: power rises, peaks at $R_L = R_s$, then falls. This is the maximum power transfer theorem, revisited in §4.10.

Units check. $V^2\,\Omega/\Omega^3 = V^2/\Omega^2 = \mathrm{W}/\Omega$. ✓

Numerical check. $V = 10\,\mathrm{V}$, $R_s = 50\,\Omega$, $R_L = 25\,\Omega$: formula gives $100 \cdot 25/75^3 = 5.926 \times 10^{-3}\ \mathrm{W}/\Omega$; central difference with $h = 10^{-3}\,\Omega$ gives 5.926×10^{-3}. ✓

Worked Example 4.9 — Inductor voltage

The current in a $L = 10\,\text{mH}$ inductor is $i(t) = I_0\,(t/\tau)\,e^{-t/\tau}$ with $I_0 = 2\,\text{A}$ and $\tau = 1\,\text{ms}$. Find $v(t) = L\,di/dt$ and the time at which $v = 0$.

Product rule. With $f = t/\tau$ and $g = e^{-t/\tau}$, $f' = 1/\tau$ and $g' = -e^{-t/\tau}/\tau$:

$$\frac{di}{dt} = \frac{I_0}{\tau}e^{-t/\tau} - \frac{I_0 t}{\tau^2}e^{-t/\tau} = \frac{I_0}{\tau}\left(1 - \frac{t}{\tau}\right)e^{-t/\tau}.$$

So $v(t) = \dfrac{LI_0}{\tau}\left(1 - \dfrac{t}{\tau}\right)e^{-t/\tau} = 20\,(1 - t/\tau)\,e^{-t/\tau}\ \text{V}$.

Zero. $v = 0$ at $t = \tau = 1\,\text{ms}$, which is exactly when the current reaches its peak $I_0/e = 0.736\,\text{A}$. At $t = 0$, $v = 20\,\text{V}$.

Units. $\text{H}\cdot\text{A/s} = \text{V}$. ✓

The mean value theorem

Rolle's theorem and the mean value theorem (MVT)

Let f be continuous on $[a, b]$ and differentiable on (a, b).

- (Rolle) If $f(a) = f(b)$, there is $c \in (a, b)$ with $f'(c) = 0$.
- (MVT) There is $c \in (a, b)$ with

$$f'(c) = \frac{f(b) - f(a)}{b - a}.$$

Proof sketch. Rolle: by the EVT f has a max and a min on $[a, b]$; if both are at the endpoints, f is constant and $f' \equiv 0$; otherwise an interior extremum has $f' = 0$ (Fermat's theorem, §4.10). MVT: apply Rolle to $g(x) = f(x) - \frac{f(b)-f(a)}{b-a}(x - a)$, which has $g(a) = g(b) = f(a)$.

In words: somewhere, the instantaneous rate equals the average rate. If a capacitor voltage rises from 0 to 5 V in 2 μs, then at some instant $dv/dt = 2.5\,\text{V}/\mu\text{s}$ exactly, and with $C = 100\,\text{pF}$ the current at that instant is $i = C\,dv/dt = 0.25\,\text{mA}$, whatever the shape of the waveform.

Three consequences used throughout the book:

1. If $f'(x) = 0$ on an interval, f is constant there.
2. If $f' = g'$ on an interval, $f - g$ is constant (the basis of "$+C$" in Ch. 5).
3. If $f' > 0$ on an interval, f is strictly increasing there; if $f' < 0$, strictly decreasing.

The MVT also gives error bounds: $|f(b) - f(a)| \le M|b - a|$ where $M = \max|f'|$. A sensor with transfer function slope at most M amplifies an input uncertainty Δx to at most $M\Delta x$.

L'Hôpital's rule

L'Hôpital's rule

Suppose f and g are differentiable near a (except possibly at a), $g'(x) \neq 0$ near a, and $\lim f = \lim g = 0$ or $\lim f = \pm\lim g = \pm\infty$. If $\lim_{x\to a} f'(x)/g'(x) = L$ (finite or infinite), then

$$\lim_{x\to a}\frac{f(x)}{g(x)} = L.$$

The same holds for one-sided limits and for $a = \pm\infty$.

Why it works (for $0/0$ with f', g' continuous and $g'(a) \neq 0$). Since $f(a) = g(a) = 0$,

$$\frac{f(x)}{g(x)} = \frac{f(x) - f(a)}{g(x) - g(a)} = \frac{[f(x) - f(a)]/(x - a)}{[g(x) - g(a)]/(x - a)} \to \frac{f'(a)}{g'(a)}.$$

The general case uses Cauchy's version of the MVT.

Other indeterminate forms ($0\cdot\infty$, $\infty - \infty$, 1^∞, 0^0, ∞^0) are first rewritten as $0/0$ or ∞/∞, usually by moving a factor to the denominator or by taking logarithms.

Worked Example 4.10 — L'Hôpital's rule

(a) $\lim_{x\to 0}\dfrac{e^x-1-x}{x^2}$. Form $0/0$. Differentiate top and bottom: $\dfrac{e^x-1}{2x}$, still $0/0$. Again: $\dfrac{e^x}{2}\to\dfrac{1}{2}$.

(b) $\lim_{x\to\infty} x^3e^{-x}=\lim\dfrac{x^3}{e^x}$. Form ∞/∞. Three applications: $\dfrac{3x^2}{e^x}\to\dfrac{6x}{e^x}\to\dfrac{6}{e^x}\to 0$. The same argument works for any power x^n: exponentials dominate.

(c) $\lim_{x\to 0^+} x\ln x$. Form $0\cdot(-\infty)$. Rewrite as $\dfrac{\ln x}{1/x}$ $(-\infty/\infty)$: $\dfrac{1/x}{-1/x^2}=-x\to 0$.

(d) $\lim_{x\to\infty}\left(1+\dfrac{a}{x}\right)^x$. Form 1^∞. Take logs: $x\ln(1+a/x)=\dfrac{\ln(1+a/x)}{1/x}$, form $0/0$. Differentiate: $\dfrac{-a/x^2\cdot 1/(1+a/x)}{-1/x^2}=\dfrac{a}{1+a/x}\to a$. So the limit is e^a.

Checks. (a) at $x=10^{-3}$: 0.500167; (b) at $x=50$: 2.4×10^{-17}; (c) at $x=10^{-6}$: -1.4×10^{-5}; (d) $a=1$, $x=10^6$: 2.7182805. ✓

Worked Example 4.11 — The critically damped limit

Two first-order stages in cascade with time constants $1/a$ and $1/b$ give an impulse response proportional to

$$h(t)=\frac{e^{-at}-e^{-bt}}{b-a}\qquad(a\neq b).$$

What happens as $a\to b$ (equal poles)?

For fixed t, treat this as a function of a. Numerator and denominator both tend to 0. Differentiate with respect to a: numerator derivative $-te^{-at}$, denominator derivative -1. So

$$\lim_{a\to b}h(t)=\lim_{a\to b}\frac{-te^{-at}}{-1}=t\,e^{-bt}.$$

This explains the appearance of the factor t in the solution of an ODE with a repeated characteristic root (Ch. 11): it is the limit of two nearly equal exponentials.

Check. $b=1$, $a=1.001$, $t=2$: $(e^{-2.002}-e^{-2})/(-0.001)=0.27040$; $te^{-t}=0.27067$ (the difference is $O(a-b)$). ✓

Common Pitfall — applying L'Hôpital where it does not apply

L'Hôpital's rule is only for $0/0$ or ∞/∞. $\lim_{x\to 0}\frac{\cos x}{x+1}=1$ by substitution, but "differentiating" gives $\frac{-\sin x}{1}\to 0$, which is wrong. Also, the rule differentiates numerator and denominator **separately**; it is not the quotient rule. Finally, if $\lim f'/g'$ fails to exist the rule says nothing: $\lim_{x\to\infty}(x+\sin x)/x=1$, although $(1+\cos x)/1$ has no limit.

Engineering Note — derivatives from measured data

Instruments give samples, not formulas. A measured current $i[n]=i(nT_s)$ is differentiated numerically by $\big(i[n+1]-i[n-1]\big)/(2T_s)$, the central difference, which is the definition of the derivative with $h=T_s$ (made symmetric for accuracy; see §4.7). Differentiation amplifies high-frequency noise, because $j\omega$ grows with ω: a 1 mV noise component at 1 MHz contributes $2\pi\times10^6\times10^{-3}\approx 6.3\times10^3$ V/s to dv/dt. Practical differentiators therefore band-limit the signal first.

4.3 Chain rule

Motivation

Most functions in engineering are compositions. A decaying sinusoid $e^{-t/\tau}\cos(\omega t+\phi)$ has the time variable buried inside an exponential and a cosine. The gain of a filter in decibels is a logarithm of a square root of a rational function of ω. A diode current is an exponential of a voltage that is itself a function of time. The chain rule differentiates compositions, and it is the most frequently used rule in calculus.

Statement

Chain rule

If g is differentiable at x and f is differentiable at $u=g(x)$, then $f\circ g$ is differentiable at x and

$$\frac{d}{dx}f\big(g(x)\big)=f'\big(g(x)\big)\,g'(x).$$

In Leibniz notation, with $y=f(u)$ and $u=g(x)$:

$$\frac{dy}{dx}=\frac{dy}{du}\,\frac{du}{dx}.$$

The Leibniz form looks like cancelling du, and that is a reliable mnemonic. Rates multiply along a chain: if y changes 3 times as fast as u, and u changes 2 times as fast as x, then y changes 6 times as fast as x. A cascade of amplifiers with small-signal gains A_1 and A_2 has overall gain A_1A_2 for exactly this reason.

Proof sketch. The naive argument writes

$$\frac{f(g(x+h))-f(g(x))}{h}=\frac{f(g(x+h))-f(g(x))}{g(x+h)-g(x)}\cdot\frac{g(x+h)-g(x)}{h},$$

and lets $h\to 0$. This fails if $g(x+h)=g(x)$ for small $h\neq 0$ (division by zero). The fix is to define

$$\phi(k)=\begin{cases}\dfrac{f(u+k)-f(u)}{k}, & k\neq 0\\[2mm] f'(u), & k=0\end{cases}$$

which is continuous at $k=0$ because f is differentiable at u. Then $f(u+k)-f(u)=\phi(k)\,k$ holds for *all* k, including $k=0$. Put $k=g(x+h)-g(x)$:

$$\frac{f(g(x+h))-f(g(x))}{h}=\phi(k)\,\frac{g(x+h)-g(x)}{h}\to f'(u)\,g'(x),$$

since $k\to 0$ as $h\to 0$ (because g is continuous). $\blacksquare$

Standard consequences

Applying the chain rule to each entry in the table of §4.2 gives the "generalized" rules, with $u=u(x)$:

$$\frac{d}{dx}u^n=nu^{n-1}u',\qquad \frac{d}{dx}e^u=e^u u',\qquad \frac{d}{dx}\ln|u|=\frac{u'}{u},$$
$$\frac{d}{dx}\sin u=\cos u\;u',\quad \frac{d}{dx}\cos u=-\sin u\;u',\quad \frac{d}{dx}\arctan u=\frac{u'}{1+u^2}.$$

For a sinusoid with angular frequency ω and phase ϕ:

$$\frac{d}{dt}A\sin(\omega t+\phi)=A\omega\cos(\omega t+\phi)=A\omega\sin\!\left(\omega t+\phi+\frac{\pi}{2}\right).$$

Differentiating a sinusoid multiplies its amplitude by ω and advances its phase by 90°. That is the time-domain meaning of the factor $j\omega=\omega\angle 90^\circ$. For an inductor, the voltage leads the current by 90°; for a capacitor, $i=C\,dv/dt$ means the current leads the voltage by 90°.

Worked Example 4.12 — A damped sinusoid

The voltage across an underdamped RLC circuit is $v(t)=V_0e^{-t/\tau}\cos(\omega_d t)$ with $V_0=10\,\text{V}$, $\tau=1\,\text{ms}$, $\omega_d=2\pi\times 1000\,\text{rad/s}$. Find dv/dt and evaluate it at $t=0$.

Product rule, then chain rule on each factor. $\frac{d}{dt}e^{-t/\tau}=-\frac{1}{\tau}e^{-t/\tau}$ and $\frac{d}{dt}\cos\omega_d t=-\omega_d\sin\omega_d t$. So

$$\frac{dv}{dt}=-V_0e^{-t/\tau}\left[\frac{1}{\tau}\cos\omega_d t+\omega_d\sin\omega_d t\right].$$

At $t=0$. $\dfrac{dv}{dt}(0)=-V_0/\tau=-10/10^{-3}=-10^4\,\text{V/s}=-10\,\text{mV/µs}$.

Compact form. With $\tan\psi=\omega_d\tau$, the bracket is $\sqrt{1/\tau^2+\omega_d^2}\,\cos(\omega_d t-\psi)$. The derivative is another damped sinusoid with the same decay, scaled by $\sqrt{\tau^{-2}+\omega_d^2}=6362\,\text{s}^{-1}$ and phase-shifted. In complex form this is immediate: $v=\text{Re}\{V_0e^{st}\}$ with $s=-1/\tau+j\omega_d$, so $\dot v=\text{Re}\{sV_0e^{st}\}$ and $|s|=6362\,\text{s}^{-1}$.

Logarithmic differentiation

For products, quotients and powers of many factors, take logarithms first. If $y=f_1^{a_1}f_2^{a_2}\cdots f_n^{a_n}$ then $\ln|y|=\sum a_k\ln|f_k|$, and differentiating with the chain rule:

$$\frac{y'}{y}=a_1\frac{f_1'}{f_1}+a_2\frac{f_2'}{f_2}+\cdots+a_n\frac{f_n'}{f_n}.$$

The quantity $y'/y=(\ln y)'$ is the **logarithmic derivative**: the fractional (relative) rate of change. It turns products into sums and is the engine of the relative sensitivity in §4.11.

The general power rule. For $y=x^r$ with real r and $x>0$: $\ln y=r\ln x$, so $y'/y=r/x$ and $y'=rx^{r-1}$. This completes the proof of the power rule for all real exponents.

Variable exponents. $y=x^x$ $(x>0)$: $\ln y=x\ln x$, so $y'/y=\ln x+1$ and $y'=x^x(1+\ln x)$. Similarly $\frac{d}{dx}a^x=a^x\ln a$, from $a^x=e^{x\ln a}$.

Worked Example 4.13 — Slope of a Bode magnitude plot

For the first-order low-pass filter $|H| = \big(1 + (\omega/\omega_c)^2\big)^{-1/2}$, the gain in decibels is $G = 20\log_{10}|H| = -10\log_{10}\big(1 + (\omega/\omega_c)^2\big)$. A Bode plot uses $x = \log_{10}\omega$ on the horizontal axis. Find the slope dG/dx in dB per decade.

Chain rule. $dG/dx = (dG/d\omega)(d\omega/dx)$. Since $\omega = 10^x$, $d\omega/dx = 10^x \ln 10 = \omega \ln 10$. And

$$\frac{dG}{d\omega} = -\frac{10}{\ln 10}\cdot\frac{2\omega/\omega_c^2}{1 + (\omega/\omega_c)^2}.$$

Multiplying,

$$\frac{dG}{dx} = -20\,\frac{(\omega/\omega_c)^2}{1 + (\omega/\omega_c)^2} \quad \text{dB/decade}.$$

Interpretation. For $\omega \ll \omega_c$ the slope is ≈ 0; at $\omega = \omega_c$ it is exactly -10 dB/decade; for $\omega \gg \omega_c$ it tends to -20 dB/decade. The asymptotic straight-line Bode plot replaces this smooth curve by its two limits, which is accurate except near the corner.

Check. $\omega = 10\omega_c$: $-20 \times 100/101 = -19.80$ dB/decade. Numerically, $G(10.01\omega_c) - G(9.99\omega_c)$ divided by $\log_{10}(10.01/9.99)$ gives -19.80. ✓

Engineering Note — why decibels and log axes

The logarithmic derivative explains the habit of plotting gain in dB against $\log\omega$. If $|H| \propto \omega^n$ over some band, then $\log|H| = n\log\omega + \text{const}$, a straight line of slope n (i.e. $20n$ dB/decade). Each pole contributes -20 dB/decade and each zero $+20$ dB/decade beyond its corner frequency because logarithms turn the product of factors in H into a sum of their contributions. The slope $d\ln|H|/d\ln\omega$ is exactly the relative sensitivity $S_\omega^{|H|}$ of §4.11.

Derivatives of inverse functions

If $y = f(x)$ is differentiable and strictly monotonic with $f'(x) \neq 0$, its inverse $x = f^{-1}(y)$ is differentiable and

$$\frac{d}{dy}f^{-1}(y) = \frac{1}{f'(x)}\bigg|_{x = f^{-1}(y)}, \qquad \text{i.e.} \qquad \frac{dx}{dy} = \frac{1}{dy/dx}.$$

Derivation. Differentiate the identity $f\big(f^{-1}(y)\big) = y$ with respect to y using the chain rule: $f'\big(f^{-1}(y)\big)\cdot(f^{-1})'(y) = 1$. Graphically, the graph of f^{-1} is the mirror image of the graph of f in the line $y = x$, which turns a slope m into $1/m$.

Arctangent. $y = \arctan x$ means $x = \tan y$ with $y \in (-\pi/2, \pi/2)$. Then $dx/dy = \sec^2 y = 1 + \tan^2 y = 1 + x^2$, so $dy/dx = 1/(1 + x^2)$.

Arcsine. $x = \sin y$, $y \in [-\pi/2, \pi/2]$: $dx/dy = \cos y = +\sqrt{1 - x^2}$ (positive on that interval), so $dy/dx = 1/\sqrt{1 - x^2}$.

Logarithm. $x = e^y$: $dx/dy = e^y = x$, so $\frac{d}{dx}\ln x = 1/x$ (a second proof).

Worked Example 4.14 — Inverse of a device characteristic

A nonlinear sensor has output $y = f(x) = x^3 + x$ (in normalized units). It is used "in reverse": the measured y is converted to $x = f^{-1}(y)$. How sensitive is the recovered x to errors in y when $y = 2$?

$f(1) = 2$, so $f^{-1}(2) = 1$. $f'(x) = 3x^2 + 1$, so $f'(1) = 4$. Hence $(f^{-1})'(2) = 1/4$: an error of 0.01 in y produces an error of only about 0.0025 in x.

Check. Solve $x^3 + x = 2.01$ numerically: $x = 1.0024953$; the change is $0.0024953 \approx 0.01/4$. ✓

We never needed a formula for f^{-1}, which would require solving a cubic.

Parametric curves

If a curve is given as $x = x(t)$, $y = y(t)$ (a phasor tip, a Lissajous figure on an oscilloscope, a trajectory in a phase plane), then wherever $dx/dt \neq 0$,

$$\frac{dy}{dx} = \frac{dy/dt}{dx/dt}.$$

This is the chain rule $\frac{dy}{dt} = \frac{dy}{dx}\frac{dx}{dt}$ solved for dy/dx. The second derivative needs one more application:

$$\frac{d^2y}{dx^2} = \frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{\frac{d}{dt}\left(\frac{dy}{dx}\right)}{dx/dt}.$$

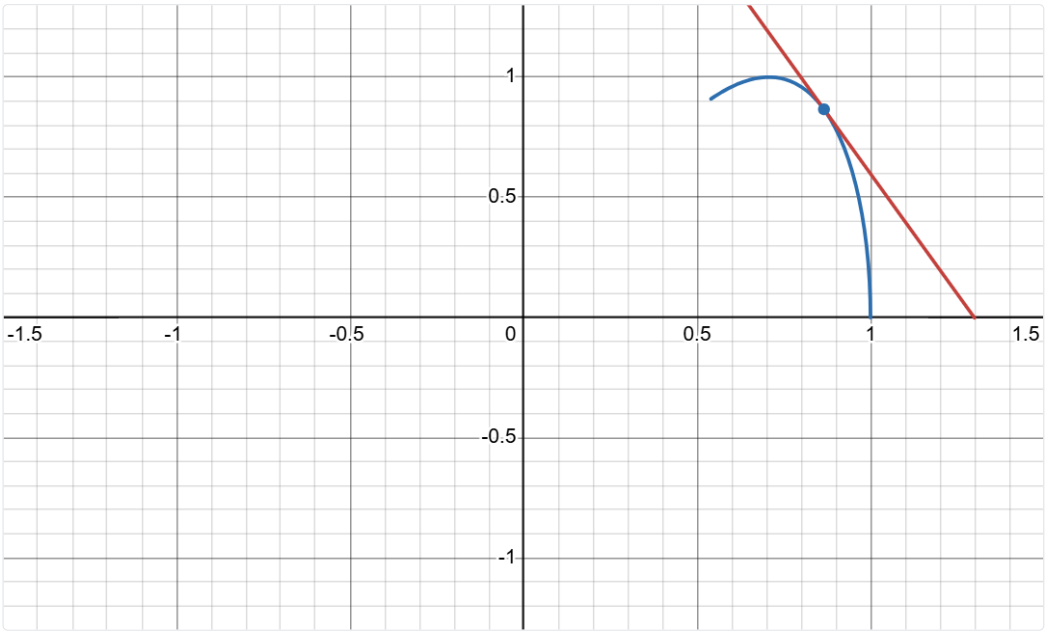
Worked Example 4.15 — Slope of a Lissajous figure

An oscilloscope in X–Y mode displays $x = \cos t$, $y = \sin 2t$. Find the slope of the trace at $t = \pi/6$ and the points where the tangent is horizontal or vertical.

$dx/dt = -\sin t$, $dy/dt = 2\cos 2t$. At $t = \pi/6$: $dx/dt = -\frac{1}{2}$, $dy/dt = 2\cdot\frac{1}{2} = 1$. Slope $= 1/(-\frac{1}{2}) = -2$, at the point $(\cos\frac{\pi}{6}, \sin\frac{\pi}{3}) = (0.866, 0.866)$.

Horizontal tangents need $dy/dt = 0$ with $dx/dt \neq 0$: $\cos 2t = 0 \Rightarrow t = \pi/4, 3\pi/4, \ldots$, giving $(\pm 0.707, \pm 1)$, the four peaks of the figure-eight.

Vertical tangents need $dx/dt = 0$ with $dy/dt \neq 0$: $t = 0, \pi$, where $dy/dt = 2$. The tangent is vertical at $(\pm 1, 0)$.



The Lissajous figure $x = \cos t$, $y = \sin 2t$ (a 1:2 frequency ratio) and its tangent at $t = \pi/6$.

Worked Example 4.16 — Small-signal conductance of a diode

The Shockley diode equation is $I = I_s\left(e^{V/(nV_T)} - 1\right)$. Find the incremental conductance $g_d = dI/dV$ and evaluate it at $I = 1\,\text{mA}$ with $nV_T = 26\,\text{mV}$.

Chain rule on $e^{V/(nV_T)}$ (inner derivative $1/(nV_T)$):

$$g_d = \frac{dI}{dV} = \frac{I_s}{nV_T} e^{V/(nV_T)} = \frac{I + I_s}{nV_T} \approx \frac{I}{nV_T}.$$

The last step uses $I_s \ll I$ (typically $I_s \sim 10^{-14}$ A). Note that g_d depends only on the bias current, not on I_s: a universal result.

Numbers. $g_d = 10^{-3}/0.026 = 38.5\,\text{mS}$, so the small-signal resistance is $r_d = 1/g_d = 26\,\Omega$.

If the voltage varies in time, the chain rule again gives $\dfrac{dI}{dt} = g_d \dfrac{dV}{dt}$: the diode responds to small, slow changes like a resistor r_d. We turn this into a full linear model in §4.8.

Worked Example 4.17 — Rate of change of an impedance magnitude

A series RLC circuit has $|Z(\omega)| = \sqrt{R^2 + X^2}$ with reactance $X(\omega) = \omega L - \dfrac{1}{\omega C}$. Find $d|Z|/d\omega$ and show that $|Z|$ has a stationary point at resonance.

Outer function $\sqrt{\cdot}$, inner function $R^2 + X^2$, and X itself depends on ω:

$$\frac{d|Z|}{d\omega} = \frac{1}{2\sqrt{R^2 + X^2}} \cdot 2X \frac{dX}{d\omega} = \frac{X}{|Z|}\left(L + \frac{1}{\omega^2 C}\right).$$

The bracket is always positive, so the sign of $d|Z|/d\omega$ is the sign of X. At resonance $\omega_0 = 1/\sqrt{LC}$, $X = 0$, so $d|Z|/d\omega = 0$: $|Z|$ has its minimum value R there.

Numbers. $R = 10\,\Omega$, $L = 1\,\text{mH}$, $C = 1\,\mu\text{F}$: $\omega_0 = 31\,623\,\text{rad/s}$. At $\omega = 1.1\omega_0$: $X = 34.785 - 28.748 = 6.037\,\Omega$, $|Z| = 11.68\,\Omega$, and $d|Z|/d\omega = (6.037/11.68)(10^{-3} + 0.826 \times 10^{-3}) = 9.44 \times 10^{-4}\,\Omega\,\text{s/rad}$.

Common Pitfall — forgetting the inner derivative, and degrees

$\frac{d}{dx}\sin(x^2) = 2x\cos(x^2)$, not $\cos(x^2)$ and not $\cos(2x)$. Every layer of a composition contributes a factor. A subtler instance: $\frac{d}{dx}\sin(x^\circ)$, with x in degrees, is $\frac{\pi}{180}\cos(x^\circ)$, because $x^\circ = \pi x/180$ radians. Calculators set to degrees silently break every derivative formula in this chapter.

4.4 Implicit differentiation

Motivation

Many relations in engineering cannot be solved explicitly for the quantity of interest. The current in a resistor–diode circuit satisfies

$$V_s = IR + nV_T \ln\!\left(1 + \frac{I}{I_s}\right),$$

which has no closed-form solution for I in elementary functions. Yet we still want dI/dV_s: how much the current moves when the supply moves. Implicit differentiation finds derivatives directly from an equation $F(x, y) = 0$ without solving it.

Method

Treat y as an (unknown) differentiable function of x, differentiate **both sides** of the equation with respect to x, applying the chain rule to every term containing y (so $\frac{d}{dx}y^2 = 2y\,y'$, $\frac{d}{dx}\sin y = \cos y\,y'$, $\frac{d}{dx}(xy) = y + xy'$), then solve the resulting linear equation for y'.

The result is always linear in y', because the chain rule produces exactly one factor y' per occurrence of y.

Worked Example 4.18 — A circle

Find dy/dx and d^2y/dx^2 on $x^2 + y^2 = r^2$.

First derivative. $2x + 2y\,y' = 0 \Rightarrow y' = -x/y$ (valid where $y \neq 0$). At $(r/\sqrt{2}, r/\sqrt{2})$ the slope is -1. The tangent is perpendicular to the radius, whose slope is y/x; the product of slopes is -1. ✓

Second derivative. Differentiate $y' = -x/y$ by the quotient rule, then substitute for y':

$$y'' = -\frac{y - xy'}{y^2} = -\frac{y + x^2/y}{y^2} = -\frac{x^2 + y^2}{y^3} = -\frac{r^2}{y^3}.$$

On the upper half ($y > 0$) the circle is concave down ($y'' < 0$), as it should be.

Check against the explicit form $y = \sqrt{r^2 - x^2}$: $y' = -x/\sqrt{r^2 - x^2} = -x/y$. ✓

Worked Example 4.19 — Tangent to the folium of Descartes

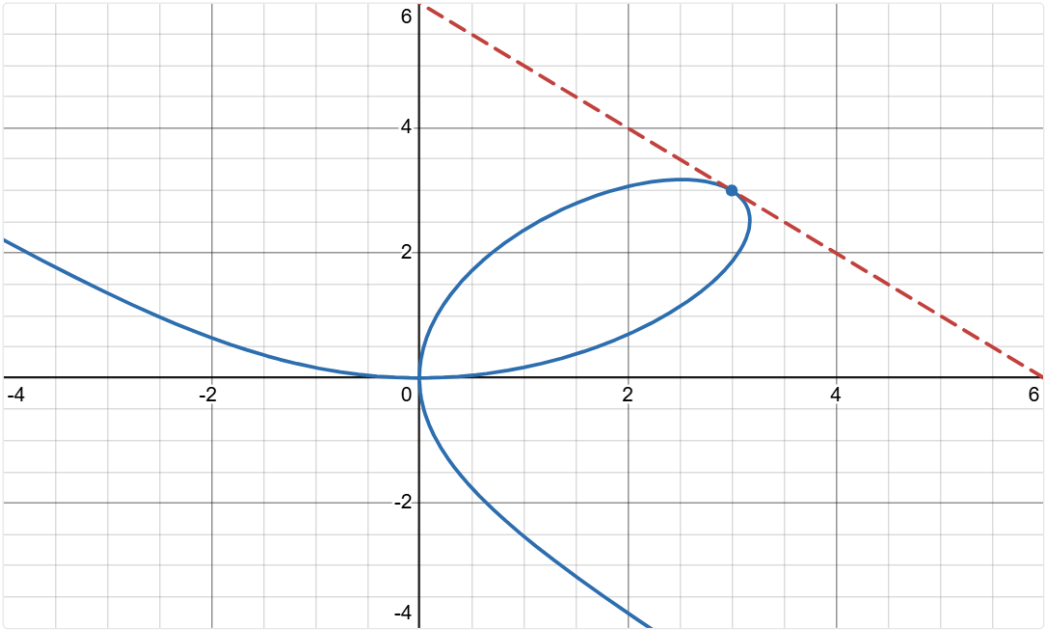
Find the tangent line to $x^3 + y^3 = 6xy$ at $(3, 3)$.

First check the point: $27 + 27 = 54 = 6 \cdot 9$. ✓ Differentiate:

$$3x^2 + 3y^2 y' = 6y + 6xy' \quad\Longrightarrow\quad y'(3y^2 - 6x) = 6y - 3x^2 \quad\Longrightarrow\quad y' = \frac{2y - x^2}{y^2 - 2x}.$$

At $(3, 3)$: $y' = (6 - 9)/(9 - 6) = -1$. Tangent: $y - 3 = -(x - 3)$, i.e. $y = 6 - x$.

Where is y' undefined? Where $y^2 = 2x$. Combined with the curve equation this gives the origin and the point $(2^{5/3}, 2^{4/3}) \approx (3.17, 2.52)$, where the tangent is vertical.



The folium of Descartes $x^3 + y^3 = 6xy$ is not the graph of a single function $y(x)$, yet implicit differentiation gives its slope at every regular point; the tangent at $(3, 3)$ is $y = 6 - x$.

The general formula and when it is valid

For a relation $F(x, y) = 0$, differentiating with respect to x (using the multivariable chain rule of §4.5) gives $F_x + F_y\,y' = 0$, so

$$\frac{dy}{dx} = -\frac{F_x}{F_y} = -\frac{\partial F/\partial x}{\partial F/\partial y} \qquad (F_y \neq 0).$$

Implicit function theorem (one-variable form, stated)

If F has continuous partial derivatives near (a, b), $F(a, b) = 0$ and $F_y(a, b) \neq 0$, then near $x = a$ the equation $F(x, y) = 0$ defines a unique differentiable function $y = y(x)$ with $y(a) = b$, and $y' = -F_x/F_y$.

The condition $F_y \neq 0$ matters. At points where $F_y = 0$ (the leftmost and rightmost points of a circle, the self-intersection of the folium at the origin), the curve may have a vertical tangent, a branch point, or may not be a function of x at all. Ch. 6 proves the theorem and extends it to systems of equations via the Jacobian.

Worked Example 4.20 — Resistor–diode circuit

A source V_s drives a resistor $R = 1\,\text{k}\Omega$ in series with a diode ($nV_T = 26\,\text{mV}$, $I_s = 10^{-14}\,\text{A}$). KVL gives

$$V_s = IR + nV_T \ln\left(1 + \frac{I}{I_s}\right).$$

Find dI/dV_s at the operating point $I = 1\,\text{mA}$.

Differentiate both sides with respect to V_s, treating $I = I(V_s)$:

$$1 = R\frac{dI}{dV_s} + nV_T \cdot \frac{1/I_s}{1 + I/I_s}\frac{dI}{dV_s} = \left(R + \frac{nV_T}{I_s + I}\right)\frac{dI}{dV_s}.$$

Hence

$$\frac{dI}{dV_s} = \frac{1}{R + r_d}, \qquad r_d = \frac{nV_T}{I + I_s} \approx \frac{nV_T}{I}.$$

Numbers. $r_d = 0.026/10^{-3} = 26\,\Omega$, so $dI/dV_s = 1/1026\,\Omega = 0.975\,\text{mS}$. A 10 mV ripple on the supply produces about $9.75\,\mu\text{A}$ of current ripple.

Interpretation. The diode behaves, for small changes, like a $26\,\Omega$ resistor in series with R: exactly the small-signal model of Example 4.16, obtained here without ever solving the nonlinear equation.

Numerical check. Solving the KVL equation numerically at $V_s \pm 1\,\text{mV}$ around the operating point and forming the central difference gives $0.9747\,\text{mS}$. ✓

Worked Example 4.21 — Horizontal tangents of an ellipse

The rotated ellipse $x^2 + xy + y^2 = 7$ passes through $(1, 2)$. Find the slope there and the points with horizontal tangents.

Differentiate: $2x + (y + xy') + 2yy' = 0 \Rightarrow y' = -\dfrac{2x + y}{x + 2y}$. At $(1, 2)$: $y' = -4/5$.

Horizontal tangents: $2x + y = 0$, i.e. $y = -2x$. Substitute: $x^2 - 2x^2 + 4x^2 = 3x^2 = 7$, so $x = \pm\sqrt{7/3} = \pm 1.528$, $y = \mp 3.055$. The ellipse's highest point is $(-1.528, 3.055)$ and its lowest $(1.528, -3.055)$.

Check. $1.528^2 + 1.528 \cdot (-3.055) + 3.055^2 = 2.333 - 4.667 + 9.333 = 7.000$. ✓

Engineering Note — implicit relations are everywhere in circuits

Any circuit containing a nonlinear element, solved by nodal analysis, produces an implicit equation (or system of equations) for the node voltages. Circuit simulators such as SPICE do not solve these explicitly. They linearize them (§4.8) and iterate with Newton's method, and the derivatives they need are exactly the implicit derivatives of this section, assembled into a Jacobian matrix (Ch. 6, Ch. 22).

Common Pitfall — differentiating y as if it were constant

When differentiating implicitly with respect to x, $\frac{d}{dx}(y^3)$ is $3y^2y'$, not $3y^2$ and not 0. Likewise, $\frac{d}{dx}(xy)$ needs the product rule: $y + xy'$. Forgetting the y' factor is the most common error in this topic and always produces an equation that cannot be solved for y' correctly.

4.5 Partial derivatives

Motivation

Engineering quantities rarely depend on one variable. The power dissipated in a resistor, $P = V^2/R$, depends on both voltage and resistance. The cutoff frequency of an RC filter, $f_c = 1/(2\pi RC)$, depends on two components. A potential $\varphi(x, y, z)$ depends on three coordinates, and a travelling wave $u(x, t)$ on position and time. To ask "how does P change if only R drifts?" we hold the other variables fixed and differentiate with respect to one. That is a partial derivative. This section is an introduction, enough for the rest of this chapter (implicit differentiation, linearization in several variables, sensitivity analysis). Ch. 6 develops multivariable calculus fully: total differentials, gradients, directional derivatives, Jacobians and differentiability.

Definition

Partial derivative

Let $f(x, y)$ be defined near (a, b). The **partial derivatives** of f at (a, b) are

$$\frac{\partial f}{\partial x}(a, b) = \lim_{h \to 0} \frac{f(a + h, b) - f(a, b)}{h}, \qquad \frac{\partial f}{\partial y}(a, b) = \lim_{h \to 0} \frac{f(a, b + h) - f(a, b)}{h},$$

when the limits exist. Other notations: f_x, $\partial_x f$, $D_1 f$; and $\left(\dfrac{\partial f}{\partial x}\right)_y$ when it is important to say which variable is held fixed. The definition extends to any number of variables: vary one, freeze all the others.

The symbol ∂ ("partial", "del", or "dee") distinguishes a partial derivative from an ordinary one. Computing $\partial f/\partial x$ needs no new rules: treat every other variable as a constant and use the one-variable rules of §4.2–4.3.

Geometric meaning. The graph of $f(x,y)$ is a surface $z = f(x,y)$. Freezing $y = b$ slices the surface with the vertical plane $y = b$, leaving a curve $z = f(x,b)$. Then $f_x(a,b)$ is the slope of that curve at $x = a$: the slope of the surface in the x-direction. Similarly, f_y is the slope in the y-direction. A topographic analogy: f_x is how steeply the ground rises as you walk due east, f_y as you walk due north.

Worked Example 4.22 — Computing partial derivatives

Find f_x and f_y for (a) $f = x^2y^3 + \sin(xy)$, (b) $f = e^{-x}\cos(3y)$, (c) $f = \sqrt{x^2+y^2}$.

(a) Holding y fixed, x^2y^3 is (y^3 times) x^2, and $\sin(xy)$ needs the chain rule with inner derivative $\partial(xy)/\partial x = y$:

$$f_x = 2xy^3 + y\cos(xy), \qquad f_y = 3x^2y^2 + x\cos(xy).$$

(b) $f_x = -e^{-x}\cos 3y$, $f_y = -3e^{-x}\sin 3y$.

(c) With $r = \sqrt{x^2+y^2}$: $f_x = \dfrac{x}{\sqrt{x^2+y^2}} = \dfrac{x}{r}$, $f_y = \dfrac{y}{r}$ (for $r \neq 0$). At $(3,4)$: $f_x = 0.6$, $f_y = 0.8$. These are the direction cosines of the point: the distance from the origin grows fastest in the radial direction.

Worked Example 4.23 — Partial derivatives of circuit formulas

(a) For $P = V^2/R$: $\dfrac{\partial P}{\partial V} = \dfrac{2V}{R}$ (units W/V = A) and $\dfrac{\partial P}{\partial R} = -\dfrac{V^2}{R^2}$ (W/Ω). At $V = 12\,\text{V}$, $R = 6\,\Omega$: $\partial P/\partial V = 4\,\text{A}$ and $\partial P/\partial R = -4\,\text{W}/\Omega$.

(b) Two resistors in parallel, $R_p = \dfrac{R_1R_2}{R_1+R_2}$. By the quotient rule with R_2 constant:

$$\frac{\partial R_p}{\partial R_1} = \frac{R_2(R_1+R_2) - R_1R_2}{(R_1+R_2)^2} = \frac{R_2^2}{(R_1+R_2)^2}, \qquad \frac{\partial R_p}{\partial R_2} = \frac{R_1^2}{(R_1+R_2)^2}.$$

With $R_1 = 1\,\text{k}\Omega$, $R_2 = 4\,\text{k}\Omega$ ($R_p = 800\,\Omega$): $\partial R_p/\partial R_1 = 16/25 = 0.64$ and $\partial R_p/\partial R_2 = 1/25 = 0.04$. The parallel combination is dominated by the smaller resistor; a $10\,\Omega$ change in R_1 moves R_p by about $6.4\,\Omega$, the same change in R_2 by only $0.4\,\Omega$.

Check. $R_1 = 1010$: $R_p = 1010 \cdot 4000/5010 = 806.39\,\Omega$, an increase of $6.39\,\Omega$. ✓

The first-order change: a preview of the total differential

If both V and R change a little, the change in P is approximately the sum of the separate effects:

$$\Delta P \approx \frac{\partial P}{\partial V}\Delta V + \frac{\partial P}{\partial R}\Delta R.$$

Why. Change V first and then R:

$$\Delta P = \big[P(V+\Delta V, R+\Delta R) - P(V, R+\Delta R)\big] + \big[P(V, R+\Delta R) - P(V,R)\big].$$

By the mean value theorem, each bracket is a one-variable derivative times the step, evaluated at an intermediate point. If the partials are continuous, the intermediate points can be replaced by (V,R) at the cost of an error that is small compared with $|\Delta V| + |\Delta R|$.

With $V = 12\,\text{V}$, $R = 6\,\Omega$, $\Delta V = +0.2\,\text{V}$ and $\Delta R = -0.1\,\Omega$: $\Delta P \approx 4(0.2) + (-4)(-0.1) = 1.2\,\text{W}$. The exact change is $12.2^2/5.9 - 24 = 1.227\,\text{W}$. The small discrepancy comes from second-order terms. The expression $df = f_x\,dx + f_y\,dy$ is the **total differential**; it underlies linearization (§4.8) and sensitivity analysis (§4.11), and is studied properly in Ch. 6.

The chain rule for several variables

If $z = f(x,y)$ and both $x = x(t)$ and $y = y(t)$ depend on t, dividing the first-order change by Δt and letting $\Delta t \to 0$ gives

$$\frac{dz}{dt} = \frac{\partial f}{\partial x}\frac{dx}{dt} + \frac{\partial f}{\partial y}\frac{dy}{dt}.$$

Each path from t to z contributes a product of derivatives, and the contributions add. Applied to $F(x, y(x)) = 0$ with $t = x$, this gives $F_x + F_y\,y' = 0$, the implicit-differentiation formula of §4.4.

Worked Example 4.24 — A heating resistor on a drifting supply

A resistor is fed from a supply whose voltage is rising at $dV/dt = 0.1\,\text{V/s}$ while the resistor heats and its resistance rises at $dR/dt = 0.02\,\Omega/\text{s}$. At the instant when $V = 12\,\text{V}$ and $R = 6\,\Omega$, how fast is the dissipated power changing?

$$\frac{dP}{dt} = \frac{\partial P}{\partial V}\frac{dV}{dt} + \frac{\partial P}{\partial R}\frac{dR}{dt} = \frac{2V}{R}(0.1) - \frac{V^2}{R^2}(0.02) = 4(0.1) - 4(0.02) = 0.32\ \text{W/s}.$$

The voltage rise increases the power by $0.40\,\text{W/s}$; the resistance rise reduces it by $0.08\,\text{W/s}$.

Units. A·(V/s) = W/s and (W/Ω)(Ω/s) = W/s. ✓

Higher partial derivatives and Clairaut's theorem

Partial derivatives can be differentiated again. With two variables there are four second partials:

$$f_{xx} = \frac{\partial^2 f}{\partial x^2}, \qquad f_{yy} = \frac{\partial^2 f}{\partial y^2}, \qquad f_{xy} = \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right) = \frac{\partial^2 f}{\partial y\,\partial x}, \qquad f_{yx} = \frac{\partial^2 f}{\partial x\,\partial y}.$$

Clairaut's (Schwarz's) theorem

If f_{xy} and f_{yx} are both continuous near (a,b), then $f_{xy}(a,b) = f_{yx}(a,b)$. The order of differentiation does not matter.

For the function of Example 4.22(a): $f_{xy} = \partial_y\big(2xy^3 + y\cos(xy)\big) = 6xy^2 + \cos(xy) - xy\sin(xy)$, and $f_{yx} = \partial_x\big(3x^2y^2 + x\cos(xy)\big) = 6xy^2 + \cos(xy) - xy\sin(xy)$. They agree.

Clairaut's theorem is behind several facts in field theory. For example, the curl of a gradient vanishes, $\nabla \times \nabla\varphi = \mathbf{0}$, because each component is a difference of equal mixed partials (Ch. 7).

Worked Example 4.25 — Checking that a function solves a PDE

(a) Show that $\varphi = \ln(x^2 + y^2)$ satisfies Laplace's equation $\varphi_{xx} + \varphi_{yy} = 0$ for $(x,y) \neq (0,0)$.

$\varphi_x = \dfrac{2x}{x^2+y^2}$. Quotient rule: $\varphi_{xx} = \dfrac{2(x^2+y^2) - 2x\cdot 2x}{(x^2+y^2)^2} = \dfrac{2(y^2-x^2)}{(x^2+y^2)^2}$. By the symmetry $x \leftrightarrow y$, $\varphi_{yy} = \dfrac{2(x^2-y^2)}{(x^2+y^2)^2}$. The sum is 0. ✓ (Up to a constant factor this is the potential of an infinite line charge.)

(b) Show that $u(x,t) = \sin(x - ct)$ satisfies the wave equation $u_{tt} = c^2 u_{xx}$.

$u_x = \cos(x-ct)$, $u_{xx} = -\sin(x-ct)$; $u_t = -c\cos(x-ct)$, $u_{tt} = -c^2\sin(x-ct)$. So $u_{tt} = c^2 u_{xx}$. ✓ The same holds for *any* twice-differentiable $g(x-ct)$, by the chain rule: a waveform travelling at speed c.

(c) Show that $u = e^{-\alpha k^2 t}\sin(kx)$ satisfies the heat (diffusion) equation $u_t = \alpha u_{xx}$.

$u_t = -\alpha k^2 e^{-\alpha k^2 t}\sin kx$ and $u_{xx} = -k^2 e^{-\alpha k^2 t}\sin kx$, so $u_t = \alpha u_{xx}$. ✓ High spatial frequencies (k large) decay fastest, as $e^{-\alpha k^2 t}$.

These checks are the starting point for Ch. 13.

Engineering Note — fields from potentials

The electric field is the negative gradient of the potential: $E_x = -\partial\varphi/\partial x$, $E_y = -\partial\varphi/\partial y$, $E_z = -\partial\varphi/\partial z$. For a point charge, $\varphi = \dfrac{q}{4\pi\varepsilon_0}(x^2+y^2+z^2)^{-1/2}$, and the chain rule gives $E_x = \dfrac{q}{4\pi\varepsilon_0}\dfrac{x}{R^3}$ with $R = \sqrt{x^2+y^2+z^2}$, and similarly for E_y, E_z. Together these give the familiar inverse-square law $|\mathbf{E}| = q/(4\pi\varepsilon_0 R^2)$, pointing radially. Partial derivatives turn one scalar function into the three components of a vector field.

Common Pitfall — partial derivatives existing is not enough

In one variable, differentiable implies continuous. In two variables, the mere existence of f_x and f_y does **not** imply continuity. The function $f(x,y) = \dfrac{xy}{x^2+y^2}$ (with $f(0,0) = 0$) has $f_x(0,0) = f_y(0,0) = 0$, because f is identically zero on both axes. Yet along the line $y = x$, $f = \tfrac{1}{2}$ everywhere except the origin, so f is not continuous at $(0,0)$. The proper notion of differentiability in several variables, and the condition (continuous partials) that guarantees it, is in Ch. 6. Also be explicit about which variables are held fixed: in thermodynamics and device physics, $(\partial f/\partial x)_y$ and $(\partial f/\partial x)_z$ are different quantities.

4.6 Higher-order derivatives

Definitions and meaning

The derivative f' is itself a function and can be differentiated again. The **second derivative** is $f'' = (f')'$, written $\dfrac{d^2 f}{dx^2}$ or $\ddot{f}$ for time derivatives; the **n-th derivative** is $f^{(n)} = \dfrac{d^n f}{dx^n}$.

Physically, if $x(t)$ is position, $\dot{x}$ is velocity, $\ddot{x}$ acceleration and $\dddot{x}$ jerk. In circuits, if $q(t)$ is the charge on a capacitor, $\dot{q} = i$ is current and $\ddot{q} = di/dt$ determines the inductor voltage $L\ddot{q}$. The series RLC equation

$$L\ddot{q} + R\dot{q} + \frac{1}{C}q = v_s(t)$$

is a statement about the zeroth, first and second derivatives of one function. Every ODE of Ch. 11 and Ch. 12 is such a statement.

Geometrically, f'' measures how the slope changes: **concavity**.

Concavity and inflection points

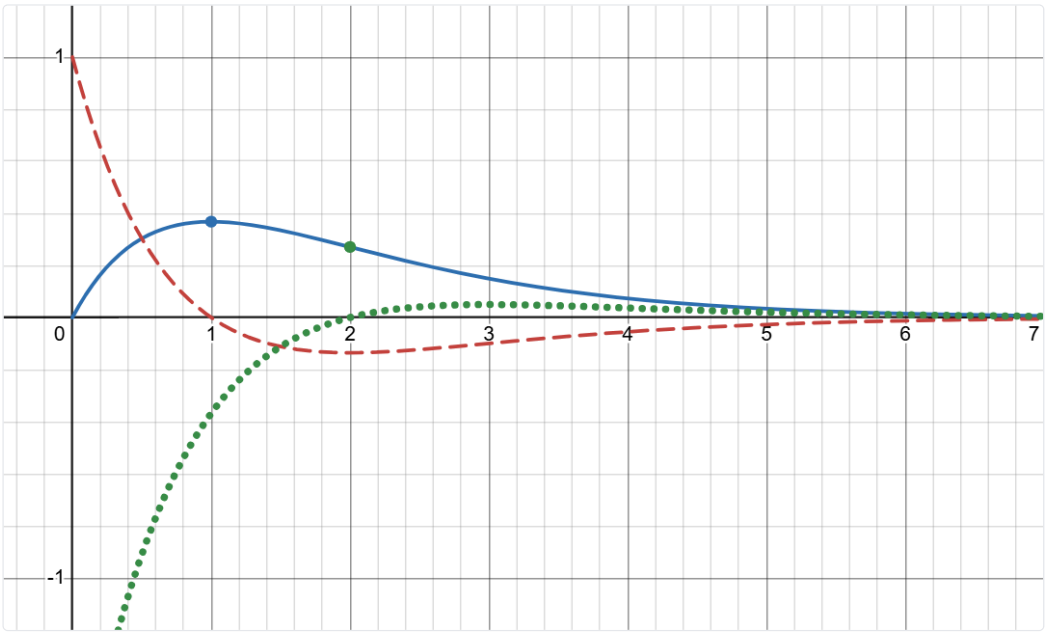
On an interval where $f'' > 0$, the slope f' is increasing and the graph is **concave up** (it lies above its tangent lines). Where $f'' < 0$, the graph is **concave down**. A point where f is continuous and the concavity changes is an **inflection point**; there $f'' = 0$ or f'' fails to exist.

Worked Example 4.26 — Shape of te^{-t}

The pulse $f(t) = te^{-t}$ (the critically damped response of Example 4.11 with $b = 1$) appears constantly in circuit transients. Find f', f'', the peak and the inflection point.

$$f' = (1 - t)e^{-t}, \qquad f'' = -e^{-t} - (1 - t)e^{-t} = (t - 2)e^{-t}.$$

- $f' = 0$ at $t = 1$; $f''(1) = -e^{-1} < 0$, so this is a maximum, $f(1) = 1/e = 0.368$.
- $f'' = 0$ at $t = 2$ and changes sign there (from $-$ to $+$), so $t = 2$ is an inflection point, with $f(2) = 2e^{-2} = 0.271$. After $t = 2$ the pulse is concave up and decays towards zero.
- At the inflection point $f'(2) = -e^{-2} = -0.135$: the pulse is falling fastest there.



The pulse te^{-t} (blue), its first derivative (red, dashed; zero at the peak) and its second derivative (green, dotted; zero at the inflection point, where the decay is steepest).

Patterns for n-th derivatives

$f(x)$	$f^{(n)}(x)$
x^m (m a positive integer)	$\dfrac{m!}{(m-n)!}x^{m-n}$ for $n \le m$; 0 for $n > m$
e^{ax}	$a^n e^{ax}$
$\sin(ax)$	$a^n \sin\left(ax + \dfrac{n\pi}{2}\right)$
$\cos(ax)$	$a^n \cos\left(ax + \dfrac{n\pi}{2}\right)$
$\dfrac{1}{1-x}$	$\dfrac{n!}{(1-x)^{n+1}}$
$\ln x$	$(-1)^{n-1}\dfrac{(n-1)!}{x^n}$ $(n \ge 1)$

Each row is proved by induction: compute the first few derivatives, guess the pattern, and check that differentiating the n-th gives the $(n+1)$-th. For example, $\frac{d}{dx}\, n!(1-x)^{-(n+1)} = n!(n+1)(1-x)^{-(n+2)} = (n+1)!(1-x)^{-(n+2)}$. The sine row says that each differentiation multiplies by a and shifts the phase by $90°$, the same fact as $(j\omega)^n$ in phasor form.

Leibniz's rule for products

General Leibniz rule

If f and g are n times differentiable,

$$(fg)^{(n)} = \sum_{k=0}^{n} \binom{n}{k} f^{(k)} g^{(n-k)}.$$

Proof sketch. For $n = 1$ this is the product rule. Assume it for n and differentiate each term with the product rule; the coefficients combine by Pascal's identity $\binom{n}{k} + \binom{n}{k-1} = \binom{n+1}{k}$, exactly as in the proof of the binomial theorem. The rule is the binomial theorem with powers replaced by derivatives.

Worked Example 4.27 — n-th derivative of $x^2 e^{2x}$

With $f = x^2$ (only f, f', f'' nonzero: $x^2, 2x, 2$) and $g = e^{2x}$ ($g^{(m)} = 2^m e^{2x}$), only three terms of Leibniz's rule survive:

$$\frac{d^n}{dx^n}\left(x^2 e^{2x}\right) = x^2\, 2^n e^{2x} + n\,(2x)\, 2^{n-1} e^{2x} + \binom{n}{2} 2 \cdot 2^{n-2} e^{2x} = 2^{n-2} e^{2x}\left(4x^2 + 4nx + n(n-1)\right).$$

Checks. $n = 1$: $2^{-1} e^{2x}(4x^2 + 4x) = e^{2x}(2x^2 + 2x)$, which matches the product rule. $n = 3$: $2e^{2x}(4x^2 + 12x + 6) = e^{2x}(8x^2 + 24x + 12)$, which matches direct differentiation (verified symbolically for $n = 1, \dots, 5$). ✓

Worked Example 4.28 — Verifying a circuit response

Show that $q(t) = e^{-t} \sin 2t$ satisfies $\ddot{q} + 2\dot{q} + 5q = 0$, the source-free equation of a series RLC circuit with (normalized) $L = 1$, $R = 2$, $1/C = 5$.

$$\dot{q} = e^{-t}(-\sin 2t + 2\cos 2t),$$
$$\ddot{q} = e^{-t}\big(\sin 2t - 2\cos 2t\big) + e^{-t}\big(-2\cos 2t - 4\sin 2t\big) = e^{-t}(-3\sin 2t - 4\cos 2t).$$

Then

$$\ddot{q} + 2\dot{q} + 5q = e^{-t}\big[(-3 - 2 + 5)\sin 2t + (-4 + 4 + 0)\cos 2t\big] = 0. \checkmark$$

The faster route uses complex exponentials: $q = \operatorname{Im}\{e^{st}\}$ with $s = -1 + 2j$, and each derivative multiplies by s, so the equation becomes $s^2 + 2s + 5 = 0$. Indeed $(-1 + 2j)^2 + 2(-1 + 2j) + 5 = (1 - 4j - 4) + (-2 + 4j) + 5 = 0$. Turning derivatives into powers of s is the central idea of Ch. 12 and Ch. 14.

Smoothness classes

A function is of class C^k on an interval if its first k derivatives exist and are continuous there; C^∞ means all derivatives exist (polynomials, e^x, $\sin x$). The hierarchy is strict:

- $|x|$ is C^0 but not differentiable at 0;
- $x|x|$ has derivative $2|x|$, so it is C^1 but not C^2;
- $x^2|x|$ is C^2 but not C^3.

Smoothness matters in practice: a waveform whose k-th derivative jumps has a Fourier spectrum that decays like $1/\omega^{k+1}$ (Ch. 15). A square wave (a jump in the function itself) has harmonics falling as $1/n$; a triangle wave (a jump in the first derivative) as $1/n^2$. Smoother edges mean less high-frequency interference, which is why digital edge rates are deliberately controlled.

Curvature

The second derivative alone does not measure how sharply a curve bends, because it depends on how steep the curve is. The **curvature** of $y = f(x)$ is

$$\kappa = \frac{|f''(x)|}{\left(1 + f'(x)^2\right)^{3/2}},$$

and the radius of curvature is $1/\kappa$. For $y = x^2$ at the origin, $\kappa = 2$, so the best-fitting circle there has radius $\tfrac{1}{2}$. For a circle of radius r, Example 4.18 gave $y'' = -r^2/y^3$ and $y' = -x/y$, so $\kappa = \dfrac{r^2/|y|^3}{(1 + x^2/y^2)^{3/2}} = \dfrac{r^2/|y|^3}{r^3/|y|^3} = \dfrac{1}{r}$, as it must be.

Engineering Note — second derivatives in measurement

The second derivative is a sensitive detector of features that are hard to see in the raw data: the "knee" of a diode or MOSFET characteristic, the onset of saturation in a magnetic core, or a peak position in a spectrum. Numerically, it is estimated by the central second difference

$$f''(x) \approx \frac{f(x + h) - 2f(x) + f(x - h)}{h^2},$$

whose error is $O(h^2)$ (derived from Taylor series in §4.7). Because of the h^2 in the denominator, noise of size σ in f produces an error of order σ/h^2 in f'': second derivatives of measured data must be heavily smoothed.

Common Pitfall — $f''(c) = 0$ does not guarantee an inflection point

For $f = x^4$, $f''(0) = 0$, but $f'' = 12x^2 \geq 0$ on both sides: no change of concavity, so no inflection point ($x = 0$ is in fact a minimum). Always check that f'' changes sign. Also note that $\dfrac{d^2y}{dx^2} \neq \left(\dfrac{dy}{dx}\right)^2$ and, for parametric curves, $\dfrac{d^2y}{dx^2} \neq \dfrac{d^2y/dt^2}{d^2x/dt^2}$ (use the formula in §4.3).

4.7 Taylor and Maclaurin series

Motivation

Polynomials are the only functions a processor can evaluate directly: they need nothing but additions and multiplications. Taylor's idea is to replace a complicated function, near a chosen point, by the polynomial that matches its value and as many derivatives as we like. This single idea gives:

- the small-signal models of diodes and transistors (keep the linear term),
- harmonic-distortion estimates (keep the quadratic and cubic terms),
- the approximations $\sin\theta \approx \theta$, $\cos\theta \approx 1 - \theta^2/2$, $(1 + x)^n \approx 1 + nx$ used throughout engineering,

- how calculators and DSP libraries compute e^x, $\sin x$ and $\ln x$,
- the error analysis of every numerical method in Ch. 22,
- a proof of Euler's formula $e^{j\theta} = \cos\theta + j\sin\theta$.

Building the Taylor polynomial

We look for a polynomial $p_n(x) = c_0 + c_1(x-a) + c_2(x-a)^2 + \cdots + c_n(x-a)^n$ with $p_n^{(k)}(a) = f^{(k)}(a)$ for $k = 0, 1, \dots, n$. Differentiating p_n k times kills all terms of degree below k and turns $c_k(x-a)^k$ into $k!\,c_k$; the higher terms still contain a factor $(x-a)$ and vanish at $x = a$. So $p_n^{(k)}(a) = k!\,c_k$, and matching gives $c_k = f^{(k)}(a)/k!$.

Taylor polynomial and series

The **Taylor polynomial of degree** n of f about $x = a$ is

$$p_n(x) = \sum_{k=0}^{n} \frac{f^{(k)}(a)}{k!}(x-a)^k = f(a) + f'(a)(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \cdots + \frac{f^{(n)}(a)}{n!}(x-a)^n.$$

Letting $n \to \infty$ gives the **Taylor series**. With $a = 0$ it is called a **Maclaurin series**.

The degree-1 polynomial $p_1(x) = f(a) + f'(a)(x-a)$ is the tangent line: the linearization of §4.8. Each further term corrects the curvature, then the rate of change of curvature, and so on.

Taylor's theorem: how big is the error?

Taylor's theorem with Lagrange remainder

If f has $n+1$ continuous derivatives on an interval containing a and x, then

$$f(x) = p_n(x) + R_n(x), \qquad R_n(x) = \frac{f^{(n+1)}(c)}{(n+1)!}(x-a)^{n+1}$$

for some c between a and x. Consequently, if $|f^{(n+1)}| \le M$ between a and x,

$$|R_n(x)| \le \frac{M\,|x-a|^{n+1}}{(n+1)!}.$$

Proof sketch. For $n = 0$ this is the mean value theorem: $f(x) = f(a) + f'(c)(x-a)$. For general n, fix x and choose the constant K so that $g(t) = f(t) - p_n(t) - K(t-a)^{n+1}$ vanishes at $t = x$. Then g and its first n derivatives vanish at $t = a$, and $g(x) = 0$ too. Rolle's theorem gives a zero of g' between a and x; applying Rolle repeatedly to $g', g'', \dots$ gives a point c with $g^{(n+1)}(c) = 0$, i.e. $f^{(n+1)}(c) = (n+1)!\,K$. Hence $R_n(x) = K(x-a)^{n+1}$ has the stated form. ∎

An equivalent integral form, $R_n(x) = \frac{1}{n!}\int_a^x f^{(n+1)}(t)(x-t)^n\,dt$, follows by repeated integration by parts (Ch. 5).

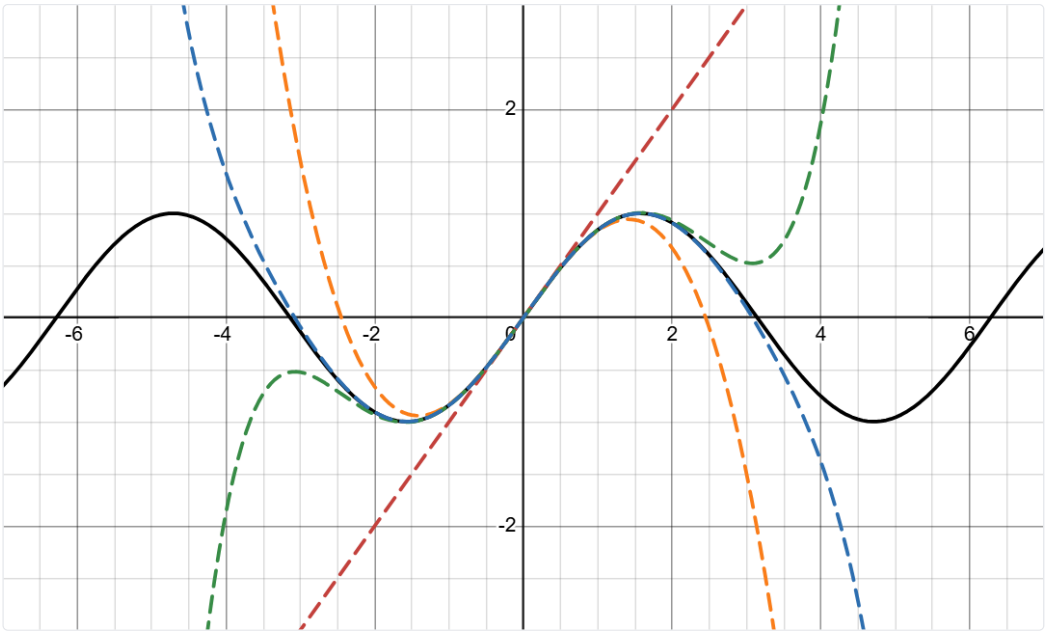
The remainder says two things. Near a, the error behaves like $|x-a|^{n+1}$: halving the distance cuts the error of a degree-n approximation by 2^{n+1}. Far from a, the factorial in the denominator usually wins in the end, but only if the derivatives do not grow faster.

The standard series

Computing derivatives at 0 gives the following Maclaurin series, valid in the stated ranges:

Function	Maclaurin series	Converges for
e^x	$1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots = \sum \frac{x^n}{n!}$	all x
$\sin x$	$x - \frac{x^3}{3!} + \frac{x^5}{5!} - \cdots$	all x
$\cos x$	$1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \cdots$	all x
$\sinh x$, $\cosh x$	as sin, cos but all signs $+$	all x
$\frac{1}{1-x}$	$1 + x + x^2 + x^3 + \cdots$	$\lvert x\rvert < 1$
$\ln(1+x)$	$x - \frac{x^2}{2} + \frac{x^3}{3} - \cdots$	$-1 < x \le 1$
$(1+x)^\alpha$	$1 + \alpha x + \frac{\alpha(\alpha-1)}{2!}x^2 + \frac{\alpha(\alpha-1)(\alpha-2)}{3!}x^3 + \cdots$	$\lvert x\rvert < 1$
$\arctan x$	$x - \frac{x^3}{3} + \frac{x^5}{5} - \cdots$	$\lvert x\rvert \le 1$
$\tan x$	$x + \frac{x^3}{3} + \frac{2x^5}{15} + \cdots$	$\lvert x\rvert < \pi/2$

Derivations. For e^x, every derivative at 0 is 1. For $\sin x$, the derivatives at 0 cycle $0, 1, 0, -1$, so only odd powers appear, with alternating signs. For $(1+x)^\alpha$, the k-th derivative at 0 is $\alpha(\alpha-1)\cdots(\alpha-k+1)$; when α is a positive integer the series terminates and is the binomial theorem. The $\ln(1+x)$ and $\arctan x$ series are obtained by integrating $1/(1+x) = 1 - x + x^2 - \cdots$ and $1/(1+x^2) = 1 - x^2 + x^4 - \cdots$ term by term.



Maclaurin polynomials of $\sin x$ of degree 1, 3, 5 and 7. Each added term extends the interval over which the polynomial hugs the curve; all of them fail eventually, since a polynomial is unbounded and $\sin x$ is not.

Radius of convergence

A power series $\sum c_n (x-a)^n$ converges for $|x-a| < \rho$ and diverges for $|x-a| > \rho$, where the **radius of convergence** ρ can often be found from the ratio test:

$$\rho = \lim_{n\to\infty} \left| \frac{c_n}{c_{n+1}} \right| \quad \text{(when this limit exists)}.$$

For e^x, $c_n = 1/n!$ and $c_n/c_{n+1} = n+1 \to \infty$: it converges everywhere. For $1/(1-x)$, $c_n = 1$ and $\rho = 1$. Inside the radius, a power series can be differentiated and integrated term by term, and the result has the same radius.

> **Engineering Note — why $1/(1+x^2)$ has radius 1**
>
> The function $1/(1+x^2)$ is perfectly smooth for every real x, yet its Maclaurin series $1 - x^2 + x^4 - \cdots$ diverges for $|x| > 1$. The reason is invisible on the real line: as a function of a complex variable, $1/(1+z^2)$ has poles at $z = \pm j$, a distance 1 from the origin. **The radius of convergence is the distance to the nearest singularity in the complex plane.** This is why the pole locations of a transfer function control how far a series expansion (a low-frequency approximation, say) can be trusted. The full story is in Ch. 18.

Euler's formula from series

Substitute $x = j\theta$ into the exponential series and separate even and odd powers, using $j^2 = -1$, $j^3 = -j$, $j^4 = 1$:

$$e^{j\theta} = 1 + j\theta - \frac{\theta^2}{2!} - j\frac{\theta^3}{3!} + \frac{\theta^4}{4!} + \cdots = \left(1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots\right) + j\left(\theta - \frac{\theta^3}{3!} + \cdots\right) = \cos\theta + j\sin\theta.$$

The rearrangement is legitimate because the exponential series converges absolutely for every complex argument.

> **Worked Example 4.29 — Computing with a remainder bound**
>
> (a) Estimate $e^{0.1}$ with the degree-3 Maclaurin polynomial and bound the error.
>
> $p_3(0.1) = 1 + 0.1 + 0.005 + 0.000166\overline{6} = 1.1051667$. The remainder is $R_3 = e^c (0.1)^4/4!$ with $0 < c < 0.1$, and $e^c < e^{0.1} < 1.2$, so $|R_3| < 1.2 \times 10^{-4}/24 = 5 \times 10^{-6}$.
>
> **Check.** $e^{0.1} = 1.1051709$; actual error $4.25 \times 10^{-6} < 5 \times 10^{-6}$. ✓
>
> (b) Estimate $\sin 0.5$ with p_5 and bound the error.
>
> $p_5(0.5) = 0.5 - 0.0208333 + 0.0002604 = 0.4794271$. Because the x^6 coefficient is zero, $p_5 = p_6$, so we may use the degree-6 remainder: $|R_6| \le |0.5|^7/7! = 1.550 \times 10^{-6}$ (all derivatives of sin are bounded by 1).
>
> **Check.** $\sin 0.5 = 0.4794255$; actual error 1.545×10^{-6}, just inside the bound. ✓

Manipulating series

Finding high derivatives is tedious. In practice series are built from the table by substitution, multiplication, division, differentiation and integration.

- **Substitution.** $e^{-x^2} = 1 - x^2 + \dfrac{x^4}{2!} - \dfrac{x^6}{3!} + \cdots$ (replace x by $-x^2$ in e^x). This is how the Gaussian error function is evaluated (Ch. 19).
- **Multiplication.** $e^x \sin x = \left(1 + x + \frac{x^2}{2} + \cdots\right)\left(x - \frac{x^3}{6} + \cdots\right) = x + x^2 + \frac{x^3}{3} + \cdots$.

- **Division.** For $\tan x = \sin x/\cos x$, write $\tan x = b_1 x + b_3 x^3 + b_5 x^5 + \cdots$ (odd function) and require $(b_1 x + b_3 x^3 + b_5 x^5)(1 - \frac{x^2}{2} + \frac{x^4}{24}) = x - \frac{x^3}{6} + \frac{x^5}{120}$. Matching powers: $b_1 = 1$; $b_3 - \frac{1}{2} = -\frac{1}{6} \Rightarrow b_3 = \frac{1}{3}$; $b_5 - \frac{b_3}{2} + \frac{1}{24} = \frac{1}{120} \Rightarrow b_5 = \frac{2}{15}$.
- **Limits.** Series settle indeterminate forms instantly: $\dfrac{x - \sin x}{x^3} = \dfrac{x^3/6 - x^5/120 + \cdots}{x^3} \to \dfrac{1}{6}$. (Three applications of L'Hôpital's rule give the same answer more slowly.)

Worked Example 4.30 — A Taylor series about a point other than 0

Expand $f(x) = \sqrt{x}$ about $a = 4$ to second order and use it to estimate $\sqrt{4.1}$.

$f = x^{1/2}$, $f' = \frac{1}{2}x^{-1/2}$, $f'' = -\frac{1}{4}x^{-3/2}$. At $x = 4$: $f = 2$, $f' = \frac{1}{4}$, $f'' = -\frac{1}{32}$. So

$$\sqrt{x} \approx 2 + \frac{x-4}{4} - \frac{(x-4)^2}{64}.$$

At $x = 4.1$: $2 + 0.025 - 0.00015625 = 2.02484375$.

Check. $\sqrt{4.1} = 2.02484567$; the error is 1.9×10^{-6}, consistent with the next term $f'''(4)(0.1)^3/6 = \frac{3}{8} \cdot 4^{-5/2} \cdot \frac{10^{-3}}{6} = 1.95 \times 10^{-6}$. ✓

Worked Example 4.31 — Harmonic distortion of an exponential device

A forward-biased diode (or a bipolar transistor) carries $i = I_Q e^{v/V_T}$, where v is the small signal added to the bias, $V_T = 26\,\text{mV}$. Let $v = V_m \cos \omega t$. Estimate the second-harmonic distortion HD_2 (amplitude of the 2ω component divided by that of the ω component) when $V_m = 2.6\,\text{mV}$.

Expand with $x = v/V_T = a\cos\omega t$, $a = V_m/V_T$:

$$\frac{i}{I_Q} = 1 + a\cos\omega t + \frac{a^2}{2}\cos^2\omega t + \frac{a^3}{6}\cos^3\omega t + \cdots$$

Use $\cos^2\theta = \frac{1}{2}(1 + \cos 2\theta)$ (Ch. 3):

$$\frac{i}{I_Q} \approx \underbrace{1 + \frac{a^2}{4}}_{\text{DC shift}} + \underbrace{a\cos\omega t}_{\text{fundamental}} + \underbrace{\frac{a^2}{4}\cos 2\omega t}_{\text{2nd harmonic}} + \cdots$$

So $\text{HD}_2 \approx \dfrac{a^2/4}{a} = \dfrac{a}{4} = \dfrac{V_m}{4V_T}$.

Numbers. $a = 2.6/26 = 0.1$, so $\text{HD}_2 \approx 2.5\,\%$. To keep distortion below $1\,\%$ the input must stay below $4 \times 0.01 \times 26 = 1.04\,\text{mV}$ peak.

Check. The exact Fourier coefficients of $e^{a\cos\omega t}$ are modified Bessel functions, giving $\text{HD}_2 = I_2(a)/I_1(a) = 0.02499$ at $a = 0.1$. ✓ (At $a = 0.5$ the estimate 0.125 is still within $1\,\%$ of the exact 0.1237.)

The DC shift $a^2/4$ is the mechanism of diode detection and mixing: a nonlinear device converts part of an AC signal into DC.

Finite-difference formulas from Taylor series

Write the Taylor expansions at $x \pm h$:

$$f(x \pm h) = f(x) \pm h f'(x) + \frac{h^2}{2}f''(x) \pm \frac{h^3}{6}f'''(x) + \frac{h^4}{24}f^{(4)}(x) \pm \cdots$$

Subtracting, adding, or using one of them gives the standard numerical derivatives and their errors:

$$\begin{aligned}
\text{forward:} \quad & \frac{f(x+h) - f(x)}{h} = f'(x) + \frac{h}{2}f''(x) + O(h^2), \\
\text{central:} \quad & \frac{f(x+h) - f(x-h)}{2h} = f'(x) + \frac{h^2}{6}f'''(x) + O(h^4), \\
\text{second:} \quad & \frac{f(x+h) - 2f(x) + f(x-h)}{h^2} = f''(x) + \frac{h^2}{12}f^{(4)}(x) + O(h^4).
\end{aligned}$$

For $f = e^x$ at $x = 0$ with $h = 0.1$, the forward difference is off by 0.0517 (predicted $h/2 \approx 0.05$), the central difference by 0.00167 (predicted $h^2/6 = 0.00167$) and the second difference by 0.00083 (predicted $h^2/12 = 0.00083$). The central difference is far better for the same number of function evaluations, because the even-order error terms cancel by symmetry.

Common Pitfall — using a series outside its radius

$\ln(1+x) = x - x^2/2 + x^3/3 - \cdots$ is useless at $x = 2$: the terms grow and the partial sums oscillate wildly. To compute $\ln 3$, use $\ln 3 = \ln\frac{1+y}{1-y}$ with $y = \frac{1}{2}$, and the rapidly convergent series $\ln\frac{1+y}{1-y} = 2\left(y + \frac{y^3}{3} + \frac{y^5}{5} + \cdots\right)$. Similarly, the binomial approximation $(1+x)^\alpha \approx 1 + \alpha x$ is only good for $|x| \ll 1$, and it is a statement about $|x|$, not $|\alpha x|$.

4.8 Linearization

The tangent-line approximation

Linearization

The **linearization** of f at a is the degree-1 Taylor polynomial

$$L(x) = f(a) + f'(a)(x - a).$$

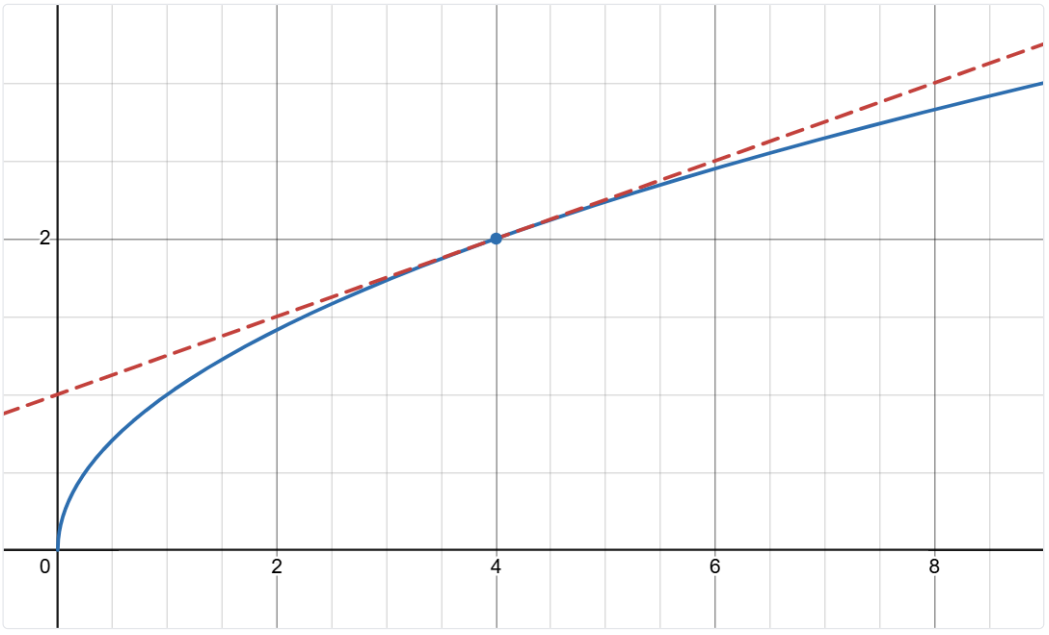
For x near a, $f(x) \approx L(x)$, with error $f(x) - L(x) = \tfrac{1}{2} f''(c)(x-a)^2$ for some c between a and x.

In terms of increments, with $\Delta x = x - a$ and $\Delta f = f(x) - f(a)$:

$$\Delta f \approx f'(a)\,\Delta x.$$

The **differential** notation writes this as $df = f'(x)\,dx$: dx is an independent increment, and df is the corresponding change *along the tangent line*. The true change Δf and the differential df differ by a term of order $(\Delta x)^2$.

Linearization is the most important approximation in engineering. Nonlinear devices (diodes, transistors, magnetic cores, sensors) are analysed by choosing an **operating point** (a bias, or quiescent point, Q) and replacing the device by its tangent line there. The slope becomes a small-signal parameter: a conductance, a transconductance, an incremental inductance.



$\sqrt{x}$ and its linearization at $x = 4$. Near the operating point the line is an excellent substitute; the error grows quadratically with distance, and the line always lies above this concave-down curve.

Worked Example 4.32 — Quick numerical estimates

(a) $\sqrt{4.1}$: with $f = \sqrt{x}$, $a = 4$, $f'(4) = \tfrac{1}{4}$: $L(4.1) = 2 + 0.1/4 = 2.025$. True: 2.024846 (error 1.5×10^{-4}, which matches $\tfrac{1}{2}|f''(4)|(0.1)^2 = 1.6 \times 10^{-4}$).

(b) $\sin 31^\circ$: with $f = \sin x$, $a = 30^\circ = \pi/6$, $\Delta x = 1^\circ = \pi/180 = 0.017453$ rad: $L = \sin\tfrac{\pi}{6} + \cos\tfrac{\pi}{6} \cdot \tfrac{\pi}{180} = 0.5 + 0.866 \times 0.017453 = 0.51511$. True: 0.51504. (Converting Δx to radians is essential.)

(c) 1.02^{10}: with $(1+x)^n \approx 1 + nx$: $1 + 10(0.02) = 1.20$. True: 1.2190. The error, $\approx \binom{10}{2}(0.02)^2 = 0.018$, is the next binomial term.

(d) Small angles: $\sin\theta \approx \theta$ at $\theta = 10^\circ = 0.17453$ rad gives 0.17453 against the true 0.17365, an error of $0.5\,\%$. The relative error of $\sin\theta \approx \theta$ is about $\theta^2/6$.

Small-signal models

Worked Example 4.33 — MOSFET transconductance

A MOSFET in saturation obeys the square law $i_D = \tfrac{k}{2}(v_{GS} - V_t)^2$ with $k = 2\ \text{mA/V}^2$ and $V_t = 0.5\ \text{V}$. It is biased at $V_{GS} = 1.0\ \text{V}$. Find I_D, the transconductance $g_m = di_D/dv_{GS}$ at the Q-point, and the error of the linear model for a $10\ \text{mV}$ signal.

Bias. Overdrive $V_{ov} = V_{GS} - V_t = 0.5\ \text{V}$, so $I_D = \tfrac{2}{2}(0.5)^2 = 0.25\ \text{mA}$.

Linearize. $g_m = k(V_{GS} - V_t) = 2 \times 0.5 = 1\ \text{mA/V}$. Equivalently $g_m = 2I_D/V_{ov} = 2(0.25)/0.5 = 1\ \text{mA/V}$.

Small-signal model. $i_D \approx I_D + g_m v_{gs}$, where $v_{gs} = v_{GS} - V_{GS}$ is the signal. For $v_{gs} = 10\ \text{mV}$, the model predicts $\Delta i_D = 10\ \mu\text{A}$.

Exact. $\Delta i_D = \tfrac{k}{2}\left[(0.51)^2 - (0.5)^2\right] = 10^{-3}(0.2601 - 0.25) = 10.1\ \mu\text{A}$. The relative error is $v_{gs}/(2V_{ov}) = 1\,\%$. Because the square law has f'' constant, the error is exactly the quadratic term $\tfrac{k}{2}v_{gs}^2 = 0.1\ \mu\text{A}$.

Worked Example 4.34 — Linearizing in two variables

The magnitude of an impedance $Z = R + jX$ is $|Z| = \sqrt{R^2 + X^2}$. Linearize it about $R = 3\,\Omega$, $X = 4\,\Omega$ and estimate $|Z|$ at $R = 3.1$, $X = 3.9$.

The two-variable linearization uses both partial derivatives (§4.5):

$$L(R, X) = |Z|_0 + \frac{\partial |Z|}{\partial R}\Delta R + \frac{\partial |Z|}{\partial X}\Delta X, \qquad \frac{\partial |Z|}{\partial R} = \frac{R}{|Z|},\ \frac{\partial |Z|}{\partial X} = \frac{X}{|Z|}.$$

At $(3, 4)$: $|Z|_0 = 5$, partials 0.6 and 0.8. So $L = 5 + 0.6(0.1) + 0.8(-0.1) = 4.98\,\Omega$.

Check. $\sqrt{3.1^2 + 3.9^2} = \sqrt{24.82} = 4.98197\,\Omega$; error $0.002\,\Omega$. ✓ Geometrically, $L(R, X)$ is the tangent plane to the cone $z = \sqrt{R^2 + X^2}$ (Ch. 6).

Linearizing a differential equation about an equilibrium

Consider a first-order system $\dot{x} = f(x)$. An **equilibrium** x^* satisfies $f(x^*) = 0$. Write $x = x^* + \delta$ with δ small. Since $\dot{x}^* = 0$,

$$\dot{\delta} = f(x^* + \delta) \approx f(x^*) + f'(x^*)\,\delta = f'(x^*)\,\delta.$$

This linear equation has solution $\delta(t) = \delta(0) e^{f'(x^*)t}$. Hence:

- if $f'(x^*) < 0$, small disturbances decay: the equilibrium is **stable**, with time constant $\tau = -1/f'(x^*)$;
- if $f'(x^*) > 0$, they grow: the equilibrium is **unstable**;
- if $f'(x^*) = 0$, linearization is inconclusive.

For systems of equations the derivative becomes a Jacobian matrix and its eigenvalues decide stability (Ch. 10).

Worked Example 4.35 — A capacitor charged by a current source into a diode

A constant current $I_0 = 1\,\text{mA}$ charges a capacitor $C = 1\,\text{nF}$ that is shunted by a diode ($I_s = 10^{-14}\,\text{A}$, $V_T = 25.85\,\text{mV}$). The capacitor voltage obeys

$$C\frac{dv}{dt} = I_0 - I_s\left(e^{v/V_T} - 1\right) \equiv C\,f(v).$$

Find the equilibrium, decide its stability and find the time constant of small deviations.

Equilibrium. $I_s(e^{v^*/V_T} - 1) = I_0 \Rightarrow v^* = V_T \ln(1 + I_0/I_s) = 0.02585 \ln(10^{11} + 1) = 0.6547\,\text{V}$. (All of I_0 flows through the diode.)

Linearize. $f'(v) = -\dfrac{I_s}{CV_T}e^{v/V_T}$, so $f'(v^*) = -\dfrac{I_0 + I_s}{CV_T} < 0$: stable.

Time constant. $\tau = -1/f'(v^*) = \dfrac{CV_T}{I_0 + I_s} \approx C\,r_d$ with $r_d = V_T/I_0 = 25.85\,\Omega$. Numerically $\tau = 10^{-9} \times 25.85 = 25.9\,\text{ns}$.

The linearized circuit is the capacitor in parallel with the diode's small-signal resistance: an RC circuit. Linearization has turned a nonlinear ODE into the most familiar circuit of all.

Newton's method

Linearization also solves equations. To solve $f(x) = 0$ starting from a guess x_n, replace f by its tangent line at x_n and solve the *linear* equation $f(x_n) + f'(x_n)(x - x_n) = 0$:

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}.$$

Quadratic convergence of Newton's method

If f is C^2 near a simple root r ($f(r) = 0$, $f'(r) \neq 0$) and x_0 is close enough to r, the errors $e_n = x_n - r$ satisfy

$$e_{n+1} \approx \frac{f''(r)}{2f'(r)}\,e_n^2.$$

The number of correct digits roughly doubles with each step.

Proof sketch. Taylor's theorem about x_n: $0 = f(r) = f(x_n) + f'(x_n)(r - x_n) + \tfrac{1}{2}f''(c)(r - x_n)^2$. Divide by $f'(x_n)$ and rearrange: $x_{n+1} - r = \dfrac{f''(c)}{2f'(x_n)}(x_n - r)^2$.

Worked Example 4.36 — Newton's method for a diode bias point

A 5 V source drives a 1 kΩ resistor in series with a diode ($I_s = 10^{-14}$ A, $V_T = 25.852$ mV). Find the diode voltage V.

KCL at the diode: $f(V) = \dfrac{5 - V}{1000} - I_s\left(e^{V/V_T} - 1\right) = 0$, with $f'(V) = -\dfrac{1}{1000} - \dfrac{I_s}{V_T}e^{V/V_T}$.

Starting from $V_0 = 0.7$ V:

n	V_n (V)	error $V_n - V^*$
0	0.700000	7.5×10^{-3}
1	0.693518	9.7×10^{-4}
2	0.692562	1.8×10^{-5}
3	0.6925436394	6.3×10^{-9}
4	0.6925436332	$< 10^{-15}$

The diode voltage is $V^* = 0.69254$ V and the current $(5 - 0.69254)/1000 = 4.3075$ mA. The error is roughly squared at each step, as the theorem predicts.

Common Pitfall — Newton's method far from the root

Started at $V_0 = 0$ V, the iteration above jumps to $V_1 \approx 5.0$ V (at 0 V the diode is nearly an open circuit, so the tangent line only sees the resistor) and then creeps back down by about one V_T per step: it needs roughly 170 iterations, and along the way $e^{V/V_T} \approx e^{193} \approx 10^{84}$. With a slightly larger source voltage the exponential overflows in floating point. Circuit simulators therefore **limit** the voltage step per iteration on junctions. Newton's method is excellent locally and unreliable globally; combine it with bracketing (§4.1) or step limiting.

Engineering Note — the limits of small-signal analysis

A linear model is valid only while the neglected quadratic term is small compared with the linear one: for the exponential device, $|v| \ll 2V_T \approx 50$ mV; for the square-law MOSFET, $|v_{gs}| \ll 2V_{ov}$. Example 4.31 quantified exactly what "small" costs in distortion. Large-signal behaviour (clipping, slewing, switching) requires the full nonlinear model, usually solved numerically.

4.9 Rates of change

Average and instantaneous rates

For a quantity $y = f(t)$, the **average rate of change** over $[t_1, t_2]$ is $\dfrac{f(t_2) - f(t_1)}{t_2 - t_1}$, the slope of a secant. The **instantaneous rate of change** at t is $f'(t)$, the slope of the tangent. The mean value theorem (§4.2) links them: somewhere in the interval the instantaneous rate equals the average.

Almost every constitutive law in circuit theory is a rate law:

Law	Rate	Units
Current	$i = \dfrac{dq}{dt}$	C/s = A
Capacitor	$i = C\dfrac{dv}{dt}$ (more generally $i = \dfrac{d(Cv)}{dt}$)	F·V/s = A
Inductor	$v = L\dfrac{di}{dt}$ (more generally $v = \dfrac{d\lambda}{dt}$, λ = flux linkage)	H·A/s = V
Faraday's law	$\mathcal{E} = -\dfrac{d\Phi}{dt}$	Wb/s = V
Power	$p = \dfrac{dW}{dt}$	J/s = W
Slew rate	$\mathrm{SR} = \max\left\lvert\dfrac{dv_o}{dt}\right\rvert$	V/s (usually V/µs)

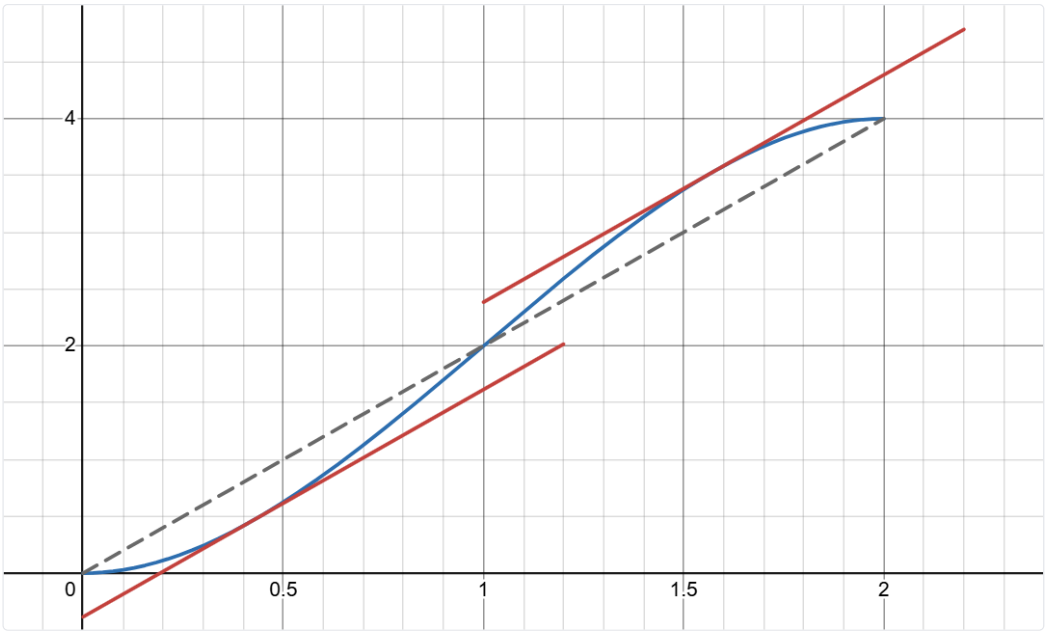
Worked Example 4.37 — Average versus instantaneous current

The charge through a conductor is $q(t) = 3t^2 - t^3$ mC for $0 \le t \le 2$ s. Find the average current over $[0, 2]$, the instantaneous current at $t = 1$ s, and the times at which the instantaneous current equals the average.

Average. $\bar{i} = \dfrac{q(2) - q(0)}{2} = \dfrac{12 - 8}{2} = 2$ mA.

Instantaneous. $i(t) = q'(t) = 6t - 3t^2$ mA, so $i(1) = 3$ mA (the maximum, since $i'(t) = 6 - 6t = 0$ there).

MVT points. $6c - 3c^2 = 2 \Rightarrow 3c^2 - 6c + 2 = 0 \Rightarrow c = 1 \pm \dfrac{1}{\sqrt{3}} = 0.423$ s or 1.577 s. Both lie in $(0, 2)$, as the MVT guarantees at least one must.



The charge $q(t) = 3t^2 - t^3$ (blue), the secant over $[0, 2]$ with slope 2 (the average current, dashed) and the two tangent lines with the same slope (red) at $t = 1 \mp 1/\sqrt{3}$.

Relative (logarithmic) rates

The **relative rate of change** is $\dfrac{\dot y}{y} = \dfrac{d}{dt}\ln y$, the fraction by which y changes per unit time. For an exponential $y = Y_0 e^{-t/\tau}$ it is constant: $\dot y / y = -1/\tau$. That is the defining property of exponential decay: the *relative* rate never changes, so the capacitor in an RC circuit loses the same *fraction* of its remaining voltage in every equal time interval. With $\tau = 2\,\text{ms}$, the instantaneous relative rate is $-500\,\text{s}^{-1}$, i.e. $-0.05\,\%$ per µs. Note that the voltage falls by $1 - e^{-1/2} = 39\,\%$, not $50\,\%$, in the first millisecond: a relative rate is instantaneous, not a percentage per finite interval.

Related rates

In a **related-rates** problem, several quantities vary with time and are linked by an equation. Differentiating the equation with respect to t (with the chain rule, as in implicit differentiation) links their rates. The procedure:

1. Name the variables and write the equation that connects them, valid at **all** times.
2. Differentiate both sides with respect to t.
3. Only **then** substitute the values at the instant of interest, and solve for the unknown rate.

Substituting before differentiating is the classic mistake: it freezes quantities that are in fact changing.

Worked Example 4.38 — A MEMS capacitive sensor

A parallel-plate capacitor has $C = \varepsilon_0 A/d$ with $A = 1\,\text{cm}^2$, held at a constant $V = 5\,\text{V}$. At the instant when $d = 10\,\mu\text{m}$, the moving plate recedes at $\dot d = 1$ mm/s. Find the current.

Step 1. $q = Cv$ and $C = \varepsilon_0 A/d$.

Step 2. Product rule: $i = \dot q = \dot C v + C\dot v$. Here $\dot v = 0$. Chain rule: $\dot C = -\dfrac{\varepsilon_0 A}{d^2}\dot d = -\dfrac{C}{d}\dot d$.

Step 3. $C = 8.854\times10^{-12}\times10^{-4}/10^{-5} = 88.54\,\text{pF}$. $\dot C = -88.54\times10^{-12}\times(10^{-3}/10^{-5}) = -8.854\,\text{nF/s}$. So

$$i = V\dot C = 5\times(-8.854\times10^{-9}) = -44.3\,\text{nA}.$$

The negative sign means charge flows *out* of the capacitor as the plates separate. This current is the output signal of a capacitive microphone or accelerometer.

Units. $\text{V}\cdot\text{F/s} = \text{C/s} = \text{A}$. ✓

Worked Example 4.39 — EMF in an expanding loop

A circular conducting loop lies in a uniform magnetic field $B = 0.5\,\text{T}$ perpendicular to its plane. Its radius increases at $\dot{r} = 2\,\text{cm/s}$. Find the induced EMF when $r = 10\,\text{cm}$.

Equation. $\Phi = B\pi r^2$, valid at all times.

Differentiate. $\dot{\Phi} = 2\pi B r\dot{r}$ (B constant), so $|\mathcal{E}| = 2\pi B r\dot{r}$.

Substitute. $|\mathcal{E}| = 2\pi(0.5)(0.1)(0.02) = 6.28\,\text{mV}$.

Interpretation. $2\pi r\dot{r}$ is the rate at which area is added (the circumference times the outward speed), and B times that is the rate at which flux is swept: the motional EMF.

Worked Example 4.40 — Slew-rate limit of an amplifier

An op-amp has slew rate $\text{SR} = 0.5\,\text{V}/\mu\text{s}$. What is the highest frequency at which it can output an undistorted 10 V-peak sine wave?

For $v_o = V_m \sin(2\pi f t)$, $\dot{v}_o = 2\pi f V_m \cos(2\pi f t)$, whose maximum magnitude is $2\pi f V_m$ (at the zero crossings, where the sine is steepest). Require $2\pi f V_m \le \text{SR}$:

$$f_{\max} = \frac{\text{SR}}{2\pi V_m} = \frac{0.5 \times 10^6}{2\pi \times 10} = 7.96\,\text{kHz}.$$

This is the **full-power bandwidth**. Above it the output becomes a triangle wave, even if the amplifier's small-signal bandwidth is far higher. Note that the limit depends on amplitude: at 1 V peak, $f_{\max} = 79.6\,\text{kHz}$.

Worked Example 4.41 — Power in reactive elements

Show that the rate of change of stored energy in an inductor equals the power delivered to it.

$W = \tfrac{1}{2}Li^2$. Chain rule: $\dfrac{dW}{dt} = \tfrac{1}{2}L \cdot 2i\dfrac{di}{dt} = i\left(L\dfrac{di}{dt}\right) = iv = p$. ✓ Likewise for a capacitor, $W = \tfrac{1}{2}Cv^2$ gives $\dot{W} = Cv\dot{v} = vi$.

For $i = I_m \sin\omega t$: $p = \tfrac{1}{2}\omega L I_m^2 \sin 2\omega t$, which averages to zero. An ideal inductor stores and returns energy; it does not dissipate it.

Common Pitfall — signs, units and constants that are not constant

Decide a sign convention first (passive sign convention: current entering the $+$ terminal) and keep it; a negative rate is information, not an error. Convert units before substituting (1 mm/s $= 10^{-3}$ m/s, μs in the denominator of a slew rate means $\times 10^6$). And remember that "$i = C\,dv/dt$" assumes C is constant: for a varying capacitance, as in Example 4.38, the full rule is $i = d(Cv)/dt$.

Engineering Note — rates as specifications

Many specifications are bounds on derivatives: slew rate (V/µs), dv/dt immunity of thyristors and gate drivers (V/ns), di/dt limits on power semiconductors (A/µs), ramp rates of power-supply sequencing, and the rate of change of frequency (RoCoF, Hz/s) in power grids. The inductor law also explains why a fast current edge through a small parasitic inductance causes trouble: 1 A switched in 1 ns through 10 nH of trace inductance produces $L\,di/dt = 10\,\text{V}$ of ground bounce.

4.10 Engineering optimization

Motivation

Design is optimization: the load that extracts the most power, the switching frequency that minimizes total loss, the cable geometry with least attenuation, the damping that gives the flattest response. When a performance measure depends smoothly on one design variable, calculus finds the best value exactly. Multivariable and constrained problems (Lagrange multipliers) are in Ch. 6; numerical optimization algorithms are in Ch. 23.

Critical points

Extrema and critical points

f has a **local maximum** at c if $f(c) \ge f(x)$ for all x near c, and an **absolute (global) maximum** on a set D if $f(c) \ge f(x)$ for all $x \in D$; similarly for minima. A **critical point** of f is an interior point c of its domain where $f'(c) = 0$ or $f'(c)$ does not exist.

Fermat's theorem

If f has a local extremum at an interior point c and $f'(c)$ exists, then $f'(c) = 0$.

Proof. Suppose c is a local maximum. For small $h > 0$, $f(c+h) - f(c) \le 0$, so $\frac{f(c+h)-f(c)}{h} \le 0$ and the right-hand limit gives $f'(c) \le 0$. For small $h < 0$ the quotient is ≥ 0, giving $f'(c) \ge 0$. Hence $f'(c) = 0$. ■

The converse fails: $f = x^3$ has $f'(0) = 0$ but no extremum at 0. Critical points are *candidates*, which must then be classified.

Classifying critical points

First-derivative test. If f' changes sign from $+$ to $-$ at c, f has a local maximum at c; from $-$ to $+$, a local minimum; no sign change, no extremum.

Second-derivative test. If $f'(c) = 0$ and $f''(c) < 0$, c is a local maximum; if $f''(c) > 0$, a local minimum; if $f''(c) = 0$, the test is inconclusive.

Why the second-derivative test works. By Taylor's theorem, $f(c+h) = f(c) + 0 \cdot h + \tfrac{1}{2}f''(c)h^2 + o(h^2)$. For small h the quadratic term dominates, and its sign is that of $f''(c)$, whichever sign h has.

The closed-interval method

When the design variable lies in a closed interval $[a, b]$ (a component range, a physical limit), the EVT guarantees an absolute maximum and minimum, and they occur either at critical points or at the endpoints. So:

1. Find the critical points in (a, b).
2. Evaluate f at them and at a and b.
3. The largest value is the absolute maximum, the smallest the absolute minimum.

For example, $f(x) = x^3 - 3x$ on $[-2, 3]$ has critical points $x = \pm 1$ (from $3x^2 - 3 = 0$). The values are $f(-2) = -2$, $f(-1) = 2$, $f(1) = -2$, $f(3) = 18$. The absolute maximum 18 is at the endpoint $x = 3$, not at the local maximum $x = -1$; the absolute minimum -2 is attained twice.

A strategy for applied problems

1. Identify the design variable and the objective, with units; write the objective as a function of one variable (use constraints to eliminate others).
2. State the feasible range (resistances are positive, frequencies lie in a band).
3. Differentiate, solve $f' = 0$, and classify.
4. Compare with endpoints and check that the answer is physically sensible.
5. Ask how sensitive the optimum is (§4.11): a flat optimum is forgiving.

Worked Example 4.42 — Maximum power transfer

Choose $R_L > 0$ to maximize $P = \dfrac{V^2 R_L}{(R_s + R_L)^2}$.

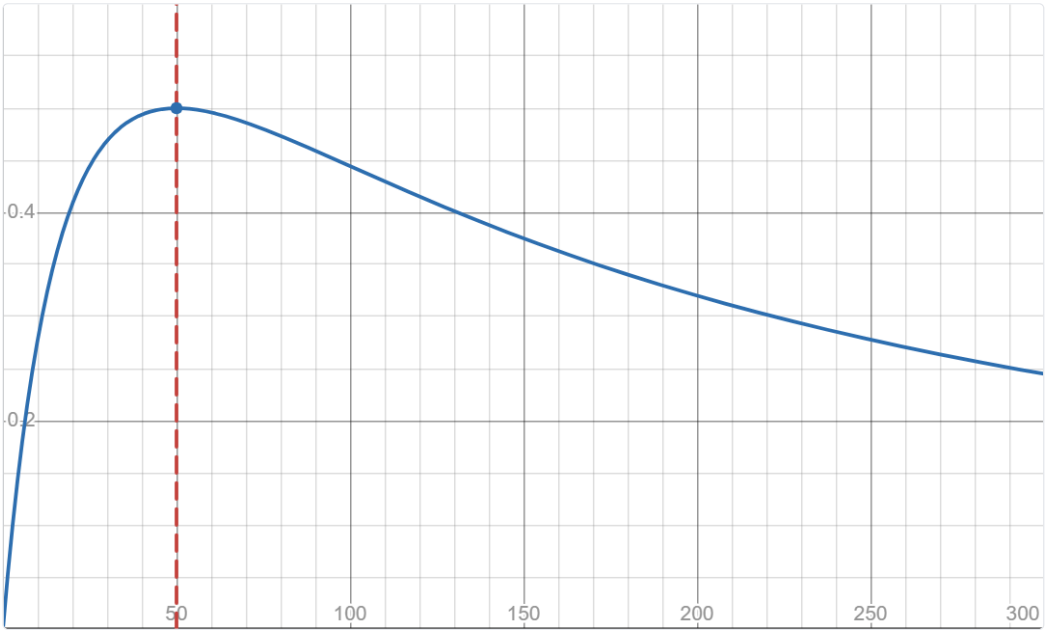
From Example 4.8, $P'(R_L) = \dfrac{V^2(R_s - R_L)}{(R_s + R_L)^3}$. The only critical point in $(0, \infty)$ is $R_L = R_s$. The derivative changes from $+$ to $-$ there, so it is a maximum; since $P \to 0$ as $R_L \to 0$ and as $R_L \to \infty$, it is the global maximum.

$$P_{\max} = \frac{V^2 R_s}{(2R_s)^2} = \frac{V^2}{4R_s}.$$

Numbers. $V = 10\,\text{V}$, $R_s = 50\,\Omega$: $P_{\max} = 0.5\,\text{W}$ at $R_L = 50\,\Omega$.

Efficiency. At the optimum, the source resistance dissipates as much as the load: efficiency is 50 %. Maximum power transfer is the right objective for weak signals (antennas, sensors, RF stages), never for power distribution, where $R_L \gg R_s$ is used to maximize efficiency.

AC version. For a source impedance $Z_s = R_s + jX_s$ and load $Z_L = R_L + jX_L$, $P = \tfrac{1}{2}|V|^2 R_L / \left[(R_s + R_L)^2 + (X_s + X_L)^2\right]$. Setting $\partial P/\partial X_L = 0$ gives $X_L = -X_s$; then $\partial P/\partial R_L = 0$ gives $R_L = R_s$. So $Z_L = Z_s^*$: **conjugate matching**.



Load power versus load resistance for $V = 10\,\text{V}$, $R_s = 50\,\Omega$. The peak is broad: the curve is flat near the optimum because $P' = 0$ there, which is the subject of Example 4.49.

Worked Example 4.43 — Optimal switching frequency

In a switching converter, losses that scale with ripple (magnetics, capacitor ESR) fall as $1/f$ while switching losses rise as f. A model is $P(f) = \dfrac{a}{f} + bf$ with $a = 2 \times 10^5$ W·Hz and $b = 2 \times 10^{-6}$ W/Hz. Find the frequency of minimum loss.

$P'(f) = -\dfrac{a}{f^2} + b = 0 \Rightarrow f^* = \sqrt{a/b}$. $P''(f) = 2a/f^3 > 0$, so it is a minimum (and the only critical point for $f > 0$, with $P \to \infty$ at both ends, so it is global).

$$f^* = \sqrt{\frac{2 \times 10^5}{2 \times 10^{-6}}} = \sqrt{10^{11}} = 316 \text{ kHz}, \qquad P(f^*) = 2\sqrt{ab} = 2\sqrt{0.4} = 1.26 \text{ W}.$$

At the optimum the two loss components are equal ($a/f^* = bf^* = \sqrt{ab}$). This **balance principle** holds whenever a cost is the sum of a term growing like x and one falling like $1/x$: copper versus core loss in a transformer, conduction versus switching loss, wire size versus cost.

Worked Example 4.44 — Resonant peak of a second-order low-pass filter

A second-order low-pass filter has

$$|H(u)| = \frac{1}{\sqrt{(1-u^2)^2 + (2\zeta u)^2}}, \qquad u = \omega/\omega_0,$$

with damping ratio $\zeta > 0$. Find the frequency and height of the resonant peak.

Simplify first. $|H|$ is largest where $D(w) = (1-w)^2 + 4\zeta^2 w$ is smallest, with $w = u^2 \geq 0$. (Maximizing a positive function is equivalent to minimizing its reciprocal; squaring is monotonic for positive quantities, so working with D avoids square roots.)

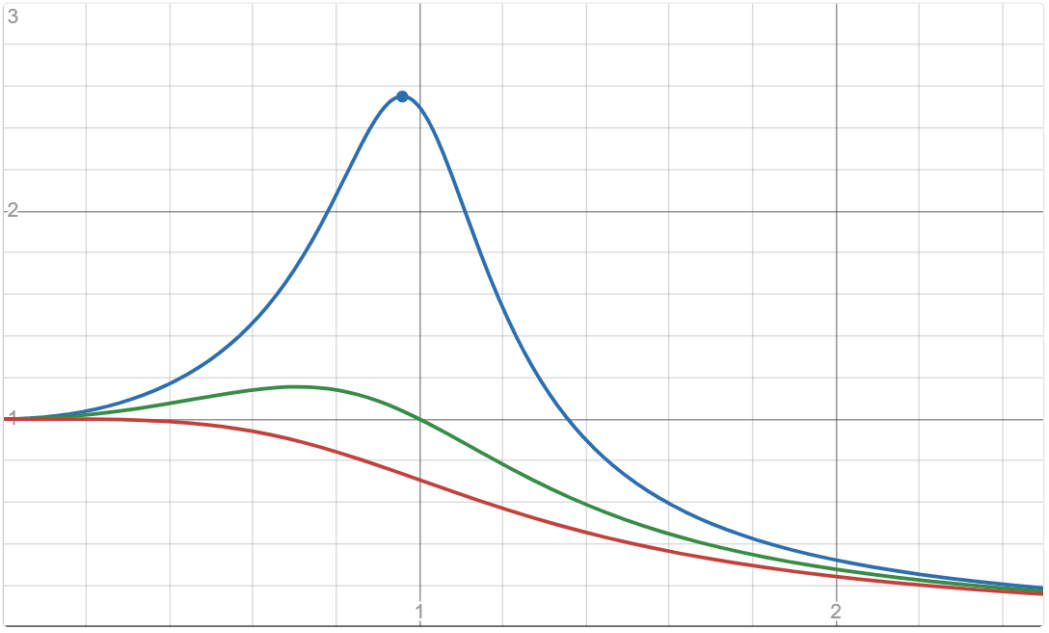
Differentiate. $D'(w) = -2(1-w) + 4\zeta^2 = 0 \Rightarrow w^* = 1 - 2\zeta^2$. $D'' = 2 > 0$: minimum.

Feasibility. $w^* \geq 0$ requires $\zeta \leq 1/\sqrt{2}$. For $\zeta > 1/\sqrt{2}$, D is increasing on $w \geq 0$, the minimum is at the endpoint $w = 0$, and there is no peak: the response falls monotonically. $\zeta = 1/\sqrt{2}$ is the **Butterworth** (maximally flat) boundary.

Peak. For $\zeta < 1/\sqrt{2}$:

$$u_{\text{peak}} = \sqrt{1 - 2\zeta^2}, \qquad D(w^*) = 4\zeta^2 - 4\zeta^4 = 4\zeta^2(1-\zeta^2), \qquad |H|_{\max} = \frac{1}{2\zeta\sqrt{1-\zeta^2}}.$$

Numbers. $\zeta = 0.2$: $u_{\text{peak}} = 0.959$ and $|H|_{\max} = 2.55$ (+8.1 dB). $\zeta = 0.5$: $u_{\text{peak}} = 0.707$, $|H|_{\max} = 1.155$ (+1.25 dB).



Second-order low-pass magnitude for $\zeta = 0.2$ (blue), 0.5 (green) and $1/\sqrt{2}$ (red, Butterworth). The peak moves below ω_0 and disappears at $\zeta = 1/\sqrt{2}$, as found in Example 4.44.

Worked Example 4.45 — Why coaxial cable is $75\,\Omega$

For a coaxial line with inner radius a and fixed outer radius b (set by the cable size), the conductor loss per unit length is proportional to

$$\alpha(a) \propto \frac{1/a + 1/b}{\ln(b/a)}.$$

Find the ratio $x = b/a$ that minimizes the loss.

One variable. With $1/a = x/b$, $\alpha \propto \dfrac{1}{b} \cdot \dfrac{x+1}{\ln x}$; minimize $g(x) = \dfrac{x+1}{\ln x}$ for $x > 1$.

Differentiate. Quotient rule:

$$g'(x) = \frac{\ln x - (x+1)/x}{(\ln x)^2} = 0 \quad \Longrightarrow \quad \ln x = 1 + \frac{1}{x}.$$

This transcendental equation has no closed-form solution. Newton's method (§4.8) on $h(x) = \ln x - 1 - 1/x$, $h'(x) = 1/x + 1/x^2$, from $x_0 = 3$: $x_1 = 3.5281$, $x_2 = 3.5904$, $x_3 = 3.59112$. So $x^* = 3.5911$.

Check it is a minimum. $g \to \infty$ as $x \to 1^+$ (denominator $\to 0$) and as $x \to \infty$ (since $x/\ln x \to \infty$), and x^* is the only critical point, so it is the global minimum.

Consequence. The characteristic impedance of an air-filled coax is $Z_0 = 60 \ln(b/a)\,\Omega = 60 \ln 3.5911 = 76.7\,\Omega$. That is why low-loss video and RF distribution cable is $75\,\Omega$. (The $50\,\Omega$ standard is a compromise between this and the $30\,\Omega$ ratio that maximizes power handling.)

Common Pitfall — forgetting endpoints and the domain

A critical point is only a candidate. The global optimum may be at an endpoint (as for $x^3 - 3x$ on $[-2, 3]$ above), may not exist on an open interval (minimize $1/x$ on $(0, \infty)$), or the critical point may be infeasible (the resonant peak of Example 4.44 for $\zeta > 1/\sqrt{2}$). Points where f' fails to exist are critical points too: the minimum of $|x - 2|$ is at the corner $x = 2$. Finally, $f''(c) = 0$ does not mean "no extremum": x^4 has a minimum at 0. Use the first-derivative test when the second-derivative test is inconclusive.

Engineering Note — optimizing a simpler function

Because $\sqrt{\cdot}$, $\ln$, squaring of positive quantities and $x \mapsto 1/x$ (on positive values, reversing the order) are monotonic, the optimizer of f is also the optimizer of f^2, $\ln f$ or $1/f$. Maximize $|H|^2$ instead of $|H|$, $\ln L$ instead of a likelihood L (Ch. 20), and gain in dB instead of linear gain. The location of the optimum is unchanged, and the algebra is usually much lighter.

4.11 Sensitivity analysis

Motivation

Real components are not their nominal values. Resistors come in 1 % or 5 % tolerances, capacitors in 10 % or 20 %; values drift with temperature and age; an op-amp's open-loop gain varies by a factor of several between units. A designer must answer: *how much does the performance change when a component changes?* The answer is a derivative, usually normalized so that percentage changes map to percentage changes. Sensitivity analysis tells you which components need tight tolerances, which can be cheap, and whether a design is robust.

Absolute and relative sensitivity

Sensitivity

Let a performance measure y depend on a parameter x (other parameters fixed). The **absolute sensitivity** is $\dfrac{\partial y}{\partial x}$ (units of y per unit of x). The **relative (normalized, Bode) sensitivity** is

$$S_x^y = \frac{x}{y}\frac{\partial y}{\partial x} = \frac{\partial y/y}{\partial x/x} = \frac{\partial \ln y}{\partial \ln x}.$$

It is dimensionless: for small changes, a 1 % change in x produces approximately an S_x^y % change in y.

The first-order change (from the linearization of §4.8, in relative form) is

$$\frac{\Delta y}{y} \approx S_x^y \frac{\Delta x}{x}.$$

Because S_x^y is a logarithmic derivative (§4.3), it obeys simple algebraic rules that make most sensitivities computable at sight.

Properties of relative sensitivity

For functions $u(x)$, $v(x)$ and constants c, n:

$$S_x^{cu} = S_x^u, \qquad S_x^{uv} = S_x^u + S_x^v, \qquad S_x^{u/v} = S_x^u - S_x^v,$$
$$S_x^{u^n} = n S_x^u, \qquad S_x^{x^n} = n, \qquad S_x^{1/u} = -S_x^u,$$
$$S_x^{y} = S_u^y \, S_x^u \ \text{(chain rule)}, \qquad S_x^{u+v} = \frac{u\,S_x^u + v\,S_x^v}{u+v}.$$

Proofs. Each follows from $S_x^y = d\ln y / d\ln x$: $\ln(uv) = \ln u + \ln v$ gives the product rule; $\ln u^n = n \ln u$ gives the power rule; and the chain rule is $\dfrac{d\ln y}{d\ln x} = \dfrac{d\ln y}{d\ln u}\dfrac{d\ln u}{d\ln x}$. For the sum, $S_x^{u+v} = \dfrac{x(u'+v')}{u+v} = \dfrac{u\cdot x u'/u + v \cdot x v'/v}{u+v}$.

So for any **monomial formula** $y = c\,x_1^{n_1} x_2^{n_2}\cdots$, the relative sensitivity to x_k is just the exponent n_k. For example, for $f_c = \dfrac{1}{2\pi RC} = \dfrac{1}{2\pi} R^{-1} C^{-1}$: $S_R^{f_c} = S_C^{f_c} = -1$.

Several parameters: worst case and statistical tolerance

If y depends on $x_1, \dots, x_n$, the total differential of §4.5 gives

$$\frac{\Delta y}{y} \approx \sum_{k=1}^{n} S_{x_k}^{y} \, \frac{\Delta x_k}{x_k}.$$

Two ways of combining tolerances follow.

- **Worst case.** If each relative error is bounded, $|\Delta x_k / x_k| \le t_k$, then

$$\left|\frac{\Delta y}{y}\right| \lesssim \sum_k \left|S_{x_k}^{y}\right| t_k.$$

This is guaranteed (to first order) but pessimistic: it assumes every component sits at the worst extreme of its tolerance simultaneously.

- **Statistical (root-sum-square, RSS).** If the parameter errors are independent random variables with relative standard deviations σ_k, then the relative standard deviation of y is approximately

$$\sigma_y \approx \sqrt{\sum_k \left(S_{x_k}^{y}\right)^2 \sigma_k^2}.$$

This is the first-order **propagation of uncertainty** (Ch. 20). It describes the spread of a production batch, and is smaller than the worst case.

Both rest on linearization, so they are reliable only when the relative changes are small enough that second-order terms are negligible.

Worked Example 4.46 — Voltage divider

$V_o = V_i \dfrac{R_2}{R_1 + R_2}$ with $R_1 = R_2 = 10\,\text{k}\Omega$, both $\pm 1\,\%$. Find the sensitivities and the tolerance of V_o.

Sensitivities. Using the quotient and sum rules, or differentiating directly:

$$S_{R_2}^{V_o} = 1 - \frac{R_2}{R_1+R_2} = \frac{R_1}{R_1+R_2}, \qquad S_{R_1}^{V_o} = -\frac{R_1}{R_1+R_2}, \qquad S_{V_i}^{V_o} = 1.$$

For equal resistors, $S_{R_2} = +0.5$ and $S_{R_1} = -0.5$.

Tolerance (taking V_i as exact). Worst case: $0.5(1\,\%) + 0.5(1\,\%) = 1\,\%$. RSS: $\sqrt{0.5^2 + 0.5^2}\,(1\,\%) = 0.71\,\%$.

Exact worst case. $R_1 = 9.9\,\text{k}\Omega$, $R_2 = 10.1\,\text{k}\Omega$ gives $V_o/V_i = 0.505$, i.e. $+1.00\,\%$. ✓

Insight. $S_{R_1} + S_{R_2} = 0$: the ratio is unchanged if both resistors drift by the same fraction (for example, with a common temperature coefficient). This is why precision dividers use matched resistor networks: tracking matters more than absolute accuracy.

Worked Example 4.47 — Cutoff frequency of an RC filter

$f_c = 1/(2\pi RC)$ with $R = 10\,\text{k}\Omega \pm 5\,\%$ and $C = 10\,\text{nF} \pm 10\,\%$ (nominal $f_c = 1.592\,\text{kHz}$). Estimate the spread of f_c.

$S_R^{f_c} = S_C^{f_c} = -1$. Worst case: $5\,\% + 10\,\% = 15\,\%$. RSS: $\sqrt{5^2 + 10^2}\,\% = 11.2\,\%$.

Exact extremes. R and C both high: $f_c/f_{c0} = 1/(1.05 \times 1.10) = 0.866$ ($-13.4\,\%$). Both low: $1/(0.95 \times 0.90) = 1.170$ ($+17.0\,\%$). The linear estimate $\pm 15\,\%$ is the average of these; the asymmetry is the second-order effect of the reciprocal. For tolerances this large, check the extremes exactly.

Design consequence. The capacitor dominates the error. Buying a $2\,\%$ capacitor (RSS $5.4\,\%$) helps far more than buying a $1\,\%$ resistor (RSS $10.05\,\%$).

Worked Example 4.48 — Series RLC: resonant frequency and Q

A series RLC circuit has $\omega_0 = \dfrac{1}{\sqrt{LC}}$ and $Q = \dfrac{1}{R}\sqrt{\dfrac{L}{C}}$. With $L = 10\,\text{mH} \pm 5\,\%$, $C = 100\,\text{nF} \pm 10\,\%$, $R = 10\,\Omega \pm 1\,\%$, find the sensitivities and tolerances.

Nominal values. $\omega_0 = 1/\sqrt{10^{-9}} = 31\,623\,\text{rad/s}$ ($f_0 = 5.03\,\text{kHz}$); $Q = 0.1\sqrt{10^5} = 31.6$.

Sensitivities (read off the exponents). $\omega_0 = L^{-1/2}C^{-1/2}$: $S_L^{\omega_0} = S_C^{\omega_0} = -\tfrac{1}{2}$, $S_R^{\omega_0} = 0$. $Q = R^{-1}L^{1/2}C^{-1/2}$: $S_R^{Q} = -1$, $S_L^{Q} = +\tfrac{1}{2}$, $S_C^{Q} = -\tfrac{1}{2}$.

Tolerances.

Quantity	Worst case	RSS
ω_0	$\tfrac{1}{2}(5) + \tfrac{1}{2}(10) = 7.5\,\%$	$\sqrt{2.5^2 + 5^2} = 5.6\,\%$
Q	$1 + 2.5 + 5 = 8.5\,\%$	$\sqrt{1^2 + 2.5^2 + 5^2} = 5.7\,\%$

The square root in ω_0 halves the effect of L and C errors: a nice property, but a tuned circuit with $Q = 31.6$ has a -3 dB bandwidth of only $\omega_0/Q \approx 3.2\,\%$ of ω_0. A $5.6\,\%$ spread in ω_0 is larger than the passband itself, so such a filter must be trimmed or built with tighter parts.

Worked Example 4.49 — The optimum is insensitive: second-order sensitivity

At an optimum, $\partial y/\partial x = 0$, so every first-order sensitivity vanishes. The change is then governed by the second derivative. For the maximum-power problem of Example 4.42, let $r = R_L/R_s$:

$$\frac{P}{P_{\max}} = \frac{4r}{(1+r)^2}.$$

At $r = 1$ the first derivative is 0. The second derivative of $4r(1+r)^{-2}$ is $\dfrac{8(r-2)}{(1+r)^4}$, which equals $-\tfrac{1}{2}$ at $r = 1$, so by Taylor's theorem

$$\frac{P}{P_{\max}} \approx 1 - \frac{1}{4}(r-1)^2.$$

Numbers. A $20\,\%$ mismatch ($r = 1.2$) is predicted to cost $0.25 \times 0.04 = 1\,\%$ of the power; exactly, $4(1.2)/2.2^2 = 0.9917$, a loss of $0.83\,\%$. ✓

This is a general and useful fact: **near an optimum, errors in the design variable cost only quadratically**. Precise matching is rarely worth paying for when the goal is maximum power; it matters much more when the goal is minimum *reflection*, which depends on mismatch linearly.

Worked Example 4.50 — Negative feedback desensitizes gain

A non-inverting amplifier has closed-loop gain $G = \dfrac{A}{1 + A\beta}$, where A is the op-amp's open-loop gain and β the feedback fraction set by resistors. With $A = 10^5$ and $\beta = 0.01$, find S_A^G and S_β^G.

Sensitivity to A. $G = A \cdot (1 + A\beta)^{-1}$, so by the product, power and sum rules

$$S_A^G = 1 - S_A^{1+A\beta} = 1 - \frac{A\beta}{1 + A\beta} = \frac{1}{1 + A\beta}.$$

Sensitivity to β. $S_\beta^G = -S_\beta^{1+A\beta} = -\dfrac{A\beta}{1 + A\beta}$.

Numbers. Loop gain $A\beta = 1000$: $G = 99.90$, $S_A^G = 1/1001 \approx 0.001$, $S_\beta^G \approx -0.999$.

Interpretation. A $10\,\%$ change in the op-amp gain changes the closed-loop gain by only about $0.01\,\%$: feedback divides the sensitivity by $1 + A\beta$. Even a $50\,\%$ drop ($A = 5 \times 10^4$, a large change for which the linear estimate predicts $0.05\,\%$) gives $G = 99.80$, a change of only $0.10\,\%$. The price is that the gain now depends almost entirely on β, i.e. on two resistors, which are cheap to make accurate. This is the central reason for negative feedback in amplifier design.

Worked Example 4.51 — Sensitivity of a strain-gauge bridge

A Wheatstone bridge excited by $V = 5\,\text{V}$ has one active strain gauge $R = R_0(1 + x)$ and three fixed resistors R_0. Its output is

$$v_o(x) = V\left(\frac{R}{R + R_0} - \frac{1}{2}\right) = V\left(\frac{1+x}{2+x} - \frac{1}{2}\right) = \frac{V}{2}\cdot\frac{x}{2+x}.$$

Find the absolute sensitivity dv_o/dx at balance and the output for a strain of 10^{-3} with gauge factor 2 (so $x = 2 \times 10^{-3}$).

$\dfrac{dv_o}{dx} = \dfrac{V}{2}\cdot\dfrac{(2+x) - x}{(2+x)^2} = \dfrac{V}{(2+x)^2}$, which is $V/4 = 1.25\,\text{V}$ per unit x at $x = 0$. Hence $v_o \approx 1.25 \times 2 \times 10^{-3} = 2.50\,\text{mV}$.

Exact. $v_o = 2.5 \times \dfrac{0.002}{2.002} = 2.4975\,\text{mV}$. The nonlinearity error is $-0.1\,\%$, about $x/2$ in relative terms, which is why bridges are operated near balance (and why half- and full-bridge arrangements, which cancel this term, are preferred).

Here the *relative* sensitivity $S_x^{v_o}$ is not useful, because the nominal output is zero; absolute sensitivity (V per unit strain) is the meaningful figure of merit. Choose the measure that matches the specification.

Engineering Note — temperature coefficients are sensitivities

A resistor's temperature coefficient of resistance (TCR) is $\alpha = \dfrac{1}{R}\dfrac{dR}{dT}$, a relative rate per kelvin, often quoted in ppm/K. Copper has $\alpha \approx 3.9 \times 10^{-3}\,\mathrm{K}^{-1}$; precision metal-film resistors reach ± 5 ppm/K. By the chain rule of sensitivities, the temperature coefficient of any performance measure is $\dfrac{1}{y}\dfrac{dy}{dT} = \sum_k S^y_{x_k}\,\alpha_k$. For the RC filter of Example 4.47, f_c drifts at $-(\alpha_R + \alpha_C)$; choosing a capacitor whose TC is equal and opposite to the resistor's ($\alpha_C = -\alpha_R$) makes the cutoff frequency first-order temperature-independent. Larger tolerance studies with many parameters and nonlinear effects use Monte Carlo simulation (Ch. 24), but the sensitivities computed here tell you which parameters matter before you start.

Common Pitfall — linear sensitivity has a range of validity

First-order sensitivity assumes small relative changes. With $\pm 10\,\%$ or $\pm 20\,\%$ tolerances, or near an optimum where the first derivative vanishes, include second-order terms or evaluate the extremes exactly (Examples 4.47 and 4.49). The RSS formula also assumes **independent** errors; components from the same reel, or resistors on one thin-film network, are correlated, and their errors may add (worst case) or cancel (Example 4.46) far more than RSS predicts. Finally, do not confuse absolute and relative sensitivity: $\partial y/\partial x$ has units and depends on the units chosen, S^y_x does not.

Summary

Topic	Key result
Limit	$\lim_{x\to a} f(x) = L$: $\forall \varepsilon > 0\ \exists \delta > 0, 0 < \lvert x-a\rvert < \delta \Rightarrow \lvert f(x) - L\rvert < \varepsilon$
Fundamental limits	$\lim_{x\to 0}\frac{\sin x}{x} = 1$, $\lim_{x\to 0}\frac{1-\cos x}{x^2} = \frac{1}{2}$, $\lim_{h\to 0}\frac{e^h-1}{h} = 1$, $\lim_{n\to\infty}(1+\frac{x}{n})^n = e^x$
Continuity	$\lim_{x\to a} f(x) = f(a)$; IVT (roots by sign change), EVT (extrema on $[a,b]$)
Derivative	$f'(x) = \lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$; differentiable $\Rightarrow$ continuous
Product, quotient	$(fg)' = f'g + fg'$, $(f/g)' = (f'g - fg')/g^2$
Complex exponential	$\frac{d}{dt}e^{st} = se^{st}$; $\frac{d}{dt} \leftrightarrow j\omega$ for phasors
Mean value theorem	$f'(c) = \frac{f(b)-f(a)}{b-a}$ for some $c \in (a,b)$
L'Hôpital	$0/0$ or ∞/∞: $\lim f/g = \lim f'/g'$
Chain rule	$\frac{d}{dx}f(g(x)) = f'(g(x))g'(x)$, $\frac{dy}{dx} = \frac{dy}{du}\frac{du}{dx}$
Logarithmic derivative	$\frac{y'}{y} = (\ln y)'$; for $y = \prod f_k^{a_k}$, $\frac{y'}{y} = \sum a_k \frac{f_k'}{f_k}$
Inverse function	$\frac{dx}{dy} = 1/\frac{dy}{dx}$
Parametric	$\frac{dy}{dx} = \frac{\dot y}{\dot x}$
Implicit	$F(x,y) = 0 \Rightarrow y' = -F_x/F_y$ $(F_y \neq 0)$
Partial derivative	$f_x = \lim_{h\to 0}\frac{f(x+h,y)-f(x,y)}{h}$; $f_{xy} = f_{yx}$ if continuous
Multivariable chain rule	$\frac{dz}{dt} = f_x\dot x + f_y\dot y$; $\Delta f \approx f_x\Delta x + f_y\Delta y$
Leibniz rule	$(fg)^{(n)} = \sum_{k=0}^{n}\binom{n}{k}f^{(k)}g^{(n-k)}$
Curvature	$\kappa = \lvert f''\rvert/(1+f'^2)^{3/2}$
Taylor series	$f(x) = \sum_{k=0}^{n}\frac{f^{(k)}(a)}{k!}(x-a)^k + \frac{f^{(n+1)}(c)}{(n+1)!}(x-a)^{n+1}$
Key series	$e^x = \sum\frac{x^n}{n!}$, $\sin x = x - \frac{x^3}{6} + \cdots$, $\cos x = 1 - \frac{x^2}{2} + \cdots$, $(1+x)^\alpha = 1 + \alpha x + \cdots$
Finite differences	central: $\frac{f(x+h)-f(x-h)}{2h} = f' + O(h^2)$; second: $\frac{f(x+h)-2f(x)+f(x-h)}{h^2} = f'' + O(h^2)$
Linearization	$f(x) \approx f(a) + f'(a)(x-a)$; diode $g_d = I_D/(nV_T)$; MOSFET $g_m = 2I_D/V_{ov}$
Equilibrium stability	$\dot x = f(x)$, $f(x^*) = 0$: stable if $f'(x^*) < 0$, $\tau = -1/f'(x^*)$
Newton's method	$x_{n+1} = x_n - f(x_n)/f'(x_n)$; $e_{n+1} \approx \frac{f''}{2f'}e_n^2$
Rates	$i = \dot q$, $i = \frac{d(Cv)}{dt}$, $v = L\frac{di}{dt}$, $\mathcal{E} = -\dot\Phi$, max $\lvert\dot v\rvert$ of a sine $= 2\pi f V_m$
Optimization	$f'(c) = 0$; $f''(c) < 0$ max, > 0 min; check endpoints; max power at $R_L = R_s$, $P_{\max} = V^2/(4R_s)$
Relative sensitivity	$S^y_x = \frac{x}{y}\frac{\partial y}{\partial x} = \frac{\partial \ln y}{\partial \ln x}$; for $y = cx^n$, $S = n$; $S^{uv} = S^u + S^v$
Tolerance	worst case $\sum\lvert S_k\rvert t_k$; RSS $\sqrt{\sum S_k^2\sigma_k^2}$; feedback $S^G_A = 1/(1+A\beta)$

Chapter 5 — Integral Calculus

> **Prerequisites:** Ch. 1, Ch. 3, Ch. 4 **Learning outcomes:** After this chapter you can
>
> - explain the definite integral as a limit of Riemann sums and use the Fundamental Theorem of Calculus to evaluate it through antiderivatives;
> - choose and apply the standard techniques — algebraic manipulation, trigonometric identities, partial fractions, trigonometric substitution, substitution and integration by parts — to reduce an integral to a table form;
> - decide whether an improper integral converges, using direct evaluation, comparison and limit-comparison tests;
> - set up and evaluate double and triple integrals over simple regions as iterated integrals;
> - approximate integrals with the trapezoidal and Simpson's rules and estimate their error;
> - compute charge, energy, work and other accumulated quantities, and the mean and RMS values of engineering waveforms.

Differentiation answers the question *how fast is it changing right now?* Integration answers the reverse question: *given the rate, how much has accumulated?* An electrical engineer meets this question constantly. The charge on a capacitor is the accumulated current, $q(t) = q(t_0) + \int_{t_0}^{t} i(\tau)\,d\tau$. The energy delivered to a load is the accumulated power, $W = \int p(t)\,dt$. The voltage a heater "feels" is the root-mean-square value of a waveform, which is the square root of an average, and an average is an integral divided by a length. The flux through a coil, the total charge in a cloud of electrons, the expected value of a noise voltage — all are integrals.

This chapter develops single-variable integration thoroughly and introduces integrals over regions of the plane and of space. Chapter 6 takes multiple integrals further with changes of variables (polar, cylindrical, spherical, general Jacobians), and Chapter 22 treats numerical integration in depth (Romberg, Gaussian quadrature, adaptive schemes). Here we lay the foundations those chapters build on.

5.1 Indefinite and definite integrals

5.1.1 Motivation: area and accumulation

Suppose a current $i(t)$ flows into a capacitor. Over a short interval Δt during which the current is nearly constant, the charge delivered is approximately $i(t)\,\Delta t$. Over a long interval $[a, b]$ we chop time into many short pieces and add:

$$Q \approx \sum_{k=1}^{n} i(t_k^*)\,\Delta t_k.$$

As the pieces shrink, the approximation becomes exact. Geometrically, each term $i(t_k^*)\,\Delta t_k$ is the area of a thin rectangle, so the limit is the *area under the curve* $i(t)$ between $t = a$ and $t = b$ (counted negative where $i < 0$). This limit is the definite integral. It is a *number* attached to a function and an interval.

Separately, differentiation (Chapter 4) suggests the question: which functions F have a given derivative f? The answer is a *family of functions*, the indefinite integral. The **Fundamental Theorem of Calculus** is the remarkable statement that these two ideas — area and anti-differentiation — are the same thing.

5.1.2 Riemann sums and the definite integral

Partition and Riemann sum

A **partition** P of $[a, b]$ is a finite set of points $a = x_0 < x_1 < \cdots < x_n = b$. Write $\Delta x_k = x_k - x_{k-1}$ and $\|P\| = \max_k \Delta x_k$ (the **mesh**). Choosing a **sample point** $x_k^* \in [x_{k-1}, x_k]$ in each subinterval, the **Riemann sum** of f is

$$S(f, P, \{x_k^*\}) = \sum_{k=1}^{n} f(x_k^*)\,\Delta x_k.$$

Definite integral

f is **(Riemann) integrable** on $[a, b]$ if there is a number I such that for every $\varepsilon > 0$ there is a $\delta > 0$ with $|S(f, P, \{x_k^*\}) - I| < \varepsilon$ for *every* partition with $\|P\| < \delta$ and *every* choice of sample points. Then

$$\int_a^b f(x)\,dx = I = \lim_{\|P\| \to 0} \sum_{k=1}^{n} f(x_k^*)\,\Delta x_k.$$

f is the **integrand**, a and b the **limits**, and x a **dummy variable**: $\int_a^b f(x)\,dx = \int_a^b f(t)\,dt$.

The notation is a fossil of the sum: $\int$ is an elongated S (*summa*), and dx recalls Δx. Dimensionally, $[\int f\,dx] = [f]\,[x]$; integrating a current in amperes over time in seconds gives coulombs.

Which functions are integrable? Not every function — the function equal to 1 on rationals and 0 on irrationals is the standard counterexample — but every function an engineer is likely to write down is.

Sufficient conditions for integrability

If f is continuous on $[a, b]$, or bounded on $[a, b]$ with only finitely many discontinuities, or monotonic on $[a, b]$, then f is Riemann integrable on $[a, b]$.

Thus square waves, sawtooth waves, rectified sinusoids and pulse trains — all piecewise continuous — can be integrated over any finite interval.

Two common special choices of Riemann sum use uniform width $h = (b-a)/n$ and sample at the left or right ends:

$$L_n = h\sum_{k=0}^{n-1} f(a+kh), \qquad R_n = h\sum_{k=1}^{n} f(a+kh).$$

For an increasing function $L_n \le \int_a^b f \le R_n$, and $R_n - L_n = h\,[f(b)-f(a)] \to 0$, which proves directly that monotone functions are integrable.

Worked Example 5.1 — An integral from the definition

Compute $\displaystyle\int_0^2 x^2\,dx$ as a limit of right-endpoint sums.

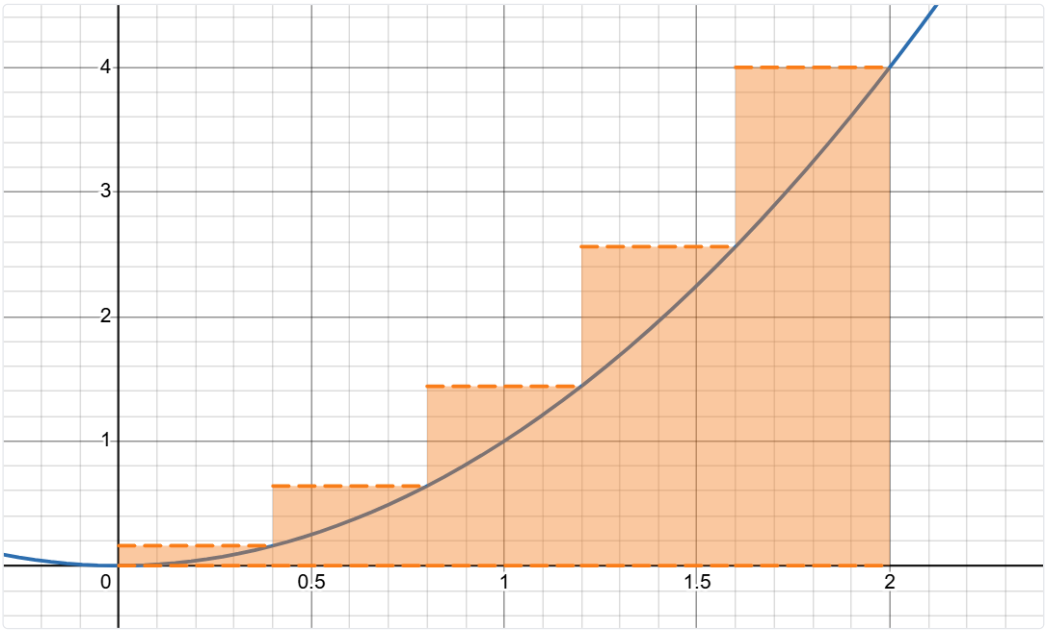
Step 1 — partition. $h = 2/n$, $x_k = 2k/n$.

Step 2 — sum. Using $\sum_{k=1}^{n} k^2 = \frac{n(n+1)(2n+1)}{6}$,

$$R_n = \sum_{k=1}^{n} \left(\frac{2k}{n}\right)^2 \frac{2}{n} = \frac{8}{n^3}\cdot\frac{n(n+1)(2n+1)}{6} = \frac{4}{3}\left(1+\frac{1}{n}\right)\left(2+\frac{1}{n}\right).$$

Step 3 — limit. As $n\to\infty$, $R_n \to \frac{4}{3}\cdot 2 = \frac{8}{3} \approx 2.6667$.

Check. $n=10$: $R_{10} = \frac{4}{3}(1.1)(2.1) = 3.08$; $n=100$: $R_{100} = \frac{4}{3}(1.01)(2.01) = 2.7068$; $n=1000$: 2.6707. The error shrinks like $1/n$, as expected for an endpoint rule (§5.7).



Right-endpoint Riemann sum with $n=5$ for $\int_0^2 x^2\,dx$: the rectangles overshoot the exact area $8/3$ because x^2 is increasing.

5.1.3 Properties of the definite integral

All of the following follow from the corresponding properties of finite sums, by passing to the limit.

Algebraic properties

For integrable f, g and constants α, β:

1. **Linearity:** $\displaystyle\int_a^b (\alpha f + \beta g)\,dx = \alpha\int_a^b f\,dx + \beta\int_a^b g\,dx$.
2. **Additivity over intervals:** $\displaystyle\int_a^c f\,dx = \int_a^b f\,dx + \int_b^c f\,dx$ for any a, b, c.
3. **Orientation:** $\displaystyle\int_b^a f\,dx = -\int_a^b f\,dx$, and $\displaystyle\int_a^a f\,dx = 0$.
4. **Monotonicity:** if $f \le g$ on $[a,b]$ $(a<b)$ then $\displaystyle\int_a^b f\,dx \le \int_a^b g\,dx$.
5. **Triangle inequality:** $\displaystyle\left|\int_a^b f\,dx\right| \le \int_a^b |f|\,dx$.
6. **Bounds:** if $m \le f(x) \le M$ on $[a,b]$ then $m(b-a) \le \displaystyle\int_a^b f\,dx \le M(b-a)$.

Property 5 is the integral form of the fact that a phasor sum can never exceed the sum of magnitudes; it is used constantly to bound errors. Property 6 leads to the following.

Mean Value Theorem for integrals

If f is continuous on $[a,b]$, there is a $c \in (a,b)$ with

$$\int_a^b f(x)\,dx = f(c)\,(b-a).$$

The number $\bar{f} = \dfrac{1}{b-a}\displaystyle\int_a^b f(x)\,dx$ is the **mean value** of f on $[a,b]$.

Proof sketch. By property 6 with $m = \min f$, $M = \max f$, the mean $\bar{f}$ lies between m and M. A continuous function takes every value between its minimum and maximum (Intermediate Value Theorem, Ch. 4), so $\bar{f} = f(c)$ for some c. $\square$

The mean value is the "DC value" of a waveform and is developed fully in §5.9.

Symmetry. If f is **even** ($f(-x) = f(x)$) then $\int_{-a}^{a} f\,dx = 2\int_0^a f\,dx$; if f is **odd** ($f(-x) = -f(x)$) then $\int_{-a}^{a} f\,dx = 0$. If f is **periodic** with period T, then $\int_c^{c+T} f\,dx$ is the same for every c — you may integrate over any convenient full period. These three facts eliminate a large share of the work in Fourier analysis (Ch. 15).

5.1.4 Antiderivatives and the indefinite integral

Antiderivative and indefinite integral

F is an **antiderivative** of f on an interval I if $F'(x) = f(x)$ for all $x \in I$. The set of all antiderivatives is the **indefinite integral**

$$\int f(x)\,dx = F(x) + C,$$

where C is an arbitrary **constant of integration**.

Why only a constant? If $F' = G' = f$ on an interval, then $(F-G)' = 0$, and by the Mean Value Theorem of differential calculus a function with zero derivative on an interval is constant. On a domain made of several disjoint intervals, the "constant" may differ on each piece: $\int \frac{dx}{x} = \ln|x| + C$ really means $\ln x + C_1$ for $x > 0$ and $\ln(-x) + C_2$ for $x < 0$.

Every differentiation rule read backwards gives an integration rule. The table below is the working vocabulary of this chapter; every entry can be checked by differentiating the right-hand side.

$f(x)$	$\int f(x)\,dx$	Condition
x^n	$\dfrac{x^{n+1}}{n+1} + C$	$n \neq -1$
$\dfrac{1}{x}$	$\ln\lvert x\rvert + C$	$x \neq 0$
e^{ax}	$\dfrac{1}{a}e^{ax} + C$	$a \neq 0$ (real or complex)
a^x	$\dfrac{a^x}{\ln a} + C$	$a > 0,\ a \neq 1$
$\sin ax$	$-\dfrac{1}{a}\cos ax + C$	
$\cos ax$	$\dfrac{1}{a}\sin ax + C$	
$\sec^2 x$	$\tan x + C$	
$\tan x$	$-\ln\lvert\cos x\rvert + C$	
$\sec x$	$\ln\lvert\sec x + \tan x\rvert + C$	
$\dfrac{1}{a^2 + x^2}$	$\dfrac{1}{a}\arctan\dfrac{x}{a} + C$	$a > 0$
$\dfrac{1}{\sqrt{a^2 - x^2}}$	$\arcsin\dfrac{x}{a} + C$	$\lvert x\rvert < a$
$\dfrac{1}{\sqrt{x^2 \pm a^2}}$	$\ln\left\lvert x + \sqrt{x^2 \pm a^2}\right\rvert + C$	
$\dfrac{1}{x^2 - a^2}$	$\dfrac{1}{2a}\ln\left\lvert\dfrac{x-a}{x+a}\right\rvert + C$	$\lvert x\rvert \neq a$
$\sinh ax,\ \cosh ax$	$\dfrac{1}{a}\cosh ax,\ \dfrac{1}{a}\sinh ax$	

The entry $\int e^{ax}dx = e^{ax}/a$ holds for complex a as well, which is why phasor methods integrate so easily: $\int e^{j\omega t}dt = \dfrac{e^{j\omega t}}{j\omega}$. Integrating a sinusoid divides its phasor by $j\omega$ — a -90° phase shift and a scaling by $1/\omega$. This is exactly the capacitor law $V = I/(j\omega C)$ (Ch. 2).

5.1.5 The Fundamental Theorem of Calculus

Fundamental Theorem of Calculus (FTC)

Let f be continuous on $[a, b]$.

Part 1. The accumulation function $A(x) = \displaystyle\int_a^x f(t)\,dt$ is differentiable on (a, b) and

$$A'(x) = f(x).$$

Part 2. If F is any antiderivative of f on $[a, b]$, then

$$\int_a^b f(x)\,dx = F(b) - F(a) \equiv \Big[F(x)\Big]_a^b.$$

Proof of Part 1. For $h \neq 0$,

$$\frac{A(x+h) - A(x)}{h} = \frac{1}{h}\int_x^{x+h} f(t)\,dt = f(c_h)$$

for some c_h between x and $x + h$, by the Mean Value Theorem for integrals. As $h \to 0$, $c_h \to x$, and continuity of f gives $f(c_h) \to f(x)$. $\square$

Proof of Part 2. A and F are both antiderivatives of f, so $F = A + C$. Then $F(b) - F(a) = A(b) - A(a) = \int_a^b f - 0$. $\square$

Part 1 says integration followed by differentiation returns the original function: integration *creates* antiderivatives, so every continuous function has one (even if, like e^{-x^2}, it cannot be written with elementary functions). Part 2 turns the computation of a limit of sums into a subtraction.

Combining Part 1 with the chain rule gives **Leibniz's rule** for variable limits:

$$\frac{d}{dx}\int_{u(x)}^{v(x)} f(t)\,dt = f\big(v(x)\big)\,v'(x) - f\big(u(x)\big)\,u'(x).$$

Worked Example 5.2 — Evaluating definite integrals with the FTC

(a) $\displaystyle\int_0^2 x^2\,dx = \Big[\frac{x^3}{3}\Big]_0^2 = \frac{8}{3}$, agreeing with Example 5.1 with no limits needed.

(b) $\displaystyle\int_0^{\pi} \sin x\,dx = \big[-\cos x\big]_0^{\pi} = -(-1) - (-1) = 2.$

(c) $\displaystyle\int_1^e \frac{3}{x}\,dx = 3\big[\ln x\big]_1^e = 3.$

(d) $\displaystyle\int_0^1 \frac{dx}{1+x^2} = \big[\arctan x\big]_0^1 = \frac{\pi}{4} \approx 0.785398.$

(e) $\displaystyle\frac{d}{dx}\int_0^{x^2} \cos t\,dt = \cos(x^2)\cdot 2x$ by Leibniz's rule. Check: the integral equals $\sin(x^2)$, whose derivative is $2x\cos(x^2)$. ✓

Worked Example 5.3 — Capacitor voltage from a current waveform

A $C = 10\ \mu\text{F}$ capacitor, initially at $v(0) = 2$ V, is driven by $i(t) = 5e^{-200t}$ mA for $t \geq 0$. Find $v(t)$ and the final voltage.

Step 1 — accumulation law. $v(t) = v(0) + \dfrac{1}{C}\displaystyle\int_0^t i(\tau)\,d\tau$.

Step 2 — integrate.

$$\int_0^t 5\times 10^{-3} e^{-200\tau}\,d\tau = 5\times 10^{-3}\Big[\frac{e^{-200\tau}}{-200}\Big]_0^t = 2.5\times 10^{-5}\big(1 - e^{-200t}\big)\ \text{C}.$$

Step 3 — divide by C. $v(t) = 2 + \dfrac{2.5\times 10^{-5}}{10^{-5}}(1 - e^{-200t}) = 2 + 2.5(1 - e^{-200t})$ V.

Step 4 — final value. As $t \to \infty$, $v \to 4.5$ V. Units: $[\text{A}\cdot\text{s/F}] = [\text{C/F}] = [\text{V}]$ ✓. At $t = 5$ ms, $v = 2 + 2.5(1 - e^{-1}) = 3.580$ V.

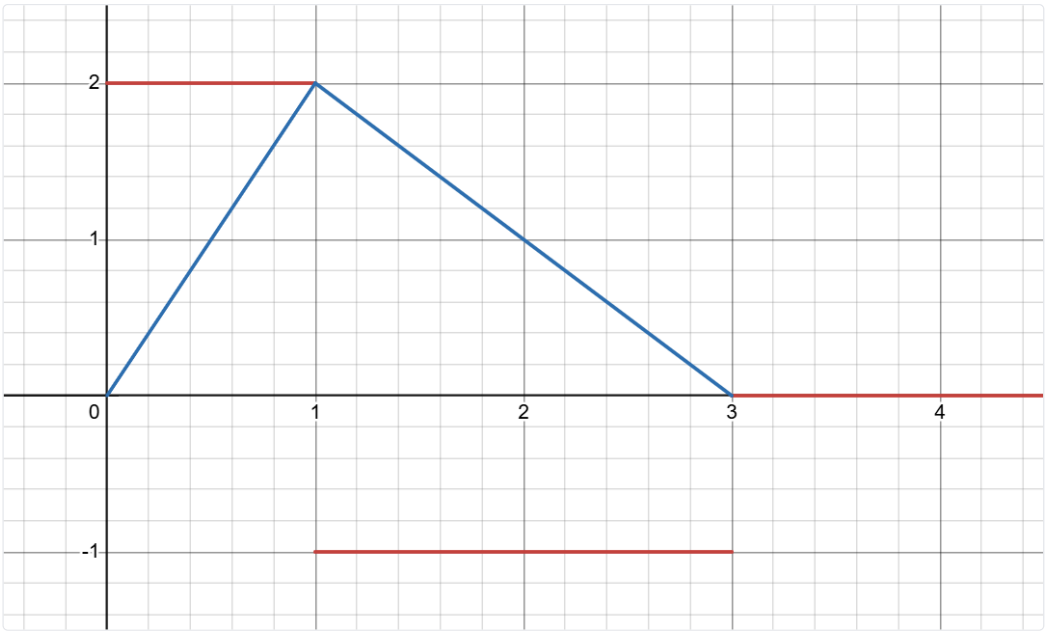
Worked Example 5.4 — Integrating a piecewise waveform

A current is $i(t) = 2$ A for $0 \leq t < 1$ ms, -1 A for $1 \leq t < 3$ ms, and 0 afterwards. Find the net charge $q(t)$ delivered from $t = 0$.

Split the integral at the breakpoints (additivity):

- $0 \leq t < 1$ ms: $q = 2t$, reaching 2 mC at $t = 1$ ms.
- $1 \leq t < 3$ ms: $q = 2\ \text{mC} - 1\cdot(t - 1\ \text{ms})$, reaching $2 - 2 = 0$ mC at $t = 3$ ms.
- $t \geq 3$ ms: $q = 0$.

The charge is a continuous piecewise-linear function even though the current jumps. **Integration smooths**: it turns jumps into kinks and kinks into smooth bends. This is why a capacitor voltage cannot jump while its current can.



Current $i(t)$ in A (red) and accumulated charge $q(t)$ in mC (blue), time in ms: the integral of a discontinuous function is continuous.

Common Pitfall — Applying the FTC across a discontinuity or singularity

$\int_{-1}^{1} \frac{dx}{x^2} = \left[-\frac{1}{x}\right]_{-1}^{1} = -2$ is **wrong**: a positive integrand cannot have a negative integral. The FTC requires $F' = f$ on the *whole* interval, and $1/x^2$ blows up at $x = 0$. The integral is improper and in fact diverges (§5.3). Always scan the interval for points where the integrand is undefined before subtracting antiderivative values.

Engineering Note — Integrators in hardware

An op-amp integrator produces $v_o(t) = -\frac{1}{RC}\int_0^t v_i(\tau)\,d\tau + v_o(0)$. The "constant of integration" is the initial capacitor voltage, which in a real circuit drifts because of input offset voltage: integrating a constant offset V_{os} gives a ramp $-V_{os}t/(RC)$ that eventually saturates the amplifier. Practical integrators add a large resistor across the capacitor to bleed this off — mathematically, replacing $\int$ by a leaky integrator with a finite time constant.

5.2 Integration techniques

5.2.1 Why technique matters

Differentiation is mechanical: the product, quotient and chain rules dispose of any elementary expression. Integration is not. There is no product rule for integrals, and some innocent-looking integrands — e^{-x^2}, $\frac{\sin x}{x}$, $\sqrt{1 - k^2 \sin^2 x}$ — have no elementary antiderivative at all. What we have instead is a toolkit of *transformations* that convert an integral into one already in the table. This section surveys the toolkit and the algebraic and trigonometric moves; the two most powerful tools, **integration by parts** and **integration by substitution**, each get a full section (§5.5 and §5.6), and the numerical fallback when everything fails is §5.7.

Even in an age of computer algebra, an engineer needs these techniques: to recognise the *form* of an answer (logarithm? arctangent? decaying exponential?), to sanity-check software output, to carry symbolic parameters such as R, L, C through a calculation, and to see the structure that a numerical answer hides. Partial fractions, in particular, are the engine of inverse Laplace and Z-transforms (Ch. 14, Ch. 17).

5.2.2 A strategy

Faced with $\int f(x)\,dx$, work down this list:

1. **Simplify algebraically.** Expand products, divide out improper fractions, split sums, cancel common factors, use $\sqrt{x^2} = |x|$ carefully.
2. **Match the table** (§5.1.4) after linearity, possibly with a linear change $x \to ax + b$.
3. **Spot a derivative.** If the integrand has the form $g(h(x))\,h'(x)$, substitute $u = h(x)$ (§5.6). Special case: $\int \frac{h'(x)}{h(x)}dx = \ln|h(x)| + C$.
4. **Trigonometric identities** for powers and products of sines and cosines (§5.2.4).
5. **Partial fractions** for rational functions (§5.2.5).
6. **Trigonometric or hyperbolic substitution** for $\sqrt{a^2 - x^2}$, $\sqrt{a^2 + x^2}$, $\sqrt{x^2 - a^2}$ (§5.6.4).
7. **Integration by parts** for products of unlike functions — polynomial × exponential, polynomial × trig, logarithms, inverse trig (§5.5).
8. **Complex exponentials** for products of exponentials and sinusoids (§5.2.6).
9. **Numerical integration** when no closed form exists or only a number is needed (§5.7).

5.2.3 Algebraic manipulation

Many integrals yield to algebra alone.

Worked Example 5.5 — Algebra first

(a) $\displaystyle\int \frac{x^3 + 2x - \sqrt{x}}{x^2}\,dx = \int \left(x + \frac{2}{x} - x^{-3/2}\right)dx = \frac{x^2}{2} + 2\ln|x| + 2x^{-1/2} + C.$

(b) $\displaystyle\int \frac{x^2}{x+1}\,dx$. The fraction is *improper* (degree of numerator $\geq$ degree of denominator), so divide first: $x^2 = (x+1)(x-1) + 1$, hence

$$\int \frac{x^2}{x+1}dx = \int \left(x - 1 + \frac{1}{x+1}\right)dx = \frac{x^2}{2} - x + \ln|x+1| + C.$$

(c) $\displaystyle\int \frac{dx}{x^2 + 4x + 13}$. **Complete the square:** $x^2 + 4x + 13 = (x+2)^2 + 9$, so

$$\int \frac{dx}{(x+2)^2 + 3^2} = \frac{1}{3}\arctan\frac{x+2}{3} + C.$$

(d) $\displaystyle\int_0^1 \frac{2x+1}{x^2+x+1}dx$. The numerator is exactly the derivative of the denominator, so the answer is $\big[\ln(x^2+x+1)\big]_0^1 = \ln 3 \approx 1.0986$.

Completing the square deserves emphasis because it is how quadratic denominators — which in circuit theory come from second-order (RLC) characteristic polynomials $s^2 + 2\zeta\omega_n s + \omega_n^2$ — are put into a recognisable form:

$$s^2 + 2\zeta\omega_n s + \omega_n^2 = (s + \zeta\omega_n)^2 + \omega_n^2(1 - \zeta^2).$$

When $\zeta < 1$ the second term is positive and an arctangent (in the time domain: a damped sinusoid) appears; when $\zeta > 1$ it is negative, the quadratic factors into real roots, and logarithms (decaying exponentials) appear instead.

5.2.4 Trigonometric integrals

The integrals of products and powers of sinusoids are the backbone of power calculations and Fourier analysis. The identities that drive them are (Ch. 3):

$$\cos^2\theta = \frac{1+\cos 2\theta}{2}, \qquad \sin^2\theta = \frac{1-\cos 2\theta}{2}, \qquad \sin\theta\cos\theta = \frac{\sin 2\theta}{2},$$

$$\begin{aligned}
\sin A\cos B &= \tfrac{1}{2}\big[\sin(A+B) + \sin(A-B)\big],\\
\cos A\cos B &= \tfrac{1}{2}\big[\cos(A-B) + \cos(A+B)\big],\\
\sin A\sin B &= \tfrac{1}{2}\big[\cos(A-B) - \cos(A+B)\big].
\end{aligned}$$

Rules for $\int \sin^m x \cos^n x\,dx$:

- If m is **odd**, save one $\sin x$, convert the remaining even power of sin to cos using $\sin^2 = 1 - \cos^2$, and substitute $u = \cos x$.
- If n is **odd**, save one $\cos x$, convert the rest to sin, and substitute $u = \sin x$.
- If both are **even**, reduce powers with the half-angle identities, repeatedly if necessary.

Worked Example 5.6 — Powers of sinusoids

(a) **Odd power.** $\displaystyle\int \sin^3 x\,dx = \int (1 - \cos^2 x)\sin x\,dx$. With $u = \cos x$, $du = -\sin x\,dx$:

$$-\int (1 - u^2)\,du = -u + \frac{u^3}{3} + C = -\cos x + \frac{\cos^3 x}{3} + C.$$

(b) **Even powers.** $\displaystyle\int \sin^2 x\cos^2 x\,dx = \int \frac{\sin^2 2x}{4}dx = \int \frac{1-\cos 4x}{8}dx = \frac{x}{8} - \frac{\sin 4x}{32} + C.$

(c) **Over a period.** For $\omega = 2\pi/T$,

$$\int_0^T \sin^2(\omega t)\,dt = \int_0^T \frac{1-\cos 2\omega t}{2}dt = \frac{T}{2} - \Big[\frac{\sin 2\omega t}{4\omega}\Big]_0^T = \frac{T}{2}.$$

The cosine term integrates to zero over a whole number of periods. This single result gives the RMS value $V_m/\sqrt{2}$ of a sinusoid (§5.9).

Check (b) numerically: $\int_0^1 \sin^2 x\cos^2 x\,dx = \frac{1}{8} - \frac{\sin 4}{32} = 0.125 + 0.02365 = 0.14865$; adaptive quadrature gives 0.148650 ✓.

Orthogonality of sinusoids

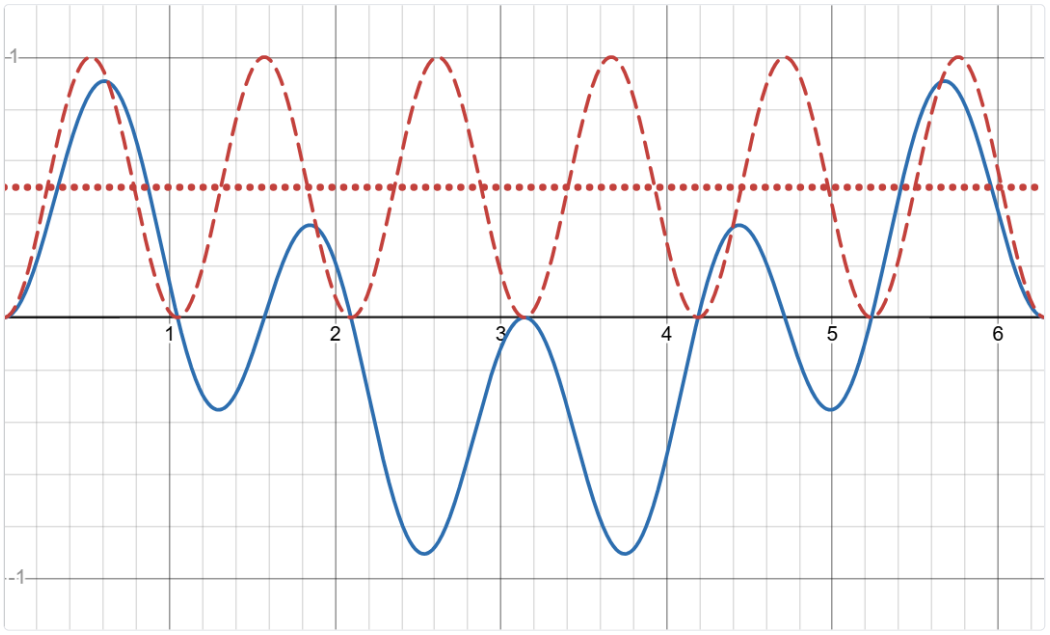
For integers $m, n \geq 1$ and $T = 2\pi/\omega_0$:

$$\int_0^T \sin(m\omega_0 t)\sin(n\omega_0 t)\,dt = \int_0^T \cos(m\omega_0 t)\cos(n\omega_0 t)\,dt = \begin{cases} T/2, & m = n \\ 0, & m \neq n \end{cases}$$

and $\displaystyle\int_0^T \sin(m\omega_0 t)\cos(n\omega_0 t)\,dt = 0$ for all m, n.

Proof. Use the product-to-sum identity. For $m \neq n$, $\sin m\theta \sin n\theta = \frac{1}{2}[\cos(m-n)\theta - \cos(m+n)\theta]$, and each cosine of a nonzero integer multiple of $\theta = \omega_0 t$ completes a whole number of cycles in $[0, T]$, integrating to zero. For $m = n$ the first cosine becomes $\cos 0 = 1$, giving $T/2$. The other cases are identical. □

Orthogonality is the reason power in different harmonics simply *adds* (Parseval's theorem, §5.9) and the reason Fourier coefficients can be computed one at a time (Ch. 15).



$\sin 2x \sin 3x$ (blue) has equal positive and negative area over $[0, 2\pi]$; $\sin^2 3x$ (red) oscillates about its mean $1/2$.

5.2.5 Partial fractions

A **rational function** $P(x)/Q(x)$ (ratio of polynomials) can always be integrated in elementary terms. The method:

1. If $\deg P \geq \deg Q$, divide to get a polynomial plus a **proper** fraction.
2. Factor Q over the reals into linear factors $(x-a)$ and irreducible quadratics (x^2+bx+c) with $b^2 < 4c$. (Over $\mathbb{C}$ every factor is linear; the real quadratics pair complex-conjugate roots.)
3. Write the proper fraction as a sum of simple terms according to this table.

Factor of Q	Terms in the expansion
$(x-a)$, simple	$\dfrac{A}{x-a}$
$(x-a)^k$, repeated	$\dfrac{A_1}{x-a} + \dfrac{A_2}{(x-a)^2} + \cdots + \dfrac{A_k}{(x-a)^k}$
x^2+bx+c, irreducible	$\dfrac{Bx+C}{x^2+bx+c}$
$(x^2+bx+c)^k$, repeated	$\displaystyle\sum_{i=1}^{k} \frac{B_i x + C_i}{(x^2+bx+c)^i}$

4. Find the constants. Fastest for simple linear factors is the **cover-up (Heaviside) rule**:

$$A = \Big[(x-a)\frac{P(x)}{Q(x)}\Big]_{x=a}.$$

For repeated factors, cover-up gives the highest-power coefficient A_k; the others follow by comparing coefficients, substituting convenient x values, or differentiating: $A_{k-i} = \dfrac{1}{i!}\dfrac{d^i}{dx^i}\Big[(x-a)^k P/Q\Big]_{x=a}$. 5. Integrate each term: $\int \frac{dx}{x-a} = \ln|x-a|$, $\int \frac{dx}{(x-a)^k} = \frac{(x-a)^{1-k}}{1-k}$ for $k \geq 2$, and quadratic terms by completing the square (split into a ln part and an arctan part).

Why the cover-up rule works. If $\frac{P}{Q} = \frac{A}{x-a} + R(x)$ where R has no pole at a, multiplying by $(x-a)$ gives $(x-a)\frac{P}{Q} = A + (x-a)R(x)$; setting $x = a$ kills the second term.

Worked Example 5.7 — Distinct linear factors

$\displaystyle\int \frac{3x+5}{(x+1)(x+2)}dx.$

Cover-up: $A = \dfrac{3(-1)+5}{-1+2} = 2$, $B = \dfrac{3(-2)+5}{-2+1} = 1$. So

$$\int \Big(\frac{2}{x+1} + \frac{1}{x+2}\Big)dx = 2\ln|x+1| + \ln|x+2| + C.$$

Check at $x=0$: $\frac{2}{1} + \frac{1}{2} = 2.5 = \frac{5}{2}$ ✓.

Worked Example 5.8 — A repeated factor

$\int \frac{x^2+1}{x(x-1)^2}dx$. Write $\frac{x^2+1}{x(x-1)^2} = \frac{A}{x} + \frac{B}{x-1} + \frac{C}{(x-1)^2}$.

- Cover x, set $x=0$: $A = \frac{1}{(-1)^2} = 1$.
- Cover $(x-1)^2$, set $x=1$: $C = \frac{1+1}{1} = 2$.
- Compare x^2 coefficients in $x^2+1 = A(x-1)^2 + Bx(x-1) + Cx$: $1 = A + B$, so $B = 0$.

$$\int \Big(\frac{1}{x} + \frac{2}{(x-1)^2}\Big)dx = \ln|x| - \frac{2}{x-1} + C.$$

Check at $x=2$: integrand $= 5/2$; $\frac{1}{2} + \frac{2}{1} = 2.5$ ✓.

Worked Example 5.9 — An irreducible quadratic

$\int_0^1 \frac{5x+3}{(x+1)(x^2+1)}dx$.

Step 1 — form. $\frac{5x+3}{(x+1)(x^2+1)} = \frac{A}{x+1} + \frac{Bx+C}{x^2+1}$.

Step 2 — constants. Cover-up at $x=-1$: $A = \frac{-5+3}{2} = -1$. Then $5x+3 = -(x^2+1) + (Bx+C)(x+1)$. Comparing x^2: $0 = -1 + B \Rightarrow B = 1$. Constants: $3 = -1 + C \Rightarrow C = 4$. (Check x terms: $5 = B + C$ ✓.)

Step 3 — integrate.

$$\int_0^1 \Big(-\frac{1}{x+1} + \frac{x}{x^2+1} + \frac{4}{x^2+1}\Big)dx = \Big[-\ln(x+1) + \tfrac{1}{2}\ln(x^2+1) + 4\arctan x\Big]_0^1.$$

Step 4 — evaluate. $-\ln 2 + \frac{1}{2}\ln 2 + 4\cdot\frac{\pi}{4} = \pi - \frac{1}{2}\ln 2 \approx 3.14159 - 0.34657 = 2.79502$.

Check: numerical quadrature gives 2.795019 ✓.

Worked Example 5.10 — A circuit-flavoured rational integral

The integral $I = \int_0^\infty \frac{d\omega}{(\omega^2+a^2)(\omega^2+b^2)}$ $(a, b > 0,\ a \neq b)$ appears in noise-bandwidth calculations for cascaded RC filters. Treat $u = \omega^2$ as the variable: cover-up on $\frac{1}{(u+a^2)(u+b^2)}$ gives

$$\frac{1}{(\omega^2+a^2)(\omega^2+b^2)} = \frac{1}{b^2-a^2}\Big(\frac{1}{\omega^2+a^2} - \frac{1}{\omega^2+b^2}\Big).$$

Each term integrates to an arctangent; on $[0,\infty)$, $\int_0^\infty \frac{d\omega}{\omega^2+a^2} = \frac{\pi}{2a}$ (an improper integral, §5.3). Hence

$$I = \frac{1}{b^2-a^2}\Big(\frac{\pi}{2a} - \frac{\pi}{2b}\Big) = \frac{\pi}{2ab(a+b)}.$$

Check with $a=1, b=2$: $\pi/12 = 0.261799$; numerical quadrature agrees.

Engineering Note — Partial fractions and system response

In the Laplace domain the response of a linear circuit is a rational function $Y(s) = P(s)/Q(s)$. The roots of Q are the **poles** (natural frequencies). Expanding Y in partial fractions decomposes the response into **modes**: each simple real pole p contributes Ae^{pt}, each repeated pole contributes $t^{k-1}e^{pt}$ terms, and each conjugate pair contributes a damped sinusoid. The cover-up coefficient A is called the **residue**, a name that returns in Ch. 18.

5.2.6 The complex-exponential method

Integrals of the form $\int e^{at}\cos bt\,dt$ and $\int e^{at}\sin bt\,dt$ can be done by parts twice (§5.5), but the fastest route uses Euler's formula. Since $e^{at}\cos bt = \mathrm{Re}\{e^{(a+jb)t}\}$ and integration commutes with taking real parts,

$$\int e^{at}\cos bt\,dt = \mathrm{Re}\left\{\frac{e^{(a+jb)t}}{a+jb}\right\} = \mathrm{Re}\left\{\frac{(a-jb)\,e^{at}(\cos bt + j\sin bt)}{a^2+b^2}\right\},$$

so

$$\int e^{at}\cos bt\,dt = \frac{e^{at}(a\cos bt + b\sin bt)}{a^2+b^2} + C, \qquad \int e^{at}\sin bt\,dt = \frac{e^{at}(a\sin bt - b\cos bt)}{a^2+b^2} + C,$$

the second from the imaginary part.

Worked Example 5.11 — Charge in a damped oscillation

The current in an underdamped RLC circuit is $i(t) = e^{-2t}\sin 4t$ A (time in seconds). Find $\int_0^\infty i(t)\,dt$, the net charge transferred.

With $a = -2$, $b = 4$, $a^2 + b^2 = 20$:

$$\int_0^\infty e^{-2t}\sin 4t\,dt = \Big[\frac{e^{-2t}(-2\sin 4t - 4\cos 4t)}{20}\Big]_0^\infty = 0 - \frac{-4}{20} = 0.2\text{ C}.$$

Shortcut: $\int_0^\infty e^{(a+jb)t}dt = \frac{-1}{a+jb}$ for $a<0$, so the answer is $\mathrm{Im}\{\frac{1}{2-4j}\} = \mathrm{Im}\{\frac{2+4j}{20}\} = 0.2$ ✓. This is the Laplace transform $\frac{4}{s^2+4s+20}$ evaluated at $s=0$ — an early glimpse of Ch. 14.

Common Pitfall — "Re" and products

$\mathrm{Re}\{\cdot\}$ commutes with integration and with multiplication by *real* quantities, but not with multiplication of two complex quantities: $\mathrm{Re}\{z_1 z_2\} \neq \mathrm{Re}\{z_1\}\,\mathrm{Re}\{z_2\}$ in general. When computing average power $\frac{1}{T}\int v(t)i(t)\,dt$ from phasors you cannot simply multiply phasors; the correct result is $\frac{1}{2}\,\mathrm{Re}\{\mathbf{V}\mathbf{I}^*\}$ (§5.9).

5.2.7 Integrals with no elementary antiderivative

Liouville's theory (19th century) shows that certain integrals cannot be expressed using finitely many elementary functions. Important examples define *new* special functions:

Integral	Name	Where it appears
$\frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$	error function $\mathrm{erf}(x)$	Gaussian noise, bit-error rate, diffusion
$\int_0^x \frac{\sin t}{t}dt$	sine integral $\mathrm{Si}(x)$	Gibbs phenomenon, ideal-filter step response
$\int_0^{\pi/2}\frac{d\theta}{\sqrt{1-k^2\sin^2\theta}}$	complete elliptic integral $K(k)$	pendulum period, coil inductance, line geometries
$\int_x^\infty \frac{e^{-t}}{t}dt$	exponential integral $E_1(x)$	radiation, transient heating

These are tabulated and built into every numerical library. Recognising that an integral *is* one of them is a useful skill; trying to "find" an elementary antiderivative for them is not.

5.3 Improper integrals

5.3.1 Motivation

The Riemann integral is defined for a *bounded* function on a *bounded* interval. Engineering keeps breaking both conditions. The total energy dissipated as a capacitor discharges is an integral from $t=0$ to $t=\infty$. The Laplace and Fourier transforms are integrals over infinite ranges. The field of a line charge involves $\int \frac{dz}{(r^2+z^2)^{3/2}}$ over the whole z-axis. The probability that Gaussian noise exceeds a threshold is a tail integral to infinity. And the potential near a point charge involves integrands that blow up like $1/R$. **Improper integrals** extend the definition to these cases by taking limits.

5.3.2 Definitions

Improper integral of Type I (infinite interval)

If f is integrable on $[a,b]$ for every $b > a$,

$$\int_a^\infty f(x)\,dx = \lim_{b\to\infty}\int_a^b f(x)\,dx,$$

provided the limit exists and is finite; the integral then **converges**, otherwise it **diverges**. Similarly $\int_{-\infty}^b f = \lim_{a\to-\infty}\int_a^b f$, and

$$\int_{-\infty}^\infty f(x)\,dx = \int_{-\infty}^c f(x)\,dx + \int_c^\infty f(x)\,dx,$$

which converges only if **both** halves converge independently (the choice of c does not matter).

Improper integral of Type II (unbounded integrand)

If f is integrable on $[a+\varepsilon, b]$ for every $\varepsilon > 0$ but unbounded near a,

$$\int_a^b f(x)\,dx = \lim_{\varepsilon\to 0^+}\int_{a+\varepsilon}^b f(x)\,dx.$$

Likewise at the right end. If the singularity is at an interior point c, split: $\int_a^b = \int_a^c + \int_c^b$, and require both to converge.

An integral can be improper for several reasons at once ($\int_0^\infty \frac{dx}{\sqrt{x}}$ is improper at both ends); split it so that each piece has only one difficulty.

5.3.3 The benchmark p-integrals

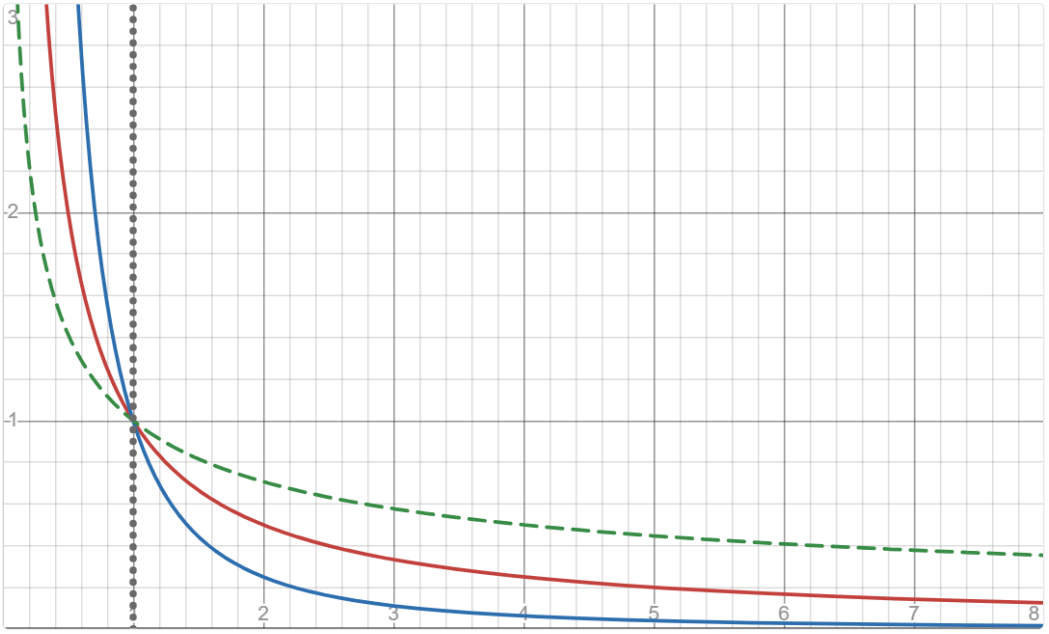
Almost every convergence question is settled by comparison with powers of x.

p-integrals

$$\int_1^\infty \frac{dx}{x^p} \begin{cases} = \dfrac{1}{p-1}, & p > 1 \\ \text{diverges}, & p \le 1 \end{cases} \qquad \int_0^1 \frac{dx}{x^p} \begin{cases} = \dfrac{1}{1-p}, & p < 1 \\ \text{diverges}, & p \ge 1 \end{cases}$$

Proof. For $p \neq 1$, $\int_1^b x^{-p}dx = \frac{b^{1-p}-1}{1-p}$. As $b \to \infty$, $b^{1-p} \to 0$ if $p > 1$ and $\to \infty$ if $p < 1$. For $p = 1$, $\int_1^b \frac{dx}{x} = \ln b \to \infty$. The $[0, 1]$ case is the same computation with ε^{1-p} as $\varepsilon \to 0^+$. $\square$

The memory aid: **at infinity a function must decay faster than $1/x$; at a singularity it must blow up slower than $1/x$.** The function $1/x$ itself fails both tests — its integral diverges logarithmically at both ends. Exponentials decay faster than any power, so $\int_0^\infty x^n e^{-ax}dx$ converges for every $n \ge 0$, $a > 0$.



$1/x$ (red) sits on the borderline: its area diverges both near 0 and towards ∞. $1/x^2$ (blue) has finite area on $[1, \infty)$; $1/\sqrt{x}$ (green) has finite area on $(0, 1]$.

Worked Example 5.12 — Direct evaluation

(a) $\displaystyle\int_0^\infty e^{-t/\tau}dt = \lim_{b\to\infty}\left[-\tau e^{-t/\tau}\right]_0^b = \tau$ for $\tau > 0$. The area under a decaying exponential equals its time constant — the basis of the "area = height × time constant" rule of thumb.

(b) $\displaystyle\int_0^1 \frac{dx}{\sqrt{x}} = \lim_{\varepsilon\to 0^+}\left[2\sqrt{x}\right]_\varepsilon^1 = 2$. A function can be infinite at a point and still enclose finite area.

(c) $\displaystyle\int_0^1 \ln x\,dx = \lim_{\varepsilon\to 0^+}\left[x\ln x - x\right]_\varepsilon^1 = -1 - \lim_{\varepsilon\to 0^+}(\varepsilon\ln\varepsilon - \varepsilon) = -1$, using $\varepsilon\ln\varepsilon \to 0$ (L'Hôpital, Ch. 4).

(d) $\displaystyle\int_{-\infty}^\infty \frac{dx}{1+x^2} = \lim_{a\to-\infty}\left[\arctan x\right]_a^0 + \lim_{b\to\infty}\left[\arctan x\right]_0^b = \frac{\pi}{2} + \frac{\pi}{2} = \pi$.

Worked Example 5.13 — Energy dissipated by a discharging capacitor

A capacitor C charged to V_0 discharges through R: $v(t) = V_0 e^{-t/RC}$. Find the total energy dissipated in R.

Step 1 — power. $p(t) = v^2/R = \dfrac{V_0^2}{R}e^{-2t/RC}$.

Step 2 — improper integral. Using Example 5.12(a) with $\tau = RC/2$,

$$W = \int_0^\infty \frac{V_0^2}{R}e^{-2t/RC}dt = \frac{V_0^2}{R}\cdot\frac{RC}{2} = \frac{1}{2}CV_0^2.$$

Interpretation. All of the stored energy $\frac{1}{2}CV_0^2$ ends up as heat, independent of R — a larger resistor dissipates less power but for longer. With $C = 100\ \mu$F, $V_0 = 12$ V: $W = 7.2$ mJ.

Worked Example 5.14 — A divergent integral in disguise

Is $\displaystyle\int_0^2 \frac{dx}{(x-1)^2}$ finite?

The integrand is singular at the interior point $x = 1$. Split at 1:

$$\int_0^1 \frac{dx}{(x-1)^2} = \lim_{\varepsilon\to 0^+}\Big[-\frac{1}{x-1}\Big]_0^{1-\varepsilon} = \lim_{\varepsilon\to 0^+}\Big(\frac{1}{\varepsilon} - 1\Big) = \infty.$$

One half diverges, so the whole integral diverges. Blindly applying the FTC gives $\big[-\frac{1}{x-1}\big]_0^2 = -1 - 1 = -2$, a negative "area" for a positive function — the same trap as in §5.1.

5.3.4 Comparison tests

Often we only need to know *whether* an improper integral converges — for example, to confirm that a Fourier or Laplace transform exists — without computing it.

Direct comparison test

Suppose $0 \le f(x) \le g(x)$ for $x \ge a$.

- If $\int_a^\infty g\,dx$ converges, so does $\int_a^\infty f\,dx$ (and $\int_a^\infty f \le \int_a^\infty g$).
- If $\int_a^\infty f\,dx$ diverges, so does $\int_a^\infty g\,dx$.

The same holds for Type II integrals near a singularity.

Proof sketch. $F(b) = \int_a^b f$ is non-decreasing in b (since $f \ge 0$) and bounded above by $\int_a^\infty g$. A bounded monotone function has a limit. □

Limit comparison test

If $f, g > 0$ for $x \ge a$ and $\displaystyle\lim_{x\to\infty}\frac{f(x)}{g(x)} = L$ with $0 < L < \infty$, then $\int_a^\infty f$ and $\int_a^\infty g$ either both converge or both diverge.

Limit comparison formalises "only the dominant behaviour matters". To test $\int_1^\infty \frac{3x+2}{x^3+5}dx$, note the integrand behaves like $3x/x^3 = 3/x^2$ for large x; the ratio to $1/x^2$ tends to 3, and $\int_1^\infty x^{-2}$ converges, so the original converges.

Absolute convergence

If $\int_a^\infty |f|\,dx$ converges then $\int_a^\infty f\,dx$ converges, and $\big|\int_a^\infty f\big| \le \int_a^\infty |f|$.

An integral that converges but not absolutely is **conditionally convergent**. The classic example is the Dirichlet integral

$$\int_0^\infty \frac{\sin x}{x}\,dx = \frac{\pi}{2},$$

which converges because the positive and negative lobes of $\sin x/x$ shrink and alternate, yet $\int_0^\infty \big|\frac{\sin x}{x}\big|dx = \infty$ (each lobe has area roughly $2/(k\pi)$, and $\sum 1/k$ diverges). This integral is the area under the sinc function and underlies the Gibbs phenomenon and the ideal low-pass filter (Ch. 16).

Worked Example 5.15 — Convergence decisions

(a) $\displaystyle\int_1^\infty e^{-x^2}dx$: for $x \ge 1$, $x^2 \ge x$, so $0 < e^{-x^2} \le e^{-x}$, and $\int_1^\infty e^{-x}dx = e^{-1}$. **Converges**, with value at most 0.3679 (actual: 0.1394).

(b) $\displaystyle\int_1^\infty \frac{\sqrt{x}+1}{x^2}dx$: dominant term $x^{1/2}/x^2 = x^{-3/2}$, $p = 3/2 > 1$. **Converges** (in fact it equals $2 + 1 = 3$).

(c) $\displaystyle\int_2^\infty \frac{dx}{\ln x}$: for $x \ge 2$, $\ln x < x$, so $\frac{1}{\ln x} > \frac{1}{x}$, and $\int_2^\infty \frac{dx}{x}$ diverges. **Diverges.**

(d) $\displaystyle\int_0^1 \frac{\cos x}{x^{2/3}}dx$: near 0, $\cos x \to 1$, so the integrand behaves like $x^{-2/3}$ with $p = 2/3 < 1$. **Converges.**

(e) $\displaystyle\int_0^\infty \frac{\sin^2 x}{x^2}dx$: near 0 the integrand $\to 1$ (no singularity at all); for large x it is bounded by $1/x^2$. **Converges** absolutely (its value is $\pi/2$).

5.3.5 Cauchy principal value

Some integrals over symmetric ranges diverge in the strict sense but have a natural "balanced" value.

Cauchy principal value

$$\mathrm{PV}\int_{-\infty}^{\infty} f(x)\,dx = \lim_{R\to\infty}\int_{-R}^{R} f(x)\,dx, \qquad \mathrm{PV}\int_a^b f(x)\,dx = \lim_{\varepsilon\to 0^+}\Big(\int_a^{c-\varepsilon} f + \int_{c+\varepsilon}^b f\Big)$$

for a singularity at $c \in (a, b)$.

For example $\int_{-\infty}^{\infty} x\,dx$ diverges, but its principal value is 0; and $\mathrm{PV}\int_{-1}^{2}\frac{dx}{x} = \lim_{\varepsilon\to 0^+}\left(\ln\varepsilon - 0 + \ln 2 - \ln\varepsilon\right) = \ln 2$. Principal values appear in the Hilbert transform (single-sideband modulation, Kramers–Kronig relations between the real and imaginary parts of a causal response) and are evaluated systematically with contour integration in Ch. 18.

> **Common Pitfall — Symmetric limits are not the definition**
>
> $\int_{-\infty}^{\infty} f\,dx$ is defined by two *independent* limits. Computing $\lim_{R\to\infty}\int_{-R}^{R} f$ gives the principal value, which can be finite even when the integral diverges. Only when the integral is known to converge do the two agree.

5.3.6 Two important improper integrals

The Gaussian integral.

$$\int_{-\infty}^{\infty} e^{-x^2}\,dx = \sqrt{\pi}.$$

Convergence follows from Example 5.15(a). The value cannot be found with single-variable antiderivatives; the standard trick squares it into a double integral over the plane and switches to polar coordinates — a computation done in Ch. 6. Scaling $x \to x/(\sigma\sqrt{2})$ gives the normalisation of the Gaussian density, $\int_{-\infty}^{\infty} e^{-x^2/2\sigma^2}\,dx = \sigma\sqrt{2\pi}$ (Ch. 19).

The Gamma function.

> **Gamma function**
>
> For $x > 0$,
>
> $$\Gamma(x) = \int_0^{\infty} t^{x-1}e^{-t}\,dt.$$

It converges at ∞ because the exponential wins, and at 0 because t^{x-1} has $p = 1 - x < 1$. Integration by parts (§5.5) gives $\Gamma(x+1) = x\,\Gamma(x)$, and $\Gamma(1) = 1$, so

$$\Gamma(n+1) = n! \qquad (n = 0, 1, 2, \dots),$$

and $\Gamma(\tfrac{1}{2}) = \sqrt{\pi}$ (substitute $t = u^2$ and use the Gaussian integral). The Gamma function makes "$\int_0^{\infty} t^n e^{-st}dt = n!/s^{n+1}$" — the Laplace transform of t^n — a one-line result.

> **Engineering Note — Existence of transforms**
>
> The Laplace transform $\int_0^{\infty} f(t)e^{-st}dt$ converges absolutely when $|f(t)| \le Me^{\alpha t}$ and $\mathrm{Re}\,s > \alpha$: compare with $\int_0^{\infty} Me^{-(\mathrm{Re}\,s-\alpha)t}dt$. That is the entire content of the "exponential order" existence theorem in Ch. 14 — a direct comparison test.

5.4 Multiple integrals

5.4.1 Motivation

Charge is rarely concentrated on a line. A semiconductor wafer carries a surface charge density $\sigma(x, y)$ in C/m²; a depletion region holds a volume charge density $\rho(x, y, z)$ in C/m³; a printed coil's inductance depends on how current is distributed across a cross-section. The total charge is obtained exactly as in §5.1 — chop, multiply by the size of each piece, add, take a limit — except that the pieces are now small rectangles of area ΔA or small boxes of volume ΔV. The result is a **double** or **triple integral**.

This section introduces multiple integrals over simple regions in Cartesian coordinates and shows how to compute them as *iterated* single integrals, so that everything from §§5.1–5.3 carries over. Chapter 6 develops the subject further: general changes of variables, the Jacobian, and polar, cylindrical and spherical coordinates.

5.4.2 Double integrals over a rectangle

> **Double integral**
>
> Let f be bounded on the rectangle $R = [a, b] \times [c, d]$. Partition $[a, b]$ and $[c, d]$, giving sub-rectangles R_{ij} of area $\Delta A_{ij} = \Delta x_i\,\Delta y_j$, and pick sample points $(x_{ij}^*, y_{ij}^*) \in R_{ij}$. If the double Riemann sum
>
> $$\sum_i \sum_j f(x_{ij}^*, y_{ij}^*)\,\Delta A_{ij}$$
>
> tends to a limit I as the largest sub-rectangle diagonal tends to zero, independent of the sample points, then
>
> $$\iint_R f(x, y)\,dA = I.$$

If $f \ge 0$, the double integral is the **volume** under the surface $z = f(x, y)$ above R. If f is a surface density (charge, mass, power per area), it is the **total amount**. With $f \equiv 1$ it is the **area** of R. Linearity, additivity over regions, monotonicity and the triangle inequality all carry over from §5.1.3. Continuous functions — and bounded functions whose discontinuities lie on finitely many smooth curves — are integrable.

Computing a two-dimensional limit directly is hopeless, but the following theorem reduces it to two one-dimensional integrals.

Fubini's theorem (rectangle)

If f is continuous on $R = [a,b] \times [c,d]$, then

$$\iint_R f(x,y)\,dA = \int_a^b \Big[\int_c^d f(x,y)\,dy\Big]dx = \int_c^d \Big[\int_a^b f(x,y)\,dx\Big]dy.$$

Proof idea. Arrange the double Riemann sum in a grid. Summing first down each column (fixed x_i) gives approximately $\big[\int_c^d f(x_i,y)\,dy\big]\Delta x_i$; summing those columns across gives a Riemann sum for the outer x-integral. Summing rows first gives the other order. Both are rearrangements of the same finite sum, and continuity ensures both limits exist and agree. □

In the inner integral the outer variable is held **constant**, exactly as in partial differentiation. The bracket is a function of the outer variable alone.

Separable integrands. If $f(x,y) = g(x)h(y)$ on a rectangle, the double integral factorises:

$$\iint_{[a,b]\times[c,d]} g(x)h(y)\,dA = \Big(\int_a^b g(x)\,dx\Big)\Big(\int_c^d h(y)\,dy\Big).$$

Worked Example 5.16 — A rectangle

Evaluate $\iint_R x^2 y\,dA$ over $R = [0,2]\times[1,3]$.

Order dy then dx:

$$\int_0^2 \Big[\int_1^3 x^2 y\,dy\Big]dx = \int_0^2 x^2\Big[\frac{y^2}{2}\Big]_1^3 dx = \int_0^2 4x^2\,dx = \frac{32}{3}.$$

Check by factorising: $\big(\int_0^2 x^2dx\big)\big(\int_1^3 y\,dy\big) = \frac{8}{3}\cdot 4 = \frac{32}{3} \approx 10.667$ ✓.

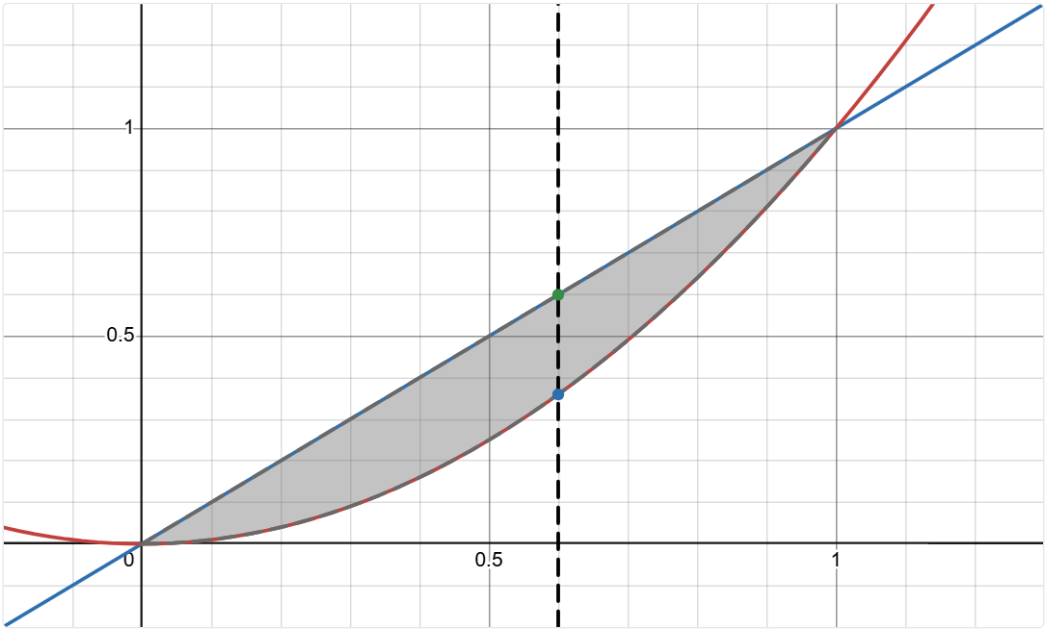
5.4.3 Double integrals over general regions

For a region D that is not a rectangle, extend f by zero outside D and integrate over an enclosing rectangle. In practice we describe D by its bounding curves.

Type I and Type II regions

- **Type I (vertically simple):** $D = \{(x,y) : a \le x \le b,\ g_1(x) \le y \le g_2(x)\}$. Then
$$\iint_D f\,dA = \int_a^b \int_{g_1(x)}^{g_2(x)} f(x,y)\,dy\,dx.$$
- **Type II (horizontally simple):** $D = \{(x,y) : c \le y \le d,\ h_1(y) \le x \le h_2(y)\}$. Then
$$\iint_D f\,dA = \int_c^d \int_{h_1(y)}^{h_2(y)} f(x,y)\,dx\,dy.$$

Recipe for setting limits. (1) Sketch D. (2) Choose the inner variable, say y. (3) Draw a vertical line through D at a typical x: it enters D on the lower curve $y = g_1(x)$ and leaves on the upper curve $y = g_2(x)$ — those are the inner limits, and they may depend on x. (4) The outer limits are the extreme x-values of D and must be **constants**. A region that is neither type is split into pieces that are.



The region between $y = x^2$ and $y = x$. A vertical line at $x = 0.6$ enters on the parabola and leaves on the line, fixing the inner y-limits.

Worked Example 5.17 — A region between two curves, both orders

Evaluate $\iint_D xy\,dA$ where D is bounded by $y = x$ and $y = x^2$.

Step 1 — sketch. The curves meet where $x = x^2$, i.e. $x = 0$ and $x = 1$. For $0 < x < 1$, $x^2 < x$.

Step 2 — Type I.

$$\int_0^1 \int_{x^2}^{x} xy\,dy\,dx = \int_0^1 x \cdot \frac{x^2 - x^4}{2}\,dx = \frac{1}{2}\left(\frac{1}{4} - \frac{1}{6}\right) = \frac{1}{24}.$$

Step 3 — Type II, as a check. A horizontal line at height y enters at $x = y$ and leaves at $x = \sqrt{y}$:

$$\int_0^1 \int_{y}^{\sqrt{y}} xy\,dx\,dy = \int_0^1 y \cdot \frac{y - y^2}{2}\,dy = \frac{1}{2}\left(\frac{1}{3} - \frac{1}{4}\right) = \frac{1}{24}\ \checkmark$$

Area of D (integrand 1): $\int_0^1 (x - x^2)dx = \frac{1}{6}$. So the **mean value** of xy over D is $\frac{1/24}{1/6} = \frac{1}{4}$.

5.4.4 Reversing the order of integration

Sometimes the inner integral in one order has no elementary antiderivative, but the other order is easy. Reversing the order means re-describing the *same region* the other way — the limits do not simply swap.

Worked Example 5.18 — Reversal rescues an impossible integral

Evaluate $I = \int_0^1 \int_x^1 e^{y^2}\,dy\,dx$.

Step 1 — the obstacle. $\int e^{y^2}\,dy$ has no elementary antiderivative.

Step 2 — describe the region. $0 \le x \le 1$, $x \le y \le 1$: the triangle with vertices $(0,0)$, $(0,1)$, $(1,1)$, lying above the line $y = x$.

Step 3 — redescribe as Type II. For fixed $y \in [0,1]$, x runs from 0 to y.

Step 4 — integrate.

$$I = \int_0^1 \int_0^y e^{y^2}\,dx\,dy = \int_0^1 y\,e^{y^2}\,dy = \left[\tfrac{1}{2}e^{y^2}\right]_0^1 = \frac{e - 1}{2} \approx 0.85914.$$

The inner integration produced the factor y, which is precisely the derivative needed for the substitution $u = y^2$ (§5.6).

Common Pitfall — Variable outer limits

The outermost limits must be constants. Writing $\int_x^1 \int_0^1 f\,dx\,dy$ is meaningless — after both integrations an x would survive. When reversing order, *always* sketch the region and read the new limits off the sketch.

5.4.5 Triple integrals

The triple integral $\iiint_E f(x,y,z)\,dV$ is defined by Riemann sums over small boxes of volume $\Delta V = \Delta x\,\Delta y\,\Delta z$. With $f \equiv 1$ it gives the volume of E; with $f = \rho$ (charge density) it gives the enclosed charge — the right-hand side of Gauss's law in integral form (Ch. 7). Fubini's theorem extends: for a solid described by

$$E = \{(x,y,z) : a \le x \le b,\ g_1(x) \le y \le g_2(x),\ u_1(x,y) \le z \le u_2(x,y)\},$$

$$\iiint_E f\,dV = \int_a^b \int_{g_1(x)}^{g_2(x)} \int_{u_1(x,y)}^{u_2(x,y)} f(x,y,z)\,dz\,dy\,dx.$$

Work from the inside out: integrate in z treating x, y as constants, then in y treating x as constant, then in x. The limits at each stage may depend only on variables that are still to be integrated.

Worked Example 5.19 — Charge in a tetrahedron

A charge density $\rho = \rho_0\, z/h$ (with ρ_0 in C/m³) fills the tetrahedron bounded by the coordinate planes and the plane $x + y + z = h$. Find the total charge.

Step 1 — limits. The base in the xy-plane is the triangle $x \ge 0$, $y \ge 0$, $x + y \le h$. Above a point (x,y), z runs from 0 to $h - x - y$.

Step 2 — innermost. $\int_0^{h-x-y} \frac{\rho_0 z}{h}dz = \frac{\rho_0}{2h}(h - x - y)^2$.

Step 3 — middle (y from 0 to $h - x$). With $w = h - x$: $\int_0^{w} \frac{\rho_0}{2h}(w - y)^2 dy = \frac{\rho_0}{2h} \cdot \frac{w^3}{3}$.

Step 4 — outer. $\int_0^h \frac{\rho_0}{6h}(h - x)^3 dx = \frac{\rho_0}{6h} \cdot \frac{h^4}{4} = \frac{\rho_0 h^3}{24}$.

Check. The volume is $h^3/6$, so the mean density is $\rho_0/4$, i.e. the mean of z/h over the tetrahedron is $1/4$ — consistent with the centroid of a tetrahedron lying a quarter of the way up from the base. Units: $[\mathrm{C/m^3}][\mathrm{m^3}] = [\mathrm{C}]$ ✓. With $h = 1$, a Monte Carlo estimate of $\iiint z\,dV$ gives $0.0417 \approx 1/24$.

5.4.6 A first look at polar coordinates

Circular regions are awkward in Cartesian form: the disc $x^2 + y^2 \le a^2$ needs limits $-\sqrt{a^2 - x^2} \le y \le \sqrt{a^2 - x^2}$. In polar coordinates (r, ϕ) it is simply $0 \le r \le a$, $0 \le \phi \le 2\pi$. The area element is **not** $dr\,d\phi$: a small polar "rectangle" has radial side dr and arc side $r\,d\phi$, so

$$dA = r\,dr\,d\phi.$$

The extra factor r is the simplest example of a **Jacobian**; Chapter 6 derives it in general and extends it to cylindrical ($dV = r\,dr\,d\phi\,dz$) and spherical ($dV = R^2 \sin\theta\,dR\,d\theta\,d\phi$) coordinates.

Worked Example 5.20 — Charge on a disc

A disc of radius a carries surface charge density $\sigma(r) = \sigma_0\, r/a$. Find the total charge.

$$Q = \int_0^{2\pi}\int_0^{a} \sigma_0 \frac{r}{a}\, r\,dr\,d\phi = 2\pi \cdot \frac{\sigma_0}{a} \cdot \frac{a^3}{3} = \frac{2\pi\sigma_0 a^2}{3}.$$

Check. A uniform density σ_0 would give $\pi a^2\sigma_0$; our density averages to $\tfrac{2}{3}\sigma_0$ over the disc (more area sits near the rim, where σ is largest), giving $\tfrac{2}{3}\pi a^2\sigma_0$ ✓. Forgetting the factor r in dA would give $\pi\sigma_0 a$ — dimensionally wrong (C/m instead of C), which is how the error is caught.

Engineering Note — Choosing coordinates

The effort of a multiple integral is set mostly by how well the coordinates fit the boundary. Parallel-plate geometries suit Cartesian coordinates; coaxial cables, wires and solenoids suit cylindrical; point charges and antennas suit spherical. Picking coordinates in which every boundary is "coordinate = constant" turns every limit into a constant and often makes the integrand separable.

5.5 Integration by parts

5.5.1 The rule and where it comes from

Substitution (§5.6) undoes the chain rule. **Integration by parts** undoes the product rule, and it is the tool for integrands that are products of *unlike* functions: $t\,e^{-t/\tau}$, $t\sin\omega t$, $\ln x$, $x^2\cos x$. It is also the mechanism behind reduction formulas, the Gamma-function recursion, the derivative rule of the Laplace transform, and — in higher dimensions — the divergence theorem and Green's identities (Ch. 7).

Start from the product rule $(uv)' = u'v + uv'$ and integrate both sides:

$$uv = \int u'v\,dx + \int uv'\,dx.$$

Rearranging gives:

Integration by parts

If u and v have continuous derivatives,

$$\int u\,dv = uv - \int v\,du, \qquad \text{i.e.} \qquad \int u(x)v'(x)\,dx = u(x)v(x) - \int u'(x)v(x)\,dx,$$

and for definite integrals

$$\int_a^b u\,dv = \Big[uv\Big]_a^b - \int_a^b v\,du.$$

The rule *trades* one integral for another. It helps when $\int v\,du$ is simpler than $\int u\,dv$, which happens when differentiating u simplifies it (a polynomial loses a degree; $\ln x$ becomes $1/x$) while integrating dv does not make it worse (exponentials and sinusoids stay the same kind).

Choosing u. A long-standing heuristic is **LIATE**: choose u as the first type present in the list

> **L**ogarithmic, **I**nverse trigonometric, **A**lgebraic (polynomials), **T**rigonometric, **E**xponential,

and let dv be the rest. Functions early in the list get simpler when differentiated; those late in the list are easy to integrate.

Worked Example 5.21 — The basic pattern

(a) $\int xe^x\,dx$. Take $u = x$, $dv = e^x dx$, so $du = dx$, $v = e^x$:

$$\int xe^x dx = xe^x - \int e^x dx = (x-1)e^x + C.$$

Check: $\frac{d}{dx}(x-1)e^x = e^x + (x-1)e^x = xe^x$ ✓.

(b) $\int x\cos 3x\,dx$. $u = x$, $dv = \cos 3x\,dx$, $v = \frac{1}{3}\sin 3x$:

$$\int x\cos 3x\,dx = \frac{x\sin 3x}{3} - \frac{1}{3}\int \sin 3x\,dx = \frac{x\sin 3x}{3} + \frac{\cos 3x}{9} + C.$$

(c) $\int \ln x\,dx$. There is no obvious product — take $u = \ln x$, $dv = dx$, so $du = dx/x$, $v = x$:

$$\int \ln x\,dx = x\ln x - \int x\cdot\frac{1}{x}dx = x\ln x - x + C.$$

(d) $\int \arctan x\,dx$. $u = \arctan x$, $dv = dx$:

$$\int \arctan x\,dx = x\arctan x - \int \frac{x}{1+x^2}dx = x\arctan x - \tfrac{1}{2}\ln(1+x^2) + C.$$

Parts (c) and (d) show the trick of taking $dv = dx$: it converts the integral of a function whose *derivative* is algebraic into an algebraic integral.

Worked Example 5.22 — Mean delay of an RC response

The impulse response of an RC low-pass filter is $h(t) = \frac{1}{\tau}e^{-t/\tau}$, $t \ge 0$, with $\int_0^\infty h\,dt = 1$. Its **mean delay** (first moment, the basis of the Elmore delay used to estimate interconnect delay in integrated circuits) is $\bar{t} = \int_0^\infty t\,h(t)\,dt$.

Step 1 — parts. $u = t$, $dv = \frac{1}{\tau}e^{-t/\tau}dt$, $v = -e^{-t/\tau}$:

$$\int_0^\infty \frac{t}{\tau}e^{-t/\tau}dt = \Big[-te^{-t/\tau}\Big]_0^\infty + \int_0^\infty e^{-t/\tau}dt.$$

Step 2 — boundary term. $te^{-t/\tau} \to 0$ as $t \to \infty$ (exponential beats polynomial) and is 0 at $t = 0$.

Step 3 — remaining integral. $\int_0^\infty e^{-t/\tau}dt = \tau$ (Example 5.12a). Hence $\bar{t} = \tau$.

The mean delay equals the time constant. With $R = 1\ \text{k}\Omega$ and $C = 1\ \text{nF}$, $\bar{t} = 1\ \mu\text{s}$.

5.5.2 Repeated parts and the tabular method

When u is a polynomial of degree n, parts must be applied n times. The bookkeeping is compressed by the **tabular method**: list u and its successive derivatives in one column (until zero), dv and its successive integrals in another, and combine diagonally with alternating signs $+, -, +, \ldots$

Worked Example 5.23 — Tabular integration

$\int x^3 e^{2x}dx$.

sign	D: derivatives of x^3	I: integrals of e^{2x}
$+$	x^3	e^{2x}
$-$	$3x^2$	$\frac{1}{2}e^{2x}$
$+$	$6x$	$\frac{1}{4}e^{2x}$
$-$	6	$\frac{1}{8}e^{2x}$
	0	$\frac{1}{16}e^{2x}$

Multiply each D entry by the I entry one row lower, with the sign of its row:

$$\int x^3e^{2x}dx = e^{2x}\Big(\frac{x^3}{2} - \frac{3x^2}{4} + \frac{6x}{8} - \frac{6}{16}\Big) + C = e^{2x}\Big(\frac{x^3}{2} - \frac{3x^2}{4} + \frac{3x}{4} - \frac{3}{8}\Big) + C.$$

Check with $\int_0^1$: formula gives $e^2(0.5 - 0.75 + 0.75 - 0.375) + 0.375 = 0.125e^2 + 0.375 = 1.29863$; numerical quadrature gives 1.298632 ✓.

5.5.3 Cyclic integrals

For $\int e^{ax}\sin bx\,dx$ two applications of parts return the original integral, which can then be solved for algebraically.

Worked Example 5.24 — Solving for the integral

$I = \int e^x \sin x \, dx$.

First parts ($u = \sin x$, $dv = e^x dx$): $I = e^x \sin x - \int e^x \cos x \, dx$.

Second parts ($u = \cos x$, $dv = e^x dx$): $\int e^x \cos x \, dx = e^x \cos x + \int e^x \sin x \, dx = e^x \cos x + I$.

So $I = e^x \sin x - e^x \cos x - I$, giving

$$I = \frac{e^x(\sin x - \cos x)}{2} + C,$$

which matches the complex-exponential formula of §5.2.6 with $a = b = 1$. Keep the *same type* of choice for u (trig both times, or exponential both times); switching sides undoes the first step and yields the useless identity $I = I$.

5.5.4 Reduction formulas

Parts can lower an exponent in a whole family of integrals at once.

Reduction formula for powers of sine

For $n \geq 2$,

$$\int \sin^n x \, dx = -\frac{\sin^{n-1} x \cos x}{n} + \frac{n-1}{n} \int \sin^{n-2} x \, dx,$$

and on $[0, \pi/2]$, where the boundary term vanishes, $I_n = \displaystyle\int_0^{\pi/2} \sin^n x \, dx$ satisfies $I_n = \dfrac{n-1}{n} I_{n-2}$ with $I_0 = \pi/2$, $I_1 = 1$.

Derivation. Write $\sin^n x = \sin^{n-1} x \cdot \sin x$, take $u = \sin^{n-1} x$, $dv = \sin x \, dx$. Then $du = (n-1)\sin^{n-2} x \cos x \, dx$, $v = -\cos x$, and

$$\int \sin^n x \, dx = -\sin^{n-1} x \cos x + (n-1) \int \sin^{n-2} x \cos^2 x \, dx.$$

Replace $\cos^2 x = 1 - \sin^2 x$: the right side contains $(n-1)\int \sin^{n-2} x \, dx - (n-1)\int \sin^n x \, dx$. Move the last term to the left, collect $n \int \sin^n x \, dx$, and divide by n. $\square$

The resulting **Wallis formulas** are

$$I_{2m} = \frac{(2m-1)(2m-3)\cdots 1}{2m(2m-2)\cdots 2} \cdot \frac{\pi}{2}, \qquad I_{2m+1} = \frac{2m(2m-2)\cdots 2}{(2m+1)(2m-1)\cdots 3}.$$

For instance $\int_0^{\pi/2} \sin^4 x \, dx = \frac{3}{4}\cdot\frac{1}{2}\cdot\frac{\pi}{2} = \frac{3\pi}{16} \approx 0.58905$. The identical formulas hold for $\cos^n x$ on $[0, \pi/2]$.

The same idea applied to $\Gamma(x+1) = \int_0^\infty t^x e^{-t} dt$ with $u = t^x$, $dv = e^{-t}dt$ gives

$$\Gamma(x+1) = \Big[-t^x e^{-t}\Big]_0^\infty + x\int_0^\infty t^{x-1} e^{-t} dt = x\,\Gamma(x),$$

the recursion quoted in §5.3.6.

5.5.5 Fourier coefficients by parts

Fourier coefficients of polynomial-shaped waveforms (ramps, sawtooth and triangle waves) are always integrals of polynomial × sinusoid, i.e. integration by parts.

Worked Example 5.25 — Sawtooth coefficients

The sawtooth $f(t) = t$ on $(-\pi, \pi)$, extended with period 2π, is odd, so only sine terms appear, with

$$b_n = \frac{1}{\pi}\int_{-\pi}^{\pi} t \sin nt \, dt = \frac{2}{\pi}\int_0^{\pi} t \sin nt \, dt.$$

Parts with $u = t$, $dv = \sin nt \, dt$, $v = -\frac{\cos nt}{n}$:

$$\int_0^{\pi} t \sin nt \, dt = \Big[-\frac{t\cos nt}{n}\Big]_0^{\pi} + \frac{1}{n}\int_0^{\pi} \cos nt \, dt = -\frac{\pi\cos n\pi}{n} + 0 = \frac{\pi(-1)^{n+1}}{n}.$$

Hence $b_n = \dfrac{2(-1)^{n+1}}{n}$: $b_1 = 2$, $b_2 = -1$, $b_3 = \frac{2}{3}$, … The $1/n$ decay reflects the jump discontinuity of the sawtooth; the triangle wave, which is continuous with a kinked derivative, has coefficients decaying like $1/n^2$ — one more integration by parts gains one more power of n. This link between smoothness and spectral decay is developed in Ch. 15.

Common Pitfall — Dropping or mishandling the boundary term

In definite integrals the term $[uv]_a^b$ is easy to forget, and for improper integrals it must be evaluated as a *limit*. In Example 5.22, $[-te^{-t/\tau}]_0^\infty = 0$ needed the fact that $te^{-t/\tau} \to 0$. Had the integrand been $t\,e^{+t}$ the boundary term would diverge and the whole computation would be meaningless.

Engineering Note — Parts in transform theory

The Laplace-transform rule $\mathcal{L}\{f'(t)\} = sF(s) - f(0)$ is a single integration by parts:

$$\int_0^\infty f'(t)e^{-st}dt = \Big[f(t)e^{-st}\Big]_0^\infty + s\int_0^\infty f(t)e^{-st}dt = -f(0) + sF(s).$$

The boundary term $-f(0)$ is how initial conditions — initial capacitor voltages and inductor currents — enter circuit analysis in the s-domain (Ch. 14).

5.6 Integration by substitution

5.6.1 The rule

The chain rule says $\frac{d}{dx}F(g(x)) = F'(g(x))\,g'(x)$. Reading it backwards: if $F' = f$, then $\int f(g(x))\,g'(x)\,dx = F(g(x)) + C$. Writing $u = g(x)$ and $du = g'(x)\,dx$ makes this look like an algebraic change of symbols.

Substitution rule

If $u = g(x)$ has a continuous derivative and f is continuous on the range of g,

$$\int f(g(x))\,g'(x)\,dx = \int f(u)\,du\Big|_{u=g(x)},$$

and for definite integrals

$$\int_a^b f(g(x))\,g'(x)\,dx = \int_{g(a)}^{g(b)} f(u)\,du.$$

Proof of the definite form. Let $F' = f$. Both sides equal $F(g(b)) - F(g(a))$: the left by the FTC applied to $(F\circ g)' = f(g)g'$, the right by the FTC applied to F. $\square$

Note that in the definite form **the limits change** and there is no need to convert back to x. Dimensionally, du carries the units of u; a correct substitution keeps $f(u)\,du$ dimensionally equal to the original integrand times dx.

How to spot it. Look for a function *inside* another function whose derivative (up to a constant factor) also appears as a factor. Typical patterns:

Pattern	Substitution	Result
$\int f(ax+b)\,dx$	$u = ax+b$	$\frac{1}{a}F(ax+b)$
$\int \frac{g'(x)}{g(x)}dx$	$u = g(x)$	$\ln\lvert g(x)\rvert$
$\int g(x)^n g'(x)\,dx$	$u = g(x)$	$\frac{g^{n+1}}{n+1}, n\neq -1$
$\int e^{g(x)}g'(x)\,dx$	$u = g(x)$	$e^{g(x)}$
$\int x\,f(x^2)\,dx$	$u = x^2$	$\frac{1}{2}F(x^2)$
$\int \frac{f(\ln x)}{x}dx$	$u = \ln x$	$F(\ln x)$

Worked Example 5.26 — Recognising the inner function

(a) $\int 2x\cos(x^2)\,dx$: $u = x^2$, $du = 2x\,dx$, giving $\int \cos u\,du = \sin(x^2) + C$.

(b) $\int \frac{x}{(x^2+a^2)^{3/2}}dx$: $u = x^2 + a^2$, $du = 2x\,dx$:

$$\frac{1}{2}\int u^{-3/2}du = -u^{-1/2} + C = -\frac{1}{\sqrt{x^2+a^2}} + C.$$

This integral gives the field on the axis of a charged ring or disc.

(c) $\int \tan x\,dx = \int \frac{\sin x}{\cos x}dx$: $u = \cos x$, $du = -\sin x\,dx$, giving $-\ln\lvert\cos x\rvert + C$.

(d) $\int \frac{e^x}{1+e^{2x}}dx$: $u = e^x$, $du = e^x dx$, giving $\int \frac{du}{1+u^2} = \arctan(e^x) + C$.

Worked Example 5.27 — Definite integrals with changed limits

(a) $\displaystyle\int_0^1 x\sqrt{1-x^2}\,dx$. Let $u = 1-x^2$, $du = -2x\,dx$; $x=0 \mapsto u=1$, $x=1 \mapsto u=0$:

$$\int_1^0 \sqrt{u}\left(-\frac{du}{2}\right) = \frac{1}{2}\int_0^1 u^{1/2}du = \frac{1}{2}\cdot\frac{2}{3} = \frac{1}{3}.$$

(b) $\displaystyle\int_1^e \frac{(\ln x)^2}{x}dx$. Let $u = \ln x$, $du = dx/x$; limits 0 to 1: $\int_0^1 u^2 du = \tfrac{1}{3}$.

(c) $\displaystyle\int_0^\infty t\,e^{-t^2/2\sigma^2}\,dt$ (a Rayleigh-type integral from fading-channel statistics). Let $u = t^2/2\sigma^2$, $du = t\,dt/\sigma^2$:

$$\sigma^2\int_0^\infty e^{-u}du = \sigma^2.$$

Common Pitfall — Forgetting to change the limits (or the dx)

In a definite integral either change the limits to u-values *or* convert the antiderivative back to x before substituting the original limits — never mix the two. Equally, every x must disappear: if after writing $du = g'(x)dx$ some stray x remains that cannot be expressed in terms of u, the substitution was the wrong one.

5.6.2 Linear substitutions: shifting and scaling

The simplest substitutions, $u = t - t_0$ and $u = at$, are used so often in signal analysis that their effects should be automatic:

$$\int_{-\infty}^{\infty} f(t-t_0)\,dt = \int_{-\infty}^{\infty} f(u)\,du, \qquad \int_{-\infty}^{\infty} f(at)\,dt = \frac{1}{|a|}\int_{-\infty}^{\infty} f(u)\,du \quad (a \neq 0).$$

A time shift does not change the area of a pulse; compressing time by a factor a divides the area by $|a|$. (For $a<0$ the limits swap, which produces the absolute value.) The same scaling argument shows why the Dirac impulse obeys $\delta(at) = \delta(t)/|a|$, and why compressing a signal in time spreads its spectrum (Ch. 16).

For a T-periodic function, the substitution $u = t - c$ proves that the integral over any full period is the same (§5.1.3), and $u = \omega t$ converts integrals over one period to the standard interval $[0, 2\pi]$:

$$\frac{1}{T}\int_0^T g(\omega t)\,dt = \frac{1}{2\pi}\int_0^{2\pi} g(\theta)\,d\theta, \qquad \omega = \frac{2\pi}{T}.$$

This is why averages of sinusoidal waveforms do not depend on frequency.

5.6.3 Symmetry by substitution

The substitution $x \to -x$ proves the even/odd rules of §5.1.3: for odd f, $\int_{-a}^{0} f(x)dx = \int_a^0 f(-u)(-du) = -\int_0^a f(u)du$, so the halves cancel. A less obvious use is the "king's rule" $x \to a+b-x$:

$$\int_a^b f(x)\,dx = \int_a^b f(a+b-x)\,dx,$$

which evaluates, for example, $\int_0^{\pi/2} \frac{\sin x}{\sin x+\cos x}dx$: adding the integral to its transformed self gives $\int_0^{\pi/2} 1\,dx = \frac{\pi}{2}$, so the integral is $\frac{\pi}{4}$.

5.6.4 Trigonometric and hyperbolic substitution

When the integrand contains $\sqrt{a^2-x^2}$, $\sqrt{a^2+x^2}$ or $\sqrt{x^2-a^2}$, an **inverse substitution** $x = g(\theta)$ chosen to turn the radicand into a perfect square removes the root. Here the new variable is introduced through x, and $dx = g'(\theta)\,d\theta$.

Radical	Substitution	Identity used	dx
$\sqrt{a^2-x^2}$	$x = a\sin\theta$, $\lvert\theta\rvert \le \frac{\pi}{2}$	$1-\sin^2 = \cos^2$	$a\cos\theta\,d\theta$
$\sqrt{a^2+x^2}$	$x = a\tan\theta$, $\lvert\theta\rvert < \frac{\pi}{2}$	$1+\tan^2 = \sec^2$	$a\sec^2\theta\,d\theta$
$\sqrt{a^2+x^2}$	$x = a\sinh u$	$1+\sinh^2 = \cosh^2$	$a\cosh u\,du$
$\sqrt{x^2-a^2}$	$x = a\sec\theta$ or $x = a\cosh u$	$\sec^2-1=\tan^2$, $\cosh^2-1=\sinh^2$	

The restricted ranges of θ make the substitution invertible and fix the sign of the square root (e.g. $\cos\theta \ge 0$ for $|\theta| \le \pi/2$).

Worked Example 5.28 — Area of a circle

Show that $\displaystyle\int_{-a}^{a}\sqrt{a^2-x^2}\,dx = \frac{\pi a^2}{2}$.

Let $x = a\sin\theta$; $x = \pm a \mapsto \theta = \pm\frac{\pi}{2}$; $\sqrt{a^2-x^2} = a\cos\theta$; $dx = a\cos\theta\,d\theta$:

$$\int_{-\pi/2}^{\pi/2} a^2\cos^2\theta\,d\theta = a^2\int_{-\pi/2}^{\pi/2}\frac{1+\cos 2\theta}{2}d\theta = a^2\cdot\frac{\pi}{2}.$$

The area of a half-disc, as it must be.

Worked Example 5.29 — Field of a finite line charge

A uniform line charge λ (C/m) lies on the z-axis from $z=-L$ to $z=L$. The radial field at distance r in the mid-plane is

$$E_r = \frac{\lambda r}{4\pi\varepsilon_0}\int_{-L}^{L}\frac{dz}{(r^2+z^2)^{3/2}}.$$

Step 1 — substitute $z = r\tan\theta$, $dz = r\sec^2\theta\,d\theta$, $r^2+z^2 = r^2\sec^2\theta$:

$$\int \frac{r\sec^2\theta\,d\theta}{r^3\sec^3\theta} = \frac{1}{r^2}\int\cos\theta\,d\theta = \frac{\sin\theta}{r^2}.$$

Step 2 — back-substitute. From the triangle with opposite side z and adjacent side r: $\sin\theta = \dfrac{z}{\sqrt{r^2+z^2}}$. So

$$\int_{-L}^{L}\frac{dz}{(r^2+z^2)^{3/2}} = \frac{2L}{r^2\sqrt{r^2+L^2}}, \qquad E_r = \frac{\lambda}{4\pi\varepsilon_0}\cdot\frac{2L}{r\sqrt{r^2+L^2}}.$$

Step 3 — limits. As $L\to\infty$ (an improper integral), $E_r \to \dfrac{\lambda}{2\pi\varepsilon_0 r}$, the infinite-line result. For $L \ll r$, $E_r \approx \dfrac{2L\lambda}{4\pi\varepsilon_0 r^2}$ — the field of a point charge $Q = 2L\lambda$, as it should be.

Check: with $r=1$, $L=2$, the integral is $4/\sqrt{5} = 1.78885$; quadrature gives 1.788854 ✓.

Worked Example 5.30 — A hyperbolic substitution

$\displaystyle\int \frac{dx}{\sqrt{x^2+a^2}}$. Let $x = a\sinh u$, $dx = a\cosh u\,du$, $\sqrt{x^2+a^2} = a\cosh u$:

$$\int du = u + C = \operatorname{arsinh}\frac{x}{a} + C = \ln\left(x+\sqrt{x^2+a^2}\right) + C',$$

the table entry of §5.1.4. The hyperbolic route avoids the awkward $\int\sec\theta\,d\theta$ that the tangent substitution produces. The same integral gives the capacitance per length of a two-wire line, $C' = \pi\varepsilon/\operatorname{arcosh}(D/d)$, where an inverse hyperbolic function appears for exactly this reason.

5.6.5 The tangent half-angle substitution

Any rational function of $\sin\theta$ and $\cos\theta$ becomes a rational function of t under

$$t = \tan\frac{\theta}{2}, \qquad \sin\theta = \frac{2t}{1+t^2}, \qquad \cos\theta = \frac{1-t^2}{1+t^2}, \qquad d\theta = \frac{2\,dt}{1+t^2},$$

after which partial fractions (§5.2.5) finish the job. It is a last resort — often clumsy — but it always works.

Worked Example 5.31 — An integral over a full period

Evaluate $\displaystyle I = \int_0^{2\pi}\frac{d\theta}{2+\cos\theta}$.

Step 1 — avoid the singular point. $t = \tan(\theta/2)$ blows up at $\theta=\pi$, so use symmetry (cos is even about π): $I = 2\int_0^{\pi}\frac{d\theta}{2+\cos\theta}$, and $\theta: 0\to\pi$ maps to $t: 0\to\infty$.

Step 2 — transform. $2+\cos\theta = \dfrac{2(1+t^2)+1-t^2}{1+t^2} = \dfrac{3+t^2}{1+t^2}$, so

$$\frac{d\theta}{2+\cos\theta} = \frac{1+t^2}{3+t^2}\cdot\frac{2\,dt}{1+t^2} = \frac{2\,dt}{3+t^2}.$$

Step 3 — integrate.

$$I = 2\int_0^{\infty}\frac{2\,dt}{t^2+3} = 4\cdot\frac{1}{\sqrt{3}}\cdot\frac{\pi}{2} = \frac{2\pi}{\sqrt{3}} \approx 3.6276.$$

Check: a 64-point trapezoidal sum over the period gives 3.627599 — and for smooth periodic integrands the trapezoidal rule is spectacularly accurate (§5.7.5). Integrals of this form are evaluated in one line by residues in Ch. 18.

Engineering Note — Substitution as change of physical variable

Engineers substitute all the time without calling it that: converting an integral over time to one over phase ($\theta=\omega t$), over frequency to one over normalised frequency ($u=\omega/\omega_c$), or over distance to one over angle as in Example 5.29. Normalising first — making the variable dimensionless — exposes the shape of the integral and leaves the physical constants outside as a prefactor whose units are easy to check.

5.7 Numerical integration

5.7.1 Why numerical integration

Three situations force us to integrate numerically:

1. **No elementary antiderivative exists** — $\int_0^1 e^{-x^2}dx$, the bit-error probability of a digital link, the inductance of a real coil.

2. **The integrand is known only at samples** — an oscilloscope or ADC record of current, voltage or temperature; the energy of a measured pulse is $\sum$ of samples, not a formula.
3. **A closed form exists but is not worth deriving** — when only a number is required, a few lines of code beat a page of algebra.

All practical methods are **quadrature rules** of the form

$$\int_a^b f(x)\,dx \approx \sum_{k=0}^{n} w_k\, f(x_k),$$

a weighted sum of samples at **nodes** x_k with **weights** w_k. This section develops the three basic Newton–Cotes rules on equally spaced nodes and their error behaviour. Chapter 22 continues with Romberg integration, Gaussian quadrature, adaptive schemes and multidimensional methods.

Throughout, $h = (b-a)/n$ and $x_k = a + kh$, $f_k = f(x_k)$.

5.7.2 The midpoint and trapezoidal rules

The **midpoint rule** replaces f on each subinterval by its value at the centre; the **trapezoidal rule** replaces it by the straight line through the end values:

$$M_n = h\sum_{k=1}^{n} f\Big(x_{k-1} + \frac{h}{2}\Big), \qquad T_n = h\Big[\tfrac12 f_0 + f_1 + f_2 + \cdots + f_{n-1} + \tfrac12 f_n\Big].$$

Each trapezoid has area $\frac{h}{2}(f_{k-1}+f_k)$; summing them gives T_n, in which interior samples appear twice and therefore get weight h.

Error of the midpoint and trapezoidal rules

If f'' is continuous on $[a,b]$, there exist $\xi, \eta \in (a,b)$ with

$$\int_a^b f\,dx - T_n = -\frac{(b-a)h^2}{12} f''(\xi), \qquad \int_a^b f\,dx - M_n = +\frac{(b-a)h^2}{24} f''(\eta).$$

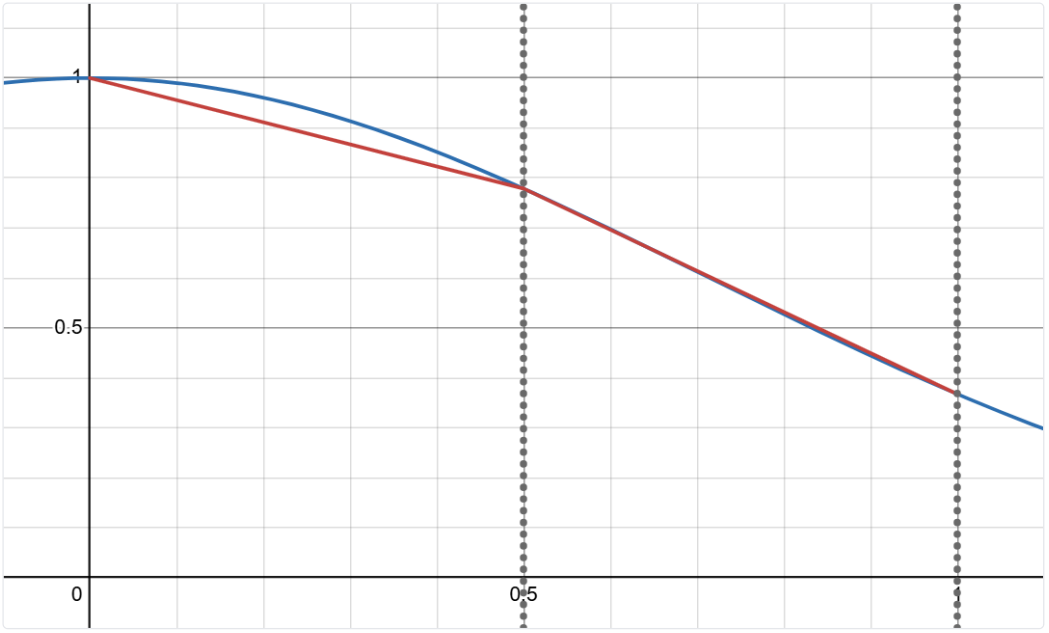
Both rules are **second order**: halving h divides the error by about 4. Both are exact for straight lines.

Derivation sketch (single panel). Expand f about the panel midpoint m with $s = x - m$: $f = f(m) + sf'(m) + \tfrac12 s^2 f''(m) + \dots$. Integrating over $s \in [-h/2, h/2]$, the odd term vanishes:

$$\int f\,dx = hf(m) + \frac{h^3}{24} f''(m) + O(h^5).$$

So the midpoint rule has local error $+\frac{h^3}{24}f''$. For the trapezoid, average the endpoint expansions $f(m \pm h/2) = f(m) \pm \frac{h}{2}f' + \frac{h^2}{8}f'' + \dots$: $\frac{h}{2}(f_{\text{left}} + f_{\text{right}}) = hf(m) + \frac{h^3}{8}f'' + \dots$, so its local error is $\frac{h^3}{24}f'' - \frac{h^3}{8}f'' = -\frac{h^3}{12}f''$. Summing $n = (b-a)/h$ panels multiplies the local error by n, giving global error $\propto (b-a)h^2$. $\square$

Two practical consequences follow. First, the midpoint error is about half the trapezoidal error and of **opposite sign**, so for a convex function ($f'' > 0$) the trapezoid overestimates and the midpoint underestimates, bracketing the true value. Second, the weighted combination $\frac{1}{3}(2M_n + T_n)$ cancels the leading error — that combination is Simpson's rule.



Trapezoidal rule with $n = 2$ for e^{-x^2} on $[0,1]$: the chords (red) lie below the concave part of the curve and above the convex tail, so the errors partly cancel.

5.7.3 Simpson's rule

Fitting a **parabola** through three consecutive samples and integrating it exactly gives, over a pair of panels,

$$\int_{x_0}^{x_2} f\,dx \approx \frac{h}{3}\bigl(f_0 + 4f_1 + f_2\bigr).$$

Derivation. Put $x_1 = 0$, so the nodes are $-h, 0, h$. For $p(x) = \alpha + \beta x + \gamma x^2$, $\int_{-h}^{h} p\,dx = 2\alpha h + \tfrac{2}{3}\gamma h^3$. From the samples, $\alpha = f_1$ and $f_0 + f_2 = 2\alpha + 2\gamma h^2$, so $\gamma h^2 = \frac{f_0+f_2}{2} - f_1$. Substituting: $2hf_1 + \frac{2h}{3}\bigl(\frac{f_0+f_2}{2} - f_1\bigr) = \frac{h}{3}(f_0 + 4f_1 + f_2)$. $\square$

Applying this to consecutive pairs requires n **even** and gives the composite rule

$$S_n = \frac{h}{3}\Bigl[f_0 + 4f_1 + 2f_2 + 4f_3 + 2f_4 + \cdots + 2f_{n-2} + 4f_{n-1} + f_n\Bigr].$$

Error of Simpson's rule

If $f^{(4)}$ is continuous on $[a,b]$ and n is even,

$$\int_a^b f\,dx - S_n = -\frac{(b-a)h^4}{180} f^{(4)}(\xi)$$

for some $\xi \in (a,b)$. Simpson's rule is **fourth order** — halving h divides the error by about 16 — and, surprisingly, exact for **cubics**, not just quadratics (the cubic term is odd about the panel centre and integrates to zero).

Worked Example 5.32 — Comparing the rules on $\int_0^1 e^{-x^2}dx$

The exact value is $\frac{\sqrt{\pi}}{2}\operatorname{erf}(1) = 0.746824133$. With $n = 4$, $h = 0.25$, the samples are

x	0	0.25	0.5	0.75	1
f	1.000000	0.939413	0.778801	0.569783	0.367879

Trapezoidal: $T_4 = 0.25\bigl[\tfrac{1}{2}(1 + 0.367879) + 0.939413 + 0.778801 + 0.569783\bigr] = 0.742984$.

Simpson: $S_4 = \frac{0.25}{3}\bigl[1 + 4(0.939413) + 2(0.778801) + 4(0.569783) + 0.367879\bigr] = 0.746855$.

Midpoint (samples at $0.125, 0.375, 0.625, 0.875$): $M_4 = 0.748747$.

Rule	$n=4$	error	$n=8$	error	ratio
Trapezoidal	0.742984	-3.84×10^{-3}	0.745866	-9.59×10^{-4}	4.0
Midpoint	0.748747	$+1.92\times10^{-3}$	0.747304	$+4.79\times10^{-4}$	4.0
Simpson	0.746855	$+3.12\times10^{-5}$	0.746826	$+1.99\times10^{-6}$	15.7

The error ratios on halving h — 4 and 16 — confirm the orders h^2 and h^4. Simpson with five samples beats the trapezoidal rule with nine by a factor of about 30. Also note M and T bracket the true value with $|E_M| \approx \tfrac{1}{2}|E_T|$.

5.7.4 Choosing n from an error bound

The error formulas give a guaranteed step size when a bound on the relevant derivative is available.

Worked Example 5.33 — How many samples for six decimals?

Find n so that the error in $\int_0^1 e^{-x^2}dx$ is below 10^{-6}.

Trapezoidal. $f'' = (4x^2 - 2)e^{-x^2}$; on $[0,1]$, $|f''| \le 2$ (at $x = 0$). Need $\frac{1\cdot h^2}{12}\cdot 2 \le 10^{-6}$, i.e. $h \le 2.449\times10^{-3}$, so $n \ge 409$. (Actual error at $n = 410$: 3.6×10^{-7}.)

Simpson. $f^{(4)} = (16x^4 - 48x^2 + 12)e^{-x^2}$; $|f^{(4)}| \le 12$ on $[0,1]$. Need $\frac{h^4}{180}\cdot 12 \le 10^{-6}$, i.e. $h \le 0.0622$, so $n \ge 16.07$; take $n = 18$ (even). (Actual error: 7.8×10^{-8}.)

The bounds are conservative — the worst-case derivative occurs only at one end — but they are *guarantees*. Twenty-odd samples for Simpson versus four hundred for the trapezoidal rule is the practical meaning of "fourth order versus second order".

5.7.5 Error estimation without derivatives: Richardson extrapolation

Derivative bounds are rarely available for measured data or complicated formulas. Instead, compute with h and $h/2$ and use the known order. If $I = T_n + Ch^2 + O(h^4)$, then $I = T_{2n} + C\frac{h^2}{4} + O(h^4)$, and eliminating C:

$$I \approx T_{2n} + \frac{T_{2n} - T_n}{3}, \qquad \text{error of } T_{2n} \approx \frac{T_{2n} - T_n}{3}.$$

From Example 5.32, $\frac{T_8 - T_4}{3} = \frac{0.745866 - 0.742984}{3} = 9.61\times10^{-4}$, an excellent estimate of the actual error 9.59×10^{-4}; the extrapolated value 0.746826 is identical to S_8 — Richardson extrapolation of the trapezoidal rule *is* Simpson's rule. Repeating the idea to eliminate $h^4, h^6, \ldots$ gives Romberg integration (Ch. 22).

Engineering Note — The trapezoidal rule and periodic signals

For a smooth **periodic** function integrated over a whole period, the trapezoidal rule is not second order but converges *exponentially* fast: the error terms of the Euler–Maclaurin expansion are differences of derivatives at the two ends, which cancel by periodicity. Example 5.31's 64-point sum was accurate to 15 digits. This is why the DFT — essentially the trapezoidal rule applied to $\frac{1}{T}\int_0^T x(t)e^{-jk\omega_0 t}dt$ — computes Fourier coefficients of band-limited periodic signals exactly, and why sampled RMS and power meters work so well on steady-state waveforms.

5.7.6 Sampled data

Worked Example 5.34 — Energy of a measured pulse

An ADC samples the current through a 10 Ω resistor every 1 ms:

t (ms)	0	1	2	3	4	5	6
i (A)	0	2.1	3.4	3.9	3.6	2.5	1.0
$p = Ri^2$ (W)	0	44.1	115.6	152.1	129.6	62.5	10.0

Estimate the energy delivered, $W = \int_0^{6\,\text{ms}} p\,dt$.

Trapezoidal: $W \approx 10^{-3}\left[\frac{1}{2}(0+10) + 44.1 + 115.6 + 152.1 + 129.6 + 62.5\right] = 0.5089\ \text{J}$.

Simpson ($n = 6$, even): $W \approx \frac{10^{-3}}{3}\left[0 + 4(44.1 + 152.1 + 62.5) + 2(115.6 + 129.6) + 10\right] = 0.5117\ \text{J}$.

The 0.5% difference indicates the sampling is adequate for an energy estimate to about two significant figures. Note that we integrated $p = Ri^2$, **not** $R\,(\int i\,dt)^2$ or $R\,(\bar{i})^2$ — the square must be taken sample by sample before integrating (§5.9).

5.7.7 Difficult integrands

The error formulas assume smooth integrands. When that fails:

- **Discontinuities or kinks** (rectified waves, PWM): place nodes at the breakpoints and integrate each smooth piece separately; otherwise the error drops only like h.
- **Integrable singularities** such as $\int_0^1 \frac{\cos x}{\sqrt{x}}dx$: remove the singularity by substitution ($x = u^2$ gives $\int_0^1 2\cos(u^2)\,du$, which is smooth), or subtract it off analytically.
- **Infinite ranges:** truncate where the tail is provably small (bound it by a comparison integral, §5.3.4), or map to a finite interval with a substitution such as $x = \frac{u}{1-u}$.
- **Rapid oscillation** ($\int f(x)\cos(\omega x)\,dx$ with large ω): ensure several samples per oscillation period, or use specialised (Filon-type, FFT-based) methods.

Common Pitfall — Simpson's rule needs an even number of panels

With an odd number of panels the composite Simpson pattern $1, 4, 2, 4, \ldots, 4, 1$ does not close. Either use Simpson's $\frac{3}{8}$ rule, $\frac{3h}{8}(f_0 + 3f_1 + 3f_2 + f_3)$, on the last three panels, or resample. Silently applying the even-n formula to odd n gives an answer that can be badly wrong.

5.8 Applications to charge, energy, and accumulated quantities

5.8.1 The accumulation principle

Every application in this section follows one pattern, worth stating explicitly because it is how integrals are *set up* rather than evaluated:

The differential-element method

To find a total Q that is built from a varying density or rate:

1. **Slice** the domain (time, length, area, volume) into small elements dt, dx, dA or dV.
2. On one element the density is essentially constant, so write the **contribution** $dQ = (\text{density}) \times (\text{size of element})$.
3. **Integrate** dQ over the domain, choosing limits that cover each element exactly once.
4. **Check** units, limiting cases and signs.

The principle covers charge from current ($dq = i\,dt$), charge from charge density ($dQ = \lambda\,d\ell$, $\sigma\,dA$, $\rho\,dV$), energy from power ($dW = p\,dt$), work from force ($dW = F\,dx$), resistance of a non-uniform conductor ($dR = \rho_e\,dx/A(x)$), flux from flux density ($d\Phi = B\,dA$), and probability from a density ($dP = f_X(x)\,dx$, Ch. 19). The table summarises the most common cases.

Accumulated quantity	Element	Integral	Units check
Charge from current	$dq = i\,dt$	$q = \int i\,dt$	A·s = C
Charge from line density	$dQ = \lambda\,d\ell$	$Q = \int \lambda\,d\ell$	(C/m)·m
Charge from surface density	$dQ = \sigma\,dA$	$Q = \iint \sigma\,dA$	(C/m²)·m²
Charge from volume density	$dQ = \rho\,dV$	$Q = \iiint \rho\,dV$	(C/m³)·m³
Energy from power	$dW = p\,dt$	$W = \int p\,dt$	W·s = J

Accumulated quantity	Element	Integral	Units check
Work against a force	$dW = F\,dx$	$W = \int F\,dx$	N·m = J
Flux linkage from voltage	$d\lambda = v\,dt$	$\lambda = \int v\,dt$	V·s = Wb
Resistance, non-uniform bar	$dR = \rho_e\,dx/A(x)$	$R = \int \rho_e\,dx/A$	(Ω·m)·m/m² = Ω
Battery charge	$dq = i\,dt$	$q = \int i\,dt$	A·h = 3600 C

5.8.2 Charge from current

Since $i = dq/dt$, the FTC gives

$$q(t) = q(t_0) + \int_{t_0}^{t} i(\tau)\,d\tau,$$

and the **net** charge passing a point between t_1 and t_2 is $\int_{t_1}^{t_2} i\,dt$, which may be zero even when large currents flow (pure AC). The **total** charge moved irrespective of direction is $\int |i|\,dt$ — the quantity that matters for electroplating, electrode wear and battery throughput.

Worked Example 5.35 — Charge in a half-cycle

A diode passes the positive half-cycles of $i(t) = I_m \sin \omega t$ with $I_m = 10$ A at $f = 50$ Hz. Find the charge passed per half-cycle and the average current.

Step 1 — integrate over one half-cycle $0 \le t \le \pi/\omega$:

$$Q = \int_0^{\pi/\omega} I_m \sin \omega t\,dt = \frac{I_m}{\omega}\big[-\cos \omega t\big]_0^{\pi/\omega} = \frac{2I_m}{\omega}.$$

Step 2 — numbers. $\omega = 100\pi$ rad/s: $Q = \dfrac{20}{100\pi} = 0.06366$ C $= 63.66$ mC.

Step 3 — average over a full period $T = 20$ ms (the diode blocks during the negative half):

$$I_{\text{avg}} = \frac{Q}{T} = \frac{0.06366}{0.02} = 3.183 \text{ A} = \frac{I_m}{\pi}.$$

This is the DC component of a half-wave rectified current (§5.9).

Worked Example 5.36 — Battery capacity under a load profile

A sensor node draws $i(t) = 20$ mA for 5 s while transmitting, then 50 μA for the remaining 595 s of each 10-minute cycle. How long does a 2000 mAh battery last (ignoring self-discharge)?

Charge per cycle: $q = 20\,\text{mA} \times 5\,\text{s} + 0.05\,\text{mA} \times 595\,\text{s} = 100 + 29.75 = 129.75$ mA·s.

Average current: $\bar{i} = 129.75/600 = 0.21625$ mA.

Lifetime: $2000\ \text{mAh}/0.21625\ \text{mA} = 9249$ h ≈ 385 days.

The integral of a piecewise-constant current is a sum of rectangles; the insight is that the "small" sleep current contributes almost a quarter of the total charge because it flows 119 times longer.

5.8.3 Energy stored in capacitors and inductors

The power into any two-terminal element is $p = vi$, so the energy delivered between t_1 and t_2 is $W = \int_{t_1}^{t_2} v\,i\,dt$. For a capacitor, $i = C\,dv/dt$; for an inductor, $v = L\,di/dt$. Substituting and changing the variable of integration (§5.6) gives two of the most-used formulas in electrical engineering.

Stored energy

A linear capacitor charged from 0 to V and a linear inductor carrying current rising from 0 to I store

$$W_C = \int_0^t v\,C\frac{dv}{dt}\,dt = C\int_0^V v\,dv = \tfrac{1}{2}CV^2, \qquad W_L = \int_0^t L\frac{di}{dt}\,i\,dt = L\int_0^I i\,di = \tfrac{1}{2}LI^2.$$

The substitution $dv = \frac{dv}{dt}dt$ removes time entirely: the stored energy depends only on the final state, not on how fast or by what path it was reached. That is the mathematical signature of a **conservative** (lossless) element.

For a *nonlinear* capacitor described by $q = q(v)$, the same argument gives $W = \int_0^V v\,\frac{dq}{dv}\,dv = \int_0^Q v\,dq$, the area between the q–v curve and the q-axis. Similarly, for a nonlinear inductor (iron core) $W = \int i\,d\lambda$, and over one cycle of an AC magnetisation the loop integral $\oint i\,d\lambda$ is the **hysteresis loss** per cycle — the area of the B–H loop scaled by core volume.

Worked Example 5.37 — Charging a capacitor through a resistor: where does the energy go?

A capacitor C is charged from 0 through R by a step V_s. The current is $i = \frac{V_s}{R} e^{-t/RC}$.

Energy supplied by the source:

$$W_s = \int_0^\infty V_s\, i\, dt = \frac{V_s^2}{R} \int_0^\infty e^{-t/RC} dt = \frac{V_s^2}{R} \cdot RC = CV_s^2.$$

Energy lost in the resistor:

$$W_R = \int_0^\infty i^2 R\, dt = \frac{V_s^2}{R} \int_0^\infty e^{-2t/RC} dt = \tfrac{1}{2} CV_s^2.$$

Energy stored: $W_C = \frac{1}{2}CV_s^2$, and $W_s = W_R + W_C$ ✓.

Exactly half the source energy is always lost, whatever R is. This is a fundamental limit of charging a capacitor from a fixed voltage, and the reason switched-capacitor and adiabatic logic circuits charge capacitances in small voltage steps: charging in N equal steps reduces the loss to $\frac{1}{2N}CV_s^2$.

Worked Example 5.38 — Energy into an inductor with a non-trivial waveform

A 2 mH inductor carries $i(t) = 3t^2$ A for $0 \le t \le 2$ s (an unusually slow ramp, for clarity). Compute the energy delivered by integrating power, then check against $\frac{1}{2}LI^2$.

$v = L\, di/dt = 2 \times 10^{-3} \cdot 6t = 0.012t$ V, so $p = vi = 0.012t \cdot 3t^2 = 0.036t^3$ W and

$$W = \int_0^2 0.036 t^3 dt = 0.036 \cdot \frac{16}{4} = 0.144 \text{ J}.$$

Final current $I = 3 \cdot 4 = 12$ A: $\frac{1}{2}LI^2 = \frac{1}{2} \cdot 0.002 \cdot 144 = 0.144$ J ✓.

5.8.4 Work and potential

Moving a charge q against an electric force requires work $W = -\int \mathbf{F} \cdot d\boldsymbol{\ell}$; along a radial line this is a single-variable integral. The **potential** of a point is the work per unit charge to bring a test charge from a reference point (usually infinity), so potential is an *improper integral* of field.

Worked Example 5.39 — Potential of a point charge

The field of a point charge Q is $E(R) = \dfrac{Q}{4\pi\varepsilon_0 R^2}$, radial. The potential at distance a relative to infinity is

$$V(a) = -\int_\infty^a E(R)\, dR = \frac{Q}{4\pi\varepsilon_0} \int_a^\infty \frac{dR}{R^2} = \frac{Q}{4\pi\varepsilon_0} \Big[-\frac{1}{R} \Big]_a^\infty = \frac{Q}{4\pi\varepsilon_0 a}.$$

The integral converges because $1/R^2$ has $p = 2 > 1$ (§5.3.3). In two dimensions the field of a line charge falls only as $1/r$, and the analogous integral **diverges** — which is why the potential of an infinite line charge can only be defined relative to a finite reference radius r_0: $V(r) = \frac{\lambda}{2\pi\varepsilon_0} \ln \frac{r_0}{r}$.

5.8.5 Charge in non-uniform distributions

When a density depends on one coordinate only, a well-chosen element reduces a multiple integral to a single one: thin strips for a planar density varying in one direction, thin **rings** ($dA = 2\pi r\, dr$) for a disc, thin **shells** ($dV = 4\pi R^2 dR$) for a sphere, thin **cylindrical shells** ($dV = 2\pi r \ell\, dr$) for a cylinder of length ℓ.

Worked Example 5.40 — Charge in a sphere with radially varying density

A sphere of radius a holds $\rho(R) = \rho_0 \big(1 - \frac{R}{a}\big)$. Find the total charge and the radius $R_{1/2}$ enclosing half of it.

Step 1 — shell element. $dQ = \rho(R)\, 4\pi R^2 dR$.

Step 2 — integrate.

$$Q = 4\pi\rho_0 \int_0^a \Big(R^2 - \frac{R^3}{a} \Big) dR = 4\pi\rho_0 \Big(\frac{a^3}{3} - \frac{a^3}{4} \Big) = \frac{\pi \rho_0 a^3}{3}.$$

Step 3 — enclosed charge as a function of radius. $Q(R) = 4\pi\rho_0 \big(\frac{R^3}{3} - \frac{R^4}{4a} \big)$. Setting $Q(R) = \frac{Q}{2}$ with $s = R/a$: $4\big(\frac{s^3}{3} - \frac{s^4}{4}\big) = \frac{1}{6}$, i.e. $3s^4 - 4s^3 + \frac{1}{2} = 0$. Newton's method (Ch. 4) gives $s \approx 0.614$.

Check. A uniform sphere with ρ_0 would hold $\frac{4}{3}\pi\rho_0 a^3$; ours holds a quarter of that, since the density averages to $\rho_0/4$ when weighted by R^2. Gauss's law then gives the field at any radius as $E = Q(R)/(4\pi\varepsilon_0 R^2)$ (Ch. 7).

Worked Example 5.41 — Energy stored in a coaxial cable

A coaxial line with inner radius a, outer radius b and dielectric permittivity ε carries charge λ per unit length. The field between the conductors is $E(r) = \dfrac{\lambda}{2\pi\varepsilon r}$, and the energy density is $w = \tfrac{1}{2}\varepsilon E^2$ (J/m³). Find the stored energy per unit length and deduce the capacitance per unit length.

Step 1 — element. A cylindrical shell of radius r, thickness dr and unit length has volume $2\pi r\,dr$.

Step 2 — integrate.

$$W' = \int_a^b \frac{1}{2}\varepsilon\Big(\frac{\lambda}{2\pi\varepsilon r}\Big)^2 2\pi r\,dr = \frac{\lambda^2}{4\pi\varepsilon}\int_a^b \frac{dr}{r} = \frac{\lambda^2}{4\pi\varepsilon}\ln\frac{b}{a}.$$

Step 3 — capacitance. Equating $W' = \dfrac{\lambda^2}{2C'}$ (the energy of a capacitor with charge λ per length) gives

$$C' = \frac{2\pi\varepsilon}{\ln(b/a)}.$$

For RG-58-like dimensions, $b/a = 3.5$, polyethylene $\varepsilon = 2.25\varepsilon_0$: $C' = \dfrac{2\pi(2.25)(8.854\times10^{-12})}{\ln 3.5} = 99.9$ pF/m, close to the datasheet value of about 100 pF/m. The logarithm comes directly from $\int dr/r$ — the borderline $p = 1$ integrand of §5.3.

5.8.6 Resistance of a non-uniform conductor

A conductor whose cross-section $A(x)$ varies slowly along its length behaves as a series chain of thin slices, each with resistance $dR = \rho_e\,dx/A(x)$. Series resistances add, so

$$R = \int_0^L \frac{\rho_e\,dx}{A(x)}.$$

Worked Example 5.42 — A tapered wire

A wire of resistivity ρ_e and length L tapers linearly in radius from a to b. Find R.

Step 1 — area. $r(x) = a + \frac{(b-a)x}{L}$, $A = \pi r^2$.

Step 2 — substitute $u = r(x)$, $dx = \frac{L}{b-a}du$:

$$R = \frac{\rho_e}{\pi}\cdot\frac{L}{b-a}\int_a^b \frac{du}{u^2} = \frac{\rho_e L}{\pi(b-a)}\Big(\frac{1}{a}-\frac{1}{b}\Big) = \frac{\rho_e L}{\pi ab}.$$

Check. For $b \to a$ this reduces to $\rho_e L/(\pi a^2)$ ✓. Note that the answer uses the *geometric* mean of the end areas, πab, not the arithmetic mean — averaging the area first and then computing $\rho_e L/\bar{A}$ underestimates R. (Copper, $\rho_e = 1.72\times10^{-8}$ Ω·m, $L = 1$ m, $a = 0.5$ mm, $b = 1$ mm: $R = 10.95$ mΩ.)

Common Pitfall — Averaging the wrong quantity

Examples 5.42 and 5.34 make the same point: the integral of a nonlinear function of a variable is not the function of the integral. $\int \frac{dx}{A} \neq \frac{L^2}{\int A\,dx}$ and $\int i^2 dt \neq \frac{1}{T}\big(\int i\,dt\big)^2$. Always build dQ from the local physics and integrate *that*.

Engineering Note — Accumulated quantities in instrumentation

Energy meters, coulomb counters (battery "fuel gauges"), and flux meters are hardware integrators. Digital versions accumulate samples, which is a rectangular or trapezoidal rule (§5.7). Their main error sources are exactly those of numerical integration — sampling too slowly for the waveform's bandwidth — plus offset drift (§5.1 Engineering Note), which an integrator turns into an ever-growing error. Coulomb counters therefore periodically re-calibrate against a known state such as "fully charged".

5.9 Mean and RMS values of functions

5.9.1 Motivation

A mains socket is "230 V", a USB charger "5 V", a class-D amplifier output "20 V RMS". These single numbers summarise waveforms that vary continuously in time. Two summaries dominate engineering practice: the **mean** (average, DC) value, which tells how much net charge or flux a waveform delivers, and the **root-mean-square (RMS)** value, which tells how much *power* it delivers to a resistor. Both are integrals, and both appear on every multimeter, datasheet and power-supply specification.

5.9.2 The mean value

Mean (average) value

The mean value of f over $[a,b]$ is

$$\bar f = \langle f \rangle = \frac{1}{b-a}\int_a^b f(t)\,dt.$$

For a T-periodic signal the **DC value** is the mean over one period, $V_{\text{dc}} = \dfrac{1}{T}\displaystyle\int_{t_0}^{t_0+T} v(t)\,dt$ (any t_0). For a non-periodic signal on $(-\infty,\infty)$ the **time average** is $\displaystyle\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} v(t)\,dt$ when the limit exists.

Geometrically $\bar f$ is the height of the rectangle on $[a,b]$ with the same area as f — the Mean Value Theorem for integrals (§5.1.3) guarantees that a continuous f actually attains it. Physically, the mean current $\bar i$ is the steady current that would carry the same charge in the same time (Example 5.35).

Basic properties follow from linearity: $\langle \alpha f + \beta g\rangle = \alpha\langle f\rangle + \beta\langle g\rangle$; the mean of a constant is itself; and the mean of any pure sinusoid over a whole number of periods is **zero**. Hence a signal $v(t) = V_0 + \sum_{n} c_n\cos(n\omega_0 t + \theta_n)$ has DC value exactly V_0. A capacitor in series blocks precisely this term; an ideal inductor in steady state has zero *mean* voltage (otherwise its current would grow without bound, since $\Delta i = \frac{1}{L}\int v\,dt$), and a capacitor in steady state has zero *mean* current. These "volt-second balance" and "charge balance" conditions are the main analytic tools for switched-mode power converters.

Worked Example 5.43 — Volt-second balance in a buck converter

In a buck converter the inductor voltage is $V_{\text{in}} - V_o$ for a fraction D of each switching period T and $-V_o$ for the rest. In steady state the mean inductor voltage is zero:

$$\frac{1}{T}\Big[(V_{\text{in}} - V_o)DT + (-V_o)(1-D)T\Big] = 0 \quad\Longrightarrow\quad V_o = D V_{\text{in}}.$$

With $V_{\text{in}} = 12$ V and $D = 0.25$, $V_o = 3$ V. One integral — a sum of two rectangles — gives the converter's fundamental conversion ratio.

5.9.3 The RMS value

Feed a waveform $v(t)$ into a resistor R. The instantaneous power is v^2/R and the mean power over a period is $\frac{1}{T}\int_0^T \frac{v^2}{R}dt$. The **effective** or RMS voltage is the DC voltage that would produce the same mean power:

$$\frac{V_{\text{rms}}^2}{R} = \frac{1}{T}\int_0^T \frac{v(t)^2}{R}\,dt.$$

RMS value

$$F_{\text{rms}} = \sqrt{\frac{1}{b-a}\int_a^b f(t)^2\,dt} = \sqrt{\langle f^2\rangle},$$

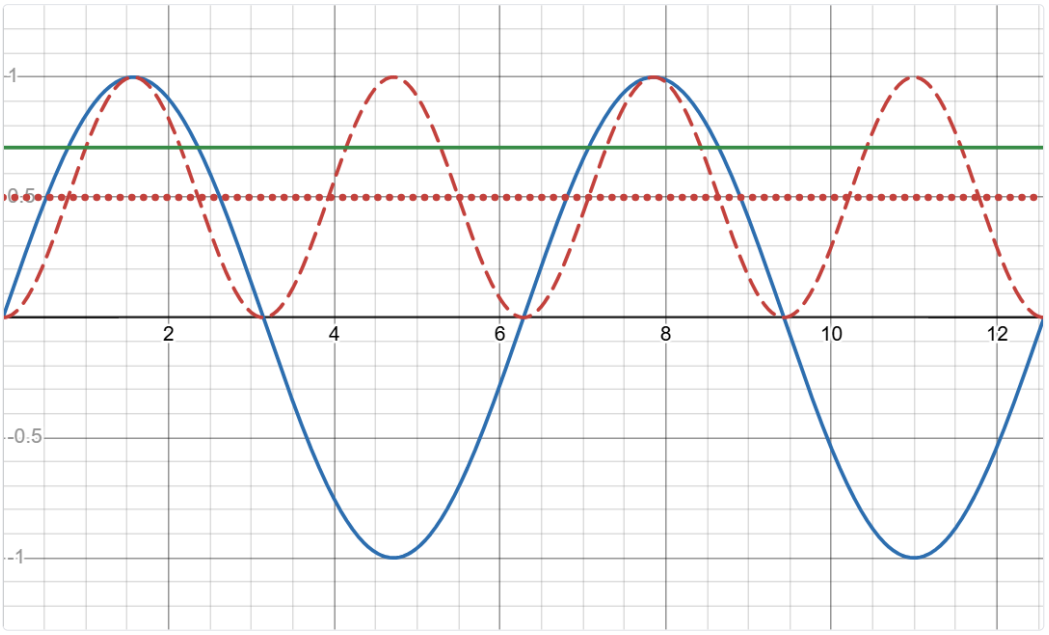
literally the **root** of the **mean** of the **square**. For periodic signals take $[a,b]$ as one period. For complex-valued signals use $|f|^2$.

Since $f^2 \ge 0$, the RMS value is always non-negative, is zero only for a signal that is zero almost everywhere, and satisfies $F_{\text{rms}} \ge |\bar f|$ (because $\langle (f-\bar f)^2\rangle \ge 0$ expands to $\langle f^2\rangle - \bar f^2 \ge 0$). Dimensionally, F_{rms} has the same units as f.

RMS of a sinusoid. For $v = V_m\sin(\omega t + \theta)$, Example 5.6(c) gives $\frac{1}{T}\int_0^T \sin^2(\omega t+\theta)\,dt = \frac{1}{2}$, so

$$V_{\text{rms}} = \frac{V_m}{\sqrt{2}} \approx 0.7071\,V_m,$$

independent of frequency and phase. A "230 V" mains supply therefore has peak $230\sqrt{2} = 325$ V.



sin t (blue), its square (red, dashed) with mean $1/2$ (red, dotted), and the RMS level $1/\sqrt{2} \approx 0.707$ (green).

5.9.4 Mean and RMS of standard waveforms

Every entry below is a short integral over one period; amplitude V_m means the peak value.

Waveform	Mean V_{dc}	Mean of $\lvert v\rvert$	RMS	Crest factor V_m/V_{rms}
Sine $V_m \sin \omega t$	0	$\dfrac{2V_m}{\pi}$	$\dfrac{V_m}{\sqrt{2}}$	$\sqrt{2} = 1.414$
Full-wave rectified sine $V_m \lvert\sin \omega t\rvert$	$\dfrac{2V_m}{\pi}$	$\dfrac{2V_m}{\pi}$	$\dfrac{V_m}{\sqrt{2}}$	1.414
Half-wave rectified sine	$\dfrac{V_m}{\pi}$	$\dfrac{V_m}{\pi}$	$\dfrac{V_m}{2}$	2
Square wave $\pm V_m$	0	V_m	V_m	1
Triangle or sawtooth, $\pm V_m$	0	$\dfrac{V_m}{2}$	$\dfrac{V_m}{\sqrt{3}}$	$\sqrt{3} = 1.732$
Pulse train, 0 to V_m, duty D	DV_m	DV_m	$\sqrt{D}\,V_m$	$\dfrac{1}{\sqrt{D}}$

Worked Example 5.44 — Deriving three table entries

(a) **Half-wave rectified sine.** Over $T = 2\pi/\omega$, $v = V_m \sin \omega t$ for $0 < t < T/2$ and 0 otherwise.

$$V_{\text{dc}} = \frac{1}{T}\int_0^{T/2} V_m \sin \omega t \, dt = \frac{1}{T}\cdot\frac{2V_m}{\omega} = \frac{V_m}{\pi}, \qquad V_{\text{rms}}^2 = \frac{1}{T}\int_0^{T/2} V_m^2 \sin^2 \omega t \, dt = \frac{1}{T}\cdot\frac{V_m^2}{2}\cdot\frac{T}{2} = \frac{V_m^2}{4}.$$

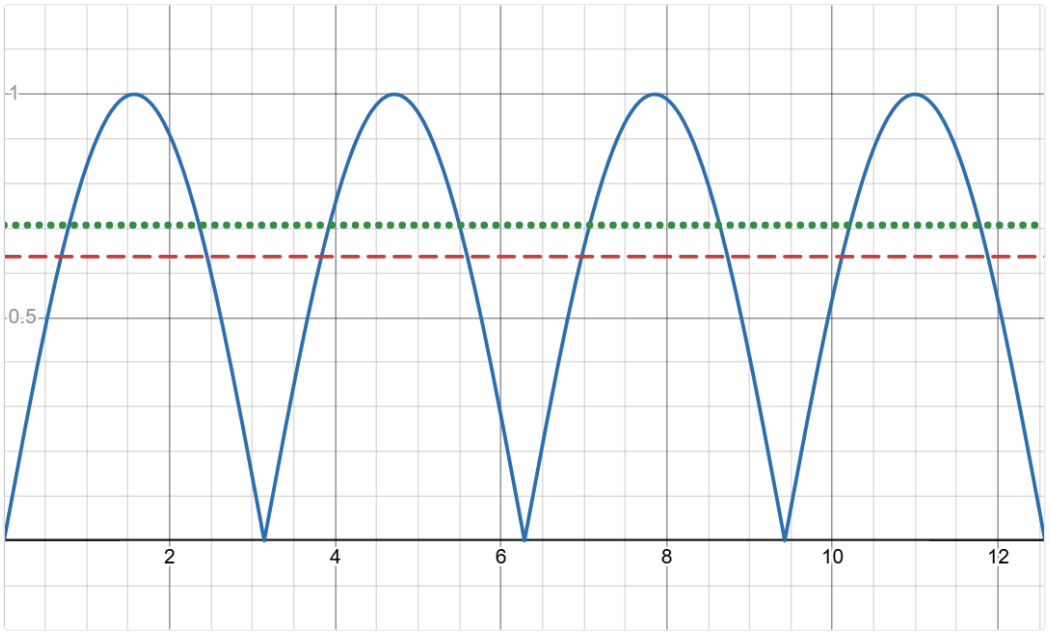
So $V_{\text{rms}} = V_m/2$: half the period carries the same power density as a full sine, so the mean square halves.

(b) **Sawtooth** $v = V_m\,\dfrac{2t - T}{T}$ on $[0, T]$ (from $-V_m$ to V_m). Substitute $u = \frac{2t-T}{T}$, $dt = \frac{T}{2}du$, $u \in [-1, 1]$:

$$V_{\text{rms}}^2 = \frac{1}{T}\int_{-1}^{1} V_m^2 u^2 \,\frac{T}{2}\,du = \frac{V_m^2}{2}\cdot\frac{2}{3} = \frac{V_m^2}{3}.$$

A triangle wave is made of the same linear pieces rearranged, so it has the same RMS value $V_m/\sqrt{3}$. RMS depends only on the *distribution of values*, not on their order in time.

(c) **Pulse train** of height V_m and duty cycle D: $v^2 = V_m^2$ for a fraction D of the time, so $\langle v^2\rangle = DV_m^2$ and $V_{\text{rms}} = \sqrt{D}\,V_m$, while $V_{\text{dc}} = DV_m$. A 12 V PWM signal at $D = 0.25$ has mean 3 V but RMS 6 V: a resistive heater driven by it dissipates $(6)^2/R$, four times what a 3 V DC supply would produce.



Full-wave rectified sine (blue) with its mean $2/\pi \approx 0.637$ (red) and RMS $1/\sqrt{2} \approx 0.707$ (green). The RMS exceeds the mean, as it always does unless the waveform is constant.

5.9.5 Mean, RMS and their combination

Write a periodic signal as its DC value plus an AC part with zero mean: $v = V_{\text{dc}} + v_{\text{ac}}$. Then

$$\langle v^2 \rangle = V_{\text{dc}}^2 + 2V_{\text{dc}}\langle v_{\text{ac}} \rangle + \langle v_{\text{ac}}^2 \rangle = V_{\text{dc}}^2 + V_{\text{ac,rms}}^2,$$

because $\langle v_{\text{ac}} \rangle = 0$. Thus

$$V_{\text{rms}} = \sqrt{V_{\text{dc}}^2 + V_{\text{ac,rms}}^2}.$$

In statistical language (Ch. 19), V_{dc} is the mean, $V_{\text{ac,rms}}$ is the standard deviation, and this is the identity $E[X^2] = \mu^2 + \sigma^2$. The RMS of a zero-mean noise voltage is its standard deviation.

Extending the argument to several harmonics uses orthogonality (§5.2.4): every cross term $\langle \cos m\omega_0 t \cos n\omega_0 t \rangle$ with $m \neq n$ vanishes.

RMS of a sum of harmonics (Parseval)

If $v(t) = V_0 + \sum_{n=1}^{N} V_n \cos(n\omega_0 t + \theta_n)$, then

$$V_{\text{rms}}^2 = V_0^2 + \sum_{n=1}^{N} \frac{V_n^2}{2} = V_0^2 + \sum_{n=1}^{N} V_{n,\text{rms}}^2.$$

Powers of different frequencies add; amplitudes do not.

Common Pitfall — Adding RMS values

RMS values of different-frequency components add **in quadrature**, not linearly: 3 V RMS at 1 kHz plus 4 V RMS at 3 kHz is 5 V RMS, not 7 V. Only components at the *same* frequency combine as phasors — and then their phase matters: two 3 V RMS sinusoids of the same frequency give anywhere from 0 to 6 V RMS.

Worked Example 5.45 — A signal with DC and harmonics

$v(t) = 5 + 10\sin\omega t + 4\sin 3\omega t$ V. Find V_{dc}, V_{rms} and the power into 8 Ω.

DC: $V_{\text{dc}} = 5$ V.

RMS: $V_{\text{rms}}^2 = 5^2 + \frac{10^2}{2} + \frac{4^2}{2} = 25 + 50 + 8 = 83$, so $V_{\text{rms}} = 9.110$ V.

Power: $P = V_{\text{rms}}^2/R = 83/8 = 10.375$ W, of which $25/8 = 3.125$ W is due to the DC component.

The **total harmonic distortion** of the AC part, $\text{THD} = \frac{\sqrt{\sum_{n\geq 2} V_{n,\text{rms}}^2}}{V_{1,\text{rms}}} = \frac{4/\sqrt{2}}{10/\sqrt{2}} = 40\%$, is itself an RMS ratio.

Worked Example 5.46 — Ripple on a DC supply

A 12 V supply carries a triangular ripple of 1 V peak-to-peak. Its AC part is a triangle of amplitude 0.5 V, with RMS $0.5/\sqrt{3} = 0.2887$ V. Then

$$V_{\text{rms}} = \sqrt{12^2 + 0.2887^2} = 12.0035 \text{ V}.$$

The ripple raises the RMS by only 0.03%; RMS is dominated by the largest component. That is why ripple is specified separately (in mV RMS or peak-to-peak) rather than inferred from a total RMS reading.

5.9.6 Average power and power factor

For a two-terminal element with periodic $v(t)$ and $i(t)$, the **average (real) power** is the mean of the instantaneous power:

$$P = \frac{1}{T}\int_0^T v(t)\, i(t)\, dt.$$

Average power for sinusoids

If $v = V_m \cos \omega t$ and $i = I_m \cos(\omega t - \varphi)$, then

$$P = \tfrac{1}{2} V_m I_m \cos\varphi = V_{\text{rms}} I_{\text{rms}} \cos\varphi = \tfrac{1}{2}\,\text{Re}\{\mathbf{V}\mathbf{I}^*\},$$

where $\mathbf{V} = V_m$ and $\mathbf{I} = I_m e^{-j\varphi}$ are peak phasors.

Derivation. By the product-to-sum identity, $v\,i = \tfrac{1}{2}V_m I_m\big[\cos\varphi + \cos(2\omega t - \varphi)\big]$. The second term oscillates at 2ω and averages to zero over a period, leaving $\tfrac{1}{2}V_m I_m \cos\varphi$. In phasor form $\mathbf{V}\mathbf{I}^* = V_m I_m e^{j\varphi}$, whose real part is $V_m I_m \cos\varphi$. □

The factor $\cos\varphi$ is the **power factor**. More generally the power factor is $P/(V_{\text{rms}} I_{\text{rms}})$, which also accounts for harmonic distortion: by orthogonality, only voltage and current harmonics of the *same* order contribute to P, while every harmonic increases I_{rms}.

Worked Example 5.47 — Real power of an inductive load

A load on 230 V RMS mains ($V_m = 325$ V) draws $I_m = 10$ A lagging by 30°.

$$P = \tfrac{1}{2}(325)(10)\cos 30^\circ = 1407 \text{ W}, \qquad S = V_{\text{rms}} I_{\text{rms}} = \tfrac{1}{2}(325)(10) = 1625 \text{ VA}.$$

Check by direct integration: numerically averaging $325\cos\omega t \cdot 10\cos(\omega t - \pi/6)$ over one period gives 1407.3 W ✓.

5.9.7 Form factor, crest factor and meters

Two dimensionless ratios describe waveform shape:

$$\text{form factor} = \frac{V_{\text{rms}}}{\langle |v| \rangle}, \qquad \text{crest factor} = \frac{V_{\text{peak}}}{V_{\text{rms}}}.$$

For a sine, the form factor is $\frac{V_m/\sqrt{2}}{2V_m/\pi} = \frac{\pi}{2\sqrt{2}} = 1.1107$ and the crest factor is $\sqrt{2}$.

Inexpensive "average-responding" AC meters rectify the signal, measure $\langle |v| \rangle$ (an easy analogue integral), and multiply by 1.1107. They read correctly only for sinusoids.

Worked Example 5.48 — Meter error on non-sinusoidal waveforms

(a) **Square wave** $\pm V_m$**.** $\langle |v| \rangle = V_m$, so the meter displays $1.1107 V_m$; the true RMS is V_m. The reading is 11.1% high.

(b) **Triangle wave** $\pm V_m$**.** $\langle |v| \rangle = V_m/2$, display $0.5554 V_m$; true RMS $V_m/\sqrt{3} = 0.5774 V_m$. The reading is 3.8% low.

(c) **PWM,** $D = 0.1$**.** $\langle v \rangle = 0.1 V_m$, display $0.111 V_m$; true RMS $\sqrt{0.1}\, V_m = 0.316 V_m$ — the meter reads barely a third of the true value. Signals with high crest factor (here $\sqrt{10} = 3.16$) are where average-responding meters fail worst, and where a "true-RMS" meter, which computes $\sqrt{\langle v^2 \rangle}$ by squaring and integrating, is essential.

5.9.8 Mean and RMS over a finite window

For non-periodic signals the value depends on the averaging window, which must therefore be stated.

Worked Example 5.49 — A decaying pulse

$v(t) = 10 e^{-t/\tau}$ V with $\tau = 1$ ms, averaged over the window $0 \le t \le T = 5$ ms.

$$\bar{v} = \frac{1}{T}\int_0^T 10 e^{-t/\tau} dt = \frac{10\tau}{T}\left(1 - e^{-T/\tau}\right) = 1.987 \text{ V},$$

$$V_{\text{rms}}^2 = \frac{1}{T}\int_0^T 100 e^{-2t/\tau} dt = \frac{100\tau}{2T}\left(1 - e^{-2T/\tau}\right) = 9.9995, \qquad V_{\text{rms}} = 3.162 \text{ V}.$$

Doubling the window to 10 ms roughly halves $\bar{v}$ and divides V_{rms} by about $\sqrt{2}$ — a transient's "average" is meaningful only together with its window. For such signals the window-independent quantities are the **total** integral $\int_0^\infty v\, dt = 10\tau = 10$ mV·s and the **energy** $\int_0^\infty v^2 dt = 50\tau = 0.05$ V²·s (the energy delivered to 1 Ω), which lead to the energy-signal concepts of Ch. 16.

Engineering Note — RMS in noise and measurement

For random signals the time-average RMS equals the ensemble standard deviation (for ergodic processes, Ch. 21). Thermal noise in a resistor has RMS voltage $\sqrt{4kTRB}$ — the square root of an *integral* of a flat power spectral density over the bandwidth B. Uncorrelated noise sources add in quadrature, for exactly the orthogonality reason that harmonics do: the mean of the product of two independent zero-mean signals is zero.

Summary

Topic	Key formula or result
Definite integral	$\displaystyle\int_a^b f\,dx = \lim_{\|P\|\to 0}\sum f(x_k^*)\,\Delta x_k$
FTC	$\displaystyle\frac{d}{dx}\int_a^x f(t)\,dt = f(x);\ \int_a^b f\,dx = F(b)-F(a)$
Leibniz rule	$\displaystyle\frac{d}{dx}\int_{u(x)}^{v(x)} f\,dt = f(v)v' - f(u)u'$
Mean value	$\displaystyle\bar f = \frac{1}{b-a}\int_a^b f\,dx = f(c)$ for some c
Complex exponential	$\displaystyle\int e^{(a+jb)t}dt = \frac{e^{(a+jb)t}}{a+jb}$
Orthogonality	$\displaystyle\int_0^T \sin m\omega_0 t\,\sin n\omega_0 t\,dt = \tfrac{T}{2}\,\delta_{mn}$
Cover-up rule	$A = \big[(x-a)P/Q\big]_{x=a}$
p-integrals	$\int_1^\infty x^{-p}dx<\infty \iff p>1;\ \int_0^1 x^{-p}dx<\infty \iff p<1$
Gaussian, Gamma	$\int_{-\infty}^{\infty} e^{-x^2}dx=\sqrt{\pi};\ \Gamma(n+1)=n!$
Fubini	$\iint_R f\,dA = \int_a^b\int_c^d f\,dy\,dx = \int_c^d\int_a^b f\,dx\,dy$
Polar area element	$dA = r\,dr\,d\phi$
Integration by parts	$\int u\,dv = uv - \int v\,du$
Substitution	$\int_a^b f(g(x))g'(x)\,dx = \int_{g(a)}^{g(b)} f(u)\,du$
Scaling	$\int_{-\infty}^{\infty} f(at)\,dt = \frac{1}{\|a\|}\int_{-\infty}^{\infty} f(u)\,du$
Trapezoidal rule	$T_n = h[\frac12 f_0 + f_1 + \cdots + f_{n-1} + \frac12 f_n]$, error $-\frac{(b-a)h^2}{12}f''(\xi)$
Simpson's rule	$S_n = \frac{h}{3}[f_0 + 4f_1 + 2f_2 + \cdots + 4f_{n-1} + f_n]$, error $-\frac{(b-a)h^4}{180}f^{(4)}(\xi)$
Richardson	$I \approx T_{2n} + (T_{2n} - T_n)/3$
Charge, energy	$q=\int i\,dt;\ W=\int p\,dt;\ W_C=\frac12 CV^2;\ W_L=\frac12 LI^2$
Non-uniform resistance	$R=\int_0^L \rho_e\,dx/A(x)$
RMS	$F_{\text{rms}}=\sqrt{\frac1T\int_0^T f^2dt}$; sine: $V_m/\sqrt2$
DC + AC	$V_{\text{rms}}^2 = V_{\text{dc}}^2 + V_{\text{ac,rms}}^2 = V_0^2 + \sum V_n^2/2$
Average power	$P=\frac1T\int_0^T v\,i\,dt = \frac12 V_m I_m\cos\varphi = \frac12\,\text{Re}\{\mathbf{V}\mathbf{I}^*\}$

Chapter 6 — Multivariable Calculus

> **Prerequisites:** Ch. 4, Ch. 5; basic vectors (dot product) and 2×2 determinants. **Learning outcomes:** After this chapter you can
>
> - describe functions of several variables through their domains, level curves and level surfaces, and decide whether limits exist;
> - compute partial derivatives, total differentials and gradients, and use them for linear approximation, sensitivity and tolerance analysis;
> - evaluate directional derivatives and build Jacobian matrices for linearisation, small-signal models and Newton's method;
> - set up and evaluate double and triple integrals, changing the order of integration when that helps;
> - change variables in integrals, in particular to polar, cylindrical and spherical coordinates;
> - locate and classify extrema of functions of several variables, with and without constraints, using the Hessian test and Lagrange multipliers.

Almost every quantity an engineer measures depends on more than one thing. The power in a resistor depends on voltage *and* resistance; the potential in a region of space depends on x, y and z; the collector current of a transistor depends on v_{BE} and v_{CE}; the cutoff frequency of a filter depends on every component value in it. Chapters 4 and 5 built derivatives and integrals for functions of one variable. This chapter extends both ideas to functions of several variables, and the extension is not merely notational: new phenomena appear (limits that depend on the direction of approach, derivatives in every direction at once, regions of integration with shape), and new tools (the gradient, the Jacobian, the Hessian, the Lagrange multiplier) become the everyday language of circuit sensitivity, field theory, nonlinear circuit solvers and optimisation.

The chapter has three movements. Sections 6.1–6.6 are **differential**: they describe how a function of several variables changes locally, culminating in the Jacobian matrix as *the* derivative of a vector function. Sections 6.7–6.9 are **integral**: they add up quantities over areas and volumes and show how to choose coordinates that fit the geometry. Sections 6.10–6.11 combine the two to find **optimal** points, with and without constraints. Chapter 7 then adds direction to the picture with vector fields, and almost every result there rests on something proved here.

6.1 Functions of several variables

Motivation

A single-variable function $y = f(x)$ is a curve; you can sketch it and read off slopes and areas. An engineer's quantities are rarely that simple. The resonant frequency of a series RLC circuit, $\omega_0 = 1/\sqrt{LC}$, is a function of two variables. The electrostatic potential $V(x, y, z)$ in a device is a function of three. The bit-error rate of a link depends on signal power, noise power, bandwidth and modulation order. Before we can differentiate or integrate such functions we need a vocabulary for describing them and a way to *see* them.

Definitions

Function of several variables

A real function of n variables assigns to each point $\mathbf{x} = (x_1, \dots, x_n)$ of a set $D \subseteq \mathbb{R}^n$ exactly one real number $f(\mathbf{x})$. The set D is the **domain** and the set of values taken is the **range**. For $n = 2$ we usually write $z = f(x, y)$; the **graph** $\{(x, y, f(x, y))\}$ is a surface in $\mathbb{R}^3$. A function of position $f(x, y, z)$ is also called a **scalar field**.

Unless stated otherwise, the domain is the largest set on which the formula makes sense: no division by zero, no square roots of negative numbers, no logarithms of non-positive numbers. Physical constraints may shrink it further (a resistance is positive, a probability lies in $[0, 1]$).

A few terms about sets in $\mathbb{R}^n$ will be needed later. A **neighbourhood** (open ball) of $\mathbf{a}$ is the set of points within distance $\delta > 0$ of $\mathbf{a}$: $\|\mathbf{x} - \mathbf{a}\| < \delta$. A point is an **interior point** of D if some neighbourhood of it lies entirely in D, and a **boundary point** if every neighbourhood contains points both in and out of D. D is **open** if all its points are interior, **closed** if it contains all its boundary points, and **bounded** if it fits inside some ball. "Closed and bounded" regions are the ones on which continuous functions are guaranteed to have a maximum and a minimum (§6.10).

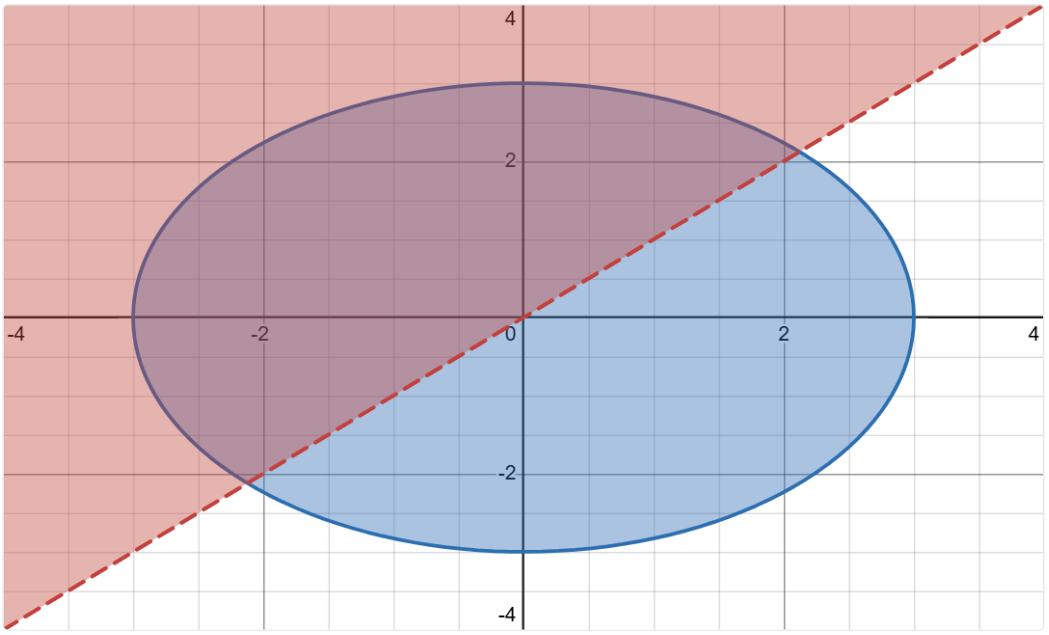
Worked Example — finding and sketching a domain

Find the domain of $f(x, y) = \sqrt{9 - x^2 - y^2} + \ln(y - x)$.

Step 1 (square root): need $9 - x^2 - y^2 \geq 0$, i.e. $x^2 + y^2 \leq 9$ — the closed disc of radius 3.

Step 2 (logarithm): need $y - x > 0$, i.e. the open half-plane above the line $y = x$.

Step 3 (intersect): $D = \{(x, y) : x^2 + y^2 \leq 9,\ y > x\}$, a half-disc. It is bounded but neither open (it contains part of the circle) nor closed (it excludes the diameter on $y = x$). Check a point: $(0, 1)$ gives $\sqrt{8} + \ln 1 = 2.828$, defined; $(1, 0)$ gives $\ln(-1)$, undefined. ✓



The domain of $\sqrt{9-x^2-y^2}+\ln(y-x)$ is where the blue disc and the red half-plane overlap; the dashed diameter itself is excluded.

Level curves and level surfaces

Because a surface is hard to draw, we usually draw **level curves** (contours) $f(x,y)=c$ for several constants c, the way a topographic map shows height. Where the contours crowd together the surface is steep; where they spread out it is flat. For $f(x,y,z)$ the analogous objects are **level surfaces** $f(x,y,z)=c$; in electrostatics these are the equipotential surfaces.

Level set

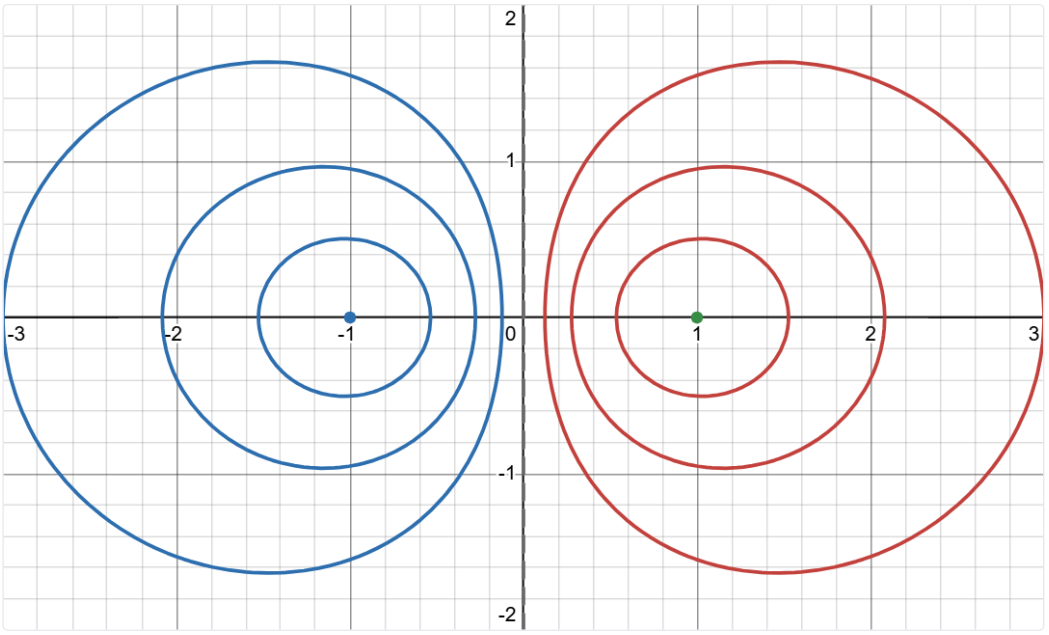
The level set of f at height c is $\{\mathbf{x}\in D : f(\mathbf{x})=c\}$. For $n=2$ it is (generically) a curve, for $n=3$ a surface. Level sets for different values of c never intersect, because f has only one value at each point.

Function	Level sets	Engineering reading
$f=x^2+y^2$	circles centred on the origin	equal-distance contours
$f=ax+by$	parallel straight lines	equipotentials of a uniform field
$f=xy$	rectangular hyperbolas	constant-power curves $P=VI$
$V=\dfrac{q}{4\pi\varepsilon_0\sqrt{x^2+y^2+z^2}}$	spheres	equipotentials of a point charge
$P=V^2/R$	curves $V^2=cR$ (parabolas in the RV-plane)	constant-dissipation curves
$\omega_0=1/\sqrt{LC}$	hyperbolas $LC=\text{const}$	all (L,C) pairs tuned to one frequency

The last row is worth a moment's thought: a whole curve of (L,C) pairs gives the same resonant frequency, and the designer moves along that curve to trade other properties (characteristic impedance $\sqrt{L/C}$, component cost). Level sets turn such design freedom into geometry.

The equipotentials of a pair of equal and opposite point charges at $(\mp1,0)$ (in the $z=0$ plane, constants dropped) are the level curves of

$$V(x,y)=\frac{1}{\sqrt{(x+1)^2+y^2}}-\frac{1}{\sqrt{(x-1)^2+y^2}}.$$



Level curves of the dipole potential: positive contours (blue) circle the positive charge, negative contours (red) the negative one, and the $V = 0$ contour is the bisecting line $x = 0$.

Three-variable functions cannot be graphed at all (the graph would live in $\mathbb{R}^4$), so level surfaces are the main visual tool. The **quadric surfaces** are the level sets of quadratic functions and appear constantly as constraint surfaces and equipotentials:

Equation	Surface
$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1$	ellipsoid (sphere if $a = b = c$)
$x^2 + y^2 = a^2$	circular cylinder along z
$z = x^2 + y^2$	paraboloid of revolution
$z^2 = x^2 + y^2$	double cone
$z = x^2 - y^2$	hyperbolic paraboloid ("saddle")
$x^2 + y^2 - z^2 = 1$	hyperboloid of one sheet

Limits and continuity

Limit and continuity

$\lim_{\mathbf{x}\to\mathbf{a}} f(\mathbf{x}) = L$ means: for every $\varepsilon > 0$ there is a $\delta > 0$ such that $|f(\mathbf{x}) - L| < \varepsilon$ whenever $0 < \|\mathbf{x} - \mathbf{a}\| < \delta$ and $\mathbf{x} \in D$. The function is **continuous** at $\mathbf{a}$ if $\lim_{\mathbf{x}\to\mathbf{a}} f(\mathbf{x}) = f(\mathbf{a})$.

The definition looks exactly like the one-variable definition in Chapter 4, but $\|\mathbf{x} - \mathbf{a}\| < \delta$ is now a disc (or ball), not an interval. That means f must approach L **along every path** into $\mathbf{a}$ — straight lines from every direction, parabolas, spirals, anything. In one variable there are only two directions of approach (left and right); in two there are infinitely many. Two consequences follow:

- If two paths give different limiting values, the limit does **not** exist.
- To prove that a limit **does** exist, you must bound $|f - L|$ by something that tends to zero independently of the path. Polar coordinates centred on $\mathbf{a}$ are the standard tool: write $x - a = r\cos\theta$, $y - b = r\sin\theta$ and show $|f - L| \le g(r)$ with $g(r) \to 0$.

Worked Example 1 — a limit that does not exist

Let $f(x, y) = \dfrac{xy}{x^2 + y^2}$ for $(x, y) \neq (0, 0)$. Along the line $y = mx$,

$$f(x, mx) = \frac{mx^2}{x^2 + m^2x^2} = \frac{m}{1 + m^2},$$

which depends on m: it is 0 along the axes ($m = 0$) and $\frac{1}{2}$ along $y = x$ ($m = 1$). Different paths give different values, so the limit at the origin does not exist, and no choice of $f(0, 0)$ makes f continuous there. In polar form $f = \frac{1}{2}\sin 2\theta$: the function depends only on the *direction* from the origin, not on the distance, so it cannot settle to a single value as $r \to 0$.

Worked Example 2 — all straight lines agree, yet no limit

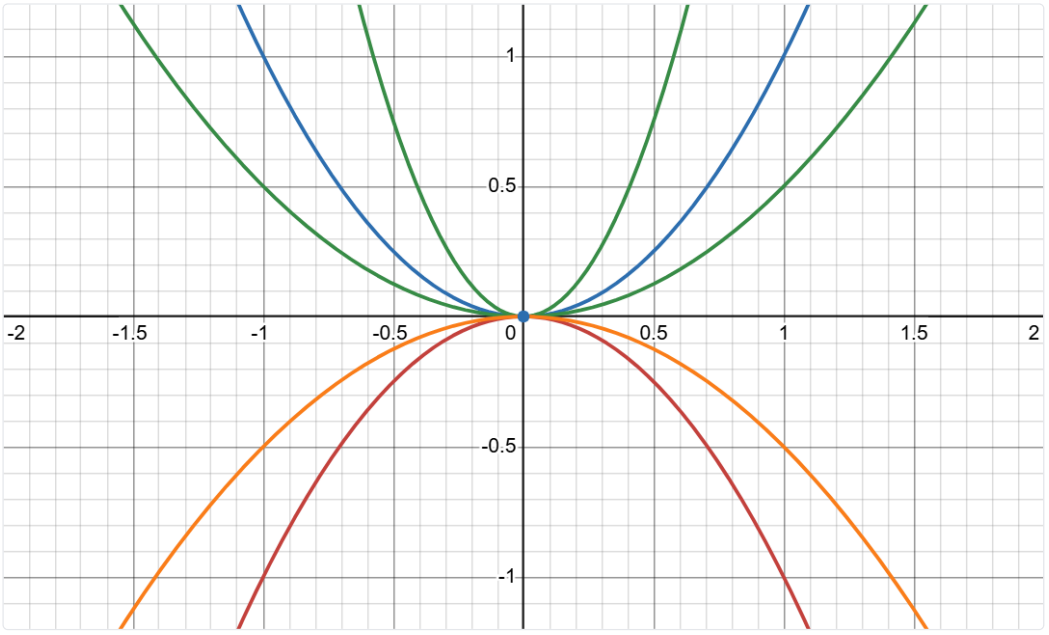
Let $f(x,y) = \dfrac{x^2 y}{x^4 + y^2}$. Along $y = mx$ $(m \neq 0)$,

$$f(x, mx) = \frac{mx^3}{x^4 + m^2 x^2} = \frac{mx}{x^2 + m^2} \to 0 \quad (x \to 0),$$

and along the axes $f = 0$ identically. Every straight line gives 0. But along the parabola $y = x^2$,

$$f(x, x^2) = \frac{x^4}{x^4 + x^4} = \frac{1}{2}.$$

So the limit does not exist. More generally, on $y = kx^2$ the value is $k/(1+k^2)$: the level curves of f are parabolas through the origin, and every one of them reaches the origin carrying its own value.



Level curves of $x^2y/(x^4+y^2)$ are parabolas $y = kx^2$ with value $k/(1+k^2)$: blue ($k = 1$) carries 0.5, green ($k = 0.5$ and $k = 3$) carry 0.4 and 0.3, red ($k = -1$) and orange ($k = -0.5$) carry -0.5 and -0.4. Every one of them enters the origin, so no single limit exists — although every straight line through the origin gives 0.

Worked Example 3 — proving a limit exists

Show that $\displaystyle\lim_{(x,y)\to(0,0)} \frac{x^3 + 2x^2y^2}{x^2 + y^2} = 0$.

In polar coordinates $x = r\cos\theta$, $y = r\sin\theta$, the denominator is r^2 and

$$f = \frac{r^3\cos^3\theta + 2r^4\cos^2\theta\sin^2\theta}{r^2} = r\cos^3\theta + 2r^2\cos^2\theta\sin^2\theta.$$

Since $|\cos\theta| \le 1$ and $|\sin\theta| \le 1$, $|f| \le r + 2r^2$, which tends to 0 as $r \to 0$ regardless of θ. Hence the limit is 0, and defining $f(0,0) = 0$ makes f continuous. Numerically, at $(0.01, 0.01)$: $f = (10^{-6} + 2\times10^{-8})/(2\times10^{-4}) = 0.0051$, small as expected.

Common Pitfall

Checking straight-line paths can prove that a limit does **not** exist, but never that it does — Worked Example 2 passes every straight-line test and still fails. Likewise, a bound in polar form must be independent of θ: $|f| \le r/|\cos\theta|$ is *not* good enough, because $\cos\theta$ can be arbitrarily small.

Building continuous functions

Polynomials in $x_1, \ldots, x_n$ are continuous everywhere. Sums, products and compositions of continuous functions are continuous; quotients are continuous wherever the denominator is non-zero. Elementary functions (e^u, $\sin u$, $\ln u$, $\sqrt{u}$, …) of continuous expressions are continuous wherever they are defined.

So $e^{-x^2-y^2}\cos(xy)$ is continuous on all of $\mathbb{R}^2$, and $\ln(1 - x^2 - y^2)$ on the open unit disc. Trouble only arises at points excluded from the formula's natural domain, as at the origin above.

Engineering Note

Real devices are continuous functions of their inputs, but their *models* are not always: piecewise device models (a diode switching between "off" and "on" regions, a MOSFET between triode and saturation) can be discontinuous or have discontinuous derivatives at region boundaries. Circuit simulators fail to converge exactly at such seams, which is why modern compact models are built from smooth functions that blend the regions together.

6.2 Partial differentiation

Motivation

The first question an engineer asks of a multi-input function is: *if I nudge one input and hold the rest, how much does the output move?* That is a partial derivative. It answers "which resistor matters most in this filter?", "how fast does the potential change as I move east?", and "what is the transistor's transconductance at this bias?". Partial derivatives are also the building blocks of everything else in the chapter — the gradient, the Jacobian and the Hessian are just partial derivatives arranged in vectors and matrices.

Definition and geometric meaning

Partial derivative

The partial derivative of $f(x, y)$ with respect to x at (a, b) is the ordinary derivative obtained by holding y fixed at b:

$$\frac{\partial f}{\partial x}(a, b) = f_x(a, b) = \lim_{h \to 0} \frac{f(a + h, b) - f(a, b)}{h}.$$

f_y is defined likewise with x held fixed. For $f(x_1, \dots, x_n)$ there are n first partial derivatives $\partial f / \partial x_i$, each obtained by varying one variable and freezing all the others.

Other notations in common use: $\partial_x f$, $D_1 f$, $\left(\dfrac{\partial f}{\partial x}\right)_y$. The last one, with the held-constant variable written as a subscript, is used in thermodynamics and wherever there is real ambiguity about what is held fixed (see the pitfall below).

Geometrically, $f_x(a, b)$ is the slope of the surface $z = f(x, y)$ in the x-direction at (a, b): slice the surface with the vertical plane $y = b$, and $f_x(a, b)$ is the slope of the resulting curve $z = f(x, b)$. Similarly $f_y(a, b)$ is the slope of the curve cut out by the plane $x = a$. The two partials therefore describe two tangent lines to the surface; together they span the tangent plane (§6.3).

Computing. Because $\partial f / \partial x$ is an ordinary derivative in disguise, every single-variable rule (power, product, quotient, chain) applies unchanged, treating the other variables as constants. For example, with $f(x, y) = x^2 y^3 + \sin(xy)$:

$$f_x = 2xy^3 + y\cos(xy), \qquad f_y = 3x^2 y^2 + x\cos(xy).$$

The y in front of $\cos(xy)$ in f_x is the inner derivative $\partial(xy)/\partial x = y$ from the chain rule.

Checking numerically. A partial derivative can always be estimated by a **finite difference**, varying one input in a simulation or on the bench:

$$f_x(a, b) \approx \frac{f(a + h, b) - f(a - h, b)}{2h} \qquad \text{(central difference, error } O(h^2)\text{)}.$$

At $(1, 2)$ the formula above gives $f_x = 16 + 2\cos 2 = 15.1677$; the central difference with $h = 10^{-3}$ gives 15.1677 to all digits shown, while the one-sided difference $[f(a + h, b) - f(a, b)]/h$ gives 15.1739, correct only to about three figures (error $O(h)$). This is the method circuit simulators fall back on for sensitivity analysis when analytic derivatives are not available, and the reason central differences are preferred (Ch. 22).

Worked Example 1 — partial derivatives of an RC low-pass response

The magnitude response of a first-order RC low-pass filter is

$$M(\omega, \tau) = \frac{1}{\sqrt{1 + \omega^2 \tau^2}}, \qquad \tau = RC.$$

Partial with respect to frequency (hold τ): write $M = (1 + \omega^2\tau^2)^{-1/2}$ and use the chain rule:

$$\frac{\partial M}{\partial \omega} = -\tfrac{1}{2}(1 + \omega^2\tau^2)^{-3/2} \cdot 2\omega\tau^2 = -\frac{\omega\tau^2}{(1 + \omega^2\tau^2)^{3/2}}.$$

Partial with respect to time constant (hold ω): by the same steps, $\partial M/\partial \tau = -\omega^2 \tau / (1 + \omega^2\tau^2)^{3/2}$.

At the cutoff $\omega\tau = 1$: $\partial M/\partial \omega = -\tau/2^{3/2} = -0.354\,\tau$ and $\partial M/\partial \tau = -\omega/2^{3/2} = -0.354\,\omega$. Units: M is dimensionless, so $\partial M/\partial\omega$ must have units of seconds (it does: τ) and $\partial M/\partial\tau$ units of s^{-1} (it does: ω). The symmetry $\omega\,\partial M/\partial\omega = \tau\,\partial M/\partial\tau$ is no accident: M depends only on the product $\omega\tau$.

Worked Example 2 — sensitivity of a parallel combination

For two resistors in parallel, $R = \dfrac{R_1 R_2}{R_1 + R_2}$. Holding R_2 fixed and using the quotient rule,

$$\frac{\partial R}{\partial R_1} = \frac{R_2(R_1 + R_2) - R_1 R_2 \cdot 1}{(R_1 + R_2)^2} = \frac{R_2^2}{(R_1 + R_2)^2},$$

and by symmetry $\partial R/\partial R_2 = R_1^2/(R_1 + R_2)^2$. With $R_1 = 1\,\mathrm{k\Omega}$, $R_2 = 4\,\mathrm{k\Omega}$: $R = 0.8\,\mathrm{k\Omega}$, $\partial R/\partial R_1 = 16/25 = 0.64$ and $\partial R/\partial R_2 = 1/25 = 0.04$.

The combination is 16 times more sensitive to the *smaller* resistor — a fact worth knowing when choosing which part needs the tighter tolerance. Both derivatives are dimensionless, as they must be (Ω/Ω). Check by finite difference: raising R_1 to $1.01\,\mathrm{k\Omega}$ gives $R = 4.04/5.01 = 0.806387\,\mathrm{k\Omega}$, an increase of $6.39\ \Omega$ for a $10\ \Omega$ change, ratio 0.639. ✓

Normalised sensitivity

Absolute partial derivatives mix units, which makes it hard to compare the influence of, say, a capacitor and a resistor. Circuit designers therefore use the **normalised (relative) sensitivity**

$$S_x^f = \frac{x}{f}\frac{\partial f}{\partial x} = \frac{\partial \ln f}{\partial \ln x} \approx \frac{\Delta f / f}{\Delta x / x},$$

the percentage change in f per percentage change in x. It is dimensionless, and for a power law $f = k x^a y^b$ it is simply the exponent: $S_x^f = a$, $S_y^f = b$.

Worked Example 3 — sensitivities of a series RLC circuit

A series RLC circuit has resonant frequency and quality factor

$$\omega_0 = (LC)^{-1/2}, \qquad Q = \frac{1}{R}\sqrt{\frac{L}{C}} = R^{-1} L^{1/2} C^{-1/2}.$$

Both are power laws, so the normalised sensitivities are read off the exponents:

$$S_L^{\omega_0} = S_C^{\omega_0} = -\tfrac{1}{2}, \quad S_R^{\omega_0} = 0; \qquad S_R^{Q} = -1, \quad S_L^{Q} = +\tfrac{1}{2}, \quad S_C^{Q} = -\tfrac{1}{2}.$$

Verify one from the definition: $\partial \omega_0 / \partial L = -\tfrac{1}{2} L^{-3/2} C^{-1/2}$, so $S_L^{\omega_0} = \dfrac{L}{(LC)^{-1/2}} \cdot \left(-\tfrac{1}{2} L^{-3/2} C^{-1/2}\right) = -\tfrac{1}{2}$. ✓

Reading: a 2 % high capacitor lowers ω_0 by about 1 % and Q by about 1 %; a 2 % high resistor leaves ω_0 alone but lowers Q by 2 %. A designer who needs an accurate centre frequency should spend money on L and C, not on R.

Common Pitfall — what is being held constant?

A partial derivative is only defined once you know which *other* variables are held fixed. For $P = VI$ with I held fixed, $\partial P / \partial V = I$. For the same resistor written as $P = V^2/R$ with R held fixed, $\partial P / \partial V = 2V/R = 2I$. Both are correct — they answer different questions (fixed current versus fixed resistance). When the context does not make this obvious, write $(\partial P / \partial V)_I$ or $(\partial P / \partial V)_R$.

Higher-order partial derivatives

Each first partial is itself a function of (x, y) and can be differentiated again, giving four second-order partials of $f(x, y)$:

$$f_{xx} = \frac{\partial^2 f}{\partial x^2}, \quad f_{yy} = \frac{\partial^2 f}{\partial y^2}, \quad f_{xy} = \frac{\partial}{\partial y}\left(\frac{\partial f}{\partial x}\right) = \frac{\partial^2 f}{\partial y\, \partial x}, \quad f_{yx} = \frac{\partial}{\partial x}\left(\frac{\partial f}{\partial y}\right) = \frac{\partial^2 f}{\partial x\, \partial y}.$$

(The subscript notation is read left to right — f_{xy} means "first x, then y" — while the fraction notation is read right to left. Fortunately the next theorem usually makes the order irrelevant.) f_{xx} measures the curvature of the x-slice; f_{xy} measures how the x-slope changes as you move in y, i.e. the *twist* of the surface.

Clairaut (Schwarz) theorem

If f_{xy} and f_{yx} both exist and are continuous on a neighbourhood of a point, they are equal there: the order of mixed differentiation does not matter. The same holds for higher derivatives: any two mixed partials involving the same number of differentiations in each variable agree if they are continuous.

Proof sketch. Consider the "second difference"

$$\Delta(h, k) = f(a+h, b+k) - f(a+h, b) - f(a, b+k) + f(a, b).$$

Grouping it as $g(a+h) - g(a)$ with $g(x) = f(x, b+k) - f(x, b)$ and applying the mean value theorem twice (first in x, then in y) gives $\Delta = hk\, f_{xy}(\xi, \eta)$ for some point (ξ, η) in the small rectangle. Grouping it the other way round, as a difference in y first, gives $\Delta = hk\, f_{yx}(\xi', \eta')$. Dividing by hk and letting $h, k \to 0$, continuity forces both mixed partials to the same value $\lim \Delta/(hk)$ at (a, b). □

Worked Example 4 — second partials and a numerical check

For $f = x^2 y^3 + \sin(xy)$, from the first partials above:

$$\begin{aligned} f_{xx} &= 2y^3 - y^2 \sin(xy), \qquad f_{yy} = 6x^2 y - x^2 \sin(xy), \\ f_{xy} &= \frac{\partial}{\partial y}\left[2xy^3 + y\cos(xy)\right] = 6xy^2 + \cos(xy) - xy\sin(xy), \\ f_{yx} &= \frac{\partial}{\partial x}\left[3x^2 y^2 + x\cos(xy)\right] = 6xy^2 + \cos(xy) - xy\sin(xy). \end{aligned}$$

The mixed partials agree, as Clairaut promises. At $(1, 2)$: $f_{xy} = 24 + \cos 2 - 2\sin 2 = 24 - 0.4161 - 1.8186 = 21.7653$. The four-point finite difference $\dfrac{f(a+h,b+h) - f(a+h,b-h) - f(a-h,b+h) + f(a-h,b-h)}{4h^2}$ with $h = 10^{-3}$ gives 21.7653. ✓

The hypotheses of Clairaut's theorem matter. The standard counterexample $f = xy(x^2 - y^2)/(x^2 + y^2)$, $f(0,0) = 0$, has $f_{xy}(0,0) = -1$ but $f_{yx}(0,0) = +1$; its second partials exist near the origin but are not continuous there. Such functions do not arise from smooth physical models, which is why engineers can (and do) swap the order of differentiation freely.

Common Pitfall — partial derivatives do not guarantee continuity

In one variable, a differentiable function is continuous. In several variables, the mere *existence* of partial derivatives guarantees nothing of the kind. The function $xy/(x^2+y^2)$ of §6.1 (with value 0 at the origin) has $f_x(0,0) = f_y(0,0) = 0$, because it is identically zero along both axes — yet it is not even continuous at the origin. Partial derivatives only probe two directions. The right multivariable notion of "differentiable" is the subject of §6.3.

Partial differential equations

Equations relating partial derivatives are **partial differential equations** (PDEs), the subject of Ch. 13. Here we only need to *check* that a given function satisfies one, which is pure partial differentiation. The three classical equations are:

Equation	Form (2-D, or 1-D plus time)	Typical physics
Laplace	$u_{xx} + u_{yy} = 0$	electrostatic potential in a charge-free region
Heat (diffusion)	$u_t = k\,u_{xx}$	heat flow, carrier diffusion, RC transmission lines
Wave	$u_{tt} = c^2 u_{xx}$	voltage on a lossless line, sound, light

Worked Example 5 — checking Laplace's equation

The potential of an infinite line charge, up to constants, is $u = \ln(x^2+y^2)$. Then

$$u_x = \frac{2x}{x^2+y^2}, \qquad u_{xx} = \frac{2(x^2+y^2) - 2x\cdot 2x}{(x^2+y^2)^2} = \frac{2y^2 - 2x^2}{(x^2+y^2)^2},$$

and by the symmetry $x \leftrightarrow y$, $u_{yy} = \dfrac{2x^2 - 2y^2}{(x^2+y^2)^2}$. Hence $u_{xx} + u_{yy} = 0$ away from the origin: u satisfies **Laplace's equation**, as every electrostatic potential in a charge-free region must. (At the origin, where the line charge sits, u is not even defined.) A function satisfying Laplace's equation is called **harmonic**.

Worked Example 6 — travelling waves and decaying modes

(a) Let $u(x,t) = g(x - ct)$ for any twice-differentiable g. With $s = x - ct$, the chain rule gives $u_x = g'(s)$, $u_{xx} = g''(s)$, $u_t = -c\,g'(s)$, $u_{tt} = c^2 g''(s)$. Hence $u_{tt} = c^2 u_{xx}$: **any** shape moving at speed c without distortion solves the wave equation. This is why a lossless transmission line carries pulses of any shape intact.

(b) Let $u(x,t) = e^{-k\beta^2 t}\sin(\beta x)$. Then $u_t = -k\beta^2 u$ and $u_{xx} = -\beta^2 u$, so $u_t = k\,u_{xx}$: a sinusoidal temperature (or charge) profile of spatial frequency β decays exponentially with time constant $1/(k\beta^2)$. Finer ripples (large β) die out faster, which is why diffusion smooths things. Units: k is in m^2/s and β in m^{-1}, so $k\beta^2$ is in s^{-1}. ✓

Engineering Note

Partial derivatives of device equations *are* the small-signal parameters on a datasheet. A MOSFET in saturation with $i_D = \tfrac{1}{2}k(v_{GS} - V_t)^2(1 + \lambda v_{DS})$ has transconductance $g_m = \partial i_D/\partial v_{GS} = k(v_{GS} - V_t)(1 + \lambda v_{DS})$ and output conductance $g_{ds} = \partial i_D/\partial v_{DS} = \tfrac{1}{2}k(v_{GS} - V_t)^2\lambda$, each evaluated at the bias point with the other voltage held fixed. Section 6.6 assembles such derivatives into a matrix.

6.3 Total differentials

Motivation

Partial derivatives answer "what if I change one input?". In practice everything changes at once: every component is off-nominal by its own tolerance, temperature shifts several parameters together, a sensor reading depends on several imperfect measurements. The **total differential** answers "what happens when all the inputs change a little, simultaneously?". It is the multivariable version of the linear approximation $\Delta y \approx f'(x)\,\Delta x$ from Chapter 4, and it leads directly to tolerance analysis, the multivariable chain rule and implicit differentiation.

Differentiability and the tangent plane

Differentiability and total differential

$f(x,y)$ is **differentiable** at (a,b) if there are constants A, B such that

$$f(a+\Delta x,\, b+\Delta y) = f(a,b) + A\,\Delta x + B\,\Delta y + \varepsilon\sqrt{\Delta x^2 + \Delta y^2},$$

with $\varepsilon \to 0$ as $(\Delta x, \Delta y) \to (0,0)$. Then necessarily $A = f_x(a,b)$ and $B = f_y(a,b)$, and the linear part

$$df = \frac{\partial f}{\partial x}\,dx + \frac{\partial f}{\partial y}\,dy$$

is called the **total differential** of f. For n variables, $df = \sum_{i=1}^{n} \dfrac{\partial f}{\partial x_i}\,dx_i$.

In words: near a point of differentiability, f is a plane plus an error that shrinks *faster than the distance* from the point. Setting $\Delta y = 0$ and dividing by Δx shows $A = f_x$; similarly $B = f_y$. So the coefficients are forced to be the partial derivatives — differentiability is the extra requirement that this plane approximates f well in **all** directions, not just along the axes.

A practical test for differentiability

If f_x and f_y exist near (a,b) and are continuous at (a,b), then f is differentiable at (a,b). A differentiable function is continuous.

Proof sketch. Write $f(a+\Delta x, b+\Delta y) - f(a,b) = [f(a+\Delta x, b+\Delta y) - f(a, b+\Delta y)] + [f(a, b+\Delta y) - f(a,b)]$. Apply the mean value theorem to each bracket: the first is $f_x(\xi, b+\Delta y)\Delta x$, the second $f_y(a,\eta)\Delta y$, with ξ between a and $a+\Delta x$ and η between b and $b+\Delta y$. Continuity of the partials lets us replace $f_x(\xi, b+\Delta y)$ by $f_x(a,b)$ and $f_y(a,\eta)$ by $f_y(a,b)$ with errors that tend to zero, which is exactly the definition. $\square$

All the functions in this book's applications have continuous partial derivatives wherever they are defined, so in practice "differentiable" means "the partials exist and are continuous", and functions such as $xy/(x^2+y^2)$ at the origin are exotic exceptions.

Geometrically, the linear part defines the **tangent plane** to the surface $z = f(x,y)$ at $(a, b, f(a,b))$:

$$z = f(a,b) + f_x(a,b)\,(x-a) + f_y(a,b)\,(y-b).$$

The **linearisation** $L(x,y)$ is the right-hand side; near (a,b), $f \approx L$.

Worked Example 1 — linear approximation of a phasor magnitude

An impedance $Z = R + jX$ has magnitude $|Z| = f(R,X) = \sqrt{R^2+X^2}$. At $R = 3\ \Omega$, $X = 4\ \Omega$, $|Z| = 5\ \Omega$. Estimate $|Z|$ when $R = 3.02\ \Omega$ and $X = 3.97\ \Omega$.

Partials: $f_R = R/\sqrt{R^2+X^2} = 3/5 = 0.6$, $f_X = X/\sqrt{R^2+X^2} = 4/5 = 0.8$ (both dimensionless).

Differential: $df = 0.6(0.02) + 0.8(-0.03) = 0.012 - 0.024 = -0.012\ \Omega$.

Estimate: $|Z| \approx 5 - 0.012 = 4.988\ \Omega$. The exact value is $\sqrt{3.02^2 + 3.97^2} = 4.98812\ \Omega$; the linearisation error, $1.2 \times 10^{-4}\ \Omega$, is of second order in the changes, as the definition promises.

Note the pattern: $f_R = \cos\angle Z$ and $f_X = \sin\angle Z$. The magnitude responds to R and X in proportion to how much each contributes to the phasor's direction.

Error and tolerance propagation

Interpreting dx_i as small errors or tolerances Δx_i turns the total differential into an error-propagation formula. Two estimates are standard:

$$\Delta f_{\text{worst}} = \sum_i \left|\frac{\partial f}{\partial x_i}\right| \Delta x_i, \qquad \Delta f_{\text{RSS}} = \sqrt{\sum_i \left(\frac{\partial f}{\partial x_i}\Delta x_i\right)^2}.$$

The **worst-case** sum assumes every error conspires in the same direction; it is guaranteed (to first order) and is what you use for safety-critical limits. The **root-sum-square** (RSS) value treats the errors as independent random variables with standard deviations Δx_i; the variance of a linear combination is the sum of the squared-weighted variances (Ch. 19, Ch. 20), so RSS gives the *typical* spread. RSS is never larger than worst case, and the gap widens as the number of contributing parameters grows.

For products of powers, $f = k x^a y^b z^c$, dividing df by f gives the handy **relative-error rule**

$$\frac{df}{f} = a\frac{dx}{x} + b\frac{dy}{y} + c\frac{dz}{z},$$

whose coefficients are the normalised sensitivities of §6.2. In words: for products and quotients, *relative* errors add, weighted by the exponents.

Worked Example 2 — power measurement uncertainty

A resistor $R = 100 \pm 1\ \Omega$ carries $V = 12 \pm 0.1$ V. Find $P = V^2/R$ and its uncertainty.

Nominal: $P = 144/100 = 1.44$ W.

Differential:

$$dP = \frac{2V}{R}\,dV - \frac{V^2}{R^2}\,dR = (0.24\ \text{A})\,dV - (0.0144\ \text{A}^2)\,dR.$$

Worst case: $\Delta P = 0.24(0.1) + 0.0144(1) = 0.024 + 0.0144 = 0.0384$ W, i.e. $2.67\,\%$. Check with the relative rule: $2(0.1/12) + 1(1/100) = 0.0167 + 0.0100 = 0.0267$. ✓

RSS: $\Delta P = \sqrt{0.024^2 + 0.0144^2} = 0.0280$ W ($1.94\,\%$).

The voltage term dominates because V enters squared: improving the voltmeter is worth more than buying a better resistor. Unit check: $(\text{V}/\Omega)\cdot\text{V} = \text{W}$ and $(\text{V}^2/\Omega^2)\cdot\Omega = \text{W}$. ✓

Worked Example 3 — tolerance of an RC cutoff frequency

A low-pass filter uses $R = 10\ \text{k}\Omega \pm 1\,\%$ and $C = 10\ \text{nF} \pm 5\,\%$. Its cutoff is $f_c = 1/(2\pi RC) = 1591.5$ Hz.

Since $f_c \propto R^{-1}C^{-1}$, the relative rule gives $\dfrac{df_c}{f_c} = -\dfrac{dR}{R} - \dfrac{dC}{C}$.

Worst case: $1\,\% + 5\,\% = 6\,\%$, so $f_c = 1591.5 \pm 95.5$ Hz.

RSS: $\sqrt{1^2 + 5^2}\,\% = 5.10\,\%$, so ± 81.2 Hz.

The capacitor tolerance is almost the whole story: replacing the 1 % resistor by a 0.1 % one would change the RSS figure only from 5.10 % to 5.00 %. The exact worst case, $1/(2\pi \cdot 0.99R \cdot 0.95C)$, is 6.33 % high; the first-order estimate (6 %) is slightly optimistic because the true dependence is curved — differentials are accurate only for *small* changes.

Common Pitfall

Two mistakes recur in tolerance work. First, adding signed terms: in Example 2 the two contributions have opposite signs, and $0.024 - 0.0144$ would grossly understate the uncertainty; take absolute values (worst case) or squares (RSS). Second, using RSS for errors that are *not* independent — two resistors from the same reel, or two parameters that both drift with temperature, are correlated, and RSS can then badly underestimate the spread.

The multivariable chain rule

Suppose $z = f(x, y)$ and the inputs themselves depend on time: $x = x(t)$, $y = y(t)$. Dividing the total differential by dt suggests the following, and the differentiability definition makes it rigorous.

Chain rule

If f is differentiable and $x(t), y(t)$ are differentiable, then

$$\frac{dz}{dt} = \frac{\partial f}{\partial x}\frac{dx}{dt} + \frac{\partial f}{\partial y}\frac{dy}{dt}.$$

If instead $x = x(u, v)$ and $y = y(u, v)$, then

$$\frac{\partial z}{\partial u} = \frac{\partial f}{\partial x}\frac{\partial x}{\partial u} + \frac{\partial f}{\partial y}\frac{\partial y}{\partial u}, \qquad \frac{\partial z}{\partial v} = \frac{\partial f}{\partial x}\frac{\partial x}{\partial v} + \frac{\partial f}{\partial y}\frac{\partial y}{\partial v}.$$

Proof sketch. From the definition of differentiability, $\Delta z = f_x \Delta x + f_y \Delta y + \varepsilon\sqrt{\Delta x^2 + \Delta y^2}$. Divide by Δt and let $\Delta t \to 0$: $\Delta x/\Delta t \to \dot{x}$, $\Delta y/\Delta t \to \dot{y}$, the square root over $|\Delta t|$ stays bounded (it tends to $\sqrt{\dot{x}^2 + \dot{y}^2}$), and $\varepsilon \to 0$. $\square$

A **tree diagram** keeps the terms straight: draw z at the top, branches to each intermediate variable (x, y), and from each of those branches down to the independent variables. Each path from z to the variable of interest contributes the product of the derivatives along it; add over all paths.

Worked Example 4 — rate of change of dissipated power

A resistor's voltage rises at $0.5\ \text{V/s}$ while self-heating raises its resistance at $2\ \Omega/\text{s}$. At the instant $V = 12$ V, $R = 100\ \Omega$, how fast is $P = V^2/R$ changing?

$$\frac{dP}{dt} = \frac{\partial P}{\partial V}\dot{V} + \frac{\partial P}{\partial R}\dot{R} = \frac{2V}{R}\dot{V} - \frac{V^2}{R^2}\dot{R} = 0.24(0.5) - 0.0144(2) = 0.120 - 0.0288 = 0.0912\ \text{W/s}.$$

The rising voltage increases the power; the rising resistance reduces it; the net effect is the sum of both paths of the tree.

Worked Example 5 — Cartesian to polar derivatives

Let $f(x, y) = x^2 + xy$ and change to polar coordinates, $x = r\cos\theta$, $y = r\sin\theta$. By the chain rule,

$$\frac{\partial f}{\partial r} = f_x\cos\theta + f_y\sin\theta, \qquad \frac{\partial f}{\partial \theta} = -f_x\, r\sin\theta + f_y\, r\cos\theta.$$

At $r = 2$, $\theta = \pi/6$: $x = \sqrt{3}$, $y = 1$, $f_x = 2x + y = 2\sqrt{3} + 1 = 4.4641$, $f_y = x = 1.7321$. Then

$$\frac{\partial f}{\partial r} = 4.4641(0.8660) + 1.7321(0.5) = 4.7321, \qquad \frac{\partial f}{\partial \theta} = -4.4641(1) + 1.7321(1.7321) = -1.4641.$$

Check directly: in polar form $f = r^2(\cos^2\theta + \sin\theta\cos\theta)$, so $f_r = 2r(\cos^2\theta + \sin\theta\cos\theta) = 4(0.75 + 0.4330) = 4.7321$ and $f_\theta = r^2(\cos 2\theta - \sin 2\theta) = 4(0.5 - 0.8660) = -1.4641$. ✓

Note that f_θ has the units of f (it is a rate per radian), whereas f_r has the units of f per metre; the factor r in the θ-equation carries the difference. This observation is the seed of the scale factors in §6.9.

Common Pitfall — cancelling partials

In one variable, $\frac{dz}{dx}\frac{dx}{dt}$ "cancels" to $\frac{dz}{dt}$. With partial derivatives the cancellation is wrong: $\frac{\partial z}{\partial x}\frac{\partial x}{\partial u}$ is only *one* of the terms in $\partial z/\partial u$. Likewise $\partial x/\partial r = \cos\theta$, but $\partial r/\partial x = x/r = \cos\theta$ too, not $1/\cos\theta$ — the reciprocal rule fails because different variables are held constant in the two derivatives (θ in one, y in the other).

Implicit differentiation

Often a relationship between variables is given implicitly, $F(x, y) = 0$, and cannot (or need not) be solved for y. Along the curve F is constant, so its total differential vanishes: $F_x\,dx + F_y\,dy = 0$, and therefore

$$\frac{dy}{dx} = -\frac{F_x}{F_y} \qquad (F_y \neq 0).$$

With three variables and $F(x, y, z) = 0$ defining $z = z(x, y)$, holding y fixed gives $F_x + F_z\,\partial z/\partial x = 0$, so

$$\frac{\partial z}{\partial x} = -\frac{F_x}{F_z}, \qquad \frac{\partial z}{\partial y} = -\frac{F_y}{F_z} \qquad (F_z \neq 0).$$

Implicit function theorem (two-variable form)

If F has continuous partial derivatives near (a, b), $F(a, b) = 0$ and $F_y(a, b) \neq 0$, then near a the equation $F(x, y) = 0$ defines a unique differentiable function $y = g(x)$ with $g(a) = b$, and $g'(x) = -F_x/F_y$.

The condition $F_y \neq 0$ is the important part: where $F_y = 0$ the curve has a vertical tangent (or a self-intersection) and y cannot be written as a single-valued function of x there. For example, on $x^2 + xy + y^2 = 7$ at $(1, 2)$: $F_x = 2x + y = 4$, $F_y = x + 2y = 5$, so $dy/dx = -4/5$.

Worked Example 6 — small-signal conductance of a real diode

A diode with series resistance obeys

$$F(I, V) = I - I_s\left(e^{(V - IR_s)/V_T} - 1\right) = 0,$$

which cannot be solved for I in elementary functions. Implicit differentiation still gives the small-signal conductance exactly. With $E = e^{(V - IR_s)/V_T}$:

$$F_V = -\frac{I_s E}{V_T}, \qquad F_I = 1 + \frac{I_s E R_s}{V_T}, \qquad \frac{dI}{dV} = -\frac{F_V}{F_I} = \frac{I_s E / V_T}{1 + R_s I_s E / V_T}.$$

From the equation itself, $I_s E = I + I_s$. Writing $r_d = V_T/(I + I_s)$ (the junction's own small-signal resistance), this simplifies to

$$\frac{dI}{dV} = \frac{1}{r_d + R_s}.$$

At $I = 1$ mA with $V_T = 25$ mV and $R_s = 10\ \Omega$ (I_s negligible): $r_d = 25\ \Omega$ and $dI/dV = 1/35$ S $= 28.6$ mS. The answer is physically obvious in hindsight — the junction resistance and the series resistance add — but the calculus delivered it without ever solving for I.

Exact differentials

The total differential of any $\phi(x, y)$ has the form $M\,dx + N\,dy$ with $M = \phi_x$, $N = \phi_y$. Conversely, given an expression $M\,dx + N\,dy$, is it the differential of something? If so, $M_y = \phi_{xy} = \phi_{yx} = N_x$ by Clairaut's theorem. The converse also holds on regions without holes:

Test for an exact differential

On a simply connected domain, with M, N continuously differentiable, $M\,dx + N\,dy$ is the total differential of some function ϕ if and only if

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}.$$

Worked Example 7 — recovering a potential function

Is $(2xy + 3)\,dx + (x^2 + 4y)\,dy$ exact? $M_y = 2x$, $N_x = 2x$: yes. To find ϕ, integrate M in x treating y as constant: $\phi = x^2y + 3x + h(y)$. Differentiate in y and match N: $x^2 + h'(y) = x^2 + 4y$, so $h' = 4y$, $h = 2y^2$. Thus $\phi = x^2y + 3x + 2y^2$ (plus any constant). Check: $\phi_x = 2xy + 3$, $\phi_y = x^2 + 4y$. ✓

This test reappears as "curl-free implies conservative" in Ch. 7 — the reason a static electric field can be written as the gradient of a potential — and in exact first-order ODEs in Ch. 11.

Taylor's theorem in two variables

The tangent plane is the first-order Taylor approximation. Adding second-order terms captures curvature, which we will need to classify maxima and minima in §6.10. Applying the one-variable Taylor series to $g(t) = f(a + th,\ b + tk)$ and using the chain rule twice gives

$$f(a + h, b + k) \approx f + f_x h + f_y k + \tfrac{1}{2}\left(f_{xx}h^2 + 2f_{xy}hk + f_{yy}k^2\right),$$

with all derivatives evaluated at (a, b). The bracket is a **quadratic form**, $\begin{bmatrix} h & k \end{bmatrix}\mathbf{H}\begin{bmatrix} h \\ k \end{bmatrix}$, built from the **Hessian matrix** $\mathbf{H}$ of second partials.

Worked Example 8 — second-order approximation

Approximate $f = e^x \cos y$ near $(0,0)$. All needed derivatives at the origin: $f = 1$, $f_x = e^x \cos y = 1$, $f_y = -e^x \sin y = 0$, $f_{xx} = 1$, $f_{xy} = -e^x \sin y = 0$, $f_{yy} = -e^x \cos y = -1$. Hence

$$e^x \cos y \approx 1 + x + \tfrac{1}{2}\left(x^2 - y^2\right).$$

At $(0.1, 0.2)$: first order gives 1.1, second order 1.085, exact 1.08314. The remaining error, 0.0019, matches the third-order terms $x^3/6 - xy^2/2 = -0.0018$. Each order improves the estimate by roughly a factor of the step size, just as in one variable.

6.4 Gradient

Motivation

The total differential $df = f_x\,dx + f_y\,dy + f_z\,dz$ has the shape of a dot product: one vector made of partial derivatives, the other made of the displacement (dx, dy, dz). Packaging the partial derivatives into a single vector — the gradient — turns a list of numbers into a geometric object with a direction and a length. That direction is the direction of steepest ascent, it is perpendicular to the level sets, and in electrostatics it *is* (minus) the electric field. The gradient is the first of the three differential operators of vector calculus, and the only one that acts on a scalar field.

Definition

Gradient

For a differentiable scalar function $f(x, y, z)$, the gradient is the vector of its first partial derivatives

$$\nabla f = \frac{\partial f}{\partial x}\hat{\mathbf{x}} + \frac{\partial f}{\partial y}\hat{\mathbf{y}} + \frac{\partial f}{\partial z}\hat{\mathbf{z}} = (f_x,\ f_y,\ f_z).$$

For $f(x_1, \dots, x_n)$, $\nabla f = (\partial f/\partial x_1, \dots, \partial f/\partial x_n)$. The symbol ∇ ("del" or "nabla") is the operator $\hat{\mathbf{x}}\,\partial_x + \hat{\mathbf{y}}\,\partial_y + \hat{\mathbf{z}}\,\partial_z$.

With $d\mathbf{r} = (dx, dy, dz)$, the total differential becomes

$$df = \nabla f \cdot d\mathbf{r},$$

and the linearisation of §6.3 becomes $f(\mathbf{r}) \approx f(\mathbf{a}) + \nabla f(\mathbf{a}) \cdot (\mathbf{r} - \mathbf{a})$. **Units:** ∇ carries m^{-1}, so the gradient of a temperature is in $\mathrm{K/m}$ and of a potential in $\mathrm{V/m}$.

Geometric properties

Properties of the gradient

Let f be differentiable at $\mathbf{a}$ with $\nabla f(\mathbf{a}) \neq \mathbf{0}$.

1. **Steepest ascent.** $\nabla f(\mathbf{a})$ points in the direction in which f increases most rapidly, and $\|\nabla f(\mathbf{a})\|$ is that maximum rate of increase (per unit distance).
2. **Normal to level sets.** $\nabla f(\mathbf{a})$ is perpendicular to the level curve (or level surface) $f = f(\mathbf{a})$ through $\mathbf{a}$.
3. **Tangent plane.** The tangent plane to the level surface $f(x, y, z) = c$ at $\mathbf{a}$ is $\nabla f(\mathbf{a}) \cdot (\mathbf{r} - \mathbf{a}) = 0$.

Proof. (1) Move a small distance ds in the unit direction $\hat{\mathbf{u}}$: $df = \nabla f \cdot \hat{\mathbf{u}}\,ds = \|\nabla f\| \cos\theta\,ds$, where θ is the angle between $\hat{\mathbf{u}}$ and ∇f. This is largest when $\theta = 0$, giving rate $\|\nabla f\|$. (2) Let $\mathbf{r}(t)$ be any curve lying in the level set, through $\mathbf{a}$ at $t = 0$. Since $f(\mathbf{r}(t)) = c$ for all t, the chain rule gives $0 = \frac{d}{dt} f(\mathbf{r}(t)) = \nabla f \cdot \mathbf{r}'(0)$. So ∇f is perpendicular to the tangent vector of *every* curve in the level set, i.e. to the level set itself. (3) The tangent plane consists of points $\mathbf{r}$ with $\mathbf{r} - \mathbf{a}$ perpendicular to the normal $\nabla f(\mathbf{a})$. $\square$

Property 2 explains a picture every electrical engineer knows: field lines cross equipotentials at right angles. Property 1 explains why field strength is greatest where equipotentials crowd together — closely spaced contours mean a large change of f per unit distance.

Worked Example 1 — normal and tangent to a level curve

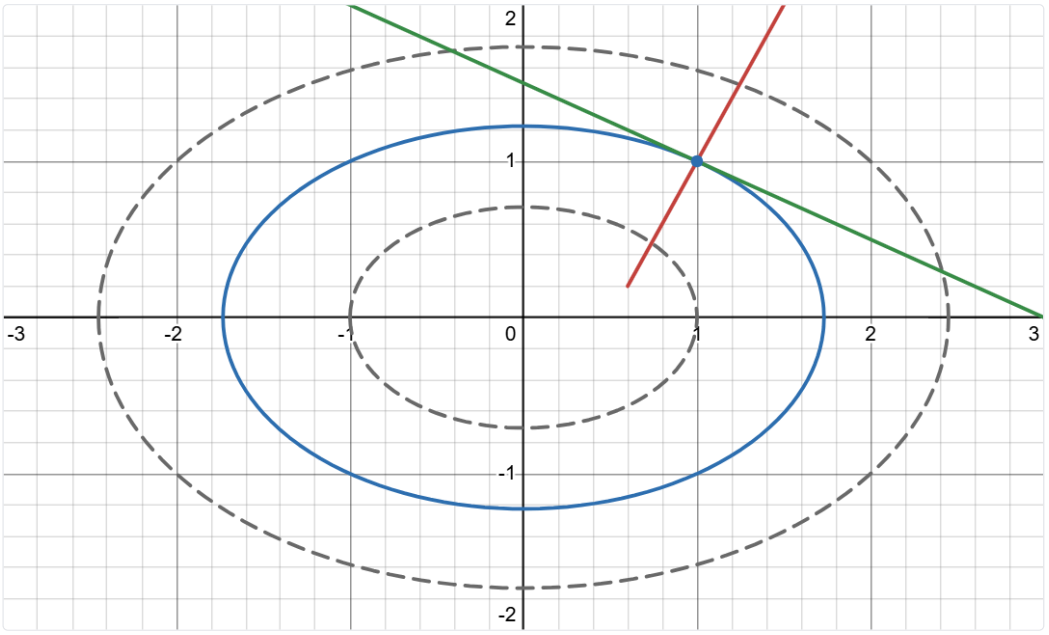
Let $f(x, y) = x^2 + 2y^2$ and take the point $(1, 1)$, which lies on the level curve $f = 3$ (an ellipse). Then $\nabla f = (2x, 4y) = (2, 4)$ at $(1, 1)$.

Tangent line: $\nabla f \cdot (x - 1,\ y - 1) = 0$, i.e. $2(x - 1) + 4(y - 1) = 0$, or $x + 2y = 3$.

Normal line (along ∇f): $(x, y) = (1, 1) + t(2, 4)$, i.e. $y - 1 = 2(x - 1)$.

Maximum rate of increase at $(1, 1)$: $\|(2, 4)\| = \sqrt{20} \approx 4.47$ units of f per unit distance, in the direction $(2, 4)/\sqrt{20} = (0.447,\ 0.894)$.

Check by implicit differentiation (§6.3): $dy/dx = -f_x/f_y = -2/4 = -\tfrac{1}{2}$, which is the slope of $x + 2y = 3$. ✓



The gradient (red, along the normal) crosses each level curve at right angles; the tangent line (green) is perpendicular to it.

Worked Example 2 — tangent plane to a level surface

Find the tangent plane and normal line to the ellipsoid $\dfrac{x^2}{4} + y^2 + \dfrac{z^2}{9} = 3$ at $(2, 1, 3)$.

Check the point: $1 + 1 + 1 = 3$. ✓

Gradient: with $F = \frac{1}{4}x^2 + y^2 + \frac{1}{9}z^2$, $\nabla F = \left(\frac{x}{2},\ 2y,\ \frac{2z}{9}\right) = \left(1,\ 2,\ \frac{2}{3}\right)$.

Tangent plane: $1(x-2) + 2(y-1) + \frac{2}{3}(z-3) = 0$; multiplying by 3, $3x + 6y + 2z = 18$. The point satisfies it: $6 + 6 + 6 = 18$. ✓

Normal line: $(x, y, z) = (2, 1, 3) + t\left(1, 2, \frac{2}{3}\right)$.

The same recipe gives the tangent plane to a graph $z = f(x, y)$: write it as the level surface $F = f(x, y) - z = 0$, whose gradient $(f_x, f_y, -1)$ reproduces the tangent-plane formula of §6.3.

Algebra of the gradient

All of the following follow at once from the corresponding single-variable rules applied component by component:

$$\nabla(af + bg) = a\nabla f + b\nabla g, \qquad \nabla(fg) = f\nabla g + g\nabla f, \qquad \nabla\left(\frac{f}{g}\right) = \frac{g\nabla f - f\nabla g}{g^2}, \qquad \nabla h(f) = h'(f)\,\nabla f.$$

The last one (chain rule) is especially useful for functions of distance. With $\mathbf{R} = (x, y, z)$ and $R = \|\mathbf{R}\| = \sqrt{x^2 + y^2 + z^2}$, $\partial R/\partial x = x/R$ and so on, giving

$$\nabla R = \frac{\mathbf{R}}{R} = \hat{\mathbf{R}}, \qquad \nabla R^n = nR^{n-1}\hat{\mathbf{R}}, \qquad \nabla\frac{1}{R} = -\frac{\hat{\mathbf{R}}}{R^2}.$$

Any function of distance alone has a gradient pointing radially, and its level sets are spheres — the geometry of every point source.

Worked Example 3 — Coulomb's law from a potential

The potential of a point charge q at the origin is $V = \dfrac{q}{4\pi\varepsilon_0 R}$. Using $\nabla(1/R) = -\hat{\mathbf{R}}/R^2$,

$$\mathbf{E} = -\nabla V = -\frac{q}{4\pi\varepsilon_0}\nabla\frac{1}{R} = \frac{q}{4\pi\varepsilon_0 R^2}\hat{\mathbf{R}},$$

which is Coulomb's law. Units: V in volts, ∇ in m^{-1}, so $\mathbf{E}$ in $\mathrm{V/m}$. ✓ Component check at $(x, y, z) = (1, 2, 2)$ m, $R = 3$ m: $\partial(1/R)/\partial x = -x/R^3 = -1/27$, matching $-\hat{\mathbf{R}}_x/R^2 = -(1/3)/9 = -1/27$. ✓

Worked Example 4 — field of the dipole on its bisector

For the 2-D dipole potential of §6.1, $V = \dfrac{1}{r_1} - \dfrac{1}{r_2}$ with $r_1 = \sqrt{(x+1)^2 + y^2}$ and $r_2 = \sqrt{(x-1)^2 + y^2}$, find $\mathbf{E} = -\nabla V$ at $(0, 1)$.

Using $\partial(1/r_1)/\partial x = -(x+1)/r_1^3$, $\partial(1/r_1)/\partial y = -y/r_1^3$, and similarly for r_2:

$$V_x = -\frac{x+1}{r_1^3} + \frac{x-1}{r_2^3}, \qquad V_y = -\frac{y}{r_1^3} + \frac{y}{r_2^3}.$$

At $(0, 1)$, $r_1 = r_2 = \sqrt{2}$, $r^3 = 2^{3/2} = 2.828$: $V_x = -\dfrac{1}{2.828} - \dfrac{1}{2.828} = -0.707$, $V_y = 0$. Hence $\mathbf{E} = (0.707,\ 0)$.

The field on the bisector points in $+x$, from the positive charge towards the negative one, and parallel to the axis — perpendicular to the $V = 0$ equipotential $x = 0$, exactly as property 2 requires.

The gradient in other coordinates (preview)

The definition $df = \nabla f \cdot d\mathbf{r}$ is coordinate-free, so it can be used to *derive* the gradient in any coordinate system. In polar coordinates a small displacement is $d\mathbf{r} = dr\,\hat{\mathbf{r}} + r\,d\theta\,\hat{\boldsymbol{\theta}}$ (moving $d\theta$ in angle covers a distance $r\,d\theta$), while $df = f_r\,dr + f_\theta\,d\theta$. Matching the two forms,

$$\nabla f = \frac{\partial f}{\partial r}\hat{\mathbf{r}} + \frac{1}{r}\frac{\partial f}{\partial \theta}\hat{\boldsymbol{\theta}}.$$

The factor $1/r$ is forced by the units: f_θ is per radian, the gradient must be per metre. The cylindrical and spherical versions follow the same way from the scale factors of §6.9 and are tabulated in Ch. 7.

Common Pitfall

Writing $\nabla f = (f_r,\ f_\theta)$ in polar coordinates — simply listing partial derivatives — is wrong, for the units reason just given. The "list of partials" recipe works only in Cartesian coordinates, where every coordinate is a length.

Gradient descent

Since $-\nabla f$ points in the direction of steepest *decrease*, a natural minimisation algorithm is to step repeatedly downhill:

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha\,\nabla f(\mathbf{x}_k),$$

with a step size $\alpha > 0$. This is the core of adaptive filtering (the LMS algorithm), neural-network training and many circuit-optimisation tools.

Worked Example 5 — gradient descent and its step-size limit

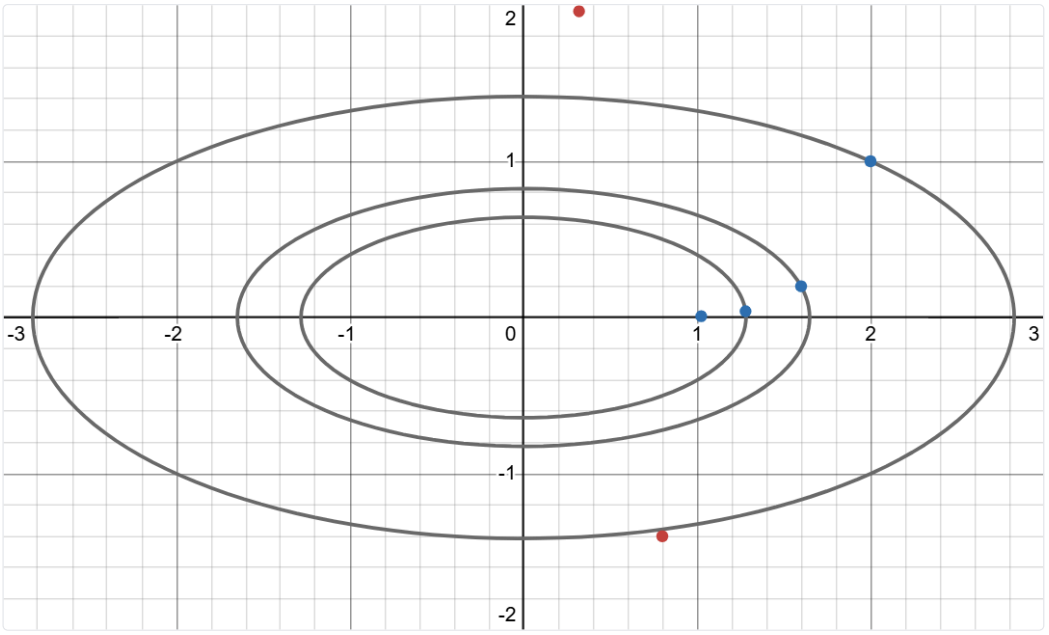
Minimise $f(x, y) = x^2 + 4y^2$ (minimum 0 at the origin) from $(2, 1)$, where $f = 8$. Here $\nabla f = (2x,\ 8y)$, so one step is

$$x_{k+1} = (1 - 2\alpha)x_k, \qquad y_{k+1} = (1 - 8\alpha)y_k.$$

With $\alpha = 0.1$: x shrinks by 0.8 and y by 0.2 per step: $(2, 1) \to (1.6, 0.2) \to (1.28, 0.04) \to (1.024, 0.008)$, with $f = 8 \to 2.72 \to 1.645 \to 1.049$. The steep y-direction converges fast; the shallow x-direction slowly.

With $\alpha = 0.3$: the y factor is $1 - 2.4 = -1.4$: y overshoots and grows, $1 \to -1.4 \to 1.96 \to -2.744$, and f *increases*, $8 \to 8.48 \to 15.47 \to 30.13$. The iteration diverges.

Stability requires $|1 - 8\alpha| < 1$, i.e. $\alpha < 0.25$, set by the *steepest* direction, while convergence speed is limited by the *shallowest* one. The ratio of curvatures ($8/2 = 4$ here) — the condition number of the Hessian — governs how badly gradient descent zig-zags (Ch. 23).



Gradient descent on $x^2 + 4y^2$: with $\alpha = 0.1$ (blue) the iterates slide down towards the minimum, each step perpendicular to the contour it leaves; with $\alpha = 0.3$ (red) they bounce across the valley onto ever higher contours.

6.5 Directional derivatives

Motivation

Partial derivatives measure change along the coordinate axes, but the axes are an arbitrary human choice. A probe moving diagonally across a circuit board, a satellite crossing a radiation pattern at an angle, an optimiser deciding which way to adjust two component values at once — each needs the rate of change in a *chosen* direction. The directional derivative supplies it, and the remarkable fact is that the gradient alone determines it for every direction at once.

Definition and the gradient formula

Directional derivative

The rate of change of f at $\mathbf{a}$ in the direction of a **unit** vector $\hat{\mathbf{u}}$ is

$$D_{\hat{\mathbf{u}}} f(\mathbf{a}) = \lim_{h \to 0} \frac{f(\mathbf{a} + h\hat{\mathbf{u}}) - f(\mathbf{a})}{h}.$$

It is the slope of the curve obtained by slicing the graph of f with the vertical plane through $\mathbf{a}$ in the direction $\hat{\mathbf{u}}$. The partial derivatives are the special cases $\hat{\mathbf{u}} = \hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$.

Directional derivative from the gradient

If f is differentiable at $\mathbf{a}$, then for every unit vector $\hat{\mathbf{u}}$

$$D_{\hat{\mathbf{u}}} f(\mathbf{a}) = \nabla f(\mathbf{a}) \cdot \hat{\mathbf{u}} = \|\nabla f(\mathbf{a})\| \cos\theta,$$

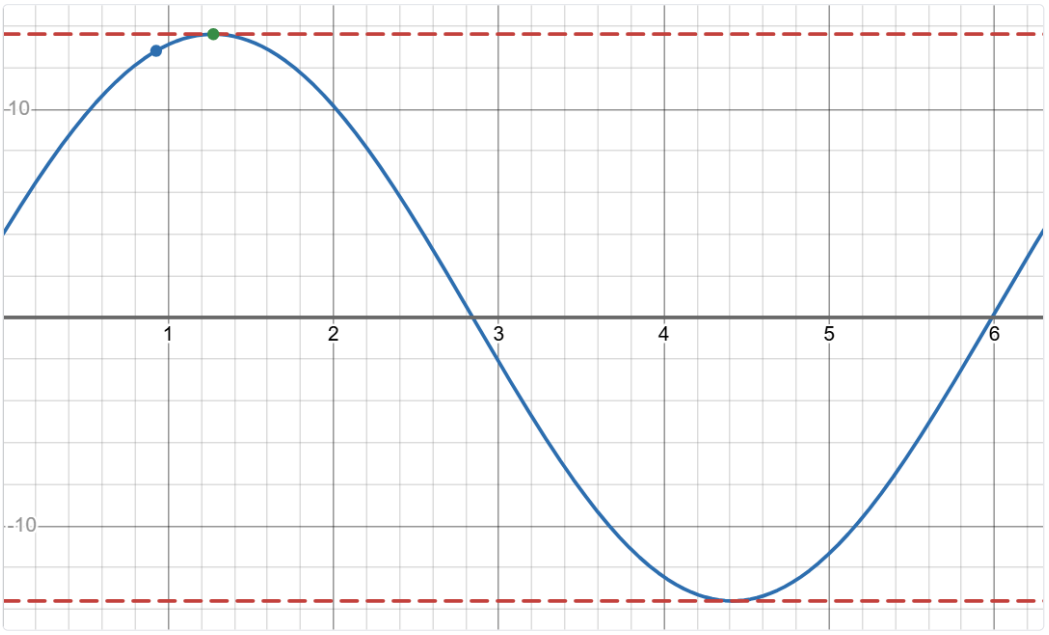
where θ is the angle between $\hat{\mathbf{u}}$ and $\nabla f(\mathbf{a})$. In two dimensions, with $\hat{\mathbf{u}} = (\cos\alpha, \sin\alpha)$, $D_{\hat{\mathbf{u}}} f = f_x \cos\alpha + f_y \sin\alpha$.

Proof. Let $g(h) = f(\mathbf{a} + h\hat{\mathbf{u}})$, a function of one variable. By definition $D_{\hat{\mathbf{u}}} f(\mathbf{a}) = g'(0)$. The point $\mathbf{a} + h\hat{\mathbf{u}}$ has coordinates $x_i = a_i + h u_i$, so $dx_i/dh = u_i$, and the chain rule of §6.3 gives $g'(0) = \sum_i f_{x_i}(\mathbf{a})\, u_i = \nabla f(\mathbf{a}) \cdot \hat{\mathbf{u}}$. $\square$

The cosine form packs the geometry of §6.4 into one line:

- the maximum value $+\|\nabla f\|$ occurs for $\hat{\mathbf{u}}$ along ∇f ($\theta = 0$);
- the minimum $-\|\nabla f\|$ for $\hat{\mathbf{u}}$ opposite to ∇f ($\theta = \pi$);
- $D_{\hat{\mathbf{u}}} f = 0$ for $\hat{\mathbf{u}}$ perpendicular to ∇f, i.e. tangent to the level set ($\theta = \pi/2$);
- reversing the direction reverses the sign: $D_{-\hat{\mathbf{u}}} f = -D_{\hat{\mathbf{u}}} f$.

So the n numbers in the gradient encode the slopes in infinitely many directions; as $\hat{\mathbf{u}}$ rotates once around the circle, $D_{\hat{\mathbf{u}}} f$ traces one period of a sinusoid of amplitude $\|\nabla f\|$.



Directional derivative of $f = x^2y + y^3$ at $(1, 2)$ (gradient $(4, 13)$) versus the direction angle α: a sinusoid of amplitude $\|\nabla f\| = \sqrt{185} \approx 13.6$, peaking along the gradient and vanishing in the two directions tangent to the level curve.

Worked Example 1 — the basic calculation

Find the rate of change of $f(x, y) = x^2y + y^3$ at $(1, 2)$ in the direction of $\mathbf{v} = (3, 4)$.

Gradient: $\nabla f = (2xy,\ x^2 + 3y^2) = (4,\ 13)$ at $(1, 2)$.

Normalise: $\|\mathbf{v}\| = 5$, so $\hat{\mathbf{u}} = (0.6,\ 0.8)$.

Dot product:

$$D_{\hat{\mathbf{u}}} f = 4(0.6) + 13(0.8) = 2.4 + 10.4 = 12.8.$$

This is less than the maximum possible rate $\|\nabla f\| = \sqrt{185} \approx 13.6$, as it must be — $(3, 4)$ is only 19.8° away from the gradient direction ($\cos\theta = 12.8/13.6 = 0.941$).

Numerical check: $[f(1.0006, 2.0008) - f(0.9994, 1.9992)]/0.002 = 12.8000$. ✓

Common Pitfall

Forgetting to normalise the direction vector. Using $\mathbf{v} = (3, 4)$ directly would give $\nabla f \cdot \mathbf{v} = 64$, five times too large. The quantity $\nabla f \cdot \mathbf{v}$ for a non-unit $\mathbf{v}$ is still meaningful — it is the rate of change *per unit time* for a point moving with velocity $\mathbf{v}$ — but it is not the slope per unit distance.

Worked Example 2 — hot spot on a circuit board

Near a power device, the board temperature is modelled by $T(x, y) = 80 - x^2 - 2y^2$ (°C, with x, y in cm, device at the origin). A probe sits at $(3, 2)$, where $T = 80 - 9 - 8 = 63\ ^\circ\text{C}$.

Gradient: $\nabla T = (-2x,\ -4y) = (-6,\ -8)\ ^\circ\text{C/cm}$, with $\|\nabla T\| = 10\ ^\circ\text{C/cm}$.

(a) *Fastest heating:* towards $\nabla T/\|\nabla T\| = (-0.6, -0.8)$, at $10\ ^\circ\text{C/cm}$. Note that this is **not** straight towards the device at the origin, which would be the direction $(-3, -2)/\sqrt{13} = (-0.832, -0.555)$; the steeper y-dependence pulls the gradient towards the y-direction.

(b) *Fastest cooling:* the opposite direction, $(0.6, 0.8)$, at $-10\ ^\circ\text{C/cm}$.

(c) *No change:* perpendicular to the gradient, $\pm(0.8, -0.6)$ — along the isotherm $x^2 + 2y^2 = 17$.

(d) *Heating at exactly* $5\ ^\circ\text{C/cm}$*:* need $10\cos\theta = 5$, $\theta = \pm 60^\circ$ from the gradient. The gradient direction has angle $\alpha_0 = \operatorname{atan2}(-8, -6) = -126.87^\circ$, so $\alpha = -66.87^\circ$ or -186.87°, i.e. $\hat{\mathbf{u}} = (0.393, -0.920)$ or $(-0.993, 0.120)$. Check the first: $-6(0.393) - 8(-0.920) = -2.36 + 7.36 = 5.0$. ✓

(e) *Towards the device:* $D = (-6, -8) \cdot (-0.832, -0.555) = 4.99 + 4.44 = 9.43\ ^\circ\text{C/cm}$, close to but below the maximum.

Worked Example 3 — a three-dimensional potential

A potential is $V(x,y,z) = xy^2 + yz^3$ (volts, coordinates in metres). Find the rate of change of V at $P=(2,-1,1)$ moving towards $Q=(4,1,2)$, and the electric field there.

Gradient: $\nabla V = (y^2,\ 2xy+z^3,\ 3yz^2) = (1,\ -3,\ -3)$ V/m at P.

Direction: $\overrightarrow{PQ} = (2,2,1)$, length 3, so $\hat{\mathbf{u}} = \tfrac{1}{3}(2,2,1)$.

Rate: $D_{\hat{\mathbf{u}}}V = \tfrac{1}{3}(2-6-3) = -\tfrac{7}{3} \approx -2.33$ V/m: the potential falls as the probe moves towards Q.

Field: $\mathbf{E} = -\nabla V = (-1,\ 3,\ 3)$ V/m, magnitude $\sqrt{19} = 4.36$ V/m. Since $D_{\hat{\mathbf{u}}}V = -\mathbf{E}\cdot\hat{\mathbf{u}}$, the result says the field has a component $+2.33$ V/m along $\overrightarrow{PQ}$, so a positive test charge would be pushed towards Q: positive charges move "downhill" in potential.

Rate of change along a curve

If a point moves along a curve $\mathbf{r}(t)$, the chain rule gives

$$\frac{d}{dt} f(\mathbf{r}(t)) = \nabla f \cdot \mathbf{r}'(t) = \|\mathbf{r}'(t)\|\, D_{\hat{\mathbf{T}}} f,$$

where $\hat{\mathbf{T}} = \mathbf{r}'/\|\mathbf{r}'\|$ is the unit tangent. The rate per unit *time* is the speed times the directional derivative along the path; the rate per unit *arc length* is the directional derivative itself. Integrating $\nabla f \cdot d\mathbf{r}$ along a path gives the total change $f(\text{end}) - f(\text{start})$, whatever the path — the fundamental theorem for line integrals of Ch. 7, and the reason the work done moving a charge between two points depends only on the potential difference.

Worked Example 4 — a sensor on a circular track

A sensor moves on the circle $\mathbf{r}(t) = (2\cos t,\ 2\sin t)$ through the temperature field $T = 80 - x^2 - 2y^2$ of Worked Example 2. How fast does its reading change, and where is it hottest?

Directly: $T(\mathbf{r}(t)) = 80 - 4\cos^2 t - 8\sin^2 t = 76 - 4\sin^2 t$, so $dT/dt = -8\sin t\cos t = -4\sin 2t$.

By the chain rule: $\nabla T = (-4\cos t,\ -8\sin t)$, $\mathbf{r}' = (-2\sin t,\ 2\cos t)$, and $\nabla T\cdot\mathbf{r}' = 8\sin t\cos t - 16\sin t\cos t = -8\sin t\cos t$. ✓

The reading is stationary where $\sin 2t = 0$: hottest ($76\ ^\circ$C) at $t = 0, \pi$ (the points $(\pm 2, 0)$) and coolest ($72\ ^\circ$C) at $t = \pm\pi/2$. At those points $\mathbf{r}'$ is tangent to an isotherm — a first glimpse of the Lagrange condition of §6.11.

Second directional derivative

Differentiating $g(h) = f(\mathbf{a} + h\hat{\mathbf{u}})$ twice gives the curvature of f along $\hat{\mathbf{u}}$:

$$D^2_{\hat{\mathbf{u}}} f = g''(0) = \sum_{i,j} f_{x_i x_j} u_i u_j = \hat{\mathbf{u}}^{\mathsf{T}} \mathbf{H}\, \hat{\mathbf{u}},$$

with $\mathbf{H}$ the Hessian. For $T = 80 - x^2 - 2y^2$, $\mathbf{H} = \operatorname{diag}(-2,-4)$, and along $\hat{\mathbf{u}} = (\cos\alpha, \sin\alpha)$ the curvature is $-2\cos^2\alpha - 4\sin^2\alpha$, between -4 and -2: the surface curves downward in every direction, which is what makes the origin a maximum (§6.10).

Common Pitfall — directional derivatives without differentiability

The formula $D_{\hat{\mathbf{u}}} f = \nabla f \cdot \hat{\mathbf{u}}$ requires f to be differentiable. For $f = x^2 y/(x^4+y^2)$ of §6.1 (with $f(0,0)=0$), every directional derivative at the origin exists: with $\hat{\mathbf{u}} = (a,b)$, $b \neq 0$,

$$D_{\hat{\mathbf{u}}} f(\mathbf{0}) = \lim_{h\to 0} \frac{h^3 a^2 b}{h\,(h^4 a^4 + h^2 b^2)} = \frac{a^2}{b},$$

and 0 when $b = 0$. But $\nabla f(\mathbf{0}) = (0,0)$, which would predict 0 in every direction. The formula fails because f is not even continuous at the origin. For smooth engineering functions this never bites, but it explains why "all directional derivatives exist" is not the definition of differentiability.

Engineering Note

In a phased-array antenna or a MIMO receiver, the received power is a function $P(\boldsymbol{\theta})$ of several steering parameters, and tracking loops adjust them along ∇P (gradient ascent). When only measurements are available, the gradient is estimated by probing two or more directions ("dithering") and solving $D_{\hat{\mathbf{u}}_k} P = \nabla P \cdot \hat{\mathbf{u}}_k$ for ∇P — two independent directions suffice in two dimensions, precisely because the gradient formula is linear in $\hat{\mathbf{u}}$.

6.6 Jacobian matrices

Motivation

So far f has produced a single number. Many engineering maps produce several: a transistor maps two terminal voltages to two currents; a coordinate change maps (r,θ) to (x,y); a nonlinear circuit's node equations map a vector of node voltages to a vector of current imbalances. For such vector functions the derivative is no longer a number or a vector but a **matrix** — the Jacobian. It is the object that makes "linearise about an operating point" precise, it is the engine of Newton's method in every circuit simulator, and its determinant is the area-scaling factor that §6.8 needs for changing variables in integrals.

Definition

A vector function $\mathbf{F}:\mathbb{R}^n\to\mathbb{R}^m$ has m component functions $F_1,\dots,F_m$, each depending on $x_1,\dots,x_n$.

Jacobian matrix

The Jacobian of $\mathbf{F}$ is the $m\times n$ matrix of first partials,

$$\mathbf{J}_{\mathbf{F}}=\frac{\partial(F_1,\dots,F_m)}{\partial(x_1,\dots,x_n)}=\begin{bmatrix}\dfrac{\partial F_1}{\partial x_1} & \cdots & \dfrac{\partial F_1}{\partial x_n}\\ \vdots & \ddots & \vdots\\ \dfrac{\partial F_m}{\partial x_1} & \cdots & \dfrac{\partial F_m}{\partial x_n}\end{bmatrix},\qquad (\mathbf{J}_{\mathbf{F}})_{ij}=\frac{\partial F_i}{\partial x_j}.$$

Row i is $(\nabla F_i)^{\mathsf T}$; column j is the rate of change of the whole output vector with respect to input x_j. When $m=n$ the matrix is square and its determinant $\det\mathbf{J}=\dfrac{\partial(F_1,\dots,F_n)}{\partial(x_1,\dots,x_n)}$ is called the **Jacobian determinant** (often just "the Jacobian").

Special cases tie together everything so far. For $m=n=1$ the Jacobian is the ordinary derivative $f'(x)$. For $m=1$ it is the gradient written as a row, $\mathbf{J}_f=(\nabla f)^{\mathsf T}$. For $n=1$ (a curve $\mathbf{r}(t)$) it is the velocity column $\mathbf{r}'(t)$.

The Jacobian as the best linear approximation

Applying the total differential to each component and stacking the results:

$$\mathbf{F}(\mathbf{x}_0+d\mathbf{x})\approx\mathbf{F}(\mathbf{x}_0)+\mathbf{J}_{\mathbf{F}}(\mathbf{x}_0)\,d\mathbf{x},\qquad\text{i.e.}\qquad d\mathbf{F}=\mathbf{J}_{\mathbf{F}}\,d\mathbf{x}.$$

Near $\mathbf{x}_0$, a smooth nonlinear map behaves like the linear map $d\mathbf{x}\mapsto\mathbf{J}\,d\mathbf{x}$ (Ch. 9). Small circles of inputs map to (approximately) small ellipses of outputs; the matrix says how they are stretched, rotated and sheared.

Chain rule in matrix form

If $\mathbf{G}:\mathbb{R}^p\to\mathbb{R}^n$ is differentiable at $\mathbf{u}$ and $\mathbf{F}:\mathbb{R}^n\to\mathbb{R}^m$ is differentiable at $\mathbf{G}(\mathbf{u})$, then

$$\mathbf{J}_{\mathbf{F}\circ\mathbf{G}}(\mathbf{u})=\mathbf{J}_{\mathbf{F}}\big(\mathbf{G}(\mathbf{u})\big)\,\mathbf{J}_{\mathbf{G}}(\mathbf{u}),$$

and for square Jacobians, $\det\mathbf{J}_{\mathbf{F}\circ\mathbf{G}}=\det\mathbf{J}_{\mathbf{F}}\cdot\det\mathbf{J}_{\mathbf{G}}$.

Proof sketch. Linearise each map: $d\mathbf{G}=\mathbf{J}_{\mathbf{G}}\,d\mathbf{u}$ and $d\mathbf{F}=\mathbf{J}_{\mathbf{F}}\,d\mathbf{G}$; substitute. Entry by entry, $(\mathbf{J}_{\mathbf{F}}\mathbf{J}_{\mathbf{G}})_{ik}=\sum_j\dfrac{\partial F_i}{\partial x_j}\dfrac{\partial x_j}{\partial u_k}$ — exactly the "sum over all paths" of the tree diagram in §6.3. The determinant statement is the product rule for determinants (Ch. 8). □

So the multivariable chain rule, with all its terms, is just matrix multiplication.

Worked Example 1 — the polar map

For $x=r\cos\theta$, $y=r\sin\theta$,

$$\frac{\partial(x,y)}{\partial(r,\theta)}=\begin{bmatrix}x_r & x_\theta\\ y_r & y_\theta\end{bmatrix}=\begin{bmatrix}\cos\theta & -r\sin\theta\\ \sin\theta & r\cos\theta\end{bmatrix},\qquad \det\mathbf{J}=r\cos^2\theta+r\sin^2\theta=r.$$

Interpretation: a small change dr moves the point dr metres radially (first column, a unit vector); a small change $d\theta$ moves it $r\,d\theta$ metres tangentially (second column, length r). The two columns are perpendicular, so a small $dr\times d\theta$ rectangle maps to a small rectangle of area $r\,dr\,d\theta$. The determinant r is exactly the area factor in $dA=r\,dr\,d\theta$ (§6.8). At the origin $\det\mathbf{J}=0$: the whole line $r=0$ (every θ) collapses to a single point.

Worked Example 2 — composing maps: squaring a complex number

The complex map $w=z^2$, with $z=u+jv$ and $w=p+jq$, is $p=u^2-v^2$, $q=2uv$. Its Jacobian is

$$\mathbf{J}_{\mathbf{F}}=\begin{bmatrix}2u & -2v\\ 2v & 2u\end{bmatrix},\qquad \det\mathbf{J}_{\mathbf{F}}=4(u^2+v^2)=4|z|^2.$$

(The pattern — equal diagonal entries, opposite off-diagonal ones — is the Cauchy–Riemann structure of an analytic function, and $\det\mathbf{J}=|dw/dz|^2=|2z|^2$; see Ch. 18.)

Now feed in polar coordinates, $u=r\cos\theta$, $v=r\sin\theta$. By the chain rule,

$$\frac{\partial(p,q)}{\partial(r,\theta)}=\begin{bmatrix}2r\cos\theta & -2r\sin\theta\\ 2r\sin\theta & 2r\cos\theta\end{bmatrix}\begin{bmatrix}\cos\theta & -r\sin\theta\\ \sin\theta & r\cos\theta\end{bmatrix}=\begin{bmatrix}2r\cos2\theta & -2r^2\sin2\theta\\ 2r\sin2\theta & 2r^2\cos2\theta\end{bmatrix}.$$

Check directly: $w=r^2e^{j2\theta}$, so $p=r^2\cos2\theta$, $q=r^2\sin2\theta$, and differentiating gives the same matrix. ✓ Determinants: $4r^2\cdot r=4r^3$ from the product, and $2r\cdot2r^2(\cos^2 2\theta+\sin^2 2\theta)=4r^3$ directly. ✓

Small-signal models

Worked Example 3 — the BJT as a two-port Jacobian

A simple model of an NPN transistor in the active region is

$$i_C = I_s e^{v_{BE}/V_T}\left(1 + \frac{v_{CE}}{V_A}\right), \qquad i_B = \frac{I_s}{\beta} e^{v_{BE}/V_T},$$

a map $(v_{BE}, v_{CE}) \mapsto (i_B, i_C)$. Its Jacobian is

$$\frac{\partial(i_B, i_C)}{\partial(v_{BE}, v_{CE})} = \begin{bmatrix} \dfrac{i_B}{V_T} & 0 \\ \dfrac{i_C}{V_T} & \dfrac{I_s e^{v_{BE}/V_T}}{V_A} \end{bmatrix} = \begin{bmatrix} 1/r_\pi & 0 \\ g_m & 1/r_o \end{bmatrix}.$$

Numbers. Bias at $I_C = 1$ mA, $V_{CE} = 5$ V, with $V_T = 25$ mV, $V_A = 100$ V, $\beta = 100$. Then $g_m = I_C/V_T = 40$ mS; $r_\pi \approx \beta/g_m = 2.5$ kΩ; and since $I_s e^{v_{BE}/V_T} = I_C/(1 + V_{CE}/V_A)$, $1/r_o = I_C/(V_A + V_{CE})$, so $r_o = 105$ kΩ.

Using it. A 1 mV change in v_{BE} changes i_C by $g_m \cdot 1\text{ mV} = 40\ \mu$A (linearised). The exact change is $1\text{ mA}\,(e^{0.04} - 1) = 40.8\ \mu$A; the 2 % discrepancy is the curvature of the exponential, and it is the origin of distortion in amplifiers driven too hard. The Jacobian entries are precisely the hybrid-π small-signal parameters, and this matrix is the device's y**-parameter** matrix at the bias point.

Engineering Note

Every two-port parameter set (y, z, h, g, $ABCD$) of a nonlinear device is a Jacobian at its bias point, expressed with different choices of which port variables are inputs. Converting between parameter sets is inverting or rearranging these matrices, which is why small-signal analysis is linear algebra (Ch. 8).

The inverse function theorem

Inverse function theorem

Let $\mathbf{F} : \mathbb{R}^n \to \mathbb{R}^n$ have continuous partial derivatives near $\mathbf{x}_0$, with $\det \mathbf{J}_\mathbf{F}(\mathbf{x}_0) \neq 0$. Then $\mathbf{F}$ has a differentiable inverse near $\mathbf{y}_0 = \mathbf{F}(\mathbf{x}_0)$, and

$$\mathbf{J}_{\mathbf{F}^{-1}}(\mathbf{y}_0) = \left[\mathbf{J}_\mathbf{F}(\mathbf{x}_0)\right]^{-1}, \qquad \det \mathbf{J}_{\mathbf{F}^{-1}} = \frac{1}{\det \mathbf{J}_\mathbf{F}}.$$

The formula follows from the chain rule applied to $\mathbf{F}^{-1} \circ \mathbf{F} = \text{identity}$, whose Jacobian is $\mathbf{I}$. The theorem says that a non-zero Jacobian determinant is what makes a change of variables locally reversible; where it vanishes (the origin in polar coordinates) the coordinates break down.

Worked Example 4 — inverse polar derivatives without differentiating

Inverting the matrix of Worked Example 1 (determinant r),

$$\frac{\partial(r,\theta)}{\partial(x,y)} = \frac{1}{r}\begin{bmatrix} r\cos\theta & r\sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\dfrac{\sin\theta}{r} & \dfrac{\cos\theta}{r} \end{bmatrix}.$$

Check directly: $r = \sqrt{x^2 + y^2}$ gives $r_x = x/r = \cos\theta$ and $r_y = y/r = \sin\theta$; $\theta = \operatorname{atan2}(y, x)$ gives $\theta_x = -y/(x^2 + y^2) = -\sin\theta/r$ and $\theta_y = x/(x^2 + y^2) = \cos\theta/r$. ✓ This resolves the puzzle of §6.3: $x_r = \cos\theta$ and $r_x = \cos\theta$ are not reciprocals; it is the *matrices* that are inverses, not their individual entries.

Sensitivity of solutions: the implicit function theorem

Suppose a system of n equations $\mathbf{F}(\mathbf{x}, \mathbf{p}) = \mathbf{0}$ determines n unknowns $\mathbf{x}$ (node voltages, say) in terms of parameters $\mathbf{p}$ (component values). Differentiating the identity $\mathbf{F}(\mathbf{x}(\mathbf{p}), \mathbf{p}) = \mathbf{0}$:

$$\mathbf{J}_\mathbf{x}\, d\mathbf{x} + \mathbf{J}_\mathbf{p}\, d\mathbf{p} = \mathbf{0} \quad \Longrightarrow \quad \frac{\partial \mathbf{x}}{\partial \mathbf{p}} = -\mathbf{J}_\mathbf{x}^{-1}\mathbf{J}_\mathbf{p},$$

valid wherever $\det \mathbf{J}_\mathbf{x} \neq 0$ (the vector **implicit function theorem**). This is the matrix version of $dy/dx = -F_x/F_y$, and it is how circuit simulators compute the sensitivity of an operating point to every component in one linear solve, reusing the Jacobian they already built for Newton's method.

Newton's method for nonlinear systems

To solve $\mathbf{F}(\mathbf{x}) = \mathbf{0}$, replace $\mathbf{F}$ by its linearisation at the current guess and solve the resulting *linear* system for the step:

$$\mathbf{J}_\mathbf{F}(\mathbf{x}_k)\,\Delta\mathbf{x} = -\mathbf{F}(\mathbf{x}_k), \qquad \mathbf{x}_{k+1} = \mathbf{x}_k + \Delta\mathbf{x}.$$

Geometrically, each component F_i is replaced by its tangent plane, and the step goes to where all the tangent planes cross zero simultaneously. Near a root with non-singular Jacobian the error is roughly *squared* at each step (**quadratic convergence**), so the number of correct digits about doubles per iteration. This is precisely how SPICE finds the DC operating point of a nonlinear circuit: each diode and transistor is replaced by its small-signal "companion model" (a Jacobian entry plus a source), the resulting linear circuit is solved, and the process repeats.

Worked Example 5 — Newton iteration for two equations

Solve $x^2 + y^2 = 4$, $xy = 1$, starting from $(x_0, y_0) = (2,\ 0.5)$.

Set up: $\mathbf{F} = (x^2 + y^2 - 4,\ xy - 1)$, $\mathbf{J} = \begin{bmatrix} 2x & 2y \\ y & x \end{bmatrix}$.

Step 1: $\mathbf{F}(2, 0.5) = (0.25,\ 0)$ and

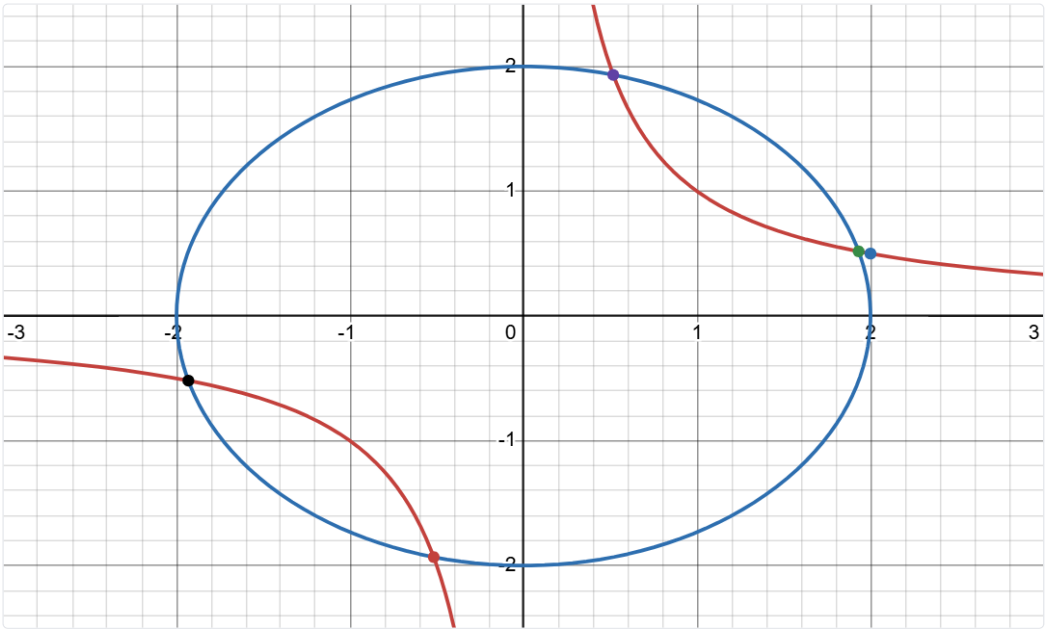
$$\mathbf{J} = \begin{bmatrix} 4 & 1 \\ 0.5 & 2 \end{bmatrix}, \qquad \det \mathbf{J} = 7.5, \qquad \Delta\mathbf{x} = \frac{1}{7.5}\begin{bmatrix} 2 & -1 \\ -0.5 & 4 \end{bmatrix}\begin{bmatrix} -0.25 \\ 0 \end{bmatrix} = \begin{bmatrix} -0.0667 \\ 0.0167 \end{bmatrix}.$$

So $(x_1, y_1) = (1.93333,\ 0.51667)$.

Further steps (same recipe):

k	x_k	y_k	error $\lVert \mathbf{x}_k - \mathbf{x}^* \rVert$
0	2.00000	0.50000	7.0×10^{-2}
1	1.93333	0.51667	1.8×10^{-3}
2	1.93185274	0.51763705	1.5×10^{-6}
3	1.93185165	0.51763809	1.1×10^{-12}

The exact root is $x^* = (\sqrt{6} + \sqrt{2})/2 = 1.93185165$, $y^* = (\sqrt{6} - \sqrt{2})/2 = 0.51763809$. Each error is roughly a constant times the square of the previous one ($1.8 \times 10^{-3} \approx 0.36\,(7.0 \times 10^{-2})^2$, $1.5 \times 10^{-6} \approx 0.47\,(1.8 \times 10^{-3})^2$): quadratic convergence.



The circle and hyperbola intersect in four points; Newton's method converges to the one nearest the starting guess. Starting near the line $y = x$, where $\det \mathbf{J} = 2(x^2 - y^2)$ vanishes, would send the first step far away.

Worked Example 6 — how the solution moves with a parameter

Replace the circle by $x^2 + y^2 = c$. How fast does the root found above move as c increases through 4?

With $\mathbf{F} = (x^2 + y^2 - c,\ xy - 1)$, $\mathbf{J}_\mathbf{x} = \begin{bmatrix} 2x & 2y \\ y & x \end{bmatrix}$ and $\mathbf{J}_c = \begin{bmatrix} -1 \\ 0 \end{bmatrix}$. The sensitivity formula gives

$$\frac{d\mathbf{x}}{dc} = -\mathbf{J}_\mathbf{x}^{-1}\mathbf{J}_c = \frac{1}{2(x^2 - y^2)}\begin{bmatrix} x & -2y \\ -y & 2x \end{bmatrix}\begin{bmatrix} 1 \\ 0 \end{bmatrix} = \frac{1}{2(x^2 - y^2)}\begin{bmatrix} x \\ -y \end{bmatrix}.$$

At the root, $x^2 - y^2 = (x + y)(x - y) = \sqrt{6} \cdot \sqrt{2} = 3.4641$, so $dx/dc = 1.93185/6.9282 = 0.2788$ and $dy/dc = -0.0747$. Re-solving with $c = 4.01$ and differencing gives $(0.2786,\ -0.0745)$. ✓ Enlarging the circle slides the intersection outward along the hyperbola, as the picture suggests.

Common Pitfall

Newton's method needs a good starting point and a non-singular Jacobian. Near a point where $\det \mathbf{J} \approx 0$ the step $\Delta\mathbf{x} = -\mathbf{J}^{-1}\mathbf{F}$ becomes huge and the iteration can jump to a different root or diverge. Circuit simulators protect themselves with damping (limiting the step, especially across exponential junctions), source stepping (ramping supplies up from zero) and "gmin" stepping (adding small conductances that keep $\mathbf{J}$ well conditioned). Never compute $\mathbf{J}^{-1}$ explicitly in practice: solve $\mathbf{J}\Delta\mathbf{x} = -\mathbf{F}$ by elimination (Ch. 8).

The Hessian as a Jacobian

The gradient ∇f is itself a vector function $\mathbb{R}^n \to \mathbb{R}^n$, and its Jacobian is the symmetric matrix of second partials:

$$\mathbf{H}_f = \mathbf{J}_{\nabla f} = \begin{bmatrix} f_{x_1x_1} & \cdots & f_{x_1x_n} \\ \vdots & \ddots & \vdots \\ f_{x_nx_1} & \cdots & f_{x_nx_n} \end{bmatrix}, \qquad \mathbf{H}^{\mathsf{T}} = \mathbf{H} \ (\text{Clairaut}).$$

Newton's method applied to $\nabla f = \mathbf{0}$ — the condition for an extremum — reads $\mathbf{H}\,\Delta\mathbf{x} = -\nabla f$, the basis of Newton-type optimisers. The Hessian also classifies critical points (§6.10).

6.7 Multiple integration

Motivation

Integration in one variable adds up a quantity distributed along a line: charge on a wire, energy over time. In two and three dimensions the same idea adds up quantities spread over areas and volumes: the total charge on a plate with non-uniform surface density, the current through a conductor cross-section with non-uniform current density, the energy stored in a field, the probability that two random noise voltages both exceed a threshold. The new ingredient is the *shape* of the region, which determines the limits of integration — and most of the skill in multiple integration lies in describing that shape correctly.

Double integrals: definition and properties

Let f be bounded on a bounded region R of the plane. Cover R with a grid of small rectangles; let the k-th rectangle inside R have area ΔA_k and contain a sample point (x_k, y_k).

Double integral

$$\iint_R f(x,y)\,dA = \lim_{\max \Delta A_k \to 0} \sum_k f(x_k, y_k)\,\Delta A_k,$$

when the limit exists and is independent of the grid and the sample points. It exists whenever f is continuous on a closed, bounded region R with a reasonably smooth boundary.

Interpretations depend on what f is:

Integrand f	$\iint_R f\,dA$ means	Units
1	area of R	m^2
height $f \geq 0$	volume under the surface $z = f(x,y)$	m^3
surface charge density ρ_s	total charge on R	C
current density J_z across a cross-section	current through it	A
joint probability density p_{XY}	probability that $(X,Y) \in R$	dimensionless

Properties of double integrals

1. **Linearity:** $\iint_R (af + bg)\,dA = a\iint_R f\,dA + b\iint_R g\,dA$.
2. **Additivity:** if $R = R_1 \cup R_2$ with R_1, R_2 overlapping only on boundaries, $\iint_R = \iint_{R_1} + \iint_{R_2}$.
3. **Monotonicity:** if $f \leq g$ on R, then $\iint_R f\,dA \leq \iint_R g\,dA$; in particular $m\,A(R) \leq \iint_R f\,dA \leq M\,A(R)$ when $m \leq f \leq M$.
4. **Mean value theorem:** if f is continuous and R connected, $\iint_R f\,dA = f(\mathbf{c})\,A(R)$ for some point $\mathbf{c} \in R$.

Iterated integrals and Fubini's theorem

The Riemann-sum definition is not a practical way to compute. Instead, we slice: on a rectangle $[a,b] \times [c,d]$, add up the rectangles in each vertical column first (an integral in y at fixed x), then add the columns (an integral in x).

Fubini's theorem

If f is continuous on the rectangle $[a,b] \times [c,d]$,

$$\iint_R f\,dA = \int_a^b \left[\int_c^d f(x,y)\,dy\right] dx = \int_c^d \left[\int_a^b f(x,y)\,dx\right] dy.$$

More generally, for a **type I** region $R = \{a \leq x \leq b,\ g_1(x) \leq y \leq g_2(x)\}$,

$$\iint_R f\,dA = \int_a^b \left[\int_{g_1(x)}^{g_2(x)} f(x,y)\,dy\right] dx,$$

and for a **type II** region $\{c \leq y \leq d,\ h_1(y) \leq x \leq h_2(y)\}$ integrate in x first, between $h_1(y)$ and $h_2(y)$.

Why it works. The inner integral $A(x) = \int_{g_1(x)}^{g_2(x)} f(x,y)\,dy$ is the area of the cross-section of the solid under f at position x. Integrating cross-sectional area along x gives volume — the slicing method of Chapter 5 — and that volume is the double integral. Slicing the other way must give the same volume.

Recipe for setting up limits.

1. Sketch the region and label its boundary curves.
2. Choose the inner variable (say y). Draw a line across the region in the y-direction at a typical x.
3. The inner limits are the y-values where the line *enters* and *leaves* the region — in general functions of x.
4. The outer limits are the extreme values of x over the whole region — always constants.
5. If the entry or exit curve changes partway across, split the region into pieces.

Worked Example 1 — a rectangle, both orders

Evaluate $\iint_R (x^2 + xy)\,dA$ over $R = [0,2] \times [0,1]$.

y first:

$$\int_0^2 \left[\int_0^1 (x^2 + xy)\,dy\right] dx = \int_0^2 \left[x^2 y + \tfrac{1}{2}xy^2\right]_{y=0}^{1} dx = \int_0^2 \left(x^2 + \tfrac{1}{2}x\right) dx = \tfrac{8}{3} + 1 = \tfrac{11}{3}.$$

x first:

$$\int_0^1 \left[\int_0^2 (x^2 + xy)\,dx\right] dy = \int_0^1 \left(\tfrac{8}{3} + 2y\right) dy = \tfrac{8}{3} + 1 = \tfrac{11}{3}.\checkmark$$

Numerically 3.6667. The average value of the integrand over the rectangle is $(11/3)/2 = 1.833$.

Worked Example 2 — area and centroid of a region between curves

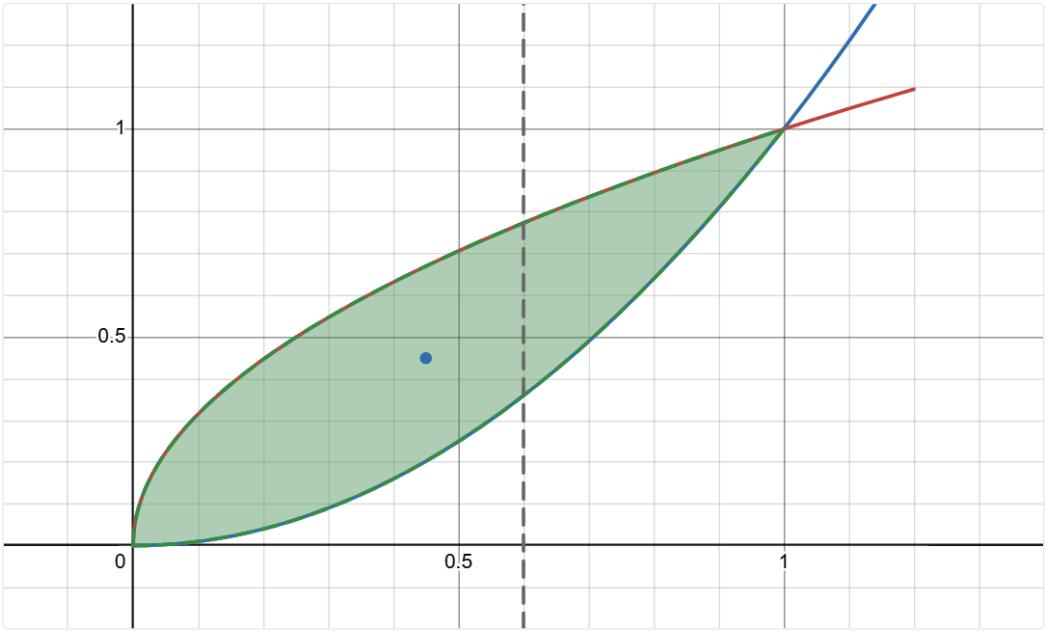
The region between $y = x^2$ and $y = \sqrt{x}$ for $0 \le x \le 1$ is type I (vertical strips from $y = x^2$ up to $y = \sqrt{x}$).

Area:

$$A = \int_0^1 \int_{x^2}^{\sqrt{x}} dy\,dx = \int_0^1 \left(\sqrt{x} - x^2\right) dx = \frac{2}{3} - \frac{1}{3} = \frac{1}{3}.$$

Centroid: $\bar{x} = \dfrac{1}{A}\iint x\,dA = 3\int_0^1 x\left(\sqrt{x} - x^2\right) dx = 3\left(\tfrac{2}{5} - \tfrac{1}{4}\right) = \tfrac{9}{20} = 0.45$. The region is symmetric about $y = x$ (swapping x and y swaps the two curves), so $\bar{y} = \bar{x} = 0.45$ without further work; direct integration, $\bar{y} = 3\int_0^1 \tfrac{1}{2}(x - x^4)\,dx = 3 \cdot \tfrac{1}{2}\left(\tfrac{1}{2} - \tfrac{1}{5}\right) = 0.45$, confirms it.

As a type II region the same set is $0 \le y \le 1$, $y^2 \le x \le \sqrt{y}$ — horizontal strips from the parabola $x = y^2$ to $x = \sqrt{y}$.



The shaded region is type I (vertical strips such as the dashed one, entering at $y = x^2$ and leaving at $y = \sqrt{x}$) and also type II (horizontal strips from $x = y^2$ to $x = \sqrt{y}$). Its centroid lies on the symmetry line $y = x$.

Worked Example 3 — charge on a triangular plate

A triangular plate occupies $0 \le y \le x \le a$ and carries surface charge density $\rho_s = \rho_0\, xy/a^2$ (ρ_0 in $\mathrm{C/m^2}$). Find the total charge.

Region: vertical strips at fixed x run from $y = 0$ to $y = x$, for $0 \le x \le a$.

$$Q = \frac{\rho_0}{a^2}\int_0^a \int_0^x xy\,dy\,dx = \frac{\rho_0}{a^2}\int_0^a x \cdot \frac{x^2}{2}\,dx = \frac{\rho_0}{a^2} \cdot \frac{a^4}{8} = \frac{\rho_0 a^2}{8}.$$

Units: $\mathrm{C/m^2} \times \mathrm{m^2} = \mathrm{C}$. ✓ *Sanity check:* the plate area is $a^2/2$ and the density ranges from 0 to ρ_0, so Q must lie between 0 and $\rho_0 a^2/2$; the answer is a quarter of the upper bound, reasonable since the density is small over most of the plate.

Reversing the order of integration

Sometimes the inner integral cannot be done in the given order, but the other order is easy. Reversing is a matter of re-describing the *same region* the other way round — never of swapping the limits mechanically.

Worked Example 4 — reversing to remove a non-elementary integral

(a) $I = \displaystyle\int_0^1 \int_y^1 e^{x^2}\,dx\,dy$ cannot be done as written, since e^{x^2} has no elementary antiderivative.

Region: $0 \le y \le 1$ and $y \le x \le 1$, i.e. the triangle $0 \le y \le x \le 1$ with vertices $(0,0)$, $(1,0)$, $(1,1)$.

Re-describe as type I: for each $x \in [0,1]$, y runs from 0 to x. Then

$$I = \int_0^1 \int_0^x e^{x^2}\,dy\,dx = \int_0^1 x\,e^{x^2}\,dx = \Big[\tfrac{1}{2}e^{x^2}\Big]_0^1 = \frac{e-1}{2} \approx 0.859.$$

(b) The same trick handles $J = \displaystyle\int_0^\pi \int_y^\pi \frac{\sin x}{x}\,dx\,dy$, whose inner integral is the non-elementary sine integral. The region is $0 \le y \le x \le \pi$, so

$$J = \int_0^\pi \int_0^x \frac{\sin x}{x}\,dy\,dx = \int_0^\pi \frac{\sin x}{x}\cdot x\,dx = \int_0^\pi \sin x\,dx = 2.$$

Numerical double integration in the original order gives 2.0000. ✓ The pattern: the inner integration in the new order produces a factor (x) that cancels the troublesome part.

Common Pitfall

The outer limits must be **constants** and the inner limits may depend only on the **outer** variable. A setup like $\int_0^1 \int_0^x f\,dx\,dy$ (inner limit depending on the inner variable) is meaningless. When reversing the order, always sketch the region: swapping $\int_0^1 \int_y^1$ into $\int_y^1 \int_0^1$ is a common and fatal error.

Triple integrals

For $f(x,y,z)$ on a solid V, the triple integral $\iiint_V f\,dV$ is defined by Riemann sums over small boxes and evaluated, by Fubini's theorem again, as three nested single integrals. A typical setup is

$$\iiint_V f\,dV = \int_a^b \int_{g_1(x)}^{g_2(x)} \int_{h_1(x,y)}^{h_2(x,y)} f(x,y,z)\,dz\,dy\,dx,$$

where for each (x,y) in the "shadow" of V on the xy-plane, z runs from the bottom surface h_1 to the top surface h_2, and the shadow itself is described as a 2-D region. With $f = 1$ the integral gives volume; with $f = \rho_v$ (volume charge density, $\mathrm{C/m^3}$) it gives charge; with $f = w_e = \tfrac{1}{2}\varepsilon\|\mathbf{E}\|^2$ it gives stored electric energy.

Worked Example 5 — separable integrand on a cube

A cube $0 \le x, y, z \le a$ carries $\rho_v = \rho_0\,xyz/a^3$. Both the region and the integrand separate, so the triple integral is a product of single integrals:

$$Q = \frac{\rho_0}{a^3}\int_0^a x\,dx \int_0^a y\,dy \int_0^a z\,dz = \frac{\rho_0}{a^3}\left(\frac{a^2}{2}\right)^3 = \frac{\rho_0 a^3}{8}.$$

Units: $\mathrm{C/m^3} \times \mathrm{m^3} = \mathrm{C}$. ✓ Because the density is a product of three linear ramps, its average over the cube is $\rho_0/8$, and $Q = (\rho_0/8)\cdot a^3$.

Worked Example 6 — the tetrahedron

Let V be the tetrahedron bounded by the coordinate planes and $x + y + z = 1$. Find its volume and the height $\bar{z}$ of its centroid.

Limits: top surface $z = 1 - x - y$, bottom $z = 0$; the shadow is the triangle $x \ge 0$, $y \ge 0$, $x + y \le 1$, i.e. $0 \le x \le 1$, $0 \le y \le 1 - x$.

Volume:

$$\int_0^1 \int_0^{1-x} (1 - x - y)\,dy\,dx = \int_0^1 \frac{(1-x)^2}{2}\,dx = \frac{1}{6}.$$

Moment:

$$\iiint_V z\,dV = \int_0^1 \int_0^{1-x} \frac{(1-x-y)^2}{2}\,dy\,dx = \int_0^1 \frac{(1-x)^3}{6}\,dx = \frac{1}{24}.$$

Hence $\bar{z} = (1/24)/(1/6) = 1/4$, and by symmetry the centroid is $\left(\tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{4}\right)$ — one quarter of the way from the base face to the opposite vertex, the standard result for any tetrahedron. Numerical triple integration gives $0.041667 = 1/24$. ✓

Averages, centroids and moments

$$\bar{f} = \frac{1}{A}\iint_R f\,dA, \qquad \bar{x} = \frac{1}{A}\iint_R x\,dA, \qquad \bar{y} = \frac{1}{A}\iint_R y\,dA,$$

with the obvious extensions to volumes, and to *weighted* centres when a density ρ multiplies the integrand and the total "mass" $\iint \rho\,dA$ replaces A. **Second moments** $\iint x^2\rho\,dA$ appear as moments of inertia in mechanics and as variances in probability (Ch. 19); the root-mean-square value of a field over an area, $\sqrt{\frac{1}{A}\iint f^2\,dA}$, is the quantity that determines average power.

Numerical double integration

When no antiderivative exists, the iterated form still allows numerical evaluation: apply any one-dimensional rule (Ch. 22) to the inner integral and again to the outer one. The two-dimensional **midpoint rule** on an $n \times n$ grid of cells of size $h \times k$ is

$$\iint_R f\,dA \approx hk \sum_{i=1}^{n}\sum_{j=1}^{n} f(x_i^*, y_j^*),$$

with (x_i^*, y_j^*) the cell centres.

Worked Example 7 — midpoint rule for a Gaussian on the unit square

$I = \iint_{[0,1]^2} e^{-(x^2+y^2)}\,dA = \left(\int_0^1 e^{-x^2}dx\right)^2 = 0.746824^2 = 0.557746$ (separable, using the tabulated 1-D value).

grid	midpoint estimate	error
2×2	0.56942	1.17×10^{-2}
4×4	0.56062	2.88×10^{-3}
8×8	0.55846	7.16×10^{-4}

Halving the cell size divides the error by about 4: the midpoint rule is second-order accurate in 2-D, as in 1-D. But the cost — the number of function evaluations — grows as n^2 in 2-D and n^d in d dimensions. For high-dimensional integrals (bit-error rates over many noise variables, yield over many component tolerances) this "curse of dimensionality" is why Monte Carlo methods take over (Ch. 24).

Engineering Note

Improper double integrals — over unbounded regions or with singular integrands — are routine in EE: the probability that a Gaussian noise vector lands outside a decision region, the energy of a field extending to infinity, the potential of a charged sheet. They are defined as limits of integrals over growing (or shrinking-hole) regions, and for non-negative integrands Fubini's theorem still allows any order. The most important one, $\iint_{\mathbb{R}^2} e^{-(x^2+y^2)}dA = \pi$, is evaluated in §6.8.

6.8 Coordinate transformations

Motivation

Cartesian coordinates make rectangles easy and everything else awkward. A disc, a sector, a region bounded by hyperbolas, an integrand containing $x^2 + y^2$ — each becomes simple in the right coordinates. Changing variables in a multiple integral is the multivariable analogue of substitution, $\int f(x)\,dx = \int f(x(u))\,x'(u)\,du$, and the role of $x'(u)$ is played by the Jacobian determinant of §6.6. The idea also has a probabilistic face: transforming random variables (from in-phase and quadrature noise to envelope and phase, say) uses exactly the same Jacobian factor.

How a map scales area

Let $x = x(u,v)$, $y = y(u,v)$ be a one-to-one, continuously differentiable map from a region S of the uv-plane onto a region R of the xy-plane, and write $\mathbf{r}(u,v) = (x(u,v), y(u,v))$. A small coordinate rectangle with corners (u,v), $(u+du,v)$, $(u,v+dv)$ is carried to an approximate **parallelogram** with sides

$$\mathbf{r}(u+du,v) - \mathbf{r}(u,v) \approx \mathbf{r}_u\,du = (x_u,\ y_u)\,du, \qquad \mathbf{r}(u,v+dv) - \mathbf{r}(u,v) \approx \mathbf{r}_v\,dv = (x_v,\ y_v)\,dv.$$

The area of a parallelogram spanned by (a_1,a_2) and (b_1,b_2) is $|a_1b_2 - a_2b_1|$, the absolute value of a 2×2 determinant. Hence

$$dA = |x_u y_v - x_v y_u|\,du\,dv = \left|\det \frac{\partial(x,y)}{\partial(u,v)}\right| du\,dv.$$

The Jacobian determinant is the local **area magnification factor** of the map. Summing over all the little parallelograms and taking the limit gives the theorem.

Change of variables in multiple integrals

Under the conditions above (one-to-one, continuously differentiable, Jacobian determinant non-zero except possibly on a set of zero area),

$$\iint_R f(x,y)\,dx\,dy = \iint_S f\big(x(u,v), y(u,v)\big)\left|\frac{\partial(x,y)}{\partial(u,v)}\right| du\,dv.$$

In three dimensions, with $(x,y,z) = \mathbf{r}(u,v,w)$, the small box becomes a parallelepiped of volume $|\det \mathbf{J}|\,du\,dv\,dw$, and

$$\iiint_V f\,dx\,dy\,dz = \iiint_W f\big(\mathbf{r}(u,v,w)\big)\left|\frac{\partial(x,y,z)}{\partial(u,v,w)}\right| du\,dv\,dw.$$

Three practical facts:

- **The absolute value is essential.** Area and volume are positive; a negative Jacobian determinant only means the map reverses orientation (like a mirror).
- **Inverse Jacobians are reciprocals** (inverse function theorem, §6.6): $\dfrac{\partial(x,y)}{\partial(u,v)} = 1 \Big/ \dfrac{\partial(u,v)}{\partial(x,y)}$. When the substitution is given as $u = u(x,y)$, $v = v(x,y)$, compute the easy Jacobian and invert it — there is no need to solve for x and y.

- **Choose the substitution to simplify the region first.** The integrand usually follows. Good choices make the boundary curves of R into coordinate lines $u = \text{const}$, $v = \text{const}$, so that S is a rectangle.

Worked Example 1 — a linear change of variables

Evaluate $\iint_D (x+y)\,dA$ over the parallelogram D bounded by $x+y=0$, $x+y=2$, $x-y=0$, $x-y=1$.

Substitution suggested by the boundaries: $u = x+y \in [0,2]$, $v = x-y \in [0,1]$; S is a rectangle.

Jacobian: $\dfrac{\partial(u,v)}{\partial(x,y)} = \det\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix} = -2$, so $\left|\dfrac{\partial(x,y)}{\partial(u,v)}\right| = \dfrac{1}{2}$.

Integral:

$$\iint_D (x+y)\,dA = \int_0^1 \int_0^2 u \cdot \tfrac{1}{2}\,du\,dv = \tfrac{1}{2}\cdot 2 \cdot 1 = 1.$$

Check: the area of D is $\iint_S \frac{1}{2}\,du\,dv = \frac{1}{2}\cdot 2\cdot 1 = 1$, and the average of $u = x+y$ over D is clearly 1 (it runs uniformly from 0 to 2), so the integral is $1 \times 1 = 1$. ✓

Worked Example 2 — the ellipse

Find the area of the ellipse $x^2/a^2 + y^2/b^2 \le 1$, and $\iint x^2\,dA$ over it.

Substitution: $x = au$, $y = bv$ maps the unit disc $u^2+v^2 \le 1$ onto the ellipse, with $\partial(x,y)/\partial(u,v) = ab$.

Area: $\iint_{\text{disc}} ab\,du\,dv = ab\cdot\pi = \pi ab$.

Second moment: $\iint x^2\,dA = \iint_{\text{disc}} a^2u^2 \cdot ab\,du\,dv = a^3b\iint_{\text{disc}} u^2\,du\,dv = a^3b\cdot\dfrac{\pi}{4}$, using the polar result $\iint_{\text{disc}} u^2 = \int_0^{2\pi}\int_0^1 r^2\cos^2\theta\, r\,dr\,d\theta = \frac{1}{4}\cdot\pi$. For $a=2$, $b=1$: $2\pi = 6.2832$, matching direct numerical integration. ✓ The linear stretch turned an ellipse problem into a circle problem.

Worked Example 3 — a region bounded by hyperbolas and lines

Find the area of the region R in the first quadrant bounded by $xy=1$, $xy=4$, $y=x$ and $y=2x$.

Substitution: $u = xy \in [1,4]$, $v = y/x \in [1,2]$ — again the boundaries become coordinate lines.

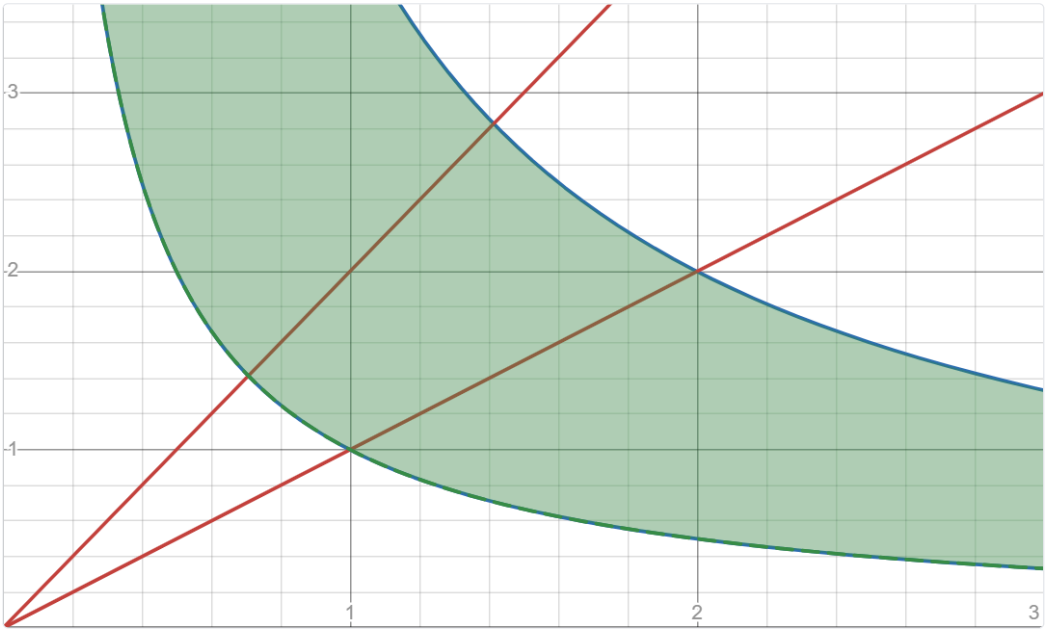
Jacobian of the easy direction:

$$\frac{\partial(u,v)}{\partial(x,y)} = \det\begin{bmatrix} y & x \\ -y/x^2 & 1/x\end{bmatrix} = \frac{y}{x} + \frac{y}{x} = 2v, \qquad \text{so} \qquad \left|\frac{\partial(x,y)}{\partial(u,v)}\right| = \frac{1}{2v}.$$

Area:

$$A = \int_1^4 \int_1^2 \frac{1}{2v}\,dv\,du = 3\cdot\tfrac{1}{2}\ln 2 = \tfrac{3}{2}\ln 2 \approx 1.0397.$$

A direct Cartesian computation would need the region split into three pieces (the entry and exit curves change at $x = 1/\sqrt{2}$, 1, $\sqrt{2}$ and 2); numerically it gives 1.0397. ✓



The region of Worked Example 3 is bounded by two hyperbolas (blue) and two lines (red); in the coordinates $u = xy$, $v = y/x$ it becomes the rectangle $[1,4]\times[1,2]$ — only the part between the red lines counts.

Polar coordinates

With $x = r\cos\theta$, $y = r\sin\theta$, the Jacobian determinant is r (§6.6), so

$$dA = r\,dr\,d\theta.$$

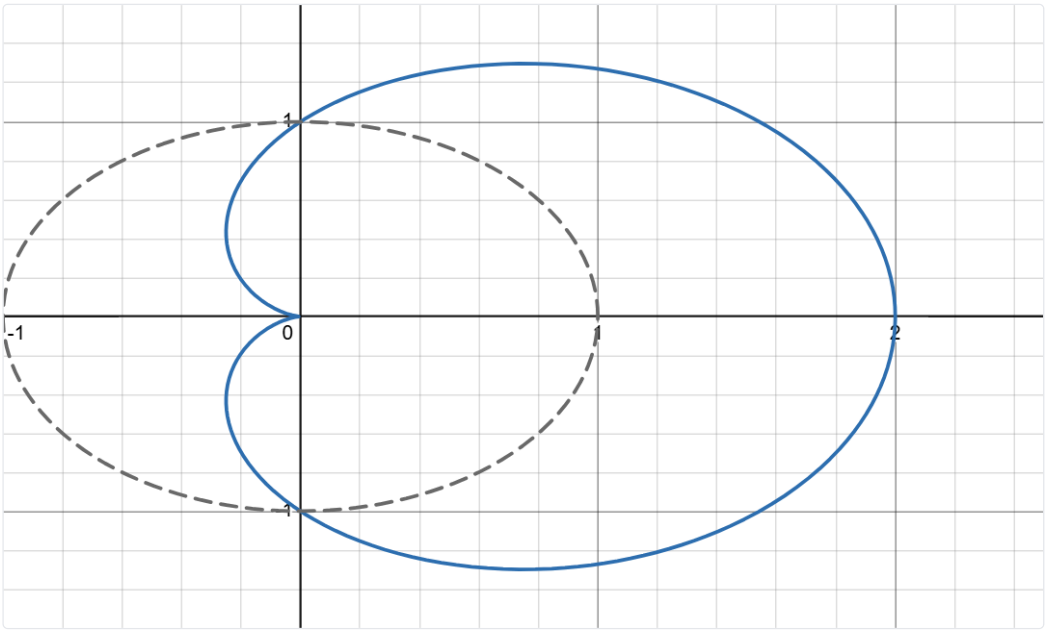
The factor r has a direct geometric meaning: the small polar "rectangle" between radii r and $r + dr$ and angles θ and $\theta + d\theta$ has radial side dr and arc side $r\,d\theta$. Use polar coordinates whenever the region is a disc, annulus, sector or is bounded by a polar curve $r = g(\theta)$, or when the integrand contains $x^2 + y^2$.

Worked Example 4 — area inside a cardioid

The cardioid $r = 1 + \cos\theta$ ($0 \le \theta < 2\pi$) — the shape of a cardioid microphone's polar pattern — encloses the region $0 \le r \le 1 + \cos\theta$. Its area is

$$A = \int_0^{2\pi}\int_0^{1+\cos\theta} r\,dr\,d\theta = \int_0^{2\pi}\frac{(1+\cos\theta)^2}{2}\,d\theta = \frac{1}{2}\int_0^{2\pi}\left(1 + 2\cos\theta + \cos^2\theta\right)d\theta = \frac{1}{2}\left(2\pi + 0 + \pi\right) = \frac{3\pi}{2}.$$

Numerically 4.712, which sits sensibly between the area of the circle of radius 1 (π) and the circle of radius 2 that just encloses the cardioid (4π).



The cardioid $r = 1 + \cos\theta$ (blue) compared with the unit circle; integrating $r\,dr$ from 0 out to the curve at each angle sweeps out its area $3\pi/2$.

Worked Example 5 — the Gaussian integral

Let $I = \int_{-\infty}^{\infty} e^{-x^2}dx$. No antiderivative exists, but the *square* of I is a double integral that polar coordinates make trivial:

$$I^2 = \int_{-\infty}^{\infty}e^{-x^2}dx\int_{-\infty}^{\infty}e^{-y^2}dy = \iint_{\mathbb{R}^2} e^{-(x^2+y^2)}\,dx\,dy = \int_0^{2\pi}\int_0^{\infty} e^{-r^2}\,r\,dr\,d\theta.$$

The factor r from the Jacobian is exactly what is needed: with $w = r^2$, $\int_0^{\infty} e^{-r^2} r\,dr = \tfrac{1}{2}\int_0^{\infty} e^{-w}dw = \tfrac{1}{2}$. Hence $I^2 = 2\pi\cdot\tfrac{1}{2} = \pi$ and

$$\int_{-\infty}^{\infty} e^{-x^2}dx = \sqrt{\pi}, \qquad \int_{-\infty}^{\infty} e^{-x^2/(2\sigma^2)}dx = \sigma\sqrt{2\pi}.$$

The second form (substitute $x \to x/(\sigma\sqrt{2})$) normalises the Gaussian (normal) distribution of thermal noise (Ch. 19) and underlies the Fourier transform of a Gaussian pulse (Ch. 16).

Worked Example 6 — the Rayleigh distribution of a noise envelope

The in-phase and quadrature components X, Y of narrowband noise are independent Gaussians with zero mean and variance σ^2, with joint density

$$p(x,y) = \frac{1}{2\pi\sigma^2}e^{-(x^2+y^2)/(2\sigma^2)}.$$

What is the probability that the envelope $R = \sqrt{X^2 + Y^2}$ exceeds a threshold ρ?

The event $R \le \rho$ is the disc of radius ρ, so in polar coordinates

$$P(R \le \rho) = \int_0^{2\pi}\int_0^{\rho}\frac{1}{2\pi\sigma^2}e^{-r^2/(2\sigma^2)}\,r\,dr\,d\theta = \left[-e^{-r^2/(2\sigma^2)}\right]_0^{\rho} = 1 - e^{-\rho^2/(2\sigma^2)}.$$

Differentiating in ρ gives the **Rayleigh density** $p_R(\rho) = \dfrac{\rho}{\sigma^2}e^{-\rho^2/(2\sigma^2)}$ — and the leading factor ρ is nothing but the polar Jacobian. For a threshold $\rho = 3\sigma$, $P(R > 3\sigma) = e^{-4.5} = 0.0111$: about 1.1 % of the time, noise alone crosses a 3σ envelope threshold. This is the basic false-alarm calculation of a radar or envelope detector (Ch. 21).

Common Pitfall

Forgetting the Jacobian. "Area of the unit disc $= \int_0^{2\pi}\int_0^1 dr\,d\theta = 2\pi$" is wrong by a factor of 2; the correct $\int_0^{2\pi}\int_0^1 r\,dr\,d\theta = \pi$. A quick check that catches this every time: integrate $f = 1$ and see whether you get the right area or volume. A second trap is a map that is not one-to-one: letting θ run over $[0, 4\pi]$ counts every point twice.

Engineering Note

The same Jacobian factor transforms probability densities. If random variables (X, Y) with joint density p_{XY} are mapped one-to-one to (U, V), then $p_{UV}(u,v) = p_{XY}(x,y)\,|\partial(x,y)/\partial(u,v)|$, because probability (like area times density) must be conserved. Worked Example 6 is the special case $(X, Y) \to (R, \Theta)$; it shows at once that the phase Θ is uniform on $[0, 2\pi)$ and independent of the envelope.

6.9 Cylindrical and spherical coordinates

Motivation

Wires, coaxial cables, solenoids and circular waveguides have an axis of symmetry; point charges, antennas seen from far away and spherical shells have a centre. Cartesian coordinates fight these geometries: the surface of a wire becomes $x^2 + y^2 = a^2$, and its cross-section a region with curved limits. In **cylindrical** and **spherical** coordinates the same surfaces become $r = a$ and $R = a$, the limits of integration become constants, and the integrals often separate into products of single integrals. This section sets up both systems, derives their volume elements from the Jacobian, and introduces the scale factors that Chapter 7 uses to write gradient, divergence and curl in curvilinear form.

Definitions and conventions

To avoid clashing with charge density ρ, this book uses (r, ϕ, z) for cylindrical and (R, θ, ϕ) for spherical coordinates, as in Cheng's field-theory text.

Cylindrical coordinates (r, ϕ, z)

$r \geq 0$ is the perpendicular distance from the z-axis, $\phi \in [0, 2\pi)$ the azimuth measured from the $+x$ axis towards $+y$, and z the usual height:

$$x = r\cos\phi, \qquad y = r\sin\phi, \qquad z = z; \qquad r = \sqrt{x^2 + y^2}, \quad \phi = \operatorname{atan2}(y, x).$$

Coordinate surfaces: $r =$ const is a circular cylinder, $\phi =$ const a half-plane hinged on the z-axis, $z =$ const a horizontal plane.

Spherical coordinates (R, θ, ϕ)

$R \geq 0$ is the distance from the origin, $\theta \in [0, \pi]$ the **polar angle** measured from the $+z$ axis, and $\phi \in [0, 2\pi)$ the same azimuth as in cylindrical coordinates:

$$x = R\sin\theta\cos\phi, \qquad y = R\sin\theta\sin\phi, \qquad z = R\cos\theta;$$

$$R = \sqrt{x^2 + y^2 + z^2}, \qquad \theta = \arccos\frac{z}{R}, \qquad \phi = \operatorname{atan2}(y, x).$$

Coordinate surfaces: $R =$ const is a sphere, $\theta =$ const a cone about the z-axis (the plane $z = 0$ when $\theta = \pi/2$), $\phi =$ const a half-plane.

The two systems are linked by $r = R\sin\theta$ and $z = R\cos\theta$: the cylindrical radius is the projection of the spherical radius onto the xy-plane. On the Earth, θ is the colatitude (90° minus latitude) and ϕ the longitude.

Worked Example 1 — converting a point

Express $P = (1,\ 1,\ \sqrt{2})$ in cylindrical and spherical coordinates.

Cylindrical: $r = \sqrt{1+1} = \sqrt{2}$, $\phi = \operatorname{atan2}(1,1) = \pi/4$, $z = \sqrt{2}$; so $P = (\sqrt{2},\ \pi/4,\ \sqrt{2})$.

Spherical: $R = \sqrt{1+1+2} = 2$, $\theta = \arccos(\sqrt{2}/2) = \pi/4$, $\phi = \pi/4$; so $P = (2,\ \pi/4,\ \pi/4)$.

Check back: $x = 2\sin\frac{\pi}{4}\cos\frac{\pi}{4} = 2\cdot\frac{1}{2} = 1$, $y = 1$, $z = 2\cos\frac{\pi}{4} = \sqrt{2}$. ✓ And $r = R\sin\theta = 2\cdot\frac{\sqrt{2}}{2} = \sqrt{2}$. ✓

For the point $(-1, -1, 0)$, $\tan\phi = y/x = 1$ would suggest $\phi = \pi/4$, but the point is in the third quadrant: $\operatorname{atan2}(-1,-1) = -3\pi/4$, i.e. $\phi = 5\pi/4$.

Common Pitfall

Mathematics texts (and some software) swap the roles of θ and ϕ in spherical coordinates, using θ for the azimuth and ϕ for the polar angle. Always check which angle is measured from the z-axis before using a formula from another source — the volume element $R^2\sin\theta$ contains the sine of the *polar* angle. Also, $\tan\phi = y/x$ alone does not fix the quadrant; use the signs of x and y (the `atan2` function).

Jacobians and volume elements

The cylindrical Jacobian is the polar one with a trivial z row and column added, so its determinant is r. For spherical coordinates,

$$\frac{\partial(x,y,z)}{\partial(R,\theta,\phi)} = \begin{bmatrix} \sin\theta\cos\phi & R\cos\theta\cos\phi & -R\sin\theta\sin\phi \\ \sin\theta\sin\phi & R\cos\theta\sin\phi & R\sin\theta\cos\phi \\ \cos\theta & -R\sin\theta & 0 \end{bmatrix}.$$

Expanding along the bottom row,

$$\begin{aligned}\det \mathbf{J} &= \cos\theta\left(R^2\sin\theta\cos\theta\cos^2\phi + R^2\sin\theta\cos\theta\sin^2\phi\right) + R\sin\theta\left(R\sin^2\theta\cos^2\phi + R\sin^2\theta\sin^2\phi\right)\\ &= R^2\sin\theta\cos^2\theta + R^2\sin^3\theta = R^2\sin\theta.\end{aligned}$$

Since $0 \le \theta \le \pi$, $\sin\theta \ge 0$ and no absolute value is needed. The determinant vanishes on the z-axis ($\theta = 0, \pi$) and at the origin, where the coordinates are degenerate (every ϕ describes the same point).

Scale factors and the geometric picture

The Jacobian can be read off without any determinant, from geometry. Each column of the Jacobian is the displacement per unit change of one coordinate, and in both systems the three columns are **mutually perpendicular** (the systems are *orthogonal*). Their lengths are the **scale factors** h_i: the distance moved per unit change of coordinate i.

- Changing r by dr moves you dr; changing z by dz moves you dz; changing ϕ by $d\phi$ moves you along a circle of radius r, a distance $r\,d\phi$.
- In spherical coordinates, changing R by dR moves you dR; changing θ by $d\theta$ moves you along a great circle (a meridian) of radius R, a distance $R\,d\theta$; changing ϕ by $d\phi$ moves you along a circle of latitude, whose radius is $r = R\sin\theta$, a distance $R\sin\theta\,d\phi$.

A small coordinate box is therefore (to first order) a rectangular box with edges h_1du_1, h_2du_2, h_3du_3, and

$$dV = h_1h_2h_3\,du_1\,du_2\,du_3, \qquad d\ell^2 = h_1^2du_1^2 + h_2^2du_2^2 + h_3^2du_3^2.$$

	Cylindrical (r,ϕ,z)	**Spherical** (R,θ,ϕ)
to Cartesian	$x = r\cos\phi,\ y = r\sin\phi,\ z = z$	$x = R\sin\theta\cos\phi,\ y = R\sin\theta\sin\phi,\ z = R\cos\theta$
from Cartesian	$r = \sqrt{x^2+y^2},\ \phi = \operatorname{atan2}(y,x)$	$R = \sqrt{x^2+y^2+z^2},\ \cos\theta = z/R$
ranges	$r \ge 0,\ 0 \le \phi < 2\pi$	$R \ge 0,\ 0 \le \theta \le \pi,\ 0 \le \phi < 2\pi$
scale factors (h_1,h_2,h_3)	$(1,\ r,\ 1)$	$(1,\ R,\ R\sin\theta)$
Jacobian determinant	r	$R^2\sin\theta$
volume element dV	$r\,dr\,d\phi\,dz$	$R^2\sin\theta\,dR\,d\theta\,d\phi$
line element $d\ell^2$	$dr^2 + r^2d\phi^2 + dz^2$	$dR^2 + R^2d\theta^2 + R^2\sin^2\theta\,d\phi^2$
surface element on $r = a$ / $R = a$	$a\,d\phi\,dz$	$a^2\sin\theta\,d\theta\,d\phi$
surface element on $z = \text{const}$ / $\theta = \text{const}$	$r\,dr\,d\phi$	$R\sin\theta\,dR\,d\phi$

The scale factors also generate the curvilinear forms of grad, div and curl in Ch. 7; for instance the gradient in spherical coordinates is $\nabla f = f_R\hat{\mathbf{R}} + \frac{1}{R}f_\theta\hat{\boldsymbol{\theta}} + \frac{1}{R\sin\theta}f_\phi\hat{\boldsymbol{\phi}}$, each partial divided by its scale factor, exactly as in the polar case of §6.4.

Unit vectors depend on position

The unit vectors of curvilinear coordinates point along the directions of increasing coordinates, and those directions change from point to point:

$$\hat{\mathbf{r}} = \cos\phi\,\hat{\mathbf{x}} + \sin\phi\,\hat{\mathbf{y}}, \qquad \hat{\boldsymbol{\phi}} = -\sin\phi\,\hat{\mathbf{x}} + \cos\phi\,\hat{\mathbf{y}}, \qquad \hat{\mathbf{z}} = \hat{\mathbf{z}};$$

$$\hat{\mathbf{R}} = \sin\theta\cos\phi\,\hat{\mathbf{x}} + \sin\theta\sin\phi\,\hat{\mathbf{y}} + \cos\theta\,\hat{\mathbf{z}}, \quad \hat{\boldsymbol{\theta}} = \cos\theta\cos\phi\,\hat{\mathbf{x}} + \cos\theta\sin\phi\,\hat{\mathbf{y}} - \sin\theta\,\hat{\mathbf{z}}, \quad \hat{\boldsymbol{\phi}} = -\sin\phi\,\hat{\mathbf{x}} + \cos\phi\,\hat{\mathbf{y}}.$$

(They are the Jacobian columns divided by the scale factors.) Each triple is orthonormal and right-handed at every point, but $\hat{\mathbf{r}}$ at $\phi = 0$ is $\hat{\mathbf{x}}$ while at $\phi = \pi$ it is $-\hat{\mathbf{x}}$.

> **Common Pitfall — integrating vectors in curvilinear coordinates**
>
> Because $\hat{\mathbf{r}}$, $\hat{\boldsymbol{\phi}}$, $\hat{\mathbf{R}}$, $\hat{\boldsymbol{\theta}}$ vary with position, they cannot be taken outside an integral. The total field of a uniformly charged ring at its centre is $\oint \hat{\mathbf{r}}\,d\phi\cdots = \mathbf{0}$, not "$2\pi\hat{\mathbf{r}}\cdots$". To integrate a vector quantity, convert the unit vectors to the constant Cartesian $\hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$ first (using the formulas above), then integrate component by component. Scalar integrands — charge, energy, power — have no such problem.

Worked examples in cylindrical coordinates

> **Worked Example 2 — current in a wire with non-uniform density**
>
> At high frequency, current crowds towards a conductor's surface (the skin effect). Model it in a wire of radius a by $J_z = J_0\,(r/a)^2$. The cross-section is $0 \le r \le a$, $0 \le \phi < 2\pi$, with $dA = r\,dr\,d\phi$, so
>
> $$I = \int_0^{2\pi}\!\!\int_0^{a} J_0\frac{r^2}{a^2}\,r\,dr\,d\phi = 2\pi\frac{J_0}{a^2}\cdot\frac{a^4}{4} = \frac{\pi J_0 a^2}{2},$$
>
> half what a uniform density J_0 would carry. Units: $\mathrm{A/m^2}\times\mathrm{m^2} = \mathrm{A}$. ✓ The factor r in dA weights the outer annuli more heavily — there is more area at large r — which is why the result is not simply "the average of $(r/a)^2$ over $[0,1]$", which would be $1/3$.

Worked Example 3 — energy stored in a coaxial cable

Between the conductors of a coaxial cable (inner radius a, outer radius b, voltage V_0, dielectric permittivity ε) the field magnitude is $E = \dfrac{V_0}{r\ln(b/a)}$. Find the stored energy per unit length and hence the capacitance per unit length.

Energy density: $w_e = \tfrac{1}{2}\varepsilon E^2 = \dfrac{\varepsilon V_0^2}{2r^2\ln^2(b/a)}$, a function of r only.

Integrate over a length ℓ: $dV = r\,dr\,d\phi\,dz$, so

$$W = \int_0^{\ell}\int_0^{2\pi}\int_a^b \frac{\varepsilon V_0^2}{2r^2\ln^2(b/a)}\, r\,dr\,d\phi\,dz = \ell\cdot 2\pi\cdot\frac{\varepsilon V_0^2}{2\ln^2(b/a)}\int_a^b\frac{dr}{r} = \frac{\pi\varepsilon\ell V_0^2}{\ln(b/a)}.$$

Capacitance: equating $W = \tfrac{1}{2}CV_0^2$ gives $C/\ell = 2\pi\varepsilon/\ln(b/a)$.

Numbers: $a = 0.5$ mm, $b = 1.75$ mm, polyethylene $\varepsilon = 2.25\varepsilon_0$: $C/\ell = 2\pi(2.25)(8.854\times10^{-12})/\ln 3.5 = 99.9$ pF/m, the familiar figure for such cables. Units: $(\mathrm{F/m})\cdot\mathrm{V}^2\cdot\mathrm{m}/1 = \mathrm{J}$ for W. ✓ The Jacobian r cancelled one power of $1/r^2$, leaving the logarithm.

Worked examples in spherical coordinates

Worked Example 4 — charge in a sphere

A sphere of radius a has $\rho_v = \rho_0(1 - R/a)$. With nothing depending on θ or ϕ, the angular integrals give

$$\int_0^{2\pi}\int_0^{\pi}\sin\theta\,d\theta\,d\phi = 2\pi\cdot 2 = 4\pi,$$

and

$$Q = 4\pi\rho_0\int_0^a\left(1-\frac{R}{a}\right)R^2\,dR = 4\pi\rho_0\left(\frac{a^3}{3}-\frac{a^3}{4}\right) = \frac{\pi\rho_0 a^3}{3}.$$

This is a quarter of what a uniform density ρ_0 would give ($\tfrac{4}{3}\pi a^3\rho_0$). For a spherically symmetric density, $dV = 4\pi R^2\,dR$: the volume of a thin shell of radius R and thickness dR.

Worked Example 5 — volume of an "ice-cream cone"

Find the volume of the solid inside the sphere $R = a$ and inside the cone $\theta = \alpha$ (i.e. $0 \le \theta \le \alpha$).

$$V = \int_0^{2\pi}\int_0^{\alpha}\int_0^{a} R^2\sin\theta\,dR\,d\theta\,d\phi = 2\pi\cdot(1-\cos\alpha)\cdot\frac{a^3}{3} = \frac{2\pi a^3}{3}(1-\cos\alpha).$$

Checks: $\alpha = \pi$ gives $\tfrac{4}{3}\pi a^3$, the whole sphere; $\alpha = \pi/2$ gives the hemisphere $\tfrac{2}{3}\pi a^3$. ✓ For $\alpha = \pi/3$, $V = \pi a^3/3$. In Cartesian coordinates the same solid would need limits involving both $\sqrt{a^2-x^2-y^2}$ and $\sqrt{x^2+y^2}\cot\alpha$; in spherical coordinates all three limits are constants.

Solid angle and antenna patterns

The angular part of the spherical surface element, $d\Omega = \sin\theta\,d\theta\,d\phi$, is the element of **solid angle**: the area of a patch on the unit sphere, measured in steradians (sr). The full sphere subtends $\int d\Omega = 4\pi$ sr, and a cone of half-angle α subtends

$$\Omega(\alpha) = \int_0^{2\pi}\int_0^{\alpha}\sin\theta\,d\theta\,d\phi = 2\pi(1-\cos\alpha)\ \text{sr},$$

which gives 2π sr for a hemisphere. Any function on the sphere — an antenna pattern, the angular distribution of scattered light — is integrated against $d\Omega$.

Worked Example 6 — radiated power and directivity

An antenna's radiation intensity $U(\theta,\phi)$ is the power radiated per steradian (W/sr); the total radiated power is $P = \oint U\,d\Omega = \int_0^{2\pi}\int_0^{\pi} U\sin\theta\,d\theta\,d\phi$, and the **directivity** is $D = 4\pi U_{\max}/P$, the ratio of peak intensity to the average over all directions.

(a) *Short (Hertzian) dipole,* $U = U_0\sin^2\theta$:

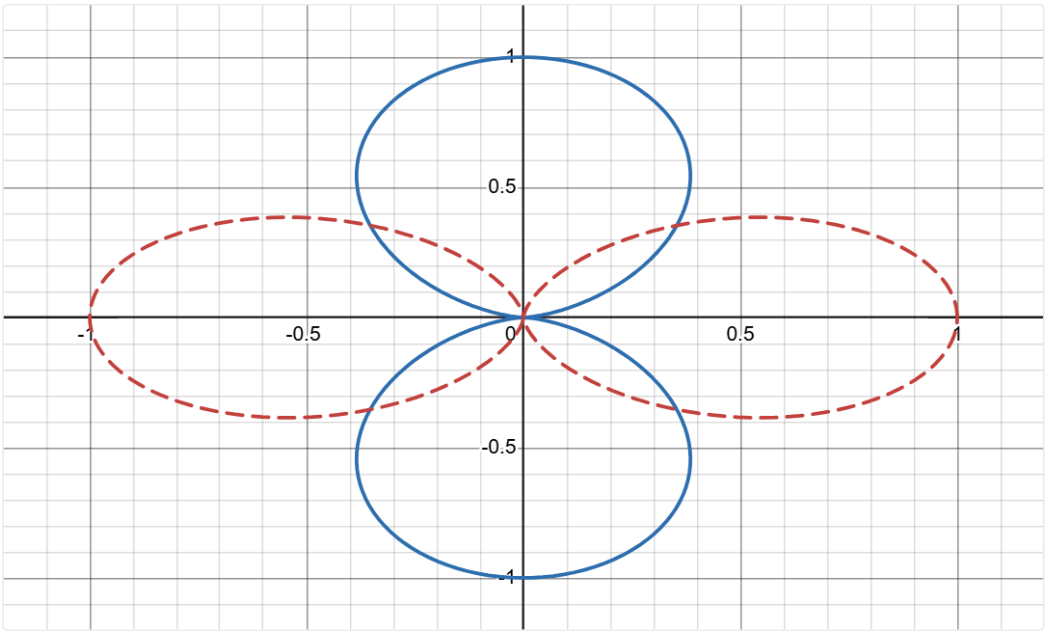
$$P = 2\pi U_0\int_0^{\pi}\sin^3\theta\,d\theta = 2\pi U_0\cdot\frac{4}{3} = \frac{8\pi U_0}{3},$$

using $\sin^3\theta = (1-\cos^2\theta)\sin\theta$ and $w = \cos\theta$: $\int_{-1}^{1}(1-w^2)\,dw = \tfrac{4}{3}$. Then $D = 4\pi U_0/(8\pi U_0/3) = 1.5$ (1.76 dBi), the textbook value for a short dipole.

(b) *A pattern radiating only into the upper hemisphere,* $U = U_0\cos^2\theta$ for $0 \le \theta \le \pi/2$ and zero below:

$$P = 2\pi U_0\int_0^{\pi/2}\cos^2\theta\sin\theta\,d\theta = 2\pi U_0\cdot\frac{1}{3} = \frac{2\pi U_0}{3}, \qquad D = \frac{4\pi U_0}{2\pi U_0/3} = 6\ (7.8\ \text{dBi}).$$

Concentrating the same peak intensity into a narrower beam reduces the total power needed — or, for fixed power, raises the peak — and directivity measures exactly that. Numerical quadrature of both angular integrals gives 1.3333 and 0.3333. ✓



Polar cuts through the z-axis, drawn with the antenna's z-axis along the horizontal: $\sin^2\theta$ (blue) is the figure-eight cross-section of the short dipole's doughnut, with nulls along the axis; $\cos^2\theta$ (red) points along the axis — in Example 6(b) only its right-hand lobe ($0 \le \theta \le \pi/2$) is present.

Engineering Note

The choice of coordinates is part of the modelling. A cylindrical problem (a long wire) in spherical coordinates is as awkward as a spherical one (a point charge) in Cartesian coordinates. Before setting up any multiple integral, ask: *on which coordinate surfaces are the boundaries, and on which coordinates does the integrand depend?* When both answers point to the same system, the integral usually separates into a product of three single integrals.

6.10 Constrained optimization

Motivation

Design is optimisation: maximise the power delivered to a load, minimise the loss in a network, fit a model to measured data with the least error, choose dimensions that use the least material. In one variable (Chapter 4) we set $f'(x) = 0$ and checked the sign of f''. With several variables the same ideas work, but "the sign of the second derivative" becomes a property of a matrix, and a new kind of critical point — the saddle — appears. Real problems almost always carry **constraints** as well: a fixed power budget, a fixed total current, a component that must fit in a box. This section treats unconstrained extrema first, then constraints handled by substitution and by searching boundaries; §6.11 gives the general method.

Local and global extrema

Extrema and critical points

f has a **local maximum** at $\mathbf{a}$ if $f(\mathbf{x}) \le f(\mathbf{a})$ for all $\mathbf{x}$ in some neighbourhood of $\mathbf{a}$, and a **global maximum** if this holds for all $\mathbf{x}$ in the domain (similarly for minima). A **critical point** (stationary point) is an interior point where $\nabla f = \mathbf{0}$, or where ∇f does not exist.

First-order necessary condition

If f is differentiable at an interior point $\mathbf{a}$ and has a local extremum there, then $\nabla f(\mathbf{a}) = \mathbf{0}$: every partial derivative vanishes, and the tangent plane is horizontal.

Proof. If f has a local maximum at $\mathbf{a}$, then the one-variable function $g(t) = f(\mathbf{a} + t\hat{\mathbf{x}}_i)$ has a local maximum at $t = 0$, so $g'(0) = f_{x_i}(\mathbf{a}) = 0$ by the one-variable result. This holds for each i. □

The condition is necessary, not sufficient. At a **saddle point** $\nabla f = \mathbf{0}$, yet f increases in some directions and decreases in others — like the middle of a mountain pass, or the origin for $f = x^2 - y^2$.

The second-derivative test

Near a critical point $\mathbf{a}$ the first-order terms of Taylor's formula (§6.3) vanish, leaving

$$f(\mathbf{a}+\mathbf{h}) - f(\mathbf{a}) \approx \tfrac{1}{2}\,\mathbf{h}^{\mathsf{T}}\mathbf{H}\,\mathbf{h} = \tfrac{1}{2}\left(f_{xx}h^2 + 2f_{xy}hk + f_{yy}k^2\right), \qquad \mathbf{h} = (h,k).$$

The sign of this **quadratic form** for small $\mathbf{h}$ in every direction decides the type of the point. Write $A = f_{xx}$, $B = f_{xy}$, $C = f_{yy}$ and, if $A \neq 0$, complete the square:

$$Ah^2 + 2Bhk + Ck^2 = A\left(h + \frac{B}{A}k\right)^2 + \frac{AC - B^2}{A}k^2.$$

If $D = AC - B^2 > 0$, both terms have the sign of A for every $(h, k) \neq \mathbf{0}$: the form is definite, positive (minimum) if $A > 0$ and negative (maximum) if $A < 0$. If $D < 0$, the two terms have opposite signs, so the form takes both signs: a saddle. If $D = 0$, the form vanishes along some direction and higher-order terms decide.

Second-derivative test (two variables)

Let $\nabla f(\mathbf{a}) = \mathbf{0}$, let f have continuous second partials near $\mathbf{a}$, and let $\mathbf{H} = \begin{bmatrix} f_{xx} & f_{xy} \\ f_{xy} & f_{yy} \end{bmatrix}$ with determinant $D = f_{xx} f_{yy} - f_{xy}^2$ at $\mathbf{a}$.

Condition at the critical point	Conclusion
$D > 0,\ f_{xx} > 0$	local minimum
$D > 0,\ f_{xx} < 0$	local maximum
$D < 0$	saddle point
$D = 0$	test inconclusive

In n variables the same reasoning applies to $\mathbf{h}^{\mathsf{T}}\mathbf{H}\mathbf{h}$: a critical point is a local minimum if $\mathbf{H}$ is **positive definite** (all eigenvalues positive), a local maximum if it is negative definite (all eigenvalues negative), and a saddle if $\mathbf{H}$ has eigenvalues of both signs. Equivalent tests via leading principal minors (Sylvester's criterion) and the eigenvalue theory are in Ch. 10; in two variables, $D > 0$ says the two eigenvalues have the same sign and f_{xx} says which.

Worked Example 1 — a minimum and a saddle

$f(x, y) = x^3 - 3x + y^2$.

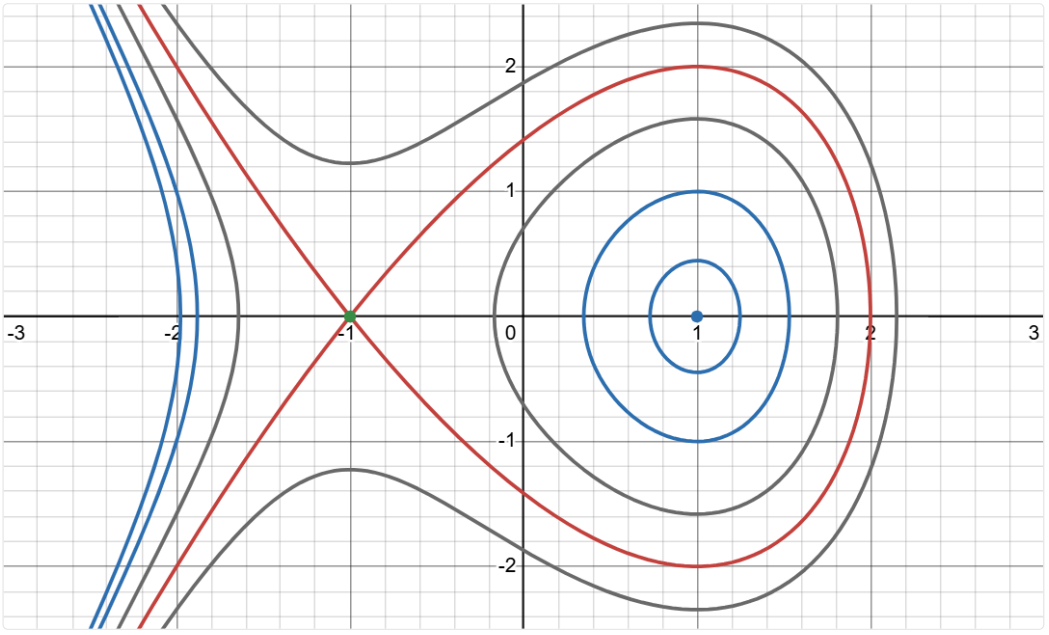
Critical points: $f_x = 3x^2 - 3 = 0$ and $f_y = 2y = 0$ give $(1, 0)$ and $(-1, 0)$.

Second partials: $f_{xx} = 6x$, $f_{yy} = 2$, $f_{xy} = 0$.

At $(1, 0)$: $D = 6 \cdot 2 - 0 = 12 > 0$ and $f_{xx} = 6 > 0$: **local minimum**, $f = -2$.

At $(-1, 0)$: $D = -6 \cdot 2 = -12 < 0$: **saddle point**, $f = 2$. Along the x-axis f has a local *maximum* at $x = -1$; along the line $x = -1$ it has a *minimum* in y.

Neither point is a global extremum: $f \to -\infty$ as $x \to -\infty$.



Level curves of $x^3 - 3x + y^2$: small closed loops (blue) surround the minimum at $(1, 0)$, while the level curve through the saddle (red, $f = 2$) crosses itself at $(-1, 0)$ — the signature of a saddle on a contour map.

Worked Example 2 — three critical points

$f(x,y) = x^4 + y^4 - 4xy$.

Critical points: $f_x = 4x^3 - 4y = 0$ gives $y = x^3$; $f_y = 4y^3 - 4x = 0$ gives $x = y^3 = x^9$. So $x(x^8 - 1) = 0$: $x = 0, \pm 1$, giving $(0,0)$, $(1,1)$, $(-1,-1)$.

Hessian: $\mathbf{H} = \begin{bmatrix} 12x^2 & -4 \\ -4 & 12y^2 \end{bmatrix}$.

At $(0,0)$: $D = 0 - 16 = -16 < 0$: saddle, $f = 0$.

At $(\pm 1, \pm 1)$: $D = 144 - 16 = 128 > 0$, $f_{xx} = 12 > 0$: local minima, $f = 1 + 1 - 4 = -2$.

Since $f \to +\infty$ in every direction (the quartic terms dominate), these two minima are also the **global** minima. Eigenvalue check at $(1,1)$: $\mathbf{H} = \begin{bmatrix} 12 & -4 \\ -4 & 12 \end{bmatrix}$ has eigenvalues 8 and 16, both positive. ✓

Worked Example 3 — least-squares line fit

A sensor is calibrated at four input levels, giving output voltages $(x_i, y_i) = (0,1), (1,3), (2,4), (3,7)$. Find the line $y = mx + b$ that minimises the sum of squared errors

$$S(m,b) = \sum_{i=1}^{4} (y_i - mx_i - b)^2 .$$

Critical point:

$$\frac{\partial S}{\partial m} = -2\sum x_i(y_i - mx_i - b) = 0, \qquad \frac{\partial S}{\partial b} = -2\sum (y_i - mx_i - b) = 0,$$

which are the **normal equations**

$$m\sum x_i^2 + b\sum x_i = \sum x_i y_i, \qquad m\sum x_i + nb = \sum y_i.$$

With $\sum x_i = 6$, $\sum x_i^2 = 14$, $\sum y_i = 15$, $\sum x_i y_i = 32$, $n = 4$: $14m + 6b = 32$ and $6m + 4b = 15$, so $m = 1.9$, $b = 0.9$.

Is it a minimum? $\mathbf{H} = 2\begin{bmatrix} \sum x_i^2 & \sum x_i \\ \sum x_i & n \end{bmatrix} = \begin{bmatrix} 28 & 12 \\ 12 & 8 \end{bmatrix}$, $D = 224 - 144 = 80 > 0$, $S_{mm} = 28 > 0$: yes — and since S is a quadratic with positive-definite Hessian, it is the global minimum.

Residuals: $0.1,\ 0.2,\ -0.7,\ 0.4$, which sum to zero (that is the second normal equation), with $S_{\min} = 0.70\ \text{V}^2$. The same calculation with many parameters is linear least squares, treated with matrices in Ch. 9 and statistically in Ch. 20.

Worked Example 4 — maximum power transfer to a complex load

A source with open-circuit RMS voltage V_s and internal impedance $Z_s = R_s + jX_s$ drives a load $Z_L = R_L + jX_L$. The load power is

$$P(R_L, X_L) = \frac{V_s^2 R_L}{(R_s + R_L)^2 + (X_s + X_L)^2}, \qquad R_L > 0.$$

Reactance first: $P_{X_L} = -\dfrac{2V_s^2 R_L (X_s + X_L)}{[(R_s + R_L)^2 + (X_s + X_L)^2]^2} = 0$ gives $X_L = -X_s$.

Then resistance: with $X_L = -X_s$, $P = V_s^2 R_L / (R_s + R_L)^2$ and $P_{R_L} = V_s^2 \dfrac{(R_s + R_L) - 2R_L}{(R_s + R_L)^3} = 0$ gives $R_L = R_s$.

So the only critical point is $Z_L = Z_s^*$ — the **conjugate match** — with $P_{\max} = V_s^2/(4R_s)$. For $V_s = 10$ V and $Z_s = 50 + j30\ \Omega$: $Z_L = 50 - j30\ \Omega$ and $P_{\max} = 100/200 = 0.5$ W.

Classification: at the critical point one finds $P_{R_L R_L} = P_{X_L X_L} = -V_s^2/(8R_s^3) < 0$ and $P_{R_L X_L} = 0$, so $D = V_s^4/(64R_s^6) > 0$ with $P_{R_L R_L} < 0$: a maximum. (Units: W/Ω^2, as a second derivative of power with respect to resistance must be.) Physically obvious too — $P \to 0$ as $R_L \to 0$, as $R_L \to \infty$ or as $|X_L| \to \infty$, so the single critical point must be the global maximum.

Common Pitfall

Checking only one variable at a time. A point can be a minimum along the x-direction and along the y-direction and still be a saddle: $f = x^2 + y^2 - 3xy$ has $f_{xx} = f_{yy} = 2 > 0$ at the origin, yet $D = 4 - 9 < 0$, and along $y = x$, $f = -x^2$ decreases. The mixed derivative f_{xy} — the twist — must be included, which is exactly what D does.

Constraints by substitution

A **constrained** problem reads

$$\text{optimise } f(\mathbf{x}) \quad \text{subject to} \quad g(\mathbf{x}) = c.$$

If the constraint can be solved for one variable, substitute and reduce the problem to an unconstrained one in fewer variables.

Worked Example 5 — an enclosure of minimum material

An open-top rectangular enclosure must hold 32 cm^3. Minimise the sheet-metal area $A = xy + 2xz + 2yz$ subject to $xyz = 32$.

Substitute $z = 32/(xy)$:

$$A(x, y) = xy + \frac{64}{y} + \frac{64}{x}, \qquad x, y > 0.$$

Critical point: $A_x = y - 64/x^2 = 0$, $A_y = x - 64/y^2 = 0$. So $yx^2 = 64$ and $xy^2 = 64$; dividing, $x = y$, then $x^3 = 64$, $x = y = 4$ cm, $z = 2$ cm.

Classify: $A_{xx} = 128/x^3 = 2$, $A_{yy} = 2$, $A_{xy} = 1$; $D = 4 - 1 = 3 > 0$, $A_{xx} > 0$: minimum, $A = 16 + 32 + 32 = 48$ cm^2. The open top makes the optimal box half as tall as it is wide.

Global extrema on closed, bounded regions

Extreme value theorem

A continuous function on a **closed and bounded** region attains a global maximum and a global minimum there. They occur either at interior critical points or on the boundary.

Hence the **closed-region method**:

1. Find the critical points of f inside the region and evaluate f there.
2. Find the extreme values of f on the boundary — a constrained problem, solved by parametrising or substituting (or by Lagrange multipliers, §6.11). Include corners and endpoints of boundary pieces.
3. The largest value from steps 1–2 is the global maximum, the smallest the global minimum.

Worked Example 6 — extremes on a disc

Find the extreme values of $T(x, y) = x^2 + 2y^2 - x$ on the disc $x^2 + y^2 \le 1$.

Interior: $T_x = 2x - 1 = 0$, $T_y = 4y = 0$ give $(\tfrac{1}{2}, 0)$, with $T = -\tfrac{1}{4}$.

Boundary: substitute $y^2 = 1 - x^2$: $T = x^2 + 2(1 - x^2) - x = 2 - x - x^2$ for $-1 \le x \le 1$. Then $dT/dx = -1 - 2x = 0$ gives $x = -\tfrac{1}{2}$, $y = \pm\tfrac{\sqrt{3}}{2}$, $T = 2 + \tfrac{1}{2} - \tfrac{1}{4} = \tfrac{9}{4}$. The endpoints of the x-interval give $T(1, 0) = 0$ and $T(-1, 0) = 2$.

Compare: $\{-\tfrac{1}{4},\ \tfrac{9}{4},\ 0,\ 2\}$: global maximum $\tfrac{9}{4}$ at $(-\tfrac{1}{2}, \pm\tfrac{\sqrt{3}}{2})$; global minimum $-\tfrac{1}{4}$ at $(\tfrac{1}{2}, 0)$.

Alternatively, parametrise the circle as $(\cos t, \sin t)$: $T = \cos^2 t + 2\sin^2 t - \cos t = 1 + \sin^2 t - \cos t$, and $dT/dt = \sin t(2\cos t + 1) = 0$ gives the same four boundary candidates.

Substitution becomes awkward when the constraint cannot be solved explicitly (try solving $x^3 + y^3 + xy = 5$ for y), when it breaks the symmetry between variables, or when there are several constraints. Lagrange's method, next, avoids all three problems.

Engineering Note

Most practical optimisation problems are solved numerically (Ch. 23), but the analysis of this section remains essential: it tells you what the optimiser should find, whether the problem has one solution or several, and whether the point it returns is a minimum or merely a saddle where the gradient happens to vanish. Convex problems — those whose Hessian is positive semidefinite everywhere, like least squares — have no saddles and no spurious local minima, which is why engineers work hard to formulate problems in convex form.

6.11 Lagrange multipliers

Motivation

Substitution solves a constrained problem by eliminating variables, which requires solving the constraint and usually destroys any symmetry the problem had. Lagrange's method keeps all the variables and treats them even-handedly, handles several constraints at once, and — as a bonus — produces a number, the multiplier, that measures how much the optimum would improve if the constraint were relaxed. In engineering that number is often the most useful output of the whole calculation: it is the marginal value of an extra watt of power budget, an extra square centimetre of board area, an extra volt of supply.

The geometric idea

Consider maximising $f(x, y)$ along the curve $g(x, y) = c$. Walk along the constraint curve and watch the level curves of f that you cross. If at some point you are *crossing* a level curve of f transversally, then moving one way along the constraint increases f and the other way decreases it — so that point is not an extremum. At a constrained extremum, therefore, the level curve of f through the point must be **tangent** to the constraint curve. Tangent curves have parallel normals, and the normals are the gradients (§6.4). Hence at the extremum

$$\nabla f = \lambda \nabla g$$

for some scalar λ. The same argument in three dimensions says that ∇f must be perpendicular to the constraint surface, i.e. parallel to its normal ∇g.

An equivalent analytic view: let $\mathbf{r}(t)$ be any curve lying in the constraint set and passing through the extremum $\mathbf{x}^*$ at $t = 0$. Then $f(\mathbf{r}(t))$ has an extremum at $t = 0$, so $\nabla f(\mathbf{x}^*) \cdot \mathbf{r}'(0) = 0$. Thus ∇f is perpendicular to every tangent direction of the constraint set — and the only vectors with that property are multiples of ∇g (or, with several constraints, combinations of the ∇g_k).

The method

Method of Lagrange multipliers

Let f and g have continuous first partial derivatives. If f has a local extremum at $\mathbf{x}^*$ subject to $g(\mathbf{x}) = c$, and $\nabla g(\mathbf{x}^*) \neq \mathbf{0}$, then there is a scalar λ such that

$$\nabla f(\mathbf{x}^*) = \lambda \, \nabla g(\mathbf{x}^*), \qquad g(\mathbf{x}^*) = c.$$

Equivalently, $(\mathbf{x}^*, \lambda)$ is a stationary point of the **Lagrangian**

$$\mathcal{L}(\mathbf{x}, \lambda) = f(\mathbf{x}) - \lambda \, \big(g(\mathbf{x}) - c\big) \, :$$

setting $\partial \mathcal{L} / \partial x_i = 0$ reproduces $\nabla f = \lambda \nabla g$, and $\partial \mathcal{L} / \partial \lambda = 0$ reproduces the constraint.

With several constraints $g_1 = c_1, \dots, g_m = c_m$ (and the ∇g_k linearly independent at $\mathbf{x}^*$), the condition becomes

$$\nabla f = \lambda_1 \nabla g_1 + \cdots + \lambda_m \nabla g_m, \qquad g_k = c_k.$$

For n variables and m constraints this is $n + m$ equations in $n + m$ unknowns. The procedure:

1. Write down $\nabla f = \lambda \nabla g$ component by component, together with the constraint.
2. Solve the system. There is no general algorithm — the equations are nonlinear — but useful tricks are: divide equations to eliminate λ; consider separately the cases where a factor is zero; exploit symmetry.
3. Evaluate f at **every** candidate and compare. Also check points where $\nabla g = \mathbf{0}$ and, for constraint curves with ends, the endpoints.

Worked Example 1 — a linear function on a circle

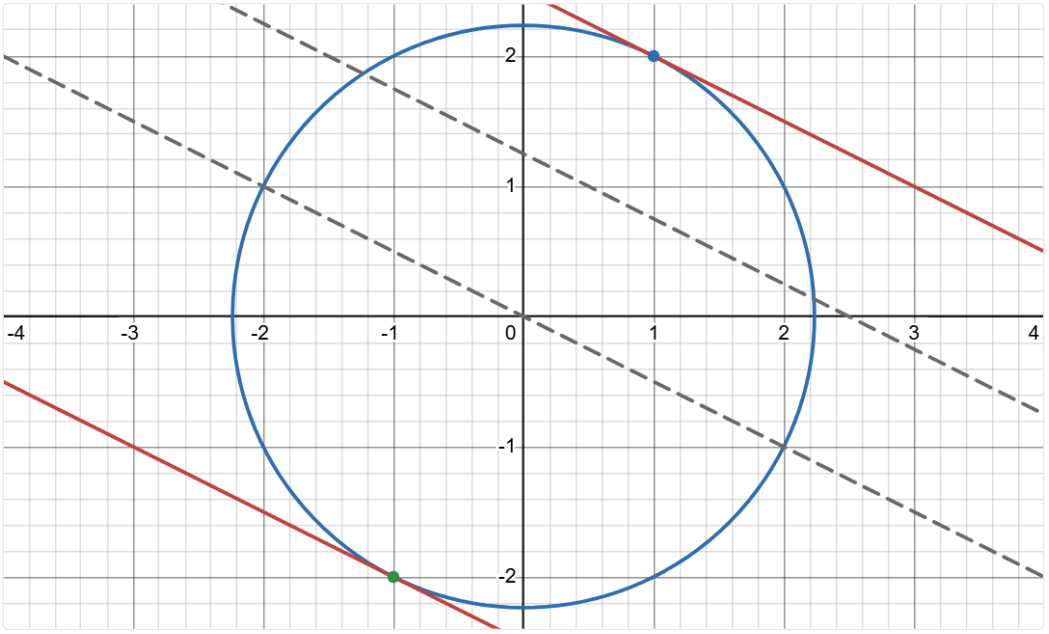
Extremise $f = x + 2y$ subject to $x^2 + y^2 = 5$.

Conditions: $\nabla f = (1, 2) = \lambda(2x, 2y)$ gives $1 = 2\lambda x$ and $2 = 2\lambda y$. Neither x nor λ can be zero, so dividing, $y/x = 2$, i.e. $y = 2x$.

Constraint: $x^2 + 4x^2 = 5$, $x = \pm 1$.

Candidates: $(1, 2)$ with $f = 5$ (maximum) and $(-1, -2)$ with $f = -5$ (minimum); $\lambda = 1/(2x) = \pm\frac{1}{2}$.

The answer is the Cauchy–Schwarz inequality in action: $|(1, 2) \cdot (x, y)| \leq \|(1, 2)\| \, \|(x, y)\| = \sqrt{5} \cdot \sqrt{5} = 5$, with equality when (x, y) is parallel to $(1, 2)$.



Level lines of $f = x + 2y$ (red and grey) sweep across the circle; the extremes occur where a level line just touches it — there the gradients of f and g are parallel.

Worked Example 2 — the disc boundary revisited

On $x^2 + y^2 = 1$, extremise $T = x^2 + 2y^2 - x$ (the boundary step of §6.10, Worked Example 6).

Conditions: $(2x - 1,\ 4y) = \lambda(2x,\ 2y)$. The second component gives $4y = 2\lambda y$, so **either** $y = 0$ **or** $\lambda = 2$.

Case $y = 0$: the constraint gives $x = \pm 1$, with $T(1, 0) = 0$ and $T(-1, 0) = 2$.

Case $\lambda = 2$: the first component gives $2x - 1 = 4x$, $x = -\tfrac{1}{2}$, and the constraint $y = \pm\tfrac{\sqrt{3}}{2}$, with $T = \tfrac{9}{4}$.

These are the same four candidates found by substitution, but obtained without breaking the symmetry of the constraint — and the case split "$y = 0$ or $\lambda = 2$" is the standard way such systems open up. Note that the substitution method found $(\pm 1, 0)$ only as *endpoints* of the x-interval; Lagrange's method finds them as genuine critical points of the constrained problem.

Worked Example 3 — closest point on a plane

Find the point of the plane $x + 2y + 2z = 9$ closest to the origin.

Minimise the squared distance $f = x^2 + y^2 + z^2$ (same minimiser as the distance, simpler derivatives).

Conditions: $(2x, 2y, 2z) = \lambda(1, 2, 2)$, so $(x, y, z) = \tfrac{\lambda}{2}(1, 2, 2)$: the closest point lies along the plane's normal, as geometry demands.

Constraint: $\tfrac{\lambda}{2}(1 + 4 + 4) = 9$, $\lambda = 2$, giving $(1, 2, 2)$ at distance 3.

Check: the point-to-plane distance formula gives $9/\sqrt{1^2 + 2^2 + 2^2} = 3$. ✓ No comparison of candidates is needed: there is only one, and f grows without bound on the plane, so it must be the minimum.

Worked Example 4 — the current divider minimises dissipation

A current I splits between resistors R_1 and R_2 in parallel. Ask which split $I_1 + I_2 = I$ **minimises** the total dissipation $P = R_1 I_1^2 + R_2 I_2^2$.

Conditions:

$$2R_1 I_1 = \lambda, \qquad 2R_2 I_2 = \lambda, \qquad I_1 + I_2 = I.$$

Hence $R_1 I_1 = R_2 I_2$ — equal voltages across both branches — and

$$I_1 = \frac{R_2}{R_1 + R_2} I, \qquad I_2 = \frac{R_1}{R_1 + R_2} I, \qquad P_{\min} = \frac{R_1 R_2}{R_1 + R_2} I^2.$$

That is exactly the current-divider rule: in a resistive network, currents distribute themselves so as to minimise heat (Maxwell's minimum-heat theorem). Here $\lambda = 2R_1 I_1 = 2IR_1R_2/(R_1 + R_2)$, twice the common branch voltage, in volts.

Numbers: $R_1 = 1\ \text{k}\Omega$, $R_2 = 4\ \text{k}\Omega$, $I = 10\ \text{mA}$: $I_1 = 8\ \text{mA}$, $I_2 = 2\ \text{mA}$, $P_{\min} = 800\ \Omega \times 10^{-4}\ \text{A}^2 = 80\ \text{mW}$. An equal split (5 mA each) would dissipate $25 + 100 = 125\ \text{mW}$.

The meaning of λ

Sensitivity interpretation of the multiplier

Let $\mathbf{x}^*(c)$ be the constrained optimum as a function of the constraint level c, with multiplier $\lambda(c)$, and let $f^*(c) = f(\mathbf{x}^*(c))$ be the optimal value. If $\mathbf{x}^*(c)$ depends differentiably on c, then

$$\lambda = \frac{df^*}{dc}.$$

Proof. By the chain rule, $\dfrac{df^*}{dc} = \nabla f(\mathbf{x}^*) \cdot \dfrac{d\mathbf{x}^*}{dc} = \lambda\, \nabla g(\mathbf{x}^*) \cdot \dfrac{d\mathbf{x}^*}{dc}$. But $g(\mathbf{x}^*(c)) = c$ for all c, so differentiating, $\nabla g \cdot \dfrac{d\mathbf{x}^*}{dc} = 1$. Hence $df^*/dc = \lambda$. □

So λ is the **shadow price** of the constraint: how much the optimal value improves per unit relaxation of the constraint. Its units are (units of f)/(units of g).

Check on Worked Example 1: with $x^2 + y^2 = c$, the maximum is $f^* = \sqrt{5c}$, so $df^*/dc = \sqrt{5}/(2\sqrt{c}) = \tfrac{1}{2}$ at $c = 5$ — and indeed $\lambda = \tfrac{1}{2}$ at $(1, 2)$. ✓

Check on Worked Example 4: $dP_{\min}/dI = 2IR_1R_2/(R_1 + R_2) = \lambda$. ✓ With the numbers above, $\lambda = 16\ \text{V}$: each extra milliampere of total current costs about 16 mW of extra dissipation.

Check on the enclosure of §6.10: with $\mathcal{L} = xy + 2xz + 2yz - \lambda(xyz - V)$, the conditions $y + 2z = \lambda yz$, $x + 2z = \lambda xz$, $2x + 2y = \lambda xy$ at $(4, 4, 2)$ give $\lambda = 1\ \text{cm}^{-1}$. Scaling says the optimal area grows as $A^* = 48\,(V/32)^{2/3}$, so $dA^*/dV = \tfrac{2}{3} \cdot \tfrac{48}{32} = 1\ \text{cm}^2/\text{cm}^3$. ✓

Two constraints

Worked Example 5 — extremes on the intersection of a plane and a cylinder

Find the maximum and minimum of $f = x + 2y + 3z$ on the curve where the plane $x - y + z = 1$ meets the cylinder $x^2 + y^2 = 1$ (an ellipse).

Conditions: $\nabla f = \lambda \nabla g_1 + \mu \nabla g_2$ with $g_1 = x - y + z$, $g_2 = x^2 + y^2$:

$$1 = \lambda + 2\mu x, \qquad 2 = -\lambda + 2\mu y, \qquad 3 = \lambda.$$

Solve: $\lambda = 3$, so $2\mu x = -2$ and $2\mu y = 5$: $x = -1/\mu$, $y = 5/(2\mu)$. The cylinder gives $\dfrac{1}{\mu^2} + \dfrac{25}{4\mu^2} = 1$, $\mu^2 = \dfrac{29}{4}$, $\mu = \pm\dfrac{\sqrt{29}}{2}$.

Then $x = \mp\dfrac{2}{\sqrt{29}}$, $y = \pm\dfrac{5}{\sqrt{29}}$, and the plane gives $z = 1 - x + y = 1 \pm \dfrac{7}{\sqrt{29}}$.

Values: $f = x + 2y + 3z = \pm\dfrac{-2 + 10 + 21}{\sqrt{29}} + 3 = 3 \pm \sqrt{29}$.

So the maximum is $3 + \sqrt{29} \approx 8.385$ at $(-0.3714,\ 0.9285,\ 2.2999)$ and the minimum $3 - \sqrt{29} \approx -2.385$. A numerical constrained optimiser started from $(1, 0, 0)$ returns the same maximiser to six figures. ✓

Second-order check: the bordered Hessian

Lagrange's condition is necessary, not sufficient. When comparing candidate values is impractical, a second-order test is available. For two variables and one constraint, form the **bordered Hessian**

$$\bar{\mathbf{H}} = \begin{bmatrix} 0 & g_x & g_y \\ g_x & \mathcal{L}_{xx} & \mathcal{L}_{xy} \\ g_y & \mathcal{L}_{xy} & \mathcal{L}_{yy} \end{bmatrix}$$

at the candidate. If $\det \bar{\mathbf{H}} > 0$ the point is a constrained local maximum; if $\det \bar{\mathbf{H}} < 0$, a constrained local minimum. (The test asks whether the Hessian of $\mathcal{L}$ is negative or positive definite *along the constraint's tangent direction*, which is all that matters.) For Worked Example 1 at $(1, 2)$ with $\lambda = \frac{1}{2}$: $\mathcal{L}_{xx} = \mathcal{L}_{yy} = -2\lambda = -1$, $\mathcal{L}_{xy} = 0$, $g_x = 2$, $g_y = 4$, and $\det \bar{\mathbf{H}} = 0 - 2(2 \cdot (-1) - 0) + 4(0 - 4 \cdot (-1)) = 4 + 16 = 20 > 0$: a maximum. ✓

Common Pitfall

Three ways to lose a solution. (1) Dividing by a quantity that might be zero — in Worked Example 2, dividing $4y = 2\lambda y$ by y loses the candidates with $y = 0$; factor instead and treat each case. (2) Ignoring points where $\nabla g = \mathbf{0}$: the theorem says nothing there (minimise $f = x$ on the cusp curve $y^2 = x^3$; the minimum at the origin, where $\nabla g = \mathbf{0}$, does not satisfy $\nabla f = \lambda \nabla g$). (3) Forgetting endpoints of a constraint curve that is not closed. And always remember that a Lagrange point may be a maximum, a minimum or neither — compare values.

Inequality constraints and water-filling

Engineering limits are usually inequalities — a power budget $\sum p_i \le P$, a current limit, non-negative powers $p_i \ge 0$. The extension of Lagrange's method is the set of **Karush–Kuhn–Tucker (KKT) conditions**: each inequality gets a multiplier that must be non-negative, and that multiplier is zero unless its constraint is **active** (holds with equality) — "complementary slackness". In effect, inactive constraints are ignored and active ones are treated as equalities; the work lies in finding which are active. The full theory is in Ch. 23; the classic EE example shows the idea.

Worked Example 6 — water-filling power allocation

A transmitter shares total power P between two parallel channels with noise powers $N_1 = 1$ and $N_2 = 3$ (in the same units as power). The total capacity in bit/s/Hz is

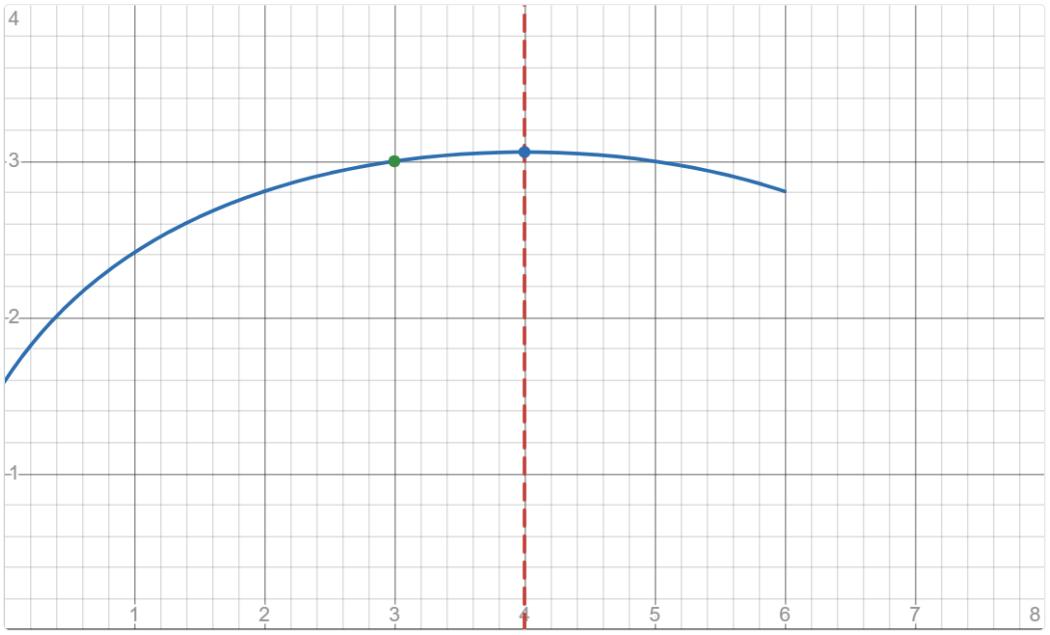
$$C = \log_2\!\left(1 + \frac{p_1}{N_1}\right) + \log_2\!\left(1 + \frac{p_2}{N_2}\right), \qquad p_1 + p_2 = P,\ \ p_1, p_2 \ge 0.$$

Lagrange conditions (both channels active): $\dfrac{1}{\ln 2} \cdot \dfrac{1}{N_i + p_i} = \lambda$, so $N_i + p_i = \nu$ with the same "water level" $\nu = 1/(\lambda \ln 2)$ for both channels.

With $P = 6$: $p_1 = \nu - 1$, $p_2 = \nu - 3$, sum $2\nu - 4 = 6$, $\nu = 5$: $p_1 = 4$, $p_2 = 2$, both non-negative, so both constraints $p_i \ge 0$ are inactive and the solution stands. Then $C = \log_2 5 + \log_2 \frac{5}{3} = 2.322 + 0.737 = 3.059$ bit/s/Hz, better than an equal split ($p_1 = p_2 = 3$: $\log_2 4 + \log_2 2 = 3$ bit/s/Hz).

With $P = 1$: the same formulas would give $\nu = 2.5$ and $p_2 = -0.5 < 0$ — impossible. So the constraint $p_2 \ge 0$ is active: $p_2 = 0$, and all power goes to the quieter channel, $p_1 = 1$, with water level $\nu = N_1 + p_1 = 2$, below the noise "floor" $N_2 = 3$ of channel 2. Then $C = \log_2 2 = 1$ bit/s/Hz.

The picture: pour total power P like water into a vessel whose floor heights are the noise levels N_i; it settles at a common level ν, and channels whose floor lies above the water get nothing. The rule "pour into the quietest channels first" is how DSL, Wi-Fi (OFDM) and MIMO systems allocate power across sub-channels.



Capacity versus the power p_1 given to the quieter channel (total $P = 6$): the curve is concave with a single maximum at $p_1 = 4$, where the marginal capacity per watt — the multiplier λ — is the same in both channels.

Engineering Note

The multiplier is often the quantity of real interest. In economic dispatch of power stations, the multiplier on the "generation equals demand" constraint is the system marginal cost (the price of one more MWh). In the water-filling example it is the marginal capacity per watt. In circuit design, it tells you which constraint — area, power, a noise specification — is binding and how much it is costing you, so you know where relaxing a specification would pay off most.

Summary

Concept	Key formula
Limit along all paths	polar test: $\lvert f - L\rvert \le g(r) \to 0$ independent of θ
Partial derivative	$f_x = \lim_{h\to 0} \dfrac{f(x+h,y) - f(x,y)}{h}$ (other variables fixed)
Normalised sensitivity	$S_x^f = \dfrac{x}{f}\dfrac{\partial f}{\partial x} = \dfrac{\partial \ln f}{\partial \ln x}$
Clairaut	$f_{xy} = f_{yx}$ (continuous second partials)
Total differential	$df = f_x\,dx + f_y\,dy = \nabla f \cdot d\mathbf{r}$
Tangent plane	$z = f(a,b) + f_x(a,b)(x-a) + f_y(a,b)(y-b)$
Worst-case / RSS error	$\sum \lvert f_{x_i}\rvert \Delta x_i \,/\, \sqrt{\sum (f_{x_i}\Delta x_i)^2}$
Relative error, $f = kx^a y^b$	$df/f = a\,dx/x + b\,dy/y$
Chain rule	$\dfrac{dz}{dt} = f_x\dot{x} + f_y\dot{y}$; $\mathbf{J}_{\mathbf{F}\circ\mathbf{G}} = \mathbf{J}_\mathbf{F}\mathbf{J}_\mathbf{G}$
Implicit derivative	$dy/dx = -F_x/F_y$; $\partial z/\partial x = -F_x/F_z$
Exact differential test	$M\,dx + N\,dy$ exact $\iff M_y = N_x$
Second-order Taylor	$f(\mathbf{a}+\mathbf{h}) \approx f + \nabla f\cdot\mathbf{h} + \tfrac{1}{2}\mathbf{h}^\mathsf{T}\mathbf{H}\mathbf{h}$
Gradient	$\nabla f = (f_x, f_y, f_z)$; normal to level sets; $\lVert\nabla f\rVert$ = max rate
Useful gradients	$\nabla R = \hat{\mathbf{R}}$, $\nabla(1/R) = -\hat{\mathbf{R}}/R^2$, $\mathbf{E} = -\nabla V$
Gradient descent	$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha\nabla f(\mathbf{x}_k)$
Directional derivative	$D_{\hat{\mathbf{u}}} f = \nabla f\cdot\hat{\mathbf{u}} = \lVert\nabla f\rVert\cos\theta$
Jacobian / linearisation	$(\mathbf{J})_{ij} = \partial F_i/\partial x_j$; $d\mathbf{F} = \mathbf{J}\,d\mathbf{x}$
Inverse function	$\mathbf{J}_{\mathbf{F}^{-1}} = \mathbf{J}_\mathbf{F}^{-1}$
Solution sensitivity	$\partial\mathbf{x}/\partial\mathbf{p} = -\mathbf{J}_\mathbf{x}^{-1}\mathbf{J}_\mathbf{p}$
Newton's method	$\mathbf{J}(\mathbf{x}_k)\Delta\mathbf{x} = -\mathbf{F}(\mathbf{x}_k)$
Fubini (type I)	$\iint_R f\,dA = \int_a^b \int_{g_1(x)}^{g_2(x)} f\,dy\,dx$
Change of variables	$dx\,dy = \left\lvert\dfrac{\partial(x,y)}{\partial(u,v)}\right\rvert du\,dv$
Polar	$dA = r\,dr\,d\theta$; $\int_{-\infty}^{\infty} e^{-x^2}dx = \sqrt{\pi}$

Concept	Key formula
Cylindrical	$dV = r\,dr\,d\phi\,dz$; scale factors $(1, r, 1)$
Spherical	$dV = R^2 \sin\theta\,dR\,d\theta\,d\phi$; scale factors $(1, R, R\sin\theta)$
Solid angle	$d\Omega = \sin\theta\,d\theta\,d\phi$; cone: $2\pi(1-\cos\alpha)$; sphere: 4π
Second-derivative test	$D = f_{xx}f_{yy} - f_{xy}^2$: $D>0$ extremum (sign of f_{xx}), $D<0$ saddle
Lagrange multipliers	$\nabla f = \lambda \nabla g,\ g = c$; several: $\nabla f = \sum \lambda_k \nabla g_k$
Multiplier sensitivity	$\lambda = df^*/dc$
Water-filling	$p_i = \max(0,\ \nu - N_i),\ \sum p_i = P$

Chapter 7 — Vector Calculus

> **Prerequisites:** Ch. 4, Ch. 5, Ch. 6 **Learning outcomes:** After this chapter you can
>
> - manipulate vectors in Cartesian, cylindrical and spherical bases, including dot, cross and triple products;
> - differentiate vector-valued functions and describe curves, velocities and field lines;
> - compute gradient, divergence, curl and Laplacian in all three coordinate systems and interpret them physically;
> - set up and evaluate line, surface and volume integrals, choosing parametrisations and orientations correctly;
> - state, apply and sketch the proofs of the theorems of Green, Stokes and Gauss (divergence theorem);
> - convert Maxwell's equations between integral and differential form, and use them to solve symmetric field problems.

Chapter 6 gave us functions of several variables and a first look at the gradient. This chapter adds the missing ingredient for field theory: **direction**. An electric field, a current density, a heat flux and the velocity of a fluid each attach a *vector* to every point of space. Engineers need to ask three kinds of question about such fields:

1. **Local questions** — at a point, how fast does a potential change, how much does a field spread out, how much does it swirl? The answers are the gradient, divergence and curl.
2. **Global questions** — how much work does a field do along a wire, how much of it flows through a surface, how much charge sits in a volume? The answers are line, surface and volume integrals.
3. **The bridge** — Green's, Stokes' and the divergence theorem say that a global integral over a boundary equals the integral of a local derivative over the inside. They are the multivariable versions of the fundamental theorem of calculus.

Put the three together and Maxwell's equations fall out in two equivalent forms — the integral form you measure, and the differential form you solve. That is the payoff in Section 7.12. Throughout, the methods are general; electromagnetics is the running motivation.

Conventions. Cartesian unit vectors are $\hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$. Cylindrical coordinates are (r, ϕ, z) with unit vectors $\hat{\mathbf{r}}, \hat{\boldsymbol{\phi}}, \hat{\mathbf{z}}$; spherical coordinates are (R, θ, ϕ) with θ the polar angle from $+z$ and unit vectors $\hat{\mathbf{R}}, \hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\phi}}$ (as in Ch. 6, §6.9). The position vector of a point is written $\mathbf{R} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}}$, with length $R = \|\mathbf{R}\|$, so that $\mathbf{R} = R\hat{\mathbf{R}}$ in spherical coordinates. A curve is written $\mathbf{r}(t)$ when it is parametrised by a variable t.

7.1 Scalars and vectors

Why the distinction matters

A **scalar** is a quantity fully described by one number (with a unit): temperature, voltage, charge, energy, resistance. A **vector** needs a magnitude *and* a direction: force, velocity, electric field, current density, magnetic flux density. Mixing them up is not a matter of taste — adding a scalar to a vector is meaningless, and the direction of a field is often the whole point (it decides, for example, whether a force accelerates or decelerates an electron, or whether flux enters or leaves a surface).

Vector

A **vector** in three-dimensional space is a quantity with magnitude and direction, which adds by the parallelogram rule. Relative to a right-handed orthonormal basis $\hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$ it is written

$$\mathbf{A} = A_x\hat{\mathbf{x}} + A_y\hat{\mathbf{y}} + A_z\hat{\mathbf{z}} = (A_x, A_y, A_z),$$

where the **components** A_x, A_y, A_z are scalars. Its **magnitude** is $\|\mathbf{A}\| = A = \sqrt{A_x^2 + A_y^2 + A_z^2}$ and, if $A \neq 0$, its **unit vector** is $\hat{\mathbf{a}}_A = \mathbf{A}/A$.

A vector is a geometric object; its components depend on the basis you choose. Rotating the axes changes the three numbers but not the arrow. This is why physical laws are written in vector form ($\mathbf{F} = q\mathbf{E}$) — they then hold in every coordinate system.

Algebra. Addition and scalar multiplication act component by component:

$$\mathbf{A} + \mathbf{B} = (A_x + B_x,\ A_y + B_y,\ A_z + B_z), \qquad c\mathbf{A} = (cA_x,\ cA_y,\ cA_z).$$

These obey the familiar laws: $\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$, $(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C})$, $c(\mathbf{A} + \mathbf{B}) = c\mathbf{A} + c\mathbf{B}$. The zero vector $\mathbf{0}$ has no direction. Geometrically, $\mathbf{A} + \mathbf{B}$ is the diagonal of the parallelogram spanned by $\mathbf{A}$ and $\mathbf{B}$, or equivalently the result of placing the tail of $\mathbf{B}$ at the head of $\mathbf{A}$.

Position and separation vectors

The **position vector** $\mathbf{R} = (x, y, z)$ points from the origin to the point $P(x, y, z)$. The vector from a *source point* P' at $\mathbf{R}'$ to a *field point* P at $\mathbf{R}$ is the **separation vector**

$$\mathbf{R} - \mathbf{R}' = (x - x',\ y - y',\ z - z'), \qquad \|\mathbf{R} - \mathbf{R}'\| = \sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2}.$$

Every inverse-square law in field theory is written in terms of it. Coulomb's law for the force on charge q at $\mathbf{R}$ due to charge q' at $\mathbf{R}'$ is

$$\mathbf{F} = \frac{qq'}{4\pi\varepsilon_0}\,\frac{\mathbf{R} - \mathbf{R}'}{\|\mathbf{R} - \mathbf{R}'\|^3}.$$

The cube in the denominator is not a typo: one power of the distance normalises the numerator to a unit vector, and the other two give the inverse-square law.

Worked Example — separation vector and unit vector

A point charge sits at $P'(1, 2, 0)$ m and we observe at $P(3, -1, 6)$ m. Find the separation vector, its length and its unit vector.

Step 1. $\mathbf{R} - \mathbf{R}' = (3-1,\ -1-2,\ 6-0) = (2, -3, 6)$ m.

Step 2. $\|\mathbf{R} - \mathbf{R}'\| = \sqrt{4 + 9 + 36} = \sqrt{49} = 7$ m.

Step 3. $\hat{\mathbf{a}} = (2, -3, 6)/7 = (0.2857,\ -0.4286,\ 0.8571)$. Check: $0.2857^2 + 0.4286^2 + 0.8571^2 = 0.0816 + 0.1837 + 0.7347 = 1.000$.

Worked Example — superposition of Coulomb forces

Charges $q_1 = +2$ nC at $(0, 0, 0)$ and $q_2 = -1$ nC at $(2, 0, 0)$ m act on a test charge $q = +1$ nC at $(0, 1, 0)$ m. Find the net force. Use $1/(4\pi\varepsilon_0) = 8.988 \times 10^9\ \mathrm{N\,m^2/C^2}$.

Step 1 — force from q_1. Separation $(0, 1, 0)$, length 1. $\mathbf{F}_1 = 8.988 \times 10^9 \cdot (2 \times 10^{-9})(1 \times 10^{-9})\,(0, 1, 0)/1^3 = (0,\ 17.98,\ 0)$ nN.

Step 2 — force from q_2. Separation $(0-2,\ 1-0,\ 0) = (-2, 1, 0)$, length $\sqrt{5}$, cube $5\sqrt{5} = 11.180$. $\mathbf{F}_2 = 8.988 \times 10^9 \cdot (-1 \times 10^{-9})(1 \times 10^{-9})\,(-2, 1, 0)/11.180 = (1.608,\ -0.804,\ 0)$ nN.

Step 3 — superpose. $\mathbf{F} = \mathbf{F}_1 + \mathbf{F}_2 = (1.608,\ 17.17,\ 0)$ nN, magnitude 17.25 nN, at $\arctan(17.17/1.608) = 84.6^\circ$ from $+x$.

The negative q_2 *attracts* the test charge towards $(2, 0, 0)$, which is why $F_{2x} > 0$ and $F_{2y} < 0$. Forces add as vectors, never as magnitudes.

Curvilinear bases

In cylindrical and spherical coordinates we also use orthonormal bases, but the basis vectors **change direction from point to point**. At a point with azimuth ϕ,

$$\hat{\mathbf{r}} = \cos\phi\,\hat{\mathbf{x}} + \sin\phi\,\hat{\mathbf{y}}, \qquad \hat{\boldsymbol{\phi}} = -\sin\phi\,\hat{\mathbf{x}} + \cos\phi\,\hat{\mathbf{y}}, \qquad \hat{\mathbf{z}} = \hat{\mathbf{z}},$$

and in spherical coordinates

$$\begin{aligned}
\hat{\mathbf{R}} &= \sin\theta\cos\phi\,\hat{\mathbf{x}} + \sin\theta\sin\phi\,\hat{\mathbf{y}} + \cos\theta\,\hat{\mathbf{z}},\\
\hat{\boldsymbol{\theta}} &= \cos\theta\cos\phi\,\hat{\mathbf{x}} + \cos\theta\sin\phi\,\hat{\mathbf{y}} - \sin\theta\,\hat{\mathbf{z}},\\
\hat{\boldsymbol{\phi}} &= -\sin\phi\,\hat{\mathbf{x}} + \cos\phi\,\hat{\mathbf{y}}.
\end{aligned}$$

Each unit vector points in the direction in which its own coordinate increases. Both triads are right-handed: $\hat{\mathbf{r}} \times \hat{\boldsymbol{\phi}} = \hat{\mathbf{z}}$ and $\hat{\mathbf{R}} \times \hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\phi}}$.

Because each triad is orthonormal, the component of $\mathbf{A}$ along a basis vector is a dot product (Section 7.2), and converting components is a rotation:

$$\begin{bmatrix} A_r \\ A_\phi \\ A_z \end{bmatrix} = \begin{bmatrix} \cos\phi & \sin\phi & 0 \\ -\sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} A_x \\ A_y \\ A_z \end{bmatrix},$$

$$\begin{bmatrix} A_R \\ A_\theta \\ A_\phi \end{bmatrix} = \begin{bmatrix} \sin\theta\cos\phi & \sin\theta\sin\phi & \cos\theta \\ \cos\theta\cos\phi & \cos\theta\sin\phi & -\sin\theta \\ -\sin\phi & \cos\phi & 0 \end{bmatrix} \begin{bmatrix} A_x \\ A_y \\ A_z \end{bmatrix}.$$

The matrices are orthogonal (rows are orthonormal), so the inverse conversion uses the transpose (Ch. 9).

Worked Example — Cartesian to cylindrical components

Express $\mathbf{A} = y\,\hat{\mathbf{x}} - x\,\hat{\mathbf{y}} + z\,\hat{\mathbf{z}}$ in cylindrical coordinates, and evaluate it at $(x, y, z) = (1, \sqrt{3}, 2)$.

Step 1. Substitute $x = r\cos\phi$, $y = r\sin\phi$: $A_x = r\sin\phi$, $A_y = -r\cos\phi$, $A_z = z$.

Step 2. Rotate: $A_r = \cos\phi\,(r\sin\phi) + \sin\phi\,(-r\cos\phi) = 0$, $A_\phi = -\sin\phi\,(r\sin\phi) + \cos\phi\,(-r\cos\phi) = -r$, $A_z = z$. So $\mathbf{A} = -r\,\hat{\boldsymbol{\phi}} + z\,\hat{\mathbf{z}}$ — a clockwise swirl (seen from $+z$) plus a vertical part. The cylindrical form makes the geometry obvious, which the Cartesian form hid.

Step 3. At $(1, \sqrt{3}, 2)$: $r = 2$, $\phi = 60^\circ$, so $\mathbf{A} = -2\hat{\boldsymbol{\phi}} + 2\hat{\mathbf{z}}$. Check in Cartesian: $\mathbf{A} = (\sqrt{3}, -1, 2)$, $\|\mathbf{A}\| = \sqrt{3 + 1 + 4} = \sqrt{8}$; cylindrical: $\sqrt{4 + 4} = \sqrt{8}$. ✓

Common Pitfall

You may **not** add the cylindrical or spherical components of vectors located at *different points*. $\hat{\mathbf{r}}$ at $\phi = 0$ is $\hat{\mathbf{x}}$, but at $\phi = \pi$ it is $-\hat{\mathbf{x}}$. Two vectors "$1\,\hat{\mathbf{r}}$" at those two points sum to zero, not to $2\hat{\mathbf{r}}$. Convert to Cartesian components before superposing contributions from many source points — this is exactly why field integrals such as the field of a ring of charge are done in Cartesian components.

Engineering Note

Field solvers and antenna-pattern software report fields in whichever basis matches the symmetry: a coaxial cable's $\mathbf{E}$ is purely $\hat{\mathbf{r}}$ and its $\mathbf{H}$ purely $\hat{\boldsymbol{\phi}}$; an antenna's far field is purely $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\phi}}$. Choosing the basis that matches the symmetry reduces a three-component problem to a one-component one.

7.2 Vector operations

There are two ways to multiply two vectors, and each answers a different geometric question. The dot product measures *how much two vectors agree*; the cross product measures *how much they span*.

The dot (scalar) product

Dot product

$$\mathbf{A}\cdot\mathbf{B} = AB\cos\theta_{AB} = A_xB_x + A_yB_y + A_zB_z,$$

where $\theta_{AB}\in[0,\pi]$ is the angle between the vectors.

Why the two forms agree. Apply the law of cosines to the triangle with sides $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{A}-\mathbf{B}$: $\|\mathbf{A}-\mathbf{B}\|^2 = A^2 + B^2 - 2AB\cos\theta_{AB}$. Expanding the left side in components gives $A^2+B^2-2(A_xB_x+A_yB_y+A_zB_z)$. Comparing the two proves the identity.

Properties: commutative, distributive, $\mathbf{A}\cdot\mathbf{A} = A^2$, and $\mathbf{A}\cdot\mathbf{B}=0$ iff the vectors are perpendicular (or one is zero). For orthonormal bases $\hat{\mathbf{x}}\cdot\hat{\mathbf{x}}=1$, $\hat{\mathbf{x}}\cdot\hat{\mathbf{y}}=0$, and so on.

Projection. The scalar component of $\mathbf{A}$ along a unit vector $\hat{\mathbf{u}}$ is $\mathbf{A}\cdot\hat{\mathbf{u}}$, and the vector projection is $(\mathbf{A}\cdot\hat{\mathbf{u}})\hat{\mathbf{u}}$. The rest, $\mathbf{A}-(\mathbf{A}\cdot\hat{\mathbf{u}})\hat{\mathbf{u}}$, is perpendicular to $\hat{\mathbf{u}}$. This decomposition into normal and tangential parts is used constantly at material boundaries.

Physically, the dot product appears whenever only the *aligned* part of a vector matters: work $dW = \mathbf{F}\cdot d\mathbf{l}$, flux $d\Phi = \mathbf{B}\cdot d\mathbf{S}$, power $p = \mathbf{F}\cdot\mathbf{v}$.

The cross (vector) product

Cross product

$$\mathbf{A}\times\mathbf{B} = AB\sin\theta_{AB}\,\hat{\mathbf{n}} = \begin{vmatrix}\hat{\mathbf{x}} & \hat{\mathbf{y}} & \hat{\mathbf{z}}\\ A_x & A_y & A_z\\ B_x & B_y & B_z\end{vmatrix} = (A_yB_z - A_zB_y,\; A_zB_x - A_xB_z,\; A_xB_y - A_yB_x),$$

where $\hat{\mathbf{n}}$ is the unit normal to the plane of $\mathbf{A}$ and $\mathbf{B}$ chosen by the **right-hand rule** (fingers from $\mathbf{A}$ to $\mathbf{B}$, thumb along $\hat{\mathbf{n}}$).

Key facts:

- $\|\mathbf{A}\times\mathbf{B}\| = AB\sin\theta_{AB}$ is the **area of the parallelogram** spanned by $\mathbf{A}$ and $\mathbf{B}$.
- $\mathbf{A}\times\mathbf{B}$ is perpendicular to both $\mathbf{A}$ and $\mathbf{B}$.
- **Anticommutative:** $\mathbf{B}\times\mathbf{A} = -\mathbf{A}\times\mathbf{B}$, hence $\mathbf{A}\times\mathbf{A}=\mathbf{0}$; parallel vectors have zero cross product.
- Distributive over addition, but **not associative**: $(\mathbf{A}\times\mathbf{B})\times\mathbf{C} \neq \mathbf{A}\times(\mathbf{B}\times\mathbf{C})$ in general.
- Cyclic basis rule: $\hat{\mathbf{x}}\times\hat{\mathbf{y}}=\hat{\mathbf{z}}$, $\hat{\mathbf{y}}\times\hat{\mathbf{z}}=\hat{\mathbf{x}}$, $\hat{\mathbf{z}}\times\hat{\mathbf{x}}=\hat{\mathbf{y}}$; the same cyclic rule holds for $(\hat{\mathbf{r}},\hat{\boldsymbol{\phi}},\hat{\mathbf{z}})$ and $(\hat{\mathbf{R}},\hat{\boldsymbol{\theta}},\hat{\boldsymbol{\phi}})$ at a given point.

Physically, the cross product appears whenever a "turning" or "sideways" effect occurs: torque $\boldsymbol{\tau}=\mathbf{r}\times\mathbf{F}$, the magnetic force $\mathbf{F}=q\mathbf{v}\times\mathbf{B}$, the Biot–Savart element $d\mathbf{B}\propto I\,d\mathbf{l}\times\hat{\mathbf{R}}/R^2$, the Poynting vector $\mathbf{S}=\mathbf{E}\times\mathbf{H}$, and the normal to a surface $\mathbf{r}_u\times\mathbf{r}_v$ (Section 7.7).

Triple products

Scalar and vector triple products

Scalar triple product.

$$\mathbf{A}\cdot(\mathbf{B}\times\mathbf{C}) = \begin{vmatrix}A_x & A_y & A_z\\ B_x & B_y & B_z\\ C_x & C_y & C_z\end{vmatrix} = \mathbf{B}\cdot(\mathbf{C}\times\mathbf{A}) = \mathbf{C}\cdot(\mathbf{A}\times\mathbf{B}).$$

Its absolute value is the volume of the parallelepiped with edges $\mathbf{A},\mathbf{B},\mathbf{C}$; it vanishes iff the three vectors are coplanar.

Vector triple product ("BAC–CAB").

$$\mathbf{A}\times(\mathbf{B}\times\mathbf{C}) = \mathbf{B}(\mathbf{A}\cdot\mathbf{C}) - \mathbf{C}(\mathbf{A}\cdot\mathbf{B}).$$

Proof sketch of BAC–CAB. Both sides are linear in each of $\mathbf{A},\mathbf{B},\mathbf{C}$, so it suffices to check basis vectors. The left side is perpendicular to $\mathbf{B}\times\mathbf{C}$, hence lies in the plane of $\mathbf{B}$ and $\mathbf{C}$; e.g. $\hat{\mathbf{x}}\times(\hat{\mathbf{x}}\times\hat{\mathbf{y}}) = \hat{\mathbf{x}}\times\hat{\mathbf{z}} = -\hat{\mathbf{y}}$, while the right side gives $\hat{\mathbf{x}}(0)-\hat{\mathbf{y}}(1) = -\hat{\mathbf{y}}$. The remaining cases are checked the same way. The identity reappears later with ∇ in place of $\mathbf{A}$ and $\mathbf{B}$: $\nabla\times(\nabla\times\mathbf{F}) = \nabla(\nabla\cdot\mathbf{F}) - \nabla^2\mathbf{F}$ (Section 7.5), the step that turns Maxwell's equations into the wave equation.

Worked Example — angle, projection and area

Let $\mathbf{A}=(1,2,2)$ and $\mathbf{B}=(3,0,4)$.

Angle. $\mathbf{A}\cdot\mathbf{B} = 3+0+8 = 11$, $A=3$, $B=5$, so $\cos\theta = 11/15$ and $\theta = 42.83^\circ$.

Projection of A on B. $\mathbf{A}\cdot\hat{\mathbf{B}} = 11/5 = 2.2$; vector projection $2.2\,(0.6,0,0.8) = (1.32,0,1.76)$. The perpendicular remainder is $(1,2,2) - (1.32,0,1.76) = (-0.32,2,0.24)$; check $(-0.32)(3)+0+(0.24)(4) = 0$. ✓

Cross product. $\mathbf{A}\times\mathbf{B} = (2\cdot4-2\cdot0,\; 2\cdot3-1\cdot4,\; 1\cdot0-2\cdot3) = (8,2,-6)$. Its length $\sqrt{64+4+36} = \sqrt{104} = 10.198$ should equal $AB\sin\theta = 15\sin42.83^\circ = 15\times0.6799 = 10.198$. ✓ So the triangle with sides $\mathbf{A}$ and $\mathbf{B}$ has area $\tfrac{1}{2}\sqrt{104} = 5.10$.

Worked Example — volume and coplanarity

Are $\mathbf{A}=(1,0,1)$, $\mathbf{B}=(2,1,0)$, $\mathbf{C}=(0,1,-2)$ coplanar?

$$\begin{vmatrix} 1 & 0 & 1 \\ 2 & 1 & 0 \\ 0 & 1 & -2 \end{vmatrix} = 1(1\cdot(-2)-0\cdot 1)-0+1(2\cdot 1-1\cdot 0) = -2+2 = 0.$$

Yes: $\mathbf{C}=\mathbf{B}-2\mathbf{A}$. Replacing $\mathbf{C}$ by $(0,1,2)$ gives determinant $1(2-0)+1(2)=4$, a parallelepiped of volume 4.

Worked Example — Lorentz force on an electron

An electron ($q=-1.602\times10^{-19}$ C) moves with $\mathbf{v}=(2\times10^{5},\ 0,\ 1\times10^{5})$ m/s through $\mathbf{E}=(0,\ 500,\ 0)$ V/m and $\mathbf{B}=(0,\ 0,\ 0.01)$ T. Find $\mathbf{F}=q(\mathbf{E}+\mathbf{v}\times\mathbf{B})$.

Step 1. $\mathbf{v}\times\mathbf{B}=(v_yB_z-v_zB_y,\ v_zB_x-v_xB_z,\ v_xB_y-v_yB_x)=(0,\ -2\times10^{3},\ 0)$ V/m. (Units: $\mathrm{m/s}\cdot\mathrm{T}=\mathrm{V/m}$.)

Step 2. $\mathbf{E}+\mathbf{v}\times\mathbf{B}=(0,\ 500-2000,\ 0)=(0,-1500,0)$ V/m.

Step 3. $\mathbf{F}=-1.602\times10^{-19}\cdot(0,-1500,0)=(0,\ 2.403\times10^{-16},\ 0)$ N.

The v_z component, parallel to $\mathbf{B}$, contributes nothing to the magnetic force — a cross product only sees the perpendicular part. Choosing $\mathbf{E}=(0,-v_xB_z,0)$ would cancel the force entirely: this is the velocity-selector (Wien filter) condition $E=vB$.

Common Pitfall

The cross product is defined only in three dimensions and depends on handedness. If you set up a left-handed axis system (for instance by drawing $\hat{\mathbf{y}}$ the wrong way on a page), every cross product — and every curl — changes sign. Always check $\hat{\mathbf{x}}\times\hat{\mathbf{y}}=\hat{\mathbf{z}}$ for your drawing.

Engineering Note

The dot product is the continuous cousin of the inner product used in signal processing (Ch. 9): correlating two signals is "dotting" them. For complex phasor fields the time-average power uses a conjugate, $\langle\mathbf{S}\rangle=\tfrac{1}{2}\,\mathrm{Re}\{\mathbf{E}\times\mathbf{H}^{*}\}$; forgetting the conjugate is a classic error.

7.3 Vector-valued functions

Definition and derivative

A trajectory, a wire, the tip of a rotating phasor, the path of an electron in a magnetron — each is a point moving through space as a parameter changes. We describe it with a vector-valued function.

Vector-valued function

A **vector-valued function** of one real variable assigns a vector to each t in an interval:

$$\mathbf{r}(t)=x(t)\hat{\mathbf{x}}+y(t)\hat{\mathbf{y}}+z(t)\hat{\mathbf{z}}.$$

Its **derivative** is

$$\mathbf{r}'(t)=\lim_{h\to0}\frac{\mathbf{r}(t+h)-\mathbf{r}(t)}{h}=x'(t)\hat{\mathbf{x}}+y'(t)\hat{\mathbf{y}}+z'(t)\hat{\mathbf{z}},$$

and its integral is likewise taken component by component. The curve is **smooth** if $\mathbf{r}'$ is continuous and never zero.

The componentwise rule works *only because* $\hat{\mathbf{x}},\hat{\mathbf{y}},\hat{\mathbf{z}}$ are constant. Geometrically, $\mathbf{r}(t+h)-\mathbf{r}(t)$ is a chord of the curve; dividing by h and letting $h\to0$ turns it into a **tangent vector**. If t is time, $\mathbf{r}'=\mathbf{v}$ is the velocity, $\|\mathbf{v}\|$ the speed, and $\mathbf{r}''=\mathbf{a}$ the acceleration.

Differentiation rules

For differentiable vector functions $\mathbf{A}(t),\mathbf{B}(t)$ and scalar $f(t)$:

$$\begin{aligned}(\mathbf{A}+\mathbf{B})'&=\mathbf{A}'+\mathbf{B}', & (f\mathbf{A})'&=f'\mathbf{A}+f\mathbf{A}',\\ (\mathbf{A}\cdot\mathbf{B})'&=\mathbf{A}'\cdot\mathbf{B}+\mathbf{A}\cdot\mathbf{B}', & (\mathbf{A}\times\mathbf{B})'&=\mathbf{A}'\times\mathbf{B}+\mathbf{A}\times\mathbf{B}',\\ \frac{d}{dt}\mathbf{A}(u(t))&=\mathbf{A}'(u)\,u'(t).\end{aligned}$$

In the cross-product rule the **order matters**.

Each rule follows by writing the product in components and applying the scalar product rule. A useful corollary: if $\|\mathbf{A}(t)\|$ is constant then $\mathbf{A}\cdot\mathbf{A}=\text{const}$, so $2\mathbf{A}\cdot\mathbf{A}'=0$ — **a vector of constant length is perpendicular to its own derivative.** A unit vector can only rotate, never stretch.

Arc length, unit tangent and curvature

The distance travelled along the curve from $t=a$ to $t=b$ is the **arc length**

$$s = \int_a^b \|\mathbf{r}'(t)\|\,dt = \int_a^b \sqrt{x'(t)^2 + y'(t)^2 + z'(t)^2}\,dt,$$

because a small step $d\mathbf{r} = \mathbf{r}'\,dt$ has length $ds = \|\mathbf{r}'\|\,dt$. The **unit tangent** is $\hat{\mathbf{T}} = \mathbf{r}'/\|\mathbf{r}'\|$, and the **curvature** $\kappa = \|d\hat{\mathbf{T}}/ds\|$ measures how fast the direction turns per metre. A convenient formula is

$$\kappa = \frac{\|\mathbf{r}' \times \mathbf{r}''\|}{\|\mathbf{r}'\|^3}.$$

A straight line has $\kappa = 0$; a circle of radius a has $\kappa = 1/a$. The arc length is independent of how the curve is parametrised: substituting $t = g(u)$ with $g' > 0$ multiplies $\|\mathbf{r}'\|$ by $g'(u)$ and dt by $1/g'(u)$ in reverse — the same cancellation that will make line integrals parametrisation-independent in Section 7.6.

Worked Example — length of a solenoid winding

A solenoid has radius $a = 5$ mm and pitch $p = 1$ mm per turn, with 100 turns. Find the wire length and the curvature of the wire.

Step 1 — parametrise. One turn is 2π of angle and advances p along z: $\mathbf{r}(t) = (a\cos t,\ a\sin t,\ bt)$ with $b = p/(2\pi) = 0.15915$ mm.

Step 2 — speed. $\mathbf{r}' = (-a\sin t,\ a\cos t,\ b)$, $\|\mathbf{r}'\| = \sqrt{a^2 + b^2} = \sqrt{25 + 0.02533} = 5.00253$ mm (constant).

Step 3 — length. $s = \int_0^{200\pi} \sqrt{a^2+b^2}\,dt = 200\pi \times 5.00253 = 3143.2$ mm $= 3.1432$ m. A flat-circle estimate $100 \times 2\pi a = 3.1416$ m is only 0.05 % low, because the pitch is small compared with the circumference.

Step 4 — curvature. $\mathbf{r}'' = (-a\cos t, -a\sin t, 0)$ and $\mathbf{r}' \times \mathbf{r}'' = (ab\sin t,\ -ab\cos t,\ a^2)$ with length $a\sqrt{a^2+b^2}$. So $\kappa = a/(a^2+b^2) = 0.19980$ mm^{-1}, a radius of curvature 5.005 mm — very slightly larger than the coil radius.

Worked Example — arc length that needs care

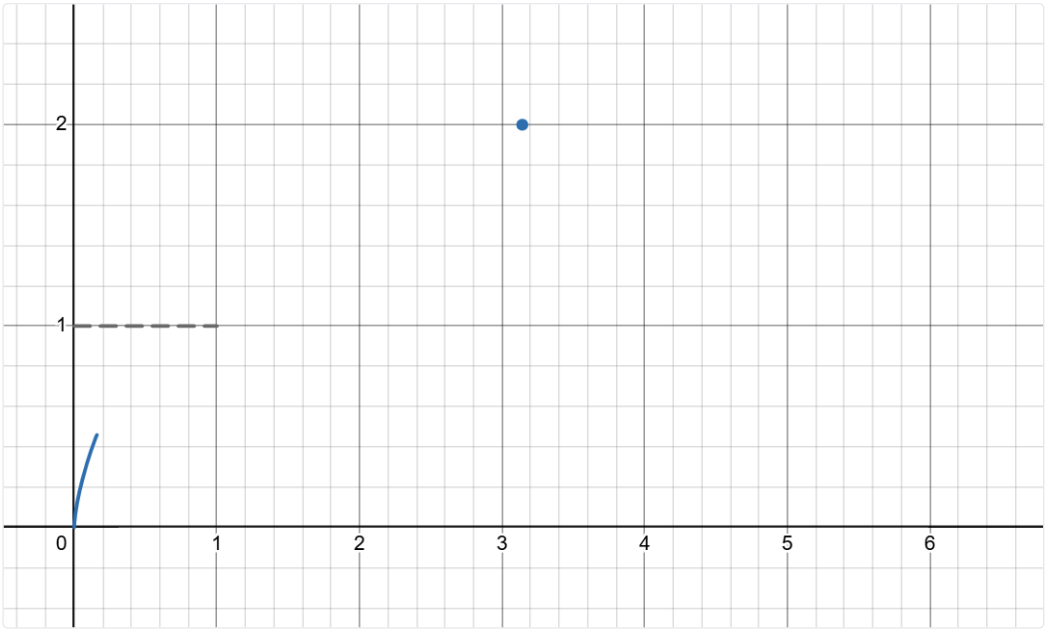
Find the length of one arch of the cycloid $\mathbf{r}(t) = (t - \sin t,\ 1 - \cos t)$, $0 \le t \le 2\pi$ — the path of a point on the rim of a rolling unit wheel.

Step 1. $\mathbf{r}' = (1 - \cos t,\ \sin t)$, so $\|\mathbf{r}'\|^2 = 1 - 2\cos t + \cos^2 t + \sin^2 t = 2 - 2\cos t = 4\sin^2(t/2)$.

Step 2. On $[0, 2\pi]$, $\sin(t/2) \ge 0$, so $\|\mathbf{r}'\| = 2\sin(t/2)$ — no absolute-value trouble.

Step 3. $s = \int_0^{2\pi} 2\sin(t/2)\,dt = \big[-4\cos(t/2)\big]_0^{2\pi} = 4 + 4 = 8$.

Note that $\mathbf{r}'(0) = \mathbf{0}$: the cycloid has a cusp there and is not smooth at the ends, but the arc-length integral is still perfectly finite.



One arch of the cycloid traced by a point on a rolling unit wheel (axle path dashed). Its length is exactly 8, four times the wheel's diameter.

Moving bases: velocity in polar and cylindrical coordinates

If a point moves with cylindrical coordinates $(r(t), \phi(t), z(t))$, its position is $\mathbf{r} = r\hat{\mathbf{r}} + z\hat{\mathbf{z}}$ — but $\hat{\mathbf{r}}$ depends on ϕ, which depends on t. Differentiating the expressions of Section 7.1 with the chain rule,

$$\frac{d\hat{\mathbf{r}}}{dt} = \dot\phi\,(-\sin\phi\,\hat{\mathbf{x}} + \cos\phi\,\hat{\mathbf{y}}) = \dot\phi\,\hat{\boldsymbol{\phi}}, \qquad \frac{d\hat{\boldsymbol{\phi}}}{dt} = -\dot\phi\,\hat{\mathbf{r}}.$$

(Both derivatives are perpendicular to the vector being differentiated, as the constant-length corollary demands.) Hence

$$\mathbf{v} = \dot r\,\hat{\mathbf{r}} + r\dot\phi\,\hat{\boldsymbol{\phi}} + \dot z\,\hat{\mathbf{z}},$$
$$\mathbf{a} = (\ddot r - r\dot\phi^2)\,\hat{\mathbf{r}} + (r\ddot\phi + 2\dot r\dot\phi)\,\hat{\boldsymbol{\phi}} + \ddot z\,\hat{\mathbf{z}}.$$

The term $-r\dot\phi^2\hat{\mathbf{r}}$ is the centripetal acceleration and $2\dot r\dot\phi\,\hat{\boldsymbol\phi}$ the Coriolis term. Neither appears if you forget that the basis vectors move. The speed formula $\|\mathbf{v}\|^2 = \dot r^2 + r^2\dot\phi^2 + \dot z^2$ is the time-derivative version of the cylindrical line element $ds^2 = dr^2 + r^2 d\phi^2 + dz^2$.

Worked Example — an electron in a uniform magnetic field

A particle of charge q and mass m moves in $\mathbf{B} = B_0\hat{\mathbf{z}}$ with no electric field. Newton's law is $m\,\dot{\mathbf{v}} = q\,\mathbf{v}\times\mathbf{B}$. Show that the motion is a helix and find its radius and frequency for an electron with $v_\perp = 10^6$ m/s in $B_0 = 0.01$ T.

Step 1 — energy is conserved. $\frac{d}{dt}\left(\frac12 m\,\mathbf{v}\cdot\mathbf{v}\right) = m\,\dot{\mathbf{v}}\cdot\mathbf{v} = q(\mathbf{v}\times\mathbf{B})\cdot\mathbf{v} = 0$ by the scalar triple product (two equal vectors). A magnetic field never changes the speed.

Step 2 — components. $\mathbf{v}\times\mathbf{B} = (v_y B_0,\ -v_x B_0,\ 0)$. With $\omega_c = qB_0/m$: $\dot v_x = \omega_c v_y$, $\dot v_y = -\omega_c v_x$, $\dot v_z = 0$.

Step 3 — solve. Try $v_x = v_\perp\cos\omega_c t$, $v_y = -v_\perp\sin\omega_c t$: then $\dot v_x = -v_\perp\omega_c\sin\omega_c t = \omega_c v_y$ ✓ and $\dot v_y = -v_\perp\omega_c\cos\omega_c t = -\omega_c v_x$ ✓. Integrating, the orbit is a circle of radius $r_c = v_\perp/|\omega_c|$ while z grows uniformly — a helix like the solenoid winding above.

Step 4 — numbers. $|\omega_c| = 1.602\times10^{-19}\times0.01/9.109\times10^{-31} = 1.759\times10^{9}$ rad/s, i.e. $f_c = |\omega_c|/2\pi = 279.9$ MHz. Radius $r_c = 10^6/1.759\times10^9 = 0.569$ mm.

Step 5 — check with the polar formula. For uniform circular motion $\dot r = \ddot r = 0$, $\ddot\phi = 0$, so $\mathbf{a} = -r\dot\phi^2\hat{\mathbf{r}}$: magnitude $r_c\omega_c^2 = v_\perp|\omega_c| = 1.759\times10^{15}$ m/s², which equals $|q|v_\perp B_0/m$ ✓.

The cyclotron frequency $\omega_c = qB/m$ is independent of speed — the fact that makes cyclotrons and magnetrons work.

Common Pitfall

"Differentiate component by component" is valid only for a **fixed** basis. Writing $\frac{d}{dt}(r\hat{\mathbf{r}}) = \dot r\hat{\mathbf{r}}$ loses the $r\dot\phi\,\hat{\boldsymbol\phi}$ term — the whole of the velocity for circular motion.

Engineering Note

A phasor $V_m e^{j\omega t}$ is a vector-valued function in the complex plane: $\mathbf{r}(t) = (V_m\cos\omega t,\ V_m\sin\omega t)$. Its derivative $j\omega V_m e^{j\omega t}$ is the tangent vector — rotated 90° ahead and scaled by ω — which is why differentiation becomes multiplication by $j\omega$ in AC analysis (Ch. 2). The polarisation of a plane wave is likewise the curve traced by the tip of $\mathbf{E}(t)$ at a fixed point: a line, circle or ellipse.

7.4 Vector fields

Definition and examples

Scalar and vector fields

A **scalar field** assigns a number $f(\mathbf{R})$ to each point of a region of space. A **vector field** assigns a vector

$$\mathbf{F}(x,y,z) = F_x(x,y,z)\,\hat{\mathbf{x}} + F_y(x,y,z)\,\hat{\mathbf{y}} + F_z(x,y,z)\,\hat{\mathbf{z}}$$

to each point. A field is **static** if it does not depend on time and **time-varying** otherwise; it is **uniform** if it is the same at every point.

Potential V, temperature T and charge density ρ are scalar fields; $\mathbf{E}$, $\mathbf{B}$, current density $\mathbf{J}$ and heat flux $\mathbf{q}$ are vector fields. Picture a vector field as an arrow attached to every point, with length showing magnitude. The components are ordinary scalar functions of several variables, so everything in Ch. 6 — continuity, partial derivatives, the chain rule — applies to each component separately.

A short catalogue of fields that recur throughout the chapter:

Field	Formula	Picture
Uniform	$\mathbf{F} = E_0\hat{\mathbf{x}}$	parallel arrows, all equal (parallel-plate capacitor)
Radial (3-D)	$\mathbf{F} = \mathbf{R} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}}$	arrows point outward, growing with distance
Point charge	$\mathbf{E} = \dfrac{q}{4\pi\varepsilon_0}\dfrac{\hat{\mathbf{R}}}{R^2}$	outward, decaying as $1/R^2$
Line charge	$\mathbf{E} = \dfrac{\rho_\ell}{2\pi\varepsilon_0 r}\hat{\mathbf{r}}$	outward from the z-axis, decaying as $1/r$
Rigid rotation	$\mathbf{F} = -y\hat{\mathbf{x}} + x\hat{\mathbf{y}} = r\hat{\boldsymbol\phi}$	circles, speed growing with r
Line current	$\mathbf{B} = \dfrac{\mu_0 I}{2\pi r}\hat{\boldsymbol\phi}$	circles, strength decaying as $1/r$

The last two both circulate around the z-axis, but (as we shall see) one has curl and the other does not. Pictures alone can mislead; the differential operators of Section 7.5 make the distinction precise.

Field lines

Field line (streamline, flux line)

A **field line** of $\mathbf{F}$ is a curve that is tangent to $\mathbf{F}$ at every point. If $\mathbf{r}(s)$ is a field line then $d\mathbf{r}/ds$ is parallel to $\mathbf{F}(\mathbf{r})$, i.e.

$$\frac{dx}{F_x} = \frac{dy}{F_y} = \frac{dz}{F_z}.$$

In two dimensions this is the first-order ODE $dy/dx = F_y/F_x$, solved by the methods of Ch. 11. Field lines never cross where $\mathbf{F} \neq \mathbf{0}$ (the tangent direction would be ambiguous); they can start or stop only where $\mathbf{F}$ vanishes or is singular — at charges, for instance. Their density is drawn proportional to the field magnitude, which is why "lines of force" became Faraday's mental model of the field.

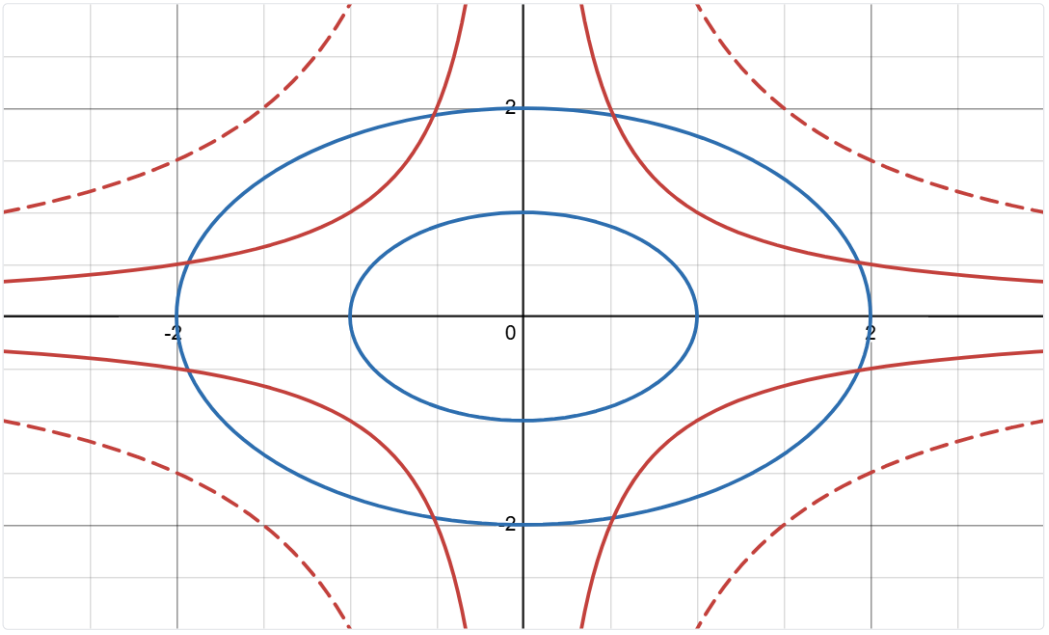
Worked Example — field lines of three planar fields

Find the field lines of (a) $\mathbf{F} = -y\hat{\mathbf{x}} + x\hat{\mathbf{y}}$, (b) $\mathbf{G} = x\hat{\mathbf{x}} - y\hat{\mathbf{y}}$, (c) $\mathbf{H} = \hat{\mathbf{x}} + 2x\hat{\mathbf{y}}$.

(a) $dy/dx = x/(-y)$, so $y\,dy = -x\,dx$ and $x^2 + y^2 = C$: **circles** about the origin, traversed counter-clockwise (at $(1,0)$ the field is $+\hat{\mathbf{y}}$).

(b) $dy/dx = -y/x$, so $dy/y = -dx/x$, $\ln|y| = -\ln|x| + c$ and $xy = C$: **rectangular hyperbolas**. Flow comes in along the y-axis and leaves along the x-axis — the field near a saddle point of a potential, e.g. the centre of a quadrupole lens.

(c) $dy/dx = 2x$, so $y = x^2 + C$: a family of **parabolas** shifted vertically.



Field lines of the rotation field $-y\hat{\mathbf{x}} + x\hat{\mathbf{y}}$ (blue circles) and of the saddle field $x\hat{\mathbf{x}} - y\hat{\mathbf{y}}$ (red hyperbolas $xy = C$).

Worked Example — field lines and equipotentials of a dipole

A small electric dipole on the z-axis has, in spherical coordinates,

$$\mathbf{E} = \frac{p}{4\pi\varepsilon_0 R^3}\left(2\cos\theta\,\hat{\mathbf{R}} + \sin\theta\,\hat{\boldsymbol{\theta}}\right), \qquad V = \frac{p\cos\theta}{4\pi\varepsilon_0 R^2}.$$

Find the field lines.

Step 1 — the field-line condition in spherical coordinates. A displacement along a curve in the plane $\phi = \text{const}$ is $dR\,\hat{\mathbf{R}} + R\,d\theta\,\hat{\boldsymbol{\theta}}$ (the scale factors of Ch. 6). Parallel to $\mathbf{E}$ means

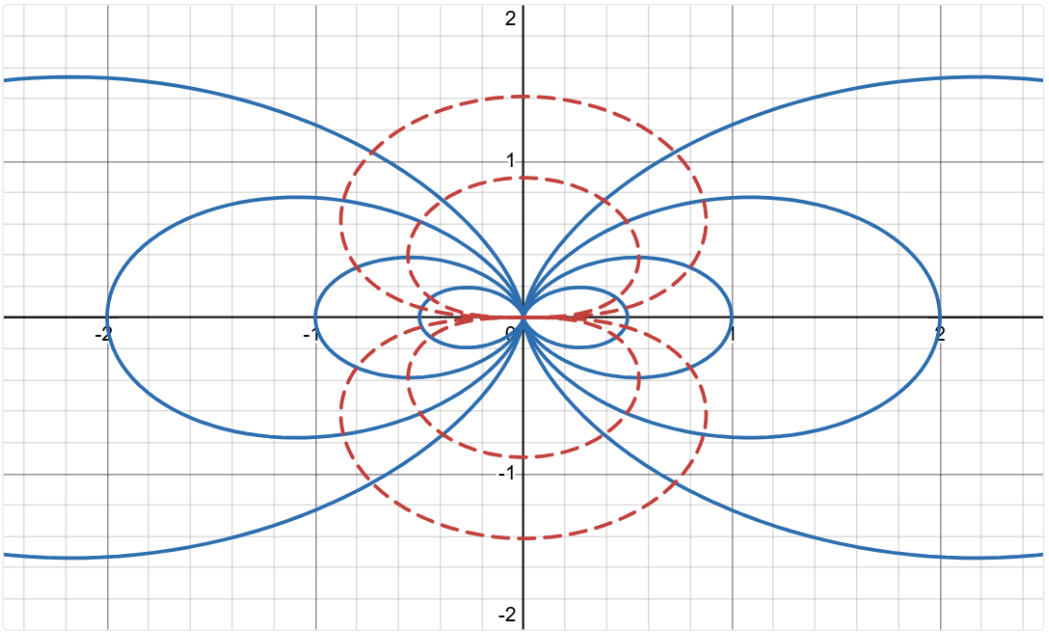
$$\frac{dR}{E_R} = \frac{R\,d\theta}{E_\theta} \quad\Longrightarrow\quad \frac{dR}{2\cos\theta} = \frac{R\,d\theta}{\sin\theta}.$$

Step 2 — separate. $\dfrac{dR}{R} = \dfrac{2\cos\theta}{\sin\theta}d\theta$, so $\ln R = 2\ln\sin\theta + c$ and

$$R = C\sin^2\theta.$$

Step 3 — check orthogonality. Equipotentials are $R^2 = K\cos\theta$. On them $2R\,dR = -K\sin\theta\,d\theta$, so $dR/(R\,d\theta) = -\tfrac{1}{2}\tan\theta$; on field lines $dR/(R\,d\theta) = 2\cot\theta$. The product of these two slopes is -1, so the families cross at right angles, as $\mathbf{E} = -\nabla V$ requires.

In the Desmos plot below the dipole axis is drawn vertically; with Desmos's polar angle ϑ measured from the horizontal, $\sin\theta = \cos\vartheta$ and $\cos\theta = \sin\vartheta$.



Dipole with its axis vertical: field lines $R = C\sin^2\theta$ (blue) leave the upper (positive) end and return to the lower end, crossing the equipotentials $R^2 = K\cos\theta$ (red, dashed) at right angles.

Worked Example — the magnetic field of a wire in Cartesian form

Convert $\mathbf{B} = \dfrac{\mu_0 I}{2\pi r}\hat{\boldsymbol{\phi}}$ to Cartesian components and evaluate it at $(3, 4, 0)$ cm for $I = 10$ A.

Step 1. $\hat{\boldsymbol{\phi}} = (-\sin\phi, \cos\phi, 0) = (-y/r,\ x/r,\ 0)$, so

$$\mathbf{B} = \frac{\mu_0 I}{2\pi}\,\frac{-y\,\hat{\mathbf{x}} + x\,\hat{\mathbf{y}}}{x^2 + y^2}.$$

Step 2. At $(0.03, 0.04)$ m, $r = 0.05$ m and $\mu_0 I/(2\pi r) = (4\pi \times 10^{-7} \times 10)/(2\pi \times 0.05) = 40\ \mu$T. Direction $\hat{\boldsymbol{\phi}} = (-0.8, 0.6, 0)$, so $\mathbf{B} = (-32,\ 24,\ 0)\ \mu$T.

The field lines are again circles, exactly like the rotation field $-y\hat{\mathbf{x}} + x\hat{\mathbf{y}}$, but the magnitude falls off as $1/r$ instead of growing as r. That difference will decide whether the curl is zero (Section 7.5). For comparison, the Earth's field is about 50 μT — which is why a 10 A cable a few centimetres from a compass upsets it.

Common Pitfall

A field-line diagram shows direction and (by density) magnitude, but **not** the path a charged particle follows. A particle's acceleration, not its velocity, is along $\mathbf{E}$; except when it starts from rest in a straight-line field, its trajectory leaves the field line.

Engineering Note

Finite-element field solvers (for PCB crosstalk, motor design, antenna feeds) compute a field at mesh nodes and display it as arrow plots, streamlines and colour maps of magnitude. Reading those plots is reading a vector field: where lines crowd, the field (and the risk of dielectric breakdown) is high; where they circulate, there is curl, hence current or changing flux.

7.5 Gradient, divergence, and curl

The del operator

All three local derivatives of a field are built from one symbolic vector, the **del** (or nabla) operator

$$\nabla = \hat{\mathbf{x}}\frac{\partial}{\partial x} + \hat{\mathbf{y}}\frac{\partial}{\partial y} + \hat{\mathbf{z}}\frac{\partial}{\partial z}.$$

∇ is not a vector in its own right — it has no magnitude until it acts on something — but in Cartesian coordinates it can be combined with a field using the three products we already know:

Operation	Acts on	Produces	Cartesian form	Measures
gradient ∇f	scalar	vector	$(f_x,\ f_y,\ f_z)$	rate and direction of steepest increase
divergence $\nabla \cdot \mathbf{F}$	vector	scalar	$\partial_x F_x + \partial_y F_y + \partial_z F_z$	net outflow per unit volume
curl $\nabla \times \mathbf{F}$	vector	vector	determinant below	circulation per unit area (rotation)
Laplacian $\nabla^2 f = \nabla \cdot \nabla f$	scalar	scalar	$f_{xx} + f_{yy} + f_{zz}$	how f differs from its local average

Each operator has a dimension of m^{-1} (or m^{-2} for the Laplacian). If V is in volts, ∇V is in V/m; if $\mathbf{D}$ is in $\mathrm{C/m^2}$, $\nabla\cdot\mathbf{D}$ is in $\mathrm{C/m^3}$, a charge density — the first hint of Gauss's law.

The best way to understand the three operators is through their **coordinate-free definitions** as limits of integrals over shrinking regions. These definitions explain what the operators mean, tell you how to compute them in any coordinate system, and are exactly the seeds from which the integral theorems of Sections 7.9–7.11 grow.

Gradient

The gradient was introduced in Ch. 6, §6.4: $df = \nabla f\cdot d\mathbf{r}$, ∇f points uphill, is normal to level surfaces, and its length is the maximum rate of increase. In integral language, for any path from $\mathbf{a}$ to $\mathbf{b}$,

$$f(\mathbf{b}) - f(\mathbf{a}) = \int_{\mathbf{a}}^{\mathbf{b}} \nabla f\cdot d\mathbf{r},$$

which is the fundamental theorem for line integrals (Section 7.6).

In curvilinear coordinates. A step du_i in coordinate u_i moves a distance $h_i\,du_i$, where the h_i are the **scale factors** of Ch. 6: $(1, r, 1)$ for cylindrical (r,ϕ,z) and $(1, R, R\sin\theta)$ for spherical (R,θ,ϕ). The component of ∇f along $\hat{\mathbf{u}}_i$ is the rate of change of f *per metre* in that direction, $\frac{1}{h_i}\frac{\partial f}{\partial u_i}$. Hence

$$\nabla f = \frac{\partial f}{\partial r}\hat{\mathbf{r}} + \frac{1}{r}\frac{\partial f}{\partial \phi}\hat{\boldsymbol{\phi}} + \frac{\partial f}{\partial z}\hat{\mathbf{z}} \qquad \text{(cylindrical)},$$
$$\nabla f = \frac{\partial f}{\partial R}\hat{\mathbf{R}} + \frac{1}{R}\frac{\partial f}{\partial \theta}\hat{\boldsymbol{\theta}} + \frac{1}{R\sin\theta}\frac{\partial f}{\partial \phi}\hat{\boldsymbol{\phi}} \qquad \text{(spherical)}.$$

Divergence

Divergence

The **divergence** of $\mathbf{F}$ at a point P is the net outward flux per unit volume of a small closed surface S enclosing P:

$$\nabla\cdot\mathbf{F} = \lim_{\Delta V\to 0}\frac{1}{\Delta V}\oint_S \mathbf{F}\cdot d\mathbf{S}.$$

In Cartesian coordinates

$$\nabla\cdot\mathbf{F} = \frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y} + \frac{\partial F_z}{\partial z}.$$

Derivation of the Cartesian formula. Take a small box with one corner at (x,y,z) and sides $\Delta x, \Delta y, \Delta z$. The flux out through the face at $x+\Delta x$ is approximately $F_x(x+\Delta x, y, z)\,\Delta y\,\Delta z$; through the opposite face at x the outward normal is $-\hat{\mathbf{x}}$, giving $-F_x(x,y,z)\,\Delta y\,\Delta z$. Together

$$\big[F_x(x+\Delta x,y,z) - F_x(x,y,z)\big]\Delta y\,\Delta z \approx \frac{\partial F_x}{\partial x}\,\Delta x\,\Delta y\,\Delta z.$$

The other two pairs of faces contribute $\partial F_y/\partial y\,\Delta V$ and $\partial F_z/\partial z\,\Delta V$. Dividing by ΔV and letting the box shrink gives the formula. The idea: only the *change* of F_x across the box in the x direction produces net outflow; a uniform field carries in as much as it carries out.

Interpretation. $\nabla\cdot\mathbf{F} > 0$ at a **source** (field lines start there, net outflow), < 0 at a **sink**, and $= 0$ where the field is **solenoidal** (whatever flows in flows out). For an electric field, sources are positive charges; for the velocity of an incompressible fluid, the divergence is zero everywhere; for current density, $\nabla\cdot\mathbf{J} = -\partial\rho/\partial t$ (charge conservation, Section 7.11).

In curvilinear coordinates. Repeat the box argument with a curvilinear box whose faces have areas $h_2h_3\,du_2\,du_3$, and so on. The faces now have different areas on the two sides, so the area factors go *inside* the derivatives:

$$\nabla\cdot\mathbf{F} = \frac{1}{h_1h_2h_3}\left[\frac{\partial}{\partial u_1}(h_2h_3F_1) + \frac{\partial}{\partial u_2}(h_3h_1F_2) + \frac{\partial}{\partial u_3}(h_1h_2F_3)\right].$$

In particular

$$\nabla\cdot\mathbf{F} = \frac{1}{r}\frac{\partial}{\partial r}(rF_r) + \frac{1}{r}\frac{\partial F_\phi}{\partial\phi} + \frac{\partial F_z}{\partial z} \qquad \text{(cylindrical)},$$
$$\nabla\cdot\mathbf{F} = \frac{1}{R^2}\frac{\partial}{\partial R}(R^2F_R) + \frac{1}{R\sin\theta}\frac{\partial}{\partial\theta}(\sin\theta\,F_\theta) + \frac{1}{R\sin\theta}\frac{\partial F_\phi}{\partial\phi} \qquad \text{(spherical)}.$$

The factor R^2 in the spherical radial term is the area of a sphere growing as R^2: a field $\propto 1/R^2$ spreads over exactly that growing area and so has zero divergence away from the origin.

Curl

Curl

The component of the **curl** of $\mathbf{F}$ along a unit vector $\hat{\mathbf{n}}$ at P is the circulation per unit area around a small loop C through P in the plane perpendicular to $\hat{\mathbf{n}}$, traversed counter-clockwise when viewed from the tip of $\hat{\mathbf{n}}$ (right-hand rule):

$$(\nabla \times \mathbf{F}) \cdot \hat{\mathbf{n}} = \lim_{\Delta S \to 0} \frac{1}{\Delta S} \oint_C \mathbf{F} \cdot d\mathbf{r}.$$

In Cartesian coordinates

$$\nabla \times \mathbf{F} = \begin{vmatrix} \hat{\mathbf{x}} & \hat{\mathbf{y}} & \hat{\mathbf{z}} \\ \partial_x & \partial_y & \partial_z \\ F_x & F_y & F_z \end{vmatrix} = \left(\frac{\partial F_z}{\partial y} - \frac{\partial F_y}{\partial z}\right)\hat{\mathbf{x}} + \left(\frac{\partial F_x}{\partial z} - \frac{\partial F_z}{\partial x}\right)\hat{\mathbf{y}} + \left(\frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y}\right)\hat{\mathbf{z}}.$$

Derivation of the z-component. Take a small rectangle in the plane $z = \text{const}$ with corner (x, y) and sides $\Delta x, \Delta y$, traversed counter-clockwise seen from $+z$. The four sides contribute approximately

$$F_x(x, y)\Delta x + F_y(x + \Delta x, y)\Delta y - F_x(x, y + \Delta y)\Delta x - F_y(x, y)\Delta y.$$

Pairing the opposite sides,

$$\big[F_y(x + \Delta x, y) - F_y(x, y)\big]\Delta y - \big[F_x(x, y + \Delta y) - F_x(x, y)\big]\Delta x \approx \left(\frac{\partial F_y}{\partial x} - \frac{\partial F_x}{\partial y}\right)\Delta x\,\Delta y.$$

Divide by the area $\Delta x\,\Delta y$ and take the limit. The x- and y-components follow by cyclic permutation $x \to y \to z \to x$.

Interpretation. Put a tiny paddle wheel in a flowing fluid with velocity $\mathbf{v}$. It spins if the flow on one side is faster than on the other; its axis aligns with $\nabla \times \mathbf{v}$ and its angular velocity is $\tfrac{1}{2}\|\nabla \times \mathbf{v}\|$. Curl is about **shear across the flow**, not about the field lines being curved: a field can circulate without curl (the wire field, below) or have curl with straight field lines (a shear flow $\mathbf{F} = y\hat{\mathbf{x}}$ has curl $-\hat{\mathbf{z}}$).

In curvilinear coordinates. The loop argument with sides $h_i\,du_i$ gives

$$\nabla \times \mathbf{F} = \frac{1}{h_1 h_2 h_3}\begin{vmatrix} h_1\hat{\mathbf{u}}_1 & h_2\hat{\mathbf{u}}_2 & h_3\hat{\mathbf{u}}_3 \\ \partial_{u_1} & \partial_{u_2} & \partial_{u_3} \\ h_1 F_1 & h_2 F_2 & h_3 F_3 \end{vmatrix},$$

which written out is

$$\nabla \times \mathbf{F} = \left(\frac{1}{r}\frac{\partial F_z}{\partial \phi} - \frac{\partial F_\phi}{\partial z}\right)\hat{\mathbf{r}} + \left(\frac{\partial F_r}{\partial z} - \frac{\partial F_z}{\partial r}\right)\hat{\boldsymbol{\phi}} + \frac{1}{r}\left(\frac{\partial (r F_\phi)}{\partial r} - \frac{\partial F_r}{\partial \phi}\right)\hat{\mathbf{z}} \quad \text{(cylindrical)},$$

$$\nabla \times \mathbf{F} = \frac{1}{R\sin\theta}\left(\frac{\partial (\sin\theta\, F_\phi)}{\partial \theta} - \frac{\partial F_\theta}{\partial \phi}\right)\hat{\mathbf{R}} + \frac{1}{R}\left(\frac{1}{\sin\theta}\frac{\partial F_R}{\partial \phi} - \frac{\partial (R F_\phi)}{\partial R}\right)\hat{\boldsymbol{\theta}} + \frac{1}{R}\left(\frac{\partial (R F_\theta)}{\partial R} - \frac{\partial F_R}{\partial \theta}\right)\hat{\boldsymbol{\phi}} \quad \text{(spherical)}.$$

The Laplacian

The divergence of a gradient is the **Laplacian**:

$$\nabla^2 f = \nabla \cdot \nabla f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2}.$$

Combining the curvilinear gradient and divergence,

$$\nabla^2 f = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial f}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 f}{\partial \phi^2} + \frac{\partial^2 f}{\partial z^2} \qquad \text{(cylindrical)},$$

$$\nabla^2 f = \frac{1}{R^2}\frac{\partial}{\partial R}\left(R^2\frac{\partial f}{\partial R}\right) + \frac{1}{R^2\sin\theta}\frac{\partial}{\partial \theta}\left(\sin\theta\frac{\partial f}{\partial \theta}\right) + \frac{1}{R^2\sin^2\theta}\frac{\partial^2 f}{\partial \phi^2} \quad \text{(spherical)}.$$

Interpretation. In one dimension, $f''(x) \approx [f(x + h) + f(x - h) - 2f(x)]/h^2$: the second derivative compares f with the average of its neighbours. In three dimensions, $\nabla^2 f$ at a point is proportional to (average of f on a small sphere) $-$ (f at the centre). A function with $\nabla^2 f = 0$ — a **harmonic** function — equals the average of its surroundings, so it can have no local maximum or minimum inside a region. That is why the electrostatic potential in a charge-free region has its extremes on the electrodes.

For a vector field, the **vector Laplacian** in Cartesian coordinates is the Laplacian of each component: $\nabla^2\mathbf{F} = (\nabla^2 F_x, \nabla^2 F_y, \nabla^2 F_z)$. In curvilinear coordinates it is *not* the Laplacian of each component (the basis vectors vary); use the identity $\nabla^2\mathbf{F} = \nabla(\nabla \cdot \mathbf{F}) - \nabla \times (\nabla \times \mathbf{F})$ instead.

Identities

Vector-calculus identities

For twice continuously differentiable f, g and $\mathbf{A}, \mathbf{B}$:

1. $\nabla \times (\nabla f) = \mathbf{0}$ — *the curl of a gradient is zero.*
2. $\nabla \cdot (\nabla \times \mathbf{A}) = 0$ — *the divergence of a curl is zero.*
3. $\nabla(fg) = f\nabla g + g\nabla f$.
4. $\nabla \cdot (f\mathbf{A}) = f\,\nabla\cdot\mathbf{A} + \mathbf{A}\cdot\nabla f$.
5. $\nabla \times (f\mathbf{A}) = f\,\nabla\times\mathbf{A} + \nabla f \times \mathbf{A}$.
6. $\nabla \cdot (\mathbf{A}\times\mathbf{B}) = \mathbf{B}\cdot(\nabla\times\mathbf{A}) - \mathbf{A}\cdot(\nabla\times\mathbf{B})$.
7. $\nabla \times (\nabla\times\mathbf{A}) = \nabla(\nabla\cdot\mathbf{A}) - \nabla^2\mathbf{A}$.

Proof of 1 and 2. For 1, the z-component is $\partial_x\partial_y f - \partial_y\partial_x f = 0$ by equality of mixed partials (Clairaut, Ch. 6); the other components are the same. For 2,

$$\nabla\cdot(\nabla\times\mathbf{A}) = \partial_x(\partial_y A_z - \partial_z A_y) + \partial_y(\partial_z A_x - \partial_x A_z) + \partial_z(\partial_x A_y - \partial_y A_x) = 0,$$

since the six terms cancel in pairs. Formally both are "$\mathbf{a}\times\mathbf{a} = \mathbf{0}$" and "$\mathbf{a}\cdot(\mathbf{a}\times\mathbf{b}) = 0$" with $\mathbf{a} = \nabla$. Identities 4–6 are product rules: each term has ∇ acting on one factor while the other is held fixed. Identity 6 is the one behind Poynting's theorem; identity 7 is BAC–CAB with ∇ and is the step to the wave equation.

These two "zero" identities have converses that are the foundation of potential theory:

Potentials

On a **simply connected** region (every closed loop can be shrunk to a point without leaving it):

- if $\nabla\times\mathbf{F} = \mathbf{0}$, there is a scalar potential f with $\mathbf{F} = \nabla f$ (the field is **irrotational** or **conservative**);
- on a region where every closed surface encloses only points of the region (e.g. all of space), if $\nabla\cdot\mathbf{F} = 0$, there is a vector potential $\mathbf{A}$ with $\mathbf{F} = \nabla\times\mathbf{A}$ (the field is **solenoidal**).

Helmholtz theorem. A field that is smooth and vanishes suitably fast at infinity is uniquely determined by its divergence and its curl, and can be split as $\mathbf{F} = -\nabla V + \nabla\times\mathbf{A}$ — an irrotational part plus a solenoidal part.

The Helmholtz theorem explains the shape of Maxwell's equations: to fix $\mathbf{E}$ and $\mathbf{B}$ you need their divergences (the charges and the absence of magnetic charge) and their curls (changing fields and currents) — exactly four equations.

Worked Example — divergence and curl in Cartesian coordinates

For $\mathbf{F} = x^2y\,\hat{\mathbf{x}} + 2yz\,\hat{\mathbf{y}} + xz^2\,\hat{\mathbf{z}}$ compute $\nabla\cdot\mathbf{F}$ and $\nabla\times\mathbf{F}$ at $(1,2,3)$, and confirm identity 2.

Divergence. $\partial_x(x^2y) + \partial_y(2yz) + \partial_z(xz^2) = 2xy + 2z + 2xz$. At $(1,2,3)$: $4 + 6 + 6 = 16$.

Curl. $(\partial_yF_z - \partial_zF_y,\ \partial_zF_x - \partial_xF_z,\ \partial_xF_y - \partial_yF_x) = (0 - 2y,\ 0 - z^2,\ 0 - x^2) = (-2y, -z^2, -x^2)$. At $(1,2,3)$: $(-4,-9,-1)$.

Identity check. $\nabla\cdot(-2y,-z^2,-x^2) = \partial_x(-2y) + \partial_y(-z^2) + \partial_z(-x^2) = 0$. ✓

So near $(1,2,3)$ the field is a strong source (net outflow 16 units per unit volume) and its local rotation axis points along $(-4,-9,-1)/\sqrt{98}$.

Worked Example — rotation field versus wire field

Compare $\mathbf{F}_1 = r\,\hat{\boldsymbol{\phi}}$ (rigid rotation) and $\mathbf{F}_2 = \dfrac{1}{r}\hat{\boldsymbol{\phi}}$ (the shape of the field of a line current).

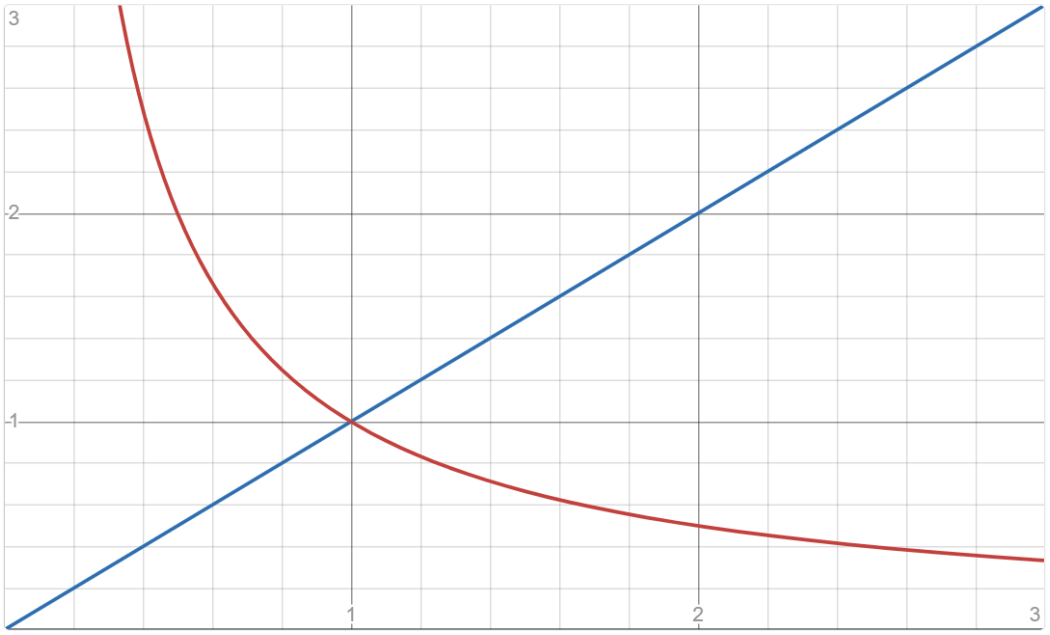
Both have only a ϕ-component that depends only on r, so $\nabla\cdot\mathbf{F} = \frac{1}{r}\partial_\phi F_\phi = 0$ for both: neither has sources.

For the curl, only the $\hat{\mathbf{z}}$ term survives: $(\nabla\times\mathbf{F})_z = \frac{1}{r}\frac{\partial}{\partial r}(rF_\phi)$.

- $\mathbf{F}_1$: $\frac{1}{r}\frac{d}{dr}(r^2) = 2$, so $\nabla\times\mathbf{F}_1 = 2\hat{\mathbf{z}}$ — uniform rotation everywhere (a paddle wheel spins at angular rate 1 = the rotation rate of the fluid, consistent with $\frac{1}{2}\|\nabla\times\mathbf{v}\|$).
- $\mathbf{F}_2$: $\frac{1}{r}\frac{d}{dr}(1) = 0$ for $r > 0$ — **irrotational**, even though its field lines are circles. The faster flow near the axis exactly compensates for the shorter path: a paddle wheel is carried around the axis without spinning.

Cartesian cross-check for $\mathbf{F}_2$. $\mathbf{F}_2 = (-y,x)/(x^2+y^2)$. $\partial_xF_y = \dfrac{(x^2+y^2) - 2x^2}{(x^2+y^2)^2} = \dfrac{y^2-x^2}{(x^2+y^2)^2}$ and $\partial_yF_x = \dfrac{-(x^2+y^2) + 2y^2}{(x^2+y^2)^2} = \dfrac{y^2-x^2}{(x^2+y^2)^2}$. Their difference is 0. ✓

Yet in Section 7.6 we will find that the circulation of $\mathbf{F}_2$ around the unit circle is 2π, not zero. The resolution is that $\mathbf{F}_2$ is undefined on the z-axis, so the region is not simply connected — all its curl is concentrated on the axis, where the current flows.



Field magnitude against distance r from the axis: rigid rotation $\|\mathbf{F}_1\| = r$ (blue) has uniform curl; the wire-type field $\|\mathbf{F}_2\| = 1/r$ (red) is curl-free for $r > 0$, although both have circular field lines.

Worked Example — the inverse-square field and $\nabla^2(1/R)$

Show that $\nabla \cdot (\hat{\mathbf{R}}/R^2) = 0$ and $\nabla^2(1/R) = 0$ for $R \neq 0$, first in spherical and then in Cartesian coordinates.

Spherical. $\nabla \cdot (\hat{\mathbf{R}}/R^2) = \dfrac{1}{R^2}\dfrac{\partial}{\partial R}\left(R^2 \cdot \dfrac{1}{R^2}\right) = \dfrac{1}{R^2}\dfrac{\partial}{\partial R}(1) = 0$. Since $\nabla(1/R) = -\hat{\mathbf{R}}/R^2$, also $\nabla^2(1/R) = 0$.

Cartesian. With $R^2 = x^2 + y^2 + z^2$, $\partial_x(1/R) = -x/R^3$ and

$$\frac{\partial^2}{\partial x^2}\frac{1}{R} = -\frac{1}{R^3} + \frac{3x^2}{R^5} = \frac{3x^2 - R^2}{R^5}.$$

Adding the y and z terms: $\nabla^2(1/R) = \dfrac{3(x^2+y^2+z^2) - 3R^2}{R^5} = 0$. ✓

The spherical calculation took one line, the Cartesian one five. The flux of $\hat{\mathbf{R}}/R^2$ through a sphere is nevertheless 4π (Section 7.7): all the divergence sits at $R = 0$. Section 7.11 makes this precise with the Dirac delta, $\nabla^2(1/R) = -4\pi\delta(\mathbf{R})$.

Worked Example — gradient and divergence in spherical coordinates

(a) Show that the dipole potential $V = \dfrac{p\cos\theta}{4\pi\varepsilon_0 R^2}$ gives the field quoted in Section 7.4. (b) Inside a sphere of uniform charge density ρ_0, $\mathbf{E} = \dfrac{\rho_0 R}{3\varepsilon_0}\hat{\mathbf{R}}$; find $\nabla \cdot \mathbf{E}$ and $\nabla \times \mathbf{E}$.

(a) $E_R = -\partial V/\partial R = \dfrac{2p\cos\theta}{4\pi\varepsilon_0 R^3}$, $E_\theta = -\dfrac{1}{R}\dfrac{\partial V}{\partial \theta} = \dfrac{p\sin\theta}{4\pi\varepsilon_0 R^3}$, $E_\phi = 0$. ✓

(b) $\nabla \cdot \mathbf{E} = \dfrac{1}{R^2}\dfrac{\partial}{\partial R}\left(R^2 \cdot \dfrac{\rho_0 R}{3\varepsilon_0}\right) = \dfrac{1}{R^2}\cdot\dfrac{3\rho_0 R^2}{3\varepsilon_0} = \dfrac{\rho_0}{\varepsilon_0}$ — exactly the charge density divided by ε_0 (Gauss's law in differential form, Section 7.12). The curl has components built from $\partial_\theta E_R$ and $\partial_\phi E_R$ and from E_θ, E_ϕ, all zero, so $\nabla \times \mathbf{E} = \mathbf{0}$: the field is conservative, as every electrostatic field must be.

Units. ρ_0/ε_0 is $(\mathrm{C/m^3})/(\mathrm{F/m}) = \mathrm{V/m^2}$, which is $[\mathbf{E}]/\mathrm{m}$ ✓.

Common Pitfall

Applying the *Cartesian* formulas to curvilinear components. For $\mathbf{F} = \hat{\mathbf{R}}$ (all $F_R = 1$) the naive "$\partial F_R/\partial R$" gives zero divergence, but the correct result is $\frac{1}{R^2}\partial_R(R^2) = 2/R$: unit arrows pointing outward everywhere *do* spread apart. Likewise $\nabla^2\mathbf{F}$ is not $(\nabla^2 F_r, \nabla^2 F_\phi, \nabla^2 F_z)$.

Common Pitfall

$\nabla \cdot \mathbf{F}$ is a scalar and $\nabla \times \mathbf{F}$ a vector; $\nabla \cdot f$ (divergence of a scalar) and $\nabla \times f$ are meaningless, and $\mathbf{F} \cdot \nabla$ is an *operator*, not the divergence: $(\mathbf{F}\cdot\nabla)g = F_x\partial_x g + F_y\partial_y g + F_z\partial_z g$ is the directional derivative of g along $\mathbf{F}$, scaled by $\|\mathbf{F}\|$.

Engineering Note

Finite-difference field solvers replace $\nabla^2 V$ by the "five-point stencil" $[V_{i+1,j} + V_{i-1,j} + V_{i,j+1} + V_{i,j-1} - 4V_{i,j}]/h^2$. Setting it to zero says each node equals the average of its four neighbours — the discrete version of the mean-value property — and iterating that averaging (Jacobi or Gauss–Seidel relaxation, Ch. 22) solves Laplace's equation for the potential between electrodes.

7.6 Line integrals

Motivation

The voltage between two points is the work per unit charge done *against* the electric field along a path: $V_{ab} = -\int_b^a \mathbf{E}\cdot d\mathbf{l}$. The EMF around a loop is $\oint \mathbf{E}\cdot d\mathbf{l}$. The total charge on a curved wire with non-uniform line density is $\int \rho_\ell \, ds$. All are integrals along a curve — **line integrals** — and they come in two kinds: integrals of a scalar with respect to arc length, and integrals of the tangential component of a vector field.

Scalar line integrals

Line integral of a scalar field

Let C be a smooth curve parametrised by $\mathbf{r}(t)$, $a \le t \le b$. The line integral of f along C with respect to arc length is

$$\int_C f\, ds = \lim_{\max \Delta s_k \to 0} \sum_k f(\mathbf{r}_k)\,\Delta s_k = \int_a^b f(\mathbf{r}(t))\,\|\mathbf{r}'(t)\|\,dt.$$

The value does not depend on the parametrisation *or on the direction* of travel (ds is a length, always positive). With $f = 1$ it gives the arc length; with $f = \rho_\ell$ the total charge; with f a linear resistance per metre, the total resistance.

Worked Example — charge on a curved wire

A quarter-circle wire of radius a in the first quadrant carries line charge density $\rho_\ell = \rho_0\, xy/a^2$. Find its total charge.

Step 1 — parametrise. $\mathbf{r}(\phi) = (a\cos\phi,\ a\sin\phi)$, $0 \le \phi \le \pi/2$; $\|\mathbf{r}'\| = a$, so $ds = a\,d\phi$.

Step 2 — integrand. $\rho_\ell = \rho_0 \cos\phi \sin\phi$.

Step 3 — integrate. $Q = \int_0^{\pi/2} \rho_0 \cos\phi\sin\phi\, a\, d\phi = \rho_0 a\left[\tfrac{1}{2}\sin^2\phi\right]_0^{\pi/2} = \tfrac{1}{2}\rho_0 a$.

Units. ρ_0 in C/m times a in m gives coulombs ✓.

Line integrals of vector fields

Line integral of a vector field (work, circulation)

For a vector field $\mathbf{F}$ and an **oriented** curve C parametrised by $\mathbf{r}(t)$, $a \le t \le b$ (direction of increasing t),

$$\int_C \mathbf{F}\cdot d\mathbf{r} = \int_C \mathbf{F}\cdot\hat{\mathbf{T}}\, ds = \int_a^b \mathbf{F}(\mathbf{r}(t))\cdot\mathbf{r}'(t)\,dt = \int_C (F_x\,dx + F_y\,dy + F_z\,dz).$$

If C is closed the integral is called the **circulation** and written $\oint_C \mathbf{F}\cdot d\mathbf{r}$.

Only the tangential component $\mathbf{F}\cdot\hat{\mathbf{T}}$ contributes. Reversing the orientation of C reverses $\hat{\mathbf{T}}$ and so **changes the sign**: $\int_{-C}\mathbf{F}\cdot d\mathbf{r} = -\int_C \mathbf{F}\cdot d\mathbf{r}$. Any other parametrisation with the same orientation gives the same value: if $t = g(u)$ with $g' > 0$, then $\mathbf{r}'(g(u))g'(u)\,du = \mathbf{r}'(t)\,dt$. For a curve made of smooth pieces (a polygon, say) add the integrals over the pieces.

The procedure — almost every line-integral computation follows these four steps:

1. Parametrise each piece of C as $\mathbf{r}(t)$, with t increasing in the direction of travel.
2. Compute $d\mathbf{r} = \mathbf{r}'(t)\,dt$.
3. Substitute $\mathbf{r}(t)$ into $\mathbf{F}$ and form the scalar $\mathbf{F}(\mathbf{r}(t))\cdot\mathbf{r}'(t)$.
4. Integrate in t from the start value to the end value.

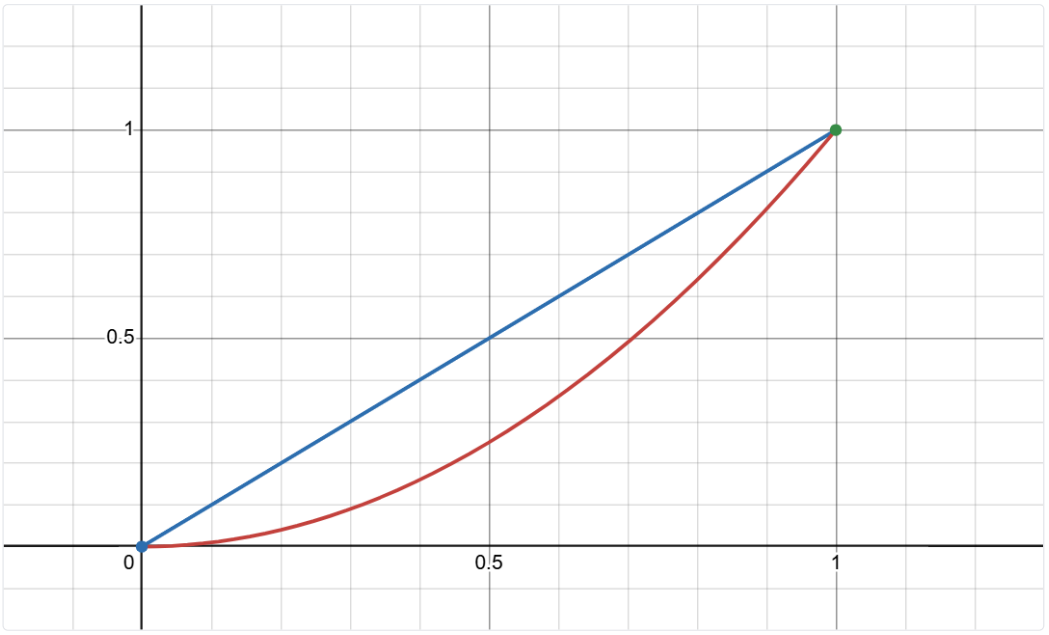
Worked Example — path dependence

Compute $\int_C \mathbf{F}\cdot d\mathbf{r}$ from $(0,0)$ to $(1,1)$ for (a) $\mathbf{F} = y\hat{\mathbf{x}} + x\hat{\mathbf{y}}$ and (b) $\mathbf{G} = -y\hat{\mathbf{x}} + x\hat{\mathbf{y}}$, along C_1: the line $y = x$, and C_2: the parabola $y = x^2$.

C_1**:** $\mathbf{r} = (t,t)$, $\mathbf{r}' = (1,1)$, $0 \le t \le 1$. (a) $\mathbf{F}\cdot\mathbf{r}' = t + t = 2t$, integral 1. (b) $\mathbf{G}\cdot\mathbf{r}' = -t + t = 0$, integral 0.

C_2**:** $\mathbf{r} = (t, t^2)$, $\mathbf{r}' = (1, 2t)$. (a) $\mathbf{F} = (t^2, t)$, $\mathbf{F}\cdot\mathbf{r}' = t^2 + 2t^2 = 3t^2$, integral 1. (b) $\mathbf{G} = (-t^2, t)$, $\mathbf{G}\cdot\mathbf{r}' = -t^2 + 2t^2 = t^2$, integral $\tfrac{1}{3}$.

$\mathbf{F}$ gives the same answer on both paths; $\mathbf{G}$ does not. The reason: $\mathbf{F} = \nabla(xy)$ is a gradient, while $\nabla\times\mathbf{G} = 2\hat{\mathbf{z}} \neq \mathbf{0}$. Going out along C_1 and back along C_2 gives a circulation $0 - \tfrac{1}{3} = -\tfrac{1}{3}$ for $\mathbf{G}$: by Green's theorem (Section 7.9) this is $-2\times$ (area between the curves $= \tfrac{1}{6}$), the minus sign because that loop runs clockwise.



Two paths from $(0,0)$ to $(1,1)$: the line C_1 (blue) and the parabola C_2 (red). A gradient field gives the same work along both; the rotation field $\mathbf{G}$ does not.

The fundamental theorem for line integrals and conservative fields

Fundamental theorem for line integrals

If f is continuously differentiable on a region containing a smooth curve C from $\mathbf{a}$ to $\mathbf{b}$, then

$$\int_C \nabla f \cdot d\mathbf{r} = f(\mathbf{b}) - f(\mathbf{a}).$$

Proof. By the chain rule, $\frac{d}{dt} f(\mathbf{r}(t)) = \nabla f \cdot \mathbf{r}'(t)$, so the integral is $\int_a^b \frac{d}{dt} f(\mathbf{r}(t))\, dt = f(\mathbf{r}(b)) - f(\mathbf{r}(a))$ by the ordinary fundamental theorem of calculus. ∎

Conservative fields — equivalent statements

For a continuous field $\mathbf{F}$ on an open connected region D, the following are equivalent:

1. $\mathbf{F} = \nabla f$ for some scalar f on D;
2. $\int_C \mathbf{F} \cdot d\mathbf{r}$ depends only on the endpoints of C (path independence);
3. $\oint_C \mathbf{F} \cdot d\mathbf{r} = 0$ for every closed curve C in D.

Each implies $\nabla \times \mathbf{F} = \mathbf{0}$; conversely $\nabla \times \mathbf{F} = \mathbf{0}$ implies 1–3 **if D is simply connected**.

Sketch. 1⇒2 is the fundamental theorem. 2⇔3: two paths with the same ends form a closed loop, and the difference of their integrals is the circulation. 2⇒1: fix $\mathbf{a}$ and define $f(\mathbf{x}) = \int_{\mathbf{a}}^{\mathbf{x}} \mathbf{F} \cdot d\mathbf{r}$ (well defined by path independence); moving the endpoint a little in the x direction along a straight segment shows $\partial f/\partial x = F_x$, and likewise for y, z. The curl statement is Stokes' theorem (Section 7.10).

Finding a potential. Given an irrotational $\mathbf{F}$ on a simply connected region, integrate one component at a time:

1. $f = \int F_x\, dx + g(y,z)$, where g is an unknown "constant" of integration;
2. differentiate with respect to y, set equal to F_y, and solve for $\partial g/\partial y$;
3. repeat for z; the leftover constant is arbitrary (only potential *differences* are physical).

Worked Example — finding and using a potential

Show that $\mathbf{F} = (2xy + z)\hat{\mathbf{x}} + x^2\hat{\mathbf{y}} + (x + 3z^2)\hat{\mathbf{z}}$ is conservative, find f with $\mathbf{F} = \nabla f$, and evaluate the work from $(0,0,0)$ to $(1,2,1)$.

Step 1 — curl test. $\partial_y F_z - \partial_z F_y = 0 - 0$, $\partial_z F_x - \partial_x F_z = 1 - 1$, $\partial_x F_y - \partial_y F_x = 2x - 2x$. All zero, and the domain ($\mathbb{R}^3$) is simply connected, so $\mathbf{F}$ is conservative.

Step 2 — integrate F_x. $f = \int (2xy + z)\, dx = x^2 y + xz + g(y,z)$.

Step 3 — match F_y. $\partial_y f = x^2 + \partial_y g = x^2$, so $g = h(z)$.

Step 4 — match F_z. $\partial_z f = x + h'(z) = x + 3z^2$, so $h = z^3 + c$. Thus $f = x^2 y + xz + z^3$.

Step 5 — work. $f(1,2,1) - f(0,0,0) = 2 + 1 + 1 = 4$.

Check along the straight line $\mathbf{r} = (t, 2t, t)$: $\mathbf{F} = (4t^2 + t,\ t^2,\ t + 3t^2)$, $\mathbf{r}' = (1,2,1)$, $\mathbf{F} \cdot \mathbf{r}' = 9t^2 + 2t$, $\int_0^1 (9t^2 + 2t)\, dt = 3 + 1 = 4$. ✓

Worked Example — circulation and the non-simply-connected trap

Compute the circulation counter-clockwise around the circle $x^2+y^2=a^2$ of (a) the rotation field $\mathbf{G}=-y\hat{\mathbf{x}}+x\hat{\mathbf{y}}$ and (b) the magnetic field of a long wire on the z-axis, $\mathbf{B}=\dfrac{\mu_0 I}{2\pi r}\hat{\boldsymbol{\phi}}$.

Parametrise. $\mathbf{r}=(a\cos\phi, a\sin\phi, 0)$, $\mathbf{r}'=a(-\sin\phi,\cos\phi,0)=a\hat{\boldsymbol{\phi}}$, so $d\mathbf{r}=a\,d\phi\,\hat{\boldsymbol{\phi}}$.

(a) $\mathbf{G}=a\hat{\boldsymbol{\phi}}$ on the circle, so $\oint \mathbf{G}\cdot d\mathbf{r}=\int_0^{2\pi} a\cdot a\,d\phi=2\pi a^2$. This equals $(\nabla\times\mathbf{G})_z\times\text{area}=2\times\pi a^2$, as the curl definition predicts.

(b) $\oint \mathbf{B}\cdot d\mathbf{r}=\int_0^{2\pi}\dfrac{\mu_0 I}{2\pi a}\,a\,d\phi=\mu_0 I$ **— independent of the radius**. This is Ampère's circuital law.

So $\mathbf{B}$ has zero curl wherever it is defined ($r>0$, Section 7.5), yet its circulation around the wire is not zero. There is no contradiction: the region $r>0$ has a hole (the wire), loops around it cannot be shrunk to a point, and "curl-free ⇒ conservative" fails. A loop that does **not** encircle the wire has zero circulation. The "potential" $\mu_0 I\phi/(2\pi)$ exists only locally; it increases by $\mu_0 I$ on every trip around the wire, like a multi-storey car park ramp.

Worked Example — voltage as a line integral

A point charge q at the origin produces $\mathbf{E}=\dfrac{q}{4\pi\varepsilon_0 R^2}\hat{\mathbf{R}}$. Find the voltage $V_{ab}=V_a-V_b=-\int_b^a \mathbf{E}\cdot d\mathbf{l}$ between a at radius R_a and b at radius R_b, along any path.

Step 1. In spherical coordinates $d\mathbf{l}=dR\,\hat{\mathbf{R}}+R\,d\theta\,\hat{\boldsymbol{\theta}}+R\sin\theta\,d\phi\,\hat{\boldsymbol{\phi}}$, so $\mathbf{E}\cdot d\mathbf{l}=\dfrac{q}{4\pi\varepsilon_0}\dfrac{dR}{R^2}$ — only the radial motion counts.

Step 2. $V_{ab}=-\dfrac{q}{4\pi\varepsilon_0}\int_{R_b}^{R_a}\dfrac{dR}{R^2}=\dfrac{q}{4\pi\varepsilon_0}\left(\dfrac{1}{R_a}-\dfrac{1}{R_b}\right)$.

Step 3 — numbers. $q=1$ nC, $R_a=1$ cm, $R_b=10$ cm: $V_{ab}=8.988\times10^{9}\times10^{-9}\times(100-10)=809$ V.

Letting $R_b\to\infty$ gives the familiar $V=q/(4\pi\varepsilon_0 R)$. The path never mattered: $\mathbf{E}=-\nabla V$ is a gradient.

Common Pitfall

Writing $d\mathbf{r}=-dR\,\hat{\mathbf{R}}$ "because the path goes inward" *and* also integrating from the larger to the smaller radius. The parametrisation and the limits together encode the direction — put it in once. If you integrate from R_b to R_a, use $d\mathbf{l}=dR\,\hat{\mathbf{R}}$ and let the limits do the work.

Engineering Note

Kirchhoff's voltage law, $\sum v_k=0$ around a loop, is the statement $\oint\mathbf{E}\cdot d\mathbf{l}=0$. It holds when the loop links no changing magnetic flux. When it does (a loop around a transformer core, or a large ground loop near a switching converter), $\oint\mathbf{E}\cdot d\mathbf{l}=-d\Phi/dt\neq0$ and "voltage between two points" becomes path-dependent: two voltmeters with differently routed leads read different values. This is the Faraday-law effect behind much measurement interference (Section 7.12).

7.7 Surface integrals

Parametrised surfaces

A surface in space is described by two parameters, just as a curve is described by one:

$$\mathbf{r}(u,v)=x(u,v)\hat{\mathbf{x}}+y(u,v)\hat{\mathbf{y}}+z(u,v)\hat{\mathbf{z}},\qquad (u,v)\in D.$$

Holding v fixed and varying u traces a curve on the surface with tangent $\mathbf{r}_u=\partial\mathbf{r}/\partial u$; similarly $\mathbf{r}_v$. A small parameter rectangle $du\times dv$ maps to a small parallelogram with edges $\mathbf{r}_u\,du$ and $\mathbf{r}_v\,dv$, whose **vector area** is

$$d\mathbf{S}=(\mathbf{r}_u\times\mathbf{r}_v)\,du\,dv,\qquad dS=\|\mathbf{r}_u\times\mathbf{r}_v\|\,du\,dv.$$

The vector $\mathbf{N}=\mathbf{r}_u\times\mathbf{r}_v$ is normal to the surface; the surface is smooth where $\mathbf{N}\neq\mathbf{0}$. The standard surfaces of field theory:

Surface	Parameters	$\mathbf{r}_u\times\mathbf{r}_v$	dS
graph $z=g(x,y)$	x,y	$(-g_x,\,-g_y,\,1)$ (upward)	$\sqrt{1+g_x^2+g_y^2}\,dx\,dy$
plane $z=\text{const}$	x,y	$\hat{\mathbf{z}}$	$dx\,dy$
cylinder $r=a$	ϕ,z	$a\,\hat{\mathbf{r}}$ (outward)	$a\,d\phi\,dz$
sphere $R=a$	θ,ϕ	$a^2\sin\theta\,\hat{\mathbf{R}}$ (outward)	$a^2\sin\theta\,d\theta\,d\phi$
disk/annulus $z=\text{const}$	r,ϕ	$r\,\hat{\mathbf{z}}$	$r\,dr\,d\phi$

Derivation for the sphere. $\mathbf{r}=a(\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta)$. Then $\mathbf{r}_\theta=a\hat{\boldsymbol{\theta}}$ and $\mathbf{r}_\phi=a\sin\theta\,\hat{\boldsymbol{\phi}}$ (lengths $h_\theta=a$, $h_\phi=a\sin\theta$), and $\hat{\boldsymbol{\theta}}\times\hat{\boldsymbol{\phi}}=\hat{\mathbf{R}}$, so $\mathbf{r}_\theta\times\mathbf{r}_\phi=a^2\sin\theta\,\hat{\mathbf{R}}$.

Scalar surface integrals and flux

Surface integrals

For a smooth surface S parametrised by $\mathbf{r}(u,v)$ over D:

- **scalar surface integral:** $\displaystyle\iint_S f\,dS = \iint_D f(\mathbf{r}(u,v))\,\|\mathbf{r}_u \times \mathbf{r}_v\|\,du\,dv$;
- **flux** of $\mathbf{F}$ through S with unit normal $\hat{\mathbf{n}}$: $\displaystyle\iint_S \mathbf{F}\cdot d\mathbf{S} = \iint_S \mathbf{F}\cdot\hat{\mathbf{n}}\,dS = \iint_D \mathbf{F}(\mathbf{r}(u,v))\cdot(\mathbf{r}_u\times\mathbf{r}_v)\,du\,dv$,

the last form being valid when $\mathbf{r}_u \times \mathbf{r}_v$ points along the chosen $\hat{\mathbf{n}}$ (otherwise change the sign). For a closed surface the flux is written $\oint_S \mathbf{F}\cdot d\mathbf{S}$ and $\hat{\mathbf{n}}$ is taken **outward**.

Flux counts how much of the field passes *through* the surface: only the normal component $\mathbf{F}\cdot\hat{\mathbf{n}}$ matters; a field tangent to the surface contributes nothing. If $\mathbf{F}$ is the velocity of a fluid, the flux is the volume flow rate (m^3/s); if it is the current density $\mathbf{J}$, the flux is the current $I = \iint \mathbf{J}\cdot d\mathbf{S}$; if it is $\mathbf{B}$, the flux Φ is in webers.

Orientation. A flux needs a choice of side. An **orientable** surface admits a continuous choice of unit normal; a closed surface is oriented outward by convention; an open surface bounded by a curve is oriented consistently with the curve's direction by the right-hand rule (Section 7.10). The Möbius strip is the standard example of a non-orientable surface — you cannot define the flux through it.

Worked Example — areas: spherical cap and paraboloid

(a) Find the area of the cap $0 \le \theta \le \alpha$ of a sphere of radius a.

$$A = \int_0^{2\pi}\int_0^{\alpha} a^2 \sin\theta\,d\theta\,d\phi = 2\pi a^2(1-\cos\alpha).$$

For $\alpha = \pi$ this is $4\pi a^2$ ✓; for $\alpha = \pi/2$, the hemisphere $2\pi a^2$ ✓. The cap's **solid angle** is $A/a^2 = 2\pi(1-\cos\alpha)$ steradians, the quantity used for antenna beam widths.

(b) Find the area of the paraboloid $z = x^2 + y^2$ below $z = 1$. Here $g_x = 2x$, $g_y = 2y$, so $dS = \sqrt{1+4x^2+4y^2}\,dx\,dy = \sqrt{1+4r^2}\,r\,dr\,d\phi$ over the unit disk:

$$A = 2\pi\int_0^1 \sqrt{1+4r^2}\,r\,dr = 2\pi\left[\frac{(1+4r^2)^{3/2}}{12}\right]_0^1 = \frac{\pi}{6}\left(5\sqrt{5}-1\right) = 5.330.$$

Sanity check: larger than the unit disk ($\pi = 3.14$) it sits above, as a curved surface must be.

Worked Example — outward flux through a sphere

Find the outward flux of $\mathbf{F} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}} = \mathbf{R}$ through the sphere $R = a$.

On the sphere $\mathbf{F} = a\hat{\mathbf{R}}$ and $d\mathbf{S} = a^2\sin\theta\,d\theta\,d\phi\,\hat{\mathbf{R}}$, so $\mathbf{F}\cdot d\mathbf{S} = a^3\sin\theta\,d\theta\,d\phi$ and

$$\oint_S \mathbf{F}\cdot d\mathbf{S} = a^3\int_0^{2\pi}\int_0^{\pi}\sin\theta\,d\theta\,d\phi = 4\pi a^3.$$

Since $\nabla\cdot\mathbf{F} = 3$ and the ball has volume $\frac{4}{3}\pi a^3$, the flux is $3\times$ volume — a preview of the divergence theorem.

By contrast, for the inverse-square field $\hat{\mathbf{R}}/R^2$ the flux is $\frac{1}{a^2}\cdot 4\pi a^2 = 4\pi$, **independent of** a. Every sphere around the origin catches all the field lines.

Worked Example — flux through a curved open surface

Find the upward flux of $\mathbf{F} = z\,\hat{\mathbf{z}}$ through the paraboloid cap S: $z = 1 - x^2 - y^2$, $z \ge 0$.

Step 1 — normal. With $g = 1 - x^2 - y^2$, $\mathbf{N} = (-g_x, -g_y, 1) = (2x, 2y, 1)$, which points upward ✓.

Step 2 — integrand. $\mathbf{F}\cdot\mathbf{N} = z\cdot 1 = 1 - x^2 - y^2 = 1 - r^2$.

Step 3 — integrate over the projection (the unit disk):

$$\iint_S \mathbf{F}\cdot d\mathbf{S} = \int_0^{2\pi}\int_0^1 (1-r^2)\,r\,dr\,d\phi = 2\pi\left(\tfrac{1}{2} - \tfrac{1}{4}\right) = \frac{\pi}{2}.$$

We will recover this from the divergence theorem in Section 7.11.

Worked Example — flux of a point charge through one face of a cube

A charge q sits at the centre of a cube of side $2d$. Find the flux of $\mathbf{E}$ through the top face, both by symmetry and directly.

By symmetry. The total outward flux through any closed surface around q is q/ε_0 (Gauss's law, Section 7.12); the six faces are equivalent, so each receives $q/(6\varepsilon_0)$.

Directly. On the top face $z = d$, $\hat{\mathbf{n}} = \hat{\mathbf{z}}$, and $\mathbf{E}\cdot\hat{\mathbf{z}} = \dfrac{q}{4\pi\varepsilon_0}\dfrac{d}{(x^2+y^2+d^2)^{3/2}}$. So

$$\Phi_E = \frac{q}{4\pi\varepsilon_0}\int_{-d}^{d}\int_{-d}^{d}\frac{d\,dx\,dy}{(x^2+y^2+d^2)^{3/2}} = \frac{q}{4\pi\varepsilon_0}\cdot\Omega,$$

where Ω is the solid angle the face subtends. Substituting $x = du$, $y = dv$ removes d, and the standard result for a rectangle $\int_{-a}^{a}\int_{-b}^{b}\frac{du\,dv}{(u^2+v^2+1)^{3/2}} = 4\arctan\dfrac{ab}{\sqrt{a^2+b^2+1}}$ with $a = b = 1$ gives

$$\Omega = 4\arctan\frac{1}{\sqrt{3}} = 4\cdot\frac{\pi}{6} = \frac{2\pi}{3}.$$

Hence $\Phi_E = \dfrac{q}{4\pi\varepsilon_0}\cdot\dfrac{2\pi}{3} = \dfrac{q}{6\varepsilon_0}$ ✓ (and $2\pi/3 = 2.0944$ was confirmed by numerical quadrature).

Worked Example — current through a conductor cross-section

A round wire of radius a carries current density $\mathbf{J} = J_0(1 - r^2/a^2)\hat{\mathbf{z}}$ (peaked on the axis). Find the total current, and the radius inside which half of it flows.

Total. $I = \iint \mathbf{J}\cdot\hat{\mathbf{z}}\,dS = \int_0^{2\pi}\int_0^a J_0\left(1-\frac{r^2}{a^2}\right) r\,dr\,d\phi = 2\pi J_0\left(\frac{a^2}{2}-\frac{a^2}{4}\right) = \frac{\pi a^2 J_0}{2}$ — half of what a uniform J_0 would give.

Half-current radius. $I(\rho) = 2\pi J_0\left(\frac{\rho^2}{2}-\frac{\rho^4}{4a^2}\right) = \frac{\pi a^2 J_0}{4}$ gives, with $s = \rho^2/a^2$, $s - \frac{s^2}{2} = \frac{1}{4}$, i.e. $s^2 - 2s + \frac{1}{2} = 0$, $s = 1 - 1/\sqrt{2} = 0.2929$, so $\rho = 0.541a$.

Common Pitfall

Forgetting the area factor. On a sphere $dS = a^2\sin\theta\,d\theta\,d\phi$, not $d\theta\,d\phi$; on a cylinder $dS = a\,d\phi\,dz$. The quickest check is to integrate 1 and see whether you get the known area. A second pitfall is projecting onto the xy-plane without the factor $\sqrt{1+g_x^2+g_y^2}$ (for scalar integrals) — for *flux* the vector $(-g_x, -g_y, 1)$ already contains the right factor.

Engineering Note

Radiated power is a flux: an antenna's total radiated power is $P = \oint\langle\mathbf{S}\rangle\cdot d\mathbf{S}$ over a large sphere, and its **directivity** compares the power per unit solid angle in the main beam with the average $P/(4\pi)$. The $\sin\theta$ in dS is why a beam near the pole of the coordinate system carries less power than one of the same angular width near the equator.

7.8 Volume integrals

Definition and the three volume elements

Volume integrals were set up in Ch. 6 as triple integrals. In field theory they answer questions such as: how much charge is in this region, how much energy is stored in this field, where is the centre of this charge distribution?

Volume integral

For a scalar field f over a region V,

$$\iiint_V f\,dV = \lim_{\max\Delta V_k\to 0}\sum_k f(\mathbf{R}_k)\,\Delta V_k,$$

evaluated as an iterated integral with

$$dV = dx\,dy\,dz = r\,dr\,d\phi\,dz = R^2\sin\theta\,dR\,d\theta\,d\phi.$$

A **vector** volume integral $\iiint_V \mathbf{F}\,dV$ is computed component by component **in Cartesian components**.

The volume elements are $h_1h_2h_3\,du_1\,du_2\,du_3$: the product of the three edge lengths of an infinitesimal coordinate box. The choice of coordinates is dictated by the shape of the region more than by the integrand: spheres and cones in spherical coordinates, cylinders and pipes in cylindrical, boxes in Cartesian.

Quantity	Volume integral
total charge	$Q = \iiint \rho\,dV$
mass, from density ρ_m	$M = \iiint \rho_m\,dV$
electrostatic energy	$W_e = \frac{1}{2}\iiint \varepsilon\|\mathbf{E}\|^2 dV$
magnetic energy	$W_m = \frac{1}{2}\iiint \mu\|\mathbf{H}\|^2 dV$
ohmic power	$P = \iiint \mathbf{J}\cdot\mathbf{E}\,dV = \iiint \sigma\|\mathbf{E}\|^2 dV$

Quantity	Volume integral
dipole moment	$\mathbf{p} = \iiint \mathbf{R}\,\rho\,dV$
potential of a distribution	$V(\mathbf{R}) = \dfrac{1}{4\pi\varepsilon_0}\iiint \dfrac{\rho(\mathbf{R}')}{\lVert\mathbf{R}-\mathbf{R}'\rVert}dV'$

Worked Example — charge in a non-uniform sphere

A sphere of radius a has charge density $\rho = \rho_0(1 - R/a)$. Find the total charge.

Step 1. The integrand depends only on R, so the angular integrals give $\int_0^{2\pi}\int_0^{\pi}\sin\theta\,d\theta\,d\phi = 4\pi$.

Step 2. $Q = 4\pi\rho_0\int_0^a\left(1-\dfrac{R}{a}\right)R^2\,dR = 4\pi\rho_0\left(\dfrac{a^3}{3}-\dfrac{a^3}{4}\right) = \dfrac{\pi\rho_0 a^3}{3}$.

Check. A uniform density ρ_0 would give $\frac{4}{3}\pi\rho_0 a^3$; the tapered sphere holds a quarter of that. Plausible: most of a ball's volume is near its surface, where this density is small.

Worked Example — charge in a cylinder (separable integrand)

A cylinder $0 \le r \le a$, $0 \le z \le L$ holds $\rho = \rho_0\,\dfrac{r}{a}\,e^{-z/L}$. Find Q.

The integrand is a product of functions of r, ϕ and z separately and the limits are constants, so the triple integral is a product of three single integrals:

$$Q = \rho_0\underbrace{\int_0^{2\pi}d\phi}_{2\pi}\underbrace{\int_0^a\frac{r}{a}\,r\,dr}_{a^2/3}\underbrace{\int_0^L e^{-z/L}dz}_{L(1-e^{-1})} = \frac{2\pi}{3}\left(1-e^{-1}\right)\rho_0 a^2 L = 1.324\,\rho_0 a^2 L.$$

Do not forget the r in dV: it turns $\int r\,dr$ into $\int r^2\,dr$ here.

Worked Example — energy stored in the field of a charged sphere

A sphere of radius a carries total charge Q uniformly through its volume. Its field (derived in Section 7.12) is $E = \dfrac{QR}{4\pi\varepsilon_0 a^3}$ inside and $E = \dfrac{Q}{4\pi\varepsilon_0 R^2}$ outside. Find the stored energy $W = \frac{\varepsilon_0}{2}\iiint E^2\,dV$ over all space.

Inside.

$$W_{\text{in}} = \frac{\varepsilon_0}{2}\left(\frac{Q}{4\pi\varepsilon_0 a^3}\right)^2\int_0^a R^2\cdot 4\pi R^2\,dR = \frac{\varepsilon_0}{2}\cdot\frac{Q^2}{16\pi^2\varepsilon_0^2 a^6}\cdot\frac{4\pi a^5}{5} = \frac{Q^2}{40\pi\varepsilon_0 a}.$$

Outside.

$$W_{\text{out}} = \frac{\varepsilon_0}{2}\cdot\frac{Q^2}{16\pi^2\varepsilon_0^2}\int_a^{\infty}\frac{4\pi R^2}{R^4}\,dR = \frac{Q^2}{8\pi\varepsilon_0 a}.$$

Total. $W = \dfrac{Q^2}{8\pi\varepsilon_0 a}\left(\dfrac{1}{5}+1\right) = \dfrac{3Q^2}{20\pi\varepsilon_0 a}$.

Numbers. $Q = 1$ nC, $a = 1$ cm: $W = 3\times10^{-18}/(20\pi\times 8.854\times10^{-12}\times 0.01) = 5.39\times10^{-7}$ J. Five-sixths of the energy is stored *outside* the charge — the field, not the charge, holds the energy.

Worked Example — a vector volume integral: dipole moment

A sphere of radius a has $\rho = \rho_0\cos\theta$ (positive in the upper half, negative in the lower). Find the total charge and the dipole moment $\mathbf{p} = \iiint \mathbf{R}\rho\,dV$.

Charge. $Q = \rho_0\int_0^a R^2 dR\int_0^{\pi}\cos\theta\sin\theta\,d\theta\int_0^{2\pi}d\phi = 0$, since $\int_0^{\pi}\cos\theta\sin\theta\,d\theta = 0$.

Dipole moment. $\mathbf{R} = R\hat{\mathbf{R}}$, but $\hat{\mathbf{R}}$ varies, so use Cartesian components: $\mathbf{R} = (R\sin\theta\cos\phi,\ R\sin\theta\sin\phi,\ R\cos\theta)$. The x- and y-components contain $\int_0^{2\pi}\cos\phi\,d\phi = 0$ and $\int_0^{2\pi}\sin\phi\,d\phi = 0$. The z-component is

$$p_z = \rho_0\int_0^a R^3\,dR\int_0^{\pi}\cos^2\theta\sin\theta\,d\theta\int_0^{2\pi}d\phi = \rho_0\cdot\frac{a^4}{4}\cdot\frac{2}{3}\cdot 2\pi = \frac{\pi\rho_0 a^4}{3}.$$

So $\mathbf{p} = \frac{1}{3}\pi\rho_0 a^4\,\hat{\mathbf{z}}$, pointing from the negative half to the positive half, as expected. Far away, this neutral sphere looks like the dipole of Section 7.4.

Common Pitfall

Integrating the spherical *components* of a vector field over a volume, e.g. writing $\iiint\hat{\mathbf{R}}\,dV = \hat{\mathbf{R}}\iiint dV$. $\hat{\mathbf{R}}$ is not a constant and cannot leave the integral; over a full sphere $\iiint\hat{\mathbf{R}}\,dV = \mathbf{0}$ by symmetry. Convert to Cartesian components first.

Engineering Note

Capacitance and inductance can be computed from energy: $C = 2W_e/V^2$ and $L = 2W_m/I^2$. Field solvers often extract L and C of interconnects this way, by integrating $\frac{1}{2}\varepsilon E^2$ and $\frac{1}{2}\mu H^2$ over the mesh — a large, numerical volume integral (Ch. 24).

7.9 Green's theorem

Statement

Green's theorem is the two-dimensional prototype of all the integral theorems. It relates a line integral around a closed plane curve to a double integral over the region inside.

Green's theorem

Let D be a bounded region of the plane whose boundary C consists of finitely many piecewise-smooth simple closed curves, oriented **positively** (as you walk along C, D is on your left — counter-clockwise for an outer boundary, clockwise for the boundary of a hole). If $P(x,y)$ and $Q(x,y)$ have continuous first partial derivatives on an open set containing D, then

$$\oint_C (P\,dx + Q\,dy) = \iint_D \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right) dA.$$

With $\mathbf{F} = P\hat{\mathbf{x}} + Q\hat{\mathbf{y}}$, the left side is the circulation $\oint \mathbf{F}\cdot d\mathbf{r}$ and the integrand on the right is $(\nabla \times \mathbf{F})\cdot\hat{\mathbf{z}}$. In words: **the circulation around the boundary equals the total curl inside.**

Proof sketch

Step 1 — the P term on a "vertically simple" region. Suppose $D = \{a \le x \le b,\ g_1(x) \le y \le g_2(x)\}$. Then

$$-\iint_D \frac{\partial P}{\partial y}\,dA = -\int_a^b \Big[P(x,g_2(x)) - P(x,g_1(x))\Big]\,dx.$$

Now compute $\oint_C P\,dx$ directly. On the bottom curve $y = g_1(x)$, traversed left to right, it gives $\int_a^b P(x,g_1(x))\,dx$. On the top curve, traversed right to left, it gives $-\int_a^b P(x,g_2(x))\,dx$. On any vertical sides $dx = 0$. The two expressions agree.

Step 2 — the Q term on a "horizontally simple" region is identical with the roles of x and y exchanged (and a sign flip that produces $+\partial Q/\partial x$).

Step 3 — general regions. Cut D into pieces that are both vertically and horizontally simple. Apply the theorem to each piece and add. The integrals along each internal cut appear twice, in opposite directions, and cancel, leaving only the outer boundary. ∎

The cancellation in Step 3 is the idea behind every integral theorem: **interior contributions cancel in pairs and only the boundary survives.** It is also how the coordinate-free definition of curl (circulation per unit area of a tiny loop) adds up to the theorem: tile D with tiny squares, each contributing $(\nabla \times \mathbf{F})_z\,\Delta A$, and the internal edges cancel.

The normal (flux) form

Apply Green's theorem to $P = -F_y$, $Q = F_x$. The outward unit normal to a counter-clockwise curve is $\hat{\mathbf{n}} = (dy, -dx)/ds$, so $\mathbf{F}\cdot\hat{\mathbf{n}}\,ds = F_x\,dy - F_y\,dx$. Hence

$$\oint_C \mathbf{F}\cdot\hat{\mathbf{n}}\,ds = \iint_D \left(\frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y}\right) dA = \iint_D \nabla\cdot\mathbf{F}\,dA\,:$$

the outward flux through the boundary equals the total divergence inside — the two-dimensional divergence theorem.

Area by a line integral

Choosing P, Q with $\partial_x Q - \partial_y P = 1$ turns the right side into the area of D. Three convenient choices:

$$A = \oint_C x\,dy = -\oint_C y\,dx = \frac{1}{2}\oint_C (x\,dy - y\,dx).$$

For a polygon with vertices $(x_1,y_1),\dots,(x_n,y_n)$ listed counter-clockwise, applying the last formula edge by edge gives the **shoelace formula**

$$A = \frac{1}{2}\sum_{k=1}^{n} (x_k y_{k+1} - x_{k+1} y_k)\,, \qquad (x_{n+1},y_{n+1}) = (x_1,y_1).$$

This is how CAD and PCB-layout tools compute the area of an arbitrary copper pour, and how a mechanical planimeter measures area by tracing the boundary.

Worked Example — verifying Green's theorem on a square

Let $P = x - y$, $Q = x^2$ on the unit square $[0,1]\times[0,1]$.

Double integral. $\partial_x Q - \partial_y P = 2x - (-1) = 2x + 1$, and $\int_0^1\int_0^1 (2x+1)\,dx\,dy = 1 + 1 = 2$.

Line integral, counter-clockwise from the origin:

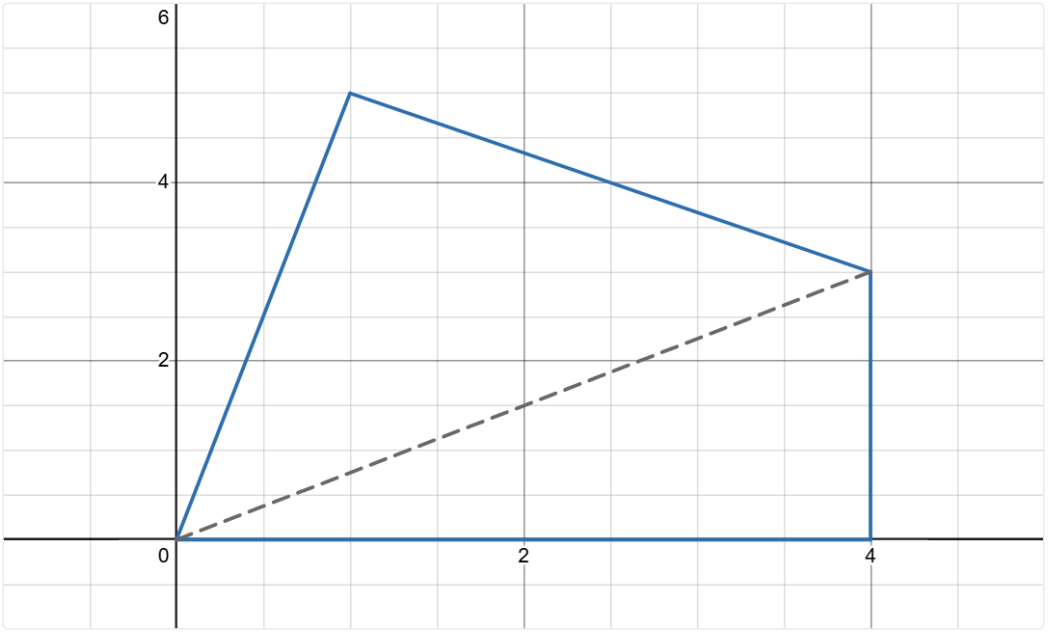
- bottom ($y = 0$, $x: 0 \to 1$, $dy = 0$): $\int_0^1 x\,dx = \frac{1}{2}$;
- right ($x = 1$, $y: 0 \to 1$, $dx = 0$): $\int_0^1 Q\,dy = \int_0^1 1\,dy = 1$;
- top ($y = 1$, $x: 1 \to 0$, $dy = 0$): $\int_1^0 (x-1)\,dx = \frac{1}{2}$;
- left ($x = 0$, $y: 1 \to 0$, $dx = 0$): $Q = 0$, contribution 0.

Total $\frac{1}{2} + 1 + \frac{1}{2} + 0 = 2$ ✓.

Worked Example — area of an ellipse and of a polygon

Ellipse. $x = a\cos t$, $y = b\sin t$, $0 \le t \le 2\pi$ (counter-clockwise). Then $x\,dy - y\,dx = (ab\cos^2 t + ab\sin^2 t)\,dt = ab\,dt$, so $A = \frac{1}{2}\int_0^{2\pi} ab\,dt = \pi ab$.

Polygon. A copper pad has vertices $(0,0)$, $(4,0)$, $(4,3)$, $(1,5)$ mm, in counter-clockwise order. Shoelace terms $x_k y_{k+1} - x_{k+1} y_k$: $(0)(0) - (4)(0) = 0$; $(4)(3) - (4)(0) = 12$; $(4)(5) - (1)(3) = 17$; $(1)(0) - (0)(5) = 0$. $A = \frac{1}{2}(0 + 12 + 17 + 0) = 14.5$ mm^2. **Check by splitting** along the diagonal from $(0,0)$ to $(4,3)$: triangle $(0,0)$, $(4,0)$, $(4,3)$ has area $\frac{1}{2}\cdot 4 \cdot 3 = 6$, and triangle $(0,0)$, $(4,3)$, $(1,5)$ has area $\frac{1}{2}|4\cdot 5 - 3\cdot 1| = 8.5$ (half the cross product of its edge vectors, Section 7.2); total 14.5 ✓. Listing the vertices clockwise would give -14.5: the sign of the shoelace sum reports the orientation.



The pad of the shoelace example. The dashed diagonal splits it into triangles of area 6 and 8.5, confirming $A = 14.5$.

Worked Example — a region with a hole

Let $\mathbf{F} = \dfrac{-y\,\hat{\mathbf{x}} + x\,\hat{\mathbf{y}}}{x^2 + y^2}$ (the wire field of Section 7.5, without constants). Evaluate $\oint \mathbf{F}\cdot d\mathbf{r}$ counter-clockwise around the ellipse C: $x^2/4 + y^2 = 1$.

Why the direct approach is unpleasant. On the ellipse $x^2 + y^2$ is not constant, and the resulting integral $\int_0^{2\pi} \frac{2\,dt}{4\cos^2 t + \sin^2 t}$ needs a substitution.

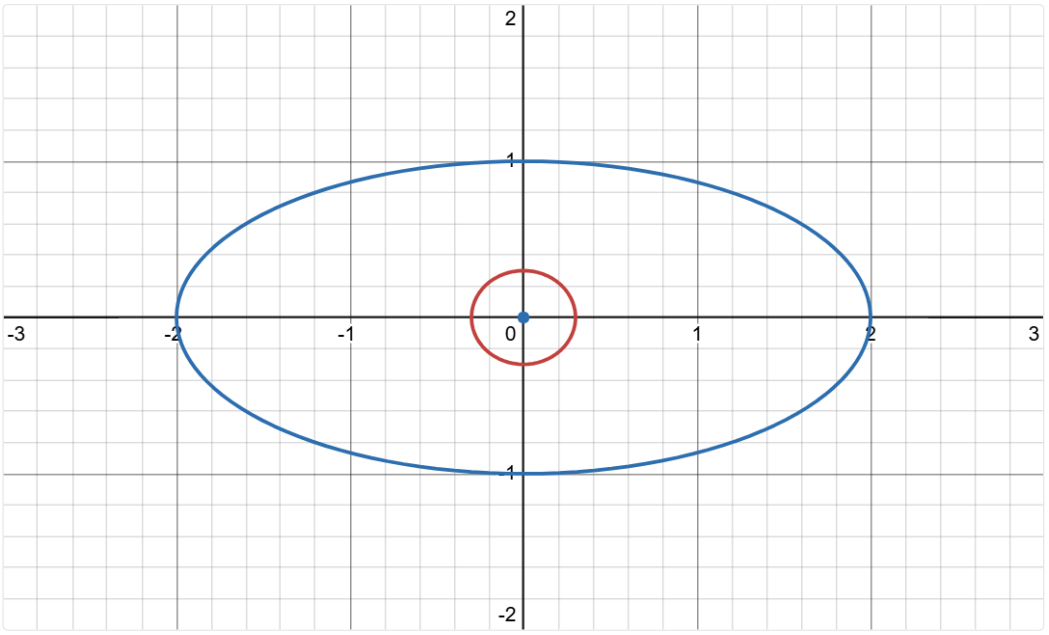
Green's theorem with a hole. $\nabla \times \mathbf{F} = \mathbf{0}$ everywhere except the origin, where $\mathbf{F}$ is undefined, so we cannot apply Green's theorem to the inside of the ellipse. Instead cut out a small circle C_ϵ of radius ϵ and apply it to the region D between C_ϵ and C. Its positively oriented boundary is C counter-clockwise plus C_ϵ clockwise:

$$\oint_C \mathbf{F}\cdot d\mathbf{r} - \oint_{C_\epsilon,\,\circlearrowleft} \mathbf{F}\cdot d\mathbf{r} = \iint_D 0\,dA = 0.$$

So the integral around the ellipse equals the integral around the small circle, which is $\int_0^{2\pi} \frac{\epsilon^2}{\epsilon^2}\,d\phi = 2\pi$.

Numerical check. $\int_0^{2\pi} \frac{2\,dt}{4\cos^2 t + \sin^2 t} = 2\cdot\frac{2\pi}{\sqrt{4\cdot 1}} = 2\pi$ using $\int_0^{2\pi} \frac{dt}{A\cos^2 t + B\sin^2 t} = \frac{2\pi}{\sqrt{AB}}$ ✓.

Any closed curve winding once around the origin gives 2π; any curve not enclosing it gives 0. The integral counts how many times the curve **winds** around the singularity — the same idea as the residue theorem of complex analysis (Ch. 18).



The ellipse (blue) and a small circle (red) around the singular point: the region between them is curl-free, so the two circulations are equal (2π).

Common Pitfall

Applying Green's theorem when P or Q is singular inside C. The hypotheses demand continuous partial derivatives on the **whole** region. Ignoring the singularity of the wire field would "prove" that $\oint \mathbf{F}\cdot d\mathbf{r} = 0$, contradicting the direct calculation.

Engineering Note

In two-dimensional field problems (long transmission lines, the cross-section of a motor), Green's theorem is the tool that turns a circulation around a conductor's cross-section into the current it carries, and a flux through a closed contour into the charge per unit length inside. Boundary-element methods for 2-D electrostatics are built on its identities.

7.10 Stokes' theorem

Statement

Green's theorem lives in a plane. Stokes' theorem lifts it to any curved surface in space: the circulation around the rim of a surface equals the flux of the curl through the surface.

Stokes' theorem

Let S be a piecewise-smooth oriented surface bounded by a piecewise-smooth simple closed curve C, with the orientation of C **induced** by that of S: if your right thumb points along the normal $\hat{\mathbf{n}}$, your fingers curl in the direction of C (equivalently, walking along C with your head along $\hat{\mathbf{n}}$, the surface is on your left). If $\mathbf{F}$ has continuous first partial derivatives on an open region containing S, then

$$\oint_C \mathbf{F}\cdot d\mathbf{r} = \iint_S (\nabla\times\mathbf{F})\cdot d\mathbf{S}.$$

For a flat surface in the xy-plane with $\hat{\mathbf{n}} = \hat{\mathbf{z}}$ this is exactly Green's theorem.

Proof sketches

Sketch 1 — tiling. Cover S with a fine mesh of small, nearly flat patches ΔS_k with normals $\hat{\mathbf{n}}_k$. By the definition of curl (Section 7.5), the circulation around the edge of patch k is approximately $(\nabla\times\mathbf{F})\cdot\hat{\mathbf{n}}_k\,\Delta S_k$. Add over all patches. Each internal edge is shared by two neighbouring patches and is traversed in opposite directions, so its contributions cancel; only the edges on the rim C survive. In the limit the sum of the right-hand sides becomes $\iint_S(\nabla\times\mathbf{F})\cdot d\mathbf{S}$. ■

Sketch 2 — reduction to Green. For a graph $z = g(x,y)$ over a region D, the parametrisation $(x,y,g(x,y))$ turns $\oint_C \mathbf{F}\cdot d\mathbf{r}$ into a plane line integral around the boundary of D, with $dz = g_x\,dx + g_y\,dy$:

$$\oint_{\partial D}\big[(F_x + F_z g_x)\,dx + (F_y + F_z g_y)\,dy\big].$$

Green's theorem converts this into a double integral over D. Expanding with the chain rule (where F_x means $F_x(x,y,g(x,y))$, so ∂_y acting on it produces $\partial_y F_x + \partial_z F_x\, g_y$), the terms with g_{xy} cancel by Clairaut and what remains is precisely $(\nabla\times\mathbf{F})\cdot(-g_x,-g_y,1)$ integrated over D — the flux of the curl through the graph. ■

Consequences

Corollaries of Stokes' theorem

1. **Surface independence.** $\iint_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S}$ depends only on the boundary curve C, not on which surface spanning C you choose. Pick the easiest one (usually a flat disk).
2. **Closed surfaces.** For a closed surface (no boundary), $\oint_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = 0$ — consistent with $\nabla \cdot (\nabla \times \mathbf{F}) = 0$ and the divergence theorem.
3. **Curl-free implies conservative** on a simply connected region: every loop bounds a surface inside the region, through which the flux of $\nabla \times \mathbf{F} = \mathbf{0}$ is zero, so every circulation vanishes (Section 7.6).
4. **The curl definition is recovered.** Applying the theorem to a tiny flat disk of area ΔS and normal $\hat{\mathbf{n}}$ and dividing by ΔS gives back $(\nabla \times \mathbf{F}) \cdot \hat{\mathbf{n}} = \lim \frac{1}{\Delta S} \oint \mathbf{F} \cdot d\mathbf{r}$.

Corollary 1 has a vivid electromagnetic meaning: the current "through a loop" is well defined only because $\nabla \cdot \mathbf{J} = 0$ for steady currents — whichever surface you stretch across the loop, the same current crosses it. When charge accumulates (a charging capacitor), two surfaces spanning the same loop can carry different conduction currents, which is the puzzle Maxwell solved with the displacement current (Section 7.12).

Worked Example — verifying Stokes' theorem on a hemisphere

Let $\mathbf{F} = z\,\hat{\mathbf{x}} + x\,\hat{\mathbf{y}} + y\,\hat{\mathbf{z}}$ and S the upper unit hemisphere $x^2 + y^2 + z^2 = 1$, $z \geq 0$, with outward (upward) normal. The boundary is the unit circle in the xy-plane, counter-clockwise seen from above.

Line integral. $\mathbf{r} = (\cos t, \sin t, 0)$, $\mathbf{r}' = (-\sin t, \cos t, 0)$, and on C, $\mathbf{F} = (0, \cos t, \sin t)$. So $\mathbf{F} \cdot \mathbf{r}' = \cos^2 t$ and $\oint = \int_0^{2\pi} \cos^2 t\, dt = \pi$.

Curl. $\nabla \times \mathbf{F} = (\partial_y y - \partial_z x,\ \partial_z z - \partial_x y,\ \partial_x x - \partial_y z) = (1, 1, 1)$.

Flux of the curl through the hemisphere. $d\mathbf{S} = \sin\theta\, d\theta\, d\phi\, \hat{\mathbf{R}}$ and $(1,1,1) \cdot \hat{\mathbf{R}} = \sin\theta\cos\phi + \sin\theta\sin\phi + \cos\theta$. The $\cos\phi$ and $\sin\phi$ terms integrate to zero over $0 \leq \phi \leq 2\pi$, leaving

$$\int_0^{2\pi} \int_0^{\pi/2} \cos\theta \sin\theta\, d\theta\, d\phi = 2\pi \cdot \tfrac{1}{2} = \pi \ \checkmark$$

Using surface independence instead. The flat unit disk also spans C, with normal $\hat{\mathbf{z}}$: $\iint (1,1,1) \cdot \hat{\mathbf{z}}\, dA = \pi$. Same answer in one line.

Worked Example — a line integral made easy

Evaluate $\oint_C \mathbf{F} \cdot d\mathbf{r}$ for $\mathbf{F} = z^2\,\hat{\mathbf{x}} + y^2\,\hat{\mathbf{y}} + x\,\hat{\mathbf{z}}$, where C is the triangle $(1,0,0) \to (0,1,0) \to (0,0,1) \to (1,0,0)$.

Step 1 — curl. $\nabla \times \mathbf{F} = (\partial_y x - \partial_z y^2,\ \partial_z z^2 - \partial_x x,\ \partial_x y^2 - \partial_y z^2) = (0,\ 2z - 1,\ 0)$.

Step 2 — surface and orientation. Take the flat triangle in the plane $x + y + z = 1$, i.e. $z = 1 - x - y$ over the projected triangle T: $x, y \geq 0$, $x + y \leq 1$. The edge vectors $(0,1,0) - (1,0,0) = (-1,1,0)$ and $(0,0,1) - (1,0,0) = (-1,0,1)$ have cross product $(1,1,1)$, so the given order of vertices corresponds to the upward normal. For the graph, $\mathbf{N} = (-g_x, -g_y, 1) = (1,1,1)$ ✓.

Step 3 — integrate. $(\nabla \times \mathbf{F}) \cdot \mathbf{N} = 2z - 1 = 2(1 - x - y) - 1 = 1 - 2x - 2y$. Over T (area $\frac{1}{2}$, with $\iint_T x\, dA = \iint_T y\, dA = \frac{1}{6}$):

$$\oint_C \mathbf{F} \cdot d\mathbf{r} = \tfrac{1}{2} - 2 \cdot \tfrac{1}{6} - 2 \cdot \tfrac{1}{6} = -\tfrac{1}{6}.$$

Check by computing the three edge integrals directly (each a polynomial in t): they sum to $-\frac{1}{6}$ ✓. One surface integral replaced three line integrals.

Worked Example — the vector potential of a solenoid

Inside a long solenoid of radius a the magnetic flux density is uniform, $\mathbf{B} = B_0\hat{\mathbf{z}}$, and outside it is (nearly) zero. A vector potential with $\nabla \times \mathbf{A} = \mathbf{B}$ is sought in the form $\mathbf{A} = A_\phi(r)\,\hat{\boldsymbol{\phi}}$. Find it inside and outside.

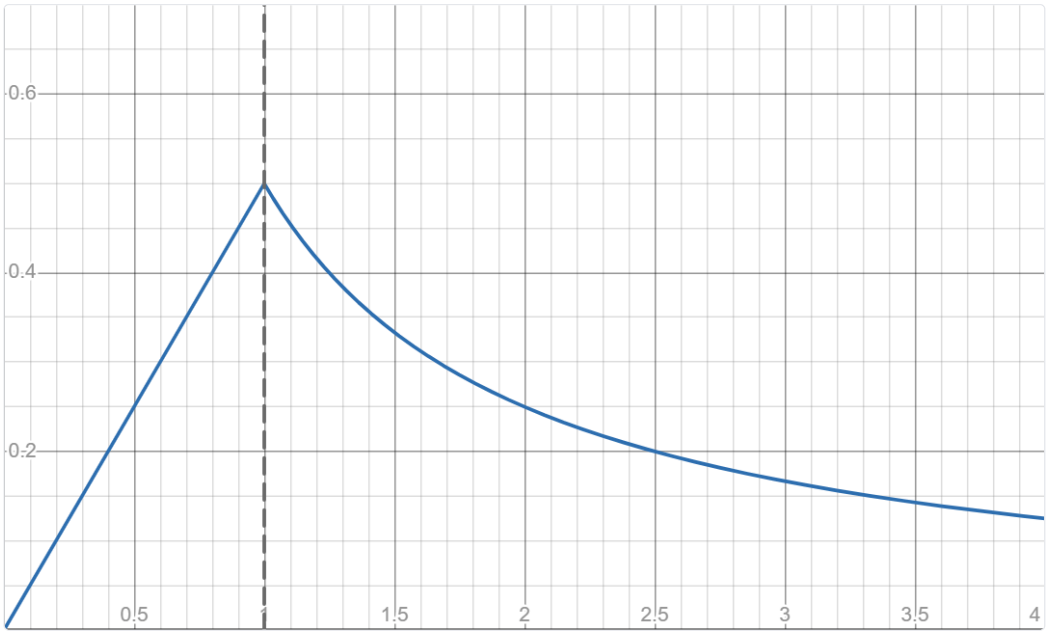
Step 1 — Stokes on a circle of radius r. $\oint \mathbf{A} \cdot d\mathbf{r} = 2\pi r A_\phi(r)$, and this equals $\iint (\nabla \times \mathbf{A}) \cdot d\mathbf{S} = \iint \mathbf{B} \cdot d\mathbf{S} = \Phi(r)$, the flux enclosed.

Step 2 — inside ($r < a$). $\Phi = B_0 \pi r^2$, so $A_\phi = B_0 r/2$.

Step 3 — outside ($r > a$). $\Phi = B_0 \pi a^2$ (all the flux), so $A_\phi = \dfrac{B_0 a^2}{2r}$.

Check with the cylindrical curl. Inside: $\frac{1}{r}\partial_r(r \cdot B_0 r/2) = B_0$ ✓. Outside: $\frac{1}{r}\partial_r(B_0 a^2/2) = 0$ ✓.

The vector potential is non-zero outside even though $\mathbf{B}$ is zero there — it "remembers" the enclosed flux through its circulation. Faraday's law (Section 7.12) uses this: a changing enclosed flux drives an EMF in a loop that lies entirely in the field-free region.



Vector potential $A_\phi(r)$ of an ideal solenoid ($B_0 = 1$, $a = 1$): it grows linearly inside and decays as $1/r$ outside, where $\mathbf{B} = \mathbf{0}$ but the circulation of $\mathbf{A}$ still equals the enclosed flux.

Common Pitfall

Mismatched orientation. If the surface normal points down but you traverse C counter-clockwise as seen from above, Stokes' theorem gives the wrong sign. Fix the curve direction first, then use the right-hand rule to choose $\hat{\mathbf{n}}$ — or vice versa — never independently.

Engineering Note

Stokes' theorem is why a current probe (Rogowski coil) works: a coil wound around a closed path measures $\oint \mathbf{B} \cdot d\mathbf{l} = \mu_0 I_{\text{enc}}$ regardless of where the conductor sits inside the loop. Likewise the voltage induced in a PCB loop depends only on the flux through the loop area, so minimising loop area (return path directly under the signal trace) minimises inductive pickup.

7.11 Divergence theorem

Statement

Divergence theorem (Gauss's theorem)

Let V be a bounded solid region whose boundary S is a closed piecewise-smooth surface with **outward** unit normal. If $\mathbf{F}$ has continuous first partial derivatives on an open region containing V, then

$$\oiint_S \mathbf{F} \cdot d\mathbf{S} = \iiint_V \nabla \cdot \mathbf{F} \, dV.$$

In words: **the net outward flux through a closed surface equals the total source strength inside.** It is the three-dimensional analogue of the flux form of Green's theorem, and the mathematical content of Gauss's law.

Proof sketches

Sketch 1 — tiling. Divide V into tiny boxes. By the definition of divergence, the outward flux of each box is $\nabla \cdot \mathbf{F}\, \Delta V_k$. Summing over all boxes, the flux through every internal face is counted twice with opposite normals and cancels; only the faces on the outer boundary S survive. ∎

Sketch 2 — one component at a time. Write $\mathbf{F} = F_x\hat{\mathbf{x}} + F_y\hat{\mathbf{y}} + F_z\hat{\mathbf{z}}$; it suffices to prove $\oint F_z\hat{\mathbf{z}} \cdot d\mathbf{S} = \iiint \partial_z F_z \, dV$ and its two companions. Let $V = \{(x,y) \in D,\ g_1(x,y) \le z \le g_2(x,y)\}$. Then

$$\iiint_V \frac{\partial F_z}{\partial z}\, dV = \iint_D \Big[F_z(x,y,g_2) - F_z(x,y,g_1)\Big]\, dx\, dy.$$

On the top surface the upward normal vector is $(-g_{2x}, -g_{2y}, 1)\, dx\, dy$, so $F_z\hat{\mathbf{z}} \cdot d\mathbf{S} = F_z(x,y,g_2)\, dx\, dy$; on the bottom the outward normal points down, giving $-F_z(x,y,g_1)\, dx\, dy$; on any vertical side walls $\hat{\mathbf{z}} \cdot \hat{\mathbf{n}} = 0$. The flux equals the volume integral. ∎

Consequences

Solenoidal fields. If $\nabla \cdot \mathbf{F} = 0$ in V, the flux into V equals the flux out: what enters through one part of the surface leaves through another. For $\mathbf{B}$ this is "no magnetic monopoles"; it is why magnetic flux through a transformer core is the same at every cross-section.

Conservation laws. Let ρ be the density of something (charge, say) and $\mathbf{J}$ its flux density. Conservation says the rate of decrease of the amount inside V equals the outflow:

$$-\frac{d}{dt}\iiint_V \rho\, dV = \oint_S \mathbf{J}\cdot d\mathbf{S} = \iiint_V \nabla\cdot\mathbf{J}\, dV.$$

Since V is arbitrary, the integrands must agree, giving the **continuity equation**

$$\nabla\cdot\mathbf{J} + \frac{\partial\rho}{\partial t} = 0.$$

The step "integral is zero for every region ⇒ integrand is zero" (valid for continuous integrands: if the integrand were positive at a point it would be positive on a small ball around it) is the device that converts every integral law into a differential one. We use it four more times in Section 7.12.

Green's identities. Apply the theorem to $\mathbf{F} = f\nabla g$, using identity 4 of Section 7.5, $\nabla\cdot(f\nabla g) = f\nabla^2 g + \nabla f\cdot\nabla g$:

$$\iiint_V \left(f\nabla^2 g + \nabla f\cdot\nabla g\right) dV = \oint_S f\,\nabla g\cdot d\mathbf{S} \qquad \text{(first identity)}.$$

Swapping f and g and subtracting:

$$\iiint_V \left(f\nabla^2 g - g\nabla^2 f\right) dV = \oint_S \left(f\nabla g - g\nabla f\right)\cdot d\mathbf{S} \qquad \text{(second identity)}.$$

Uniqueness of solutions of Poisson's equation

If $\nabla^2 V = -\rho/\varepsilon$ in V and V is prescribed on the boundary S, the solution is unique.

Proof. Let V_1, V_2 be two solutions and $w = V_1 - V_2$. Then $\nabla^2 w = 0$ inside and $w = 0$ on S. The first identity with $f = g = w$ gives $\iiint \|\nabla w\|^2 dV = \oint w\nabla w\cdot d\mathbf{S} = 0$, so $\nabla w = \mathbf{0}$, w is constant, and it is zero because it vanishes on S. ■ This theorem is what licenses the method of images and every "guess the solution and check it" approach in electrostatics (Ch. 13).

Point sources and the delta function

The inverse-square field $\hat{\mathbf{R}}/R^2$ has zero divergence for $R \neq 0$, yet its flux through any sphere about the origin is 4π. The divergence theorem cannot be applied naively to a region containing the origin because the field is singular there. Two ways to handle it:

- **Excise the singularity** (as with the hole in Green's theorem): for any closed surface S enclosing the origin, apply the theorem to the region between S and a small sphere S_ϵ. The divergence is zero there, so the flux through S equals the flux through S_ϵ, which is 4π. If S does not enclose the origin, the flux is 0.
- **Use the Dirac delta** (Ch. 14, Ch. 16): define $\delta(\mathbf{R}) = \delta(x)\delta(y)\delta(z)$, with $\iiint_V \delta(\mathbf{R})\, dV = 1$ if V contains the origin and 0 otherwise. Then the flux results above are summarised as

$$\nabla\cdot\frac{\hat{\mathbf{R}}}{R^2} = 4\pi\,\delta(\mathbf{R}), \qquad \nabla^2\frac{1}{R} = -4\pi\,\delta(\mathbf{R}).$$

The second formula says that $G(\mathbf{R},\mathbf{R}') = \dfrac{1}{4\pi\|\mathbf{R}-\mathbf{R}'\|}$ is the **Green's function** of $-\nabla^2$: the potential of a unit point source. Superposing point sources gives the solution of Poisson's equation in free space, $V(\mathbf{R}) = \dfrac{1}{4\pi\varepsilon_0}\iiint \dfrac{\rho(\mathbf{R}')}{\|\mathbf{R}-\mathbf{R}'\|}dV'$ — the same superposition-of-impulse-responses idea as convolution in circuit theory.

Worked Example — verifying the theorem on a cube

Let $\mathbf{F} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}}$ and $V = [0,1]^3$.

Volume side. $\nabla\cdot\mathbf{F} = 3$, so $\iiint 3\, dV = 3$.

Surface side. On the face $x = 1$, $\hat{\mathbf{n}} = \hat{\mathbf{x}}$ and $\mathbf{F}\cdot\hat{\mathbf{n}} = x = 1$: flux 1. On $x = 0$, $\mathbf{F}\cdot(-\hat{\mathbf{x}}) = -x = 0$: flux 0. The y and z faces behave the same way. Total $1 + 1 + 1 = 3$ ✓.

Worked Example — a flux that is easier as a volume integral

Find the outward flux of $\mathbf{F} = x^3\hat{\mathbf{x}} + y^3\hat{\mathbf{y}} + z^3\hat{\mathbf{z}}$ through the sphere $R = a$.

Direct route (hard). $\mathbf{F}\cdot\hat{\mathbf{R}} = (x^4+y^4+z^4)/a$ on the sphere — an awkward angular integral.

Divergence theorem. $\nabla\cdot\mathbf{F} = 3(x^2+y^2+z^2) = 3R^2$, so

$$\oint_S \mathbf{F}\cdot d\mathbf{S} = \int_0^{2\pi}\int_0^{\pi}\int_0^{a} 3R^2\cdot R^2\sin\theta\, dR\, d\theta\, d\phi = 3\cdot\frac{a^5}{5}\cdot 2\cdot 2\pi = \frac{12\pi a^5}{5}.$$

Cross-check of the direct route. By symmetry $\oint x^4\, dS = \oint y^4\, dS = \oint z^4\, dS$, and $\oint z^4\, dS = a^4\cdot a^2\int_0^{2\pi}\int_0^{\pi}\cos^4\theta\sin\theta\, d\theta\, d\phi = a^6\cdot\frac{2}{5}\cdot 2\pi = \frac{4\pi a^6}{5}$. So the flux is $\frac{3}{a}\cdot\frac{4\pi a^6}{5} = \frac{12\pi a^5}{5}$ ✓.

Worked Example — closing an open surface

Recover the flux $\pi/2$ of $\mathbf{F} = z\hat{\mathbf{z}}$ through the paraboloid cap $z = 1 - x^2 - y^2$, $z \geq 0$ (Section 7.7), using the divergence theorem.

Step 1 — close the surface with the disk $z = 0$, $r \leq 1$. The closed surface encloses the solid V under the cap.

Step 2 — volume integral. $\nabla \cdot \mathbf{F} = 1$, so $\iiint_V 1\, dV$ is the volume: $\int_0^{2\pi} \int_0^1 (1 - r^2)\, r\, dr\, d\phi = \pi/2$.

Step 3 — subtract the disk. On the disk $z = 0$, so $\mathbf{F} = \mathbf{0}$ and its flux is 0.

Result. Flux through the cap $= \pi/2 - 0 = \pi/2$ ✓. "Close the surface, use the volume integral, subtract the easy lid" is a standard trick.

Worked Example — Gauss's law for an arbitrary surface

A point charge q at the origin has $\mathbf{E} = \dfrac{q}{4\pi\varepsilon_0} \dfrac{\hat{\mathbf{R}}}{R^2}$. Find the flux of $\mathbf{E}$ out of (a) the cube $|x|, |y|, |z| \leq 1$; (b) the cube $1 \leq x \leq 3$, $|y|, |z| \leq 1$.

(a) The cube encloses the origin. By the excision argument the flux equals that through a small sphere: $\dfrac{q}{4\pi\varepsilon_0} \cdot 4\pi = \dfrac{q}{\varepsilon_0}$. (Consistent with the per-face result $q/(6\varepsilon_0)$ of Section 7.7.)

(b) The origin lies outside; $\nabla \cdot \mathbf{E} = 0$ throughout, so the flux is 0 — the field lines that enter through the face $x = 1$ all leave through the other five faces.

Common Pitfall

Using an inward normal, or forgetting a piece of the boundary. The divergence theorem needs the **whole** closed boundary with **outward** normals. For a region with an internal cavity (a hollow sphere), the boundary includes the inner surface with its normal pointing *into the cavity* — away from the material.

Engineering Note

The finite-volume method used in thermal simulators and in many TCAD semiconductor-device solvers is the divergence theorem applied cell by cell: each mesh cell's stored quantity changes by the sum of fluxes through its faces. Because each face flux is shared by two cells with opposite signs, the scheme conserves charge (or heat) exactly — the discrete version of the interior-cancellation argument.

7.12 Applications to electromagnetic field theory

Everything in this chapter was built for this section. Maxwell's equations are four statements about the fields $\mathbf{E}, \mathbf{D}, \mathbf{H}, \mathbf{B}$; in **integral form** they are statements about line integrals around loops and fluxes through surfaces — the form in which they were discovered and are measured. Stokes' theorem and the divergence theorem turn them into **differential form** — local partial differential equations that hold at every point and can be solved. The mathematics is the subject here; the physics is the motivation.

The field quantities

Symbol	Name	SI unit
$\mathbf{E}$	electric field intensity	V/m
$\mathbf{D}$	electric flux density	$\mathrm{C/m^2}$
$\mathbf{H}$	magnetic field intensity	A/m
$\mathbf{B}$	magnetic flux density	$\mathrm{T} = \mathrm{Wb/m^2}$
$\mathbf{J}$	(free) current density	$\mathrm{A/m^2}$
ρ	(free) volume charge density	$\mathrm{C/m^3}$

In a linear, isotropic medium the **constitutive relations** are $\mathbf{D} = \varepsilon\mathbf{E}$, $\mathbf{B} = \mu\mathbf{H}$, $\mathbf{J} = \sigma\mathbf{E}$ (Ohm's law), with $\varepsilon = \varepsilon_r\varepsilon_0$, $\mu = \mu_r\mu_0$, $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m and $\mu_0 \approx 4\pi \times 10^{-7}$ H/m.

Maxwell's equations in integral form

Maxwell's equations — integral form

For any closed surface S enclosing a volume V, and any open surface S bounded by a closed curve C (orientations related by the right-hand rule):

$$\begin{aligned}
&\text{Gauss's law:} && \oint_S \mathbf{D} \cdot d\mathbf{S} = \iiint_V \rho\, dV = Q_{\text{enc}}, \\
&\text{no magnetic charge:} && \oint_S \mathbf{B} \cdot d\mathbf{S} = 0, \\
&\text{Faraday's law:} && \oint_C \mathbf{E} \cdot d\mathbf{l} = -\frac{d}{dt} \iint_S \mathbf{B} \cdot d\mathbf{S}, \\
&\text{Ampère–Maxwell law:} && \oint_C \mathbf{H} \cdot d\mathbf{l} = \iint_S \left(\mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \right) \cdot d\mathbf{S}.
\end{aligned}$$

Read with the vocabulary of this chapter:

- **Gauss:** the outward flux of $\mathbf{D}$ through a closed surface is the enclosed charge.
- **No monopoles:** the net flux of $\mathbf{B}$ out of any closed surface is zero; flux lines of $\mathbf{B}$ close on themselves.
- **Faraday:** the circulation of $\mathbf{E}$ (the EMF) around a loop is minus the rate of change of magnetic flux through it.
- **Ampère–Maxwell:** the circulation of $\mathbf{H}$ around a loop is the total current — conduction plus displacement — through it.

From integral form to differential form

The recipe is the same each time: (1) turn the boundary integral into an integral over the inside using Stokes or Gauss; (2) move everything to one side under a single integral; (3) since the region is arbitrary, the integrand vanishes.

Gauss's law. By the divergence theorem, $\oint_S \mathbf{D}\cdot d\mathbf{S} = \iiint_V \nabla\cdot\mathbf{D}\,dV$. Hence $\iiint_V (\nabla\cdot\mathbf{D}-\rho)\,dV = 0$ for every V, so

$$\nabla\cdot\mathbf{D} = \rho.$$

No magnetic charge. The same argument gives $\nabla\cdot\mathbf{B} = 0$.

Faraday's law. For a stationary surface the time derivative passes inside the integral. By Stokes' theorem $\oint_C \mathbf{E}\cdot d\mathbf{l} = \iint_S (\nabla\times\mathbf{E})\cdot d\mathbf{S}$, so $\iint_S \left(\nabla\times\mathbf{E} + \dfrac{\partial\mathbf{B}}{\partial t}\right)\cdot d\mathbf{S} = 0$ for every surface S. Choosing tiny flat surfaces with each of the three normal directions shows that each component of the bracket vanishes:

$$\nabla\times\mathbf{E} = -\frac{\partial\mathbf{B}}{\partial t}.$$

Ampère–Maxwell law. Identically,

$$\nabla\times\mathbf{H} = \mathbf{J} + \frac{\partial\mathbf{D}}{\partial t}.$$

Maxwell's equations — differential form

$$\nabla\cdot\mathbf{D} = \rho, \quad \nabla\times\mathbf{E} = -\frac{\partial\mathbf{B}}{\partial t},$$
$$\nabla\cdot\mathbf{B} = 0, \quad \nabla\times\mathbf{H} = \mathbf{J} + \frac{\partial\mathbf{D}}{\partial t}.$$

For time-harmonic fields with phasor convention $\mathbf{E}(\mathbf{R},t) = \mathrm{Re}\{\mathbf{E}(\mathbf{R})e^{j\omega t}\}$, $\partial/\partial t \to j\omega$:

$$\nabla\times\mathbf{E} = -j\omega\mathbf{B}, \qquad \nabla\times\mathbf{H} = \mathbf{J} + j\omega\mathbf{D}.$$

Law	Integral form	Theorem used	Differential form
Gauss	$\oint \mathbf{D}\cdot d\mathbf{S} = Q_{\text{enc}}$	divergence	$\nabla\cdot\mathbf{D} = \rho$
No monopoles	$\oint \mathbf{B}\cdot d\mathbf{S} = 0$	divergence	$\nabla\cdot\mathbf{B} = 0$
Faraday	$\oint \mathbf{E}\cdot d\mathbf{l} = -\dfrac{d\Phi}{dt}$	Stokes	$\nabla\times\mathbf{E} = -\partial_t\mathbf{B}$
Ampère–Maxwell	$\oint \mathbf{H}\cdot d\mathbf{l} = I_{\text{enc}} + \dfrac{d}{dt}\iint \mathbf{D}\cdot d\mathbf{S}$	Stokes	$\nabla\times\mathbf{H} = \mathbf{J} + \partial_t\mathbf{D}$

The integral forms are best for problems with high symmetry (where the field can be pulled out of the integral) and for circuits and measurements; the differential forms are best for deriving wave equations, boundary-value problems and numerical methods. The two divergence equations are, by the Helmholtz theorem, exactly what is needed alongside the two curl equations to fix the fields.

Why the displacement current is required

Take the divergence of Ampère's law without Maxwell's term, $\nabla\times\mathbf{H} = \mathbf{J}$. Since the divergence of a curl is zero (identity 2 of Section 7.5), this would force $\nabla\cdot\mathbf{J} = 0$ — but the continuity equation (Section 7.11) says $\nabla\cdot\mathbf{J} = -\partial\rho/\partial t$, which is non-zero whenever charge accumulates (as on a charging capacitor plate). With Maxwell's term,

$$0 = \nabla\cdot(\nabla\times\mathbf{H}) = \nabla\cdot\mathbf{J} + \frac{\partial}{\partial t}\nabla\cdot\mathbf{D} = \nabla\cdot\mathbf{J} + \frac{\partial\rho}{\partial t},$$

which is precisely charge conservation. A vector identity, not an experiment, demanded the extra term — and that term is what makes electromagnetic waves possible.

Potentials, Poisson's and Laplace's equations

Since $\nabla\cdot\mathbf{B} = 0$, there is a vector potential with $\mathbf{B} = \nabla\times\mathbf{A}$ (Section 7.5). Substituting into Faraday's law gives $\nabla\times(\mathbf{E} + \partial_t\mathbf{A}) = \mathbf{0}$, so the bracket is a gradient:

$$\mathbf{E} = -\nabla V - \frac{\partial\mathbf{A}}{\partial t}.$$

In electrostatics $\mathbf{E} = -\nabla V$; inserting into $\nabla\cdot(\varepsilon\mathbf{E}) = \rho$ with constant ε gives **Poisson's equation**, and in charge-free regions **Laplace's equation**:

$$\nabla^2 V = -\frac{\rho}{\varepsilon}, \qquad \nabla^2 V = 0.$$

These are solved by separation of variables in Ch. 13 and numerically in Ch. 22; uniqueness was proved in Section 7.11.

The wave equation

In a source-free ($\rho = 0$, $\mathbf{J} = \mathbf{0}$), linear, homogeneous medium, take the curl of Faraday's law and use Ampère–Maxwell:

$$\nabla \times (\nabla \times \mathbf{E}) = -\frac{\partial}{\partial t}\nabla \times \mathbf{B} = -\mu\frac{\partial}{\partial t}\left(\varepsilon\frac{\partial \mathbf{E}}{\partial t}\right) = -\mu\varepsilon\frac{\partial^2 \mathbf{E}}{\partial t^2}.$$

By identity 7, $\nabla \times (\nabla \times \mathbf{E}) = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2\mathbf{E} = -\nabla^2\mathbf{E}$, because $\nabla \cdot \mathbf{E} = 0$ here. Therefore

$$\nabla^2 \mathbf{E} = \mu\varepsilon\frac{\partial^2 \mathbf{E}}{\partial t^2}, \qquad u = \frac{1}{\sqrt{\mu\varepsilon}}.$$

In vacuum $u = 1/\sqrt{\mu_0\varepsilon_0} = 2.998 \times 10^8$ m/s — the speed of light, predicted from two constants measured with capacitors and coils. In phasor form ($\partial_t \to j\omega$) it becomes the **Helmholtz equation** $\nabla^2\mathbf{E} + k^2\mathbf{E} = \mathbf{0}$ with wavenumber $k = \omega\sqrt{\mu\varepsilon}$. The same equation holds for $\mathbf{H}$.

Boundary conditions from the integral forms

At an interface between two media the fields can jump, and the differential equations (which need derivatives) do not apply on the interface itself. The integral forms do.

- **Normal components — pillbox.** Apply Gauss's law to a thin pillbox straddling the interface, faces of area ΔS on either side, height $\to 0$. The side-wall flux vanishes, leaving $(\mathbf{D}_1 - \mathbf{D}_2)\cdot\hat{\mathbf{n}}\,\Delta S = \rho_s \Delta S$, where $\hat{\mathbf{n}}$ points from medium 2 into medium 1 and ρ_s is surface charge. Likewise for $\mathbf{B}$ with zero right side.
- **Tangential components — thin loop.** Apply Faraday's law to a thin rectangular loop straddling the interface, sides Δl parallel to it, height $\to 0$. The enclosed flux vanishes with the area, leaving $(\mathbf{E}_1 - \mathbf{E}_2)\cdot\hat{\mathbf{t}}\,\Delta l = 0$. For $\mathbf{H}$ the right side is a surface current $J_s \Delta l$.

$$\hat{\mathbf{n}}\cdot(\mathbf{D}_1 - \mathbf{D}_2) = \rho_s, \quad \hat{\mathbf{n}}\cdot(\mathbf{B}_1 - \mathbf{B}_2) = 0, \quad \hat{\mathbf{n}}\times(\mathbf{E}_1 - \mathbf{E}_2) = \mathbf{0}, \quad \hat{\mathbf{n}}\times(\mathbf{H}_1 - \mathbf{H}_2) = \mathbf{J}_s.$$

These are exactly the "shrink the region onto the boundary" arguments by which we defined divergence and curl, now used on a surface where the fields are discontinuous.

Energy flow: Poynting's theorem

Identity 6 of Section 7.5 and the two curl equations give

$$\nabla\cdot(\mathbf{E}\times\mathbf{H}) = \mathbf{H}\cdot(\nabla\times\mathbf{E}) - \mathbf{E}\cdot(\nabla\times\mathbf{H}) = -\mathbf{H}\cdot\frac{\partial\mathbf{B}}{\partial t} - \mathbf{E}\cdot\mathbf{J} - \mathbf{E}\cdot\frac{\partial\mathbf{D}}{\partial t}.$$

For a linear medium $\mathbf{H}\cdot\partial_t\mathbf{B} = \partial_t(\tfrac{1}{2}\mu H^2)$ and $\mathbf{E}\cdot\partial_t\mathbf{D} = \partial_t(\tfrac{1}{2}\varepsilon E^2)$. Integrating over a volume and applying the divergence theorem:

$$-\oint_S (\mathbf{E}\times\mathbf{H})\cdot d\mathbf{S} = \frac{d}{dt}\iiint_V \left(\tfrac{1}{2}\varepsilon E^2 + \tfrac{1}{2}\mu H^2\right) dV + \iiint_V \mathbf{E}\cdot\mathbf{J}\, dV.$$

Power flowing **in** through the surface (flux of the Poynting vector $\mathbf{S} = \mathbf{E}\times\mathbf{H}$, in $\mathrm{W/m^2}$) equals the rate of increase of stored field energy plus the power dissipated. It is the field version of "power in = $\frac{d}{dt}$(energy stored) + I^2R".

Worked examples

Worked Example — Gauss's law: the uniformly charged sphere

A sphere of radius a in free space holds charge Q uniformly ($\rho_0 = 3Q/(4\pi a^3)$). Find $\mathbf{E}$ everywhere and check the differential form.

Step 1 — symmetry. By spherical symmetry $\mathbf{E} = E_R(R)\hat{\mathbf{R}}$. On a Gaussian sphere of radius R, $\mathbf{D}\cdot d\mathbf{S} = \varepsilon_0 E_R\, dS$ with E_R constant, so $\oint \mathbf{D}\cdot d\mathbf{S} = 4\pi R^2\varepsilon_0 E_R$.

Step 2 — enclosed charge. For $R \ge a$, $Q_{\text{enc}} = Q$. For $R < a$, $Q_{\text{enc}} = Q\,R^3/a^3$.

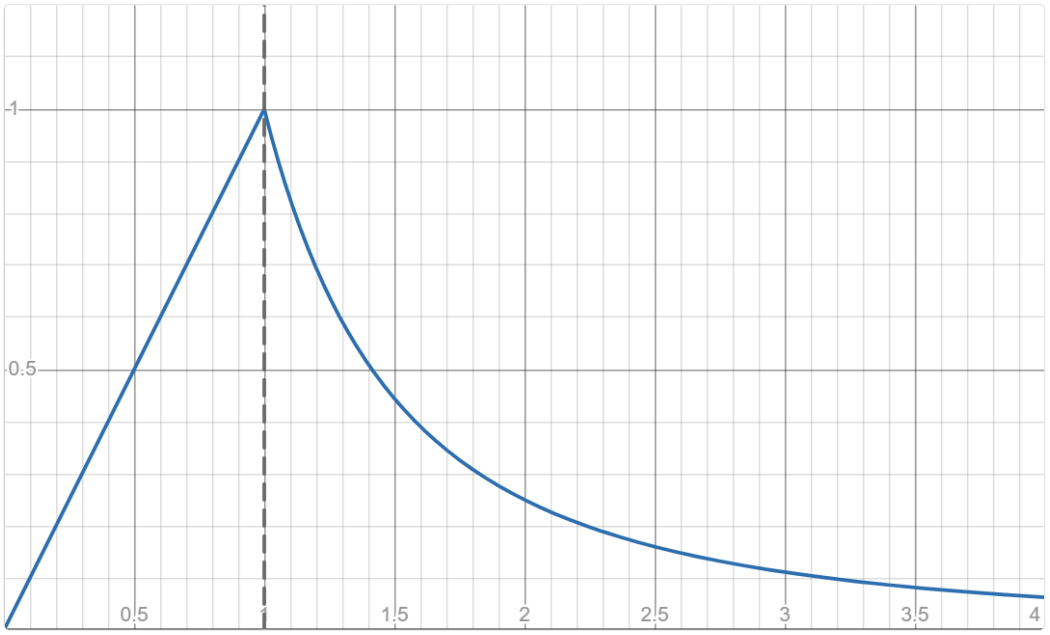
Step 3 — solve.

$$E_R = \begin{cases} \dfrac{QR}{4\pi\varepsilon_0 a^3}, & R < a, \\[2mm] \dfrac{Q}{4\pi\varepsilon_0 R^2}, & R \ge a. \end{cases}$$

Both branches give $Q/(4\pi\varepsilon_0 a^2)$ at $R = a$: the field is continuous (no surface charge).

Step 4 — differential check. Inside, $\nabla\cdot\mathbf{E} = \frac{1}{R^2}\partial_R\big(R^2\cdot\frac{QR}{4\pi\varepsilon_0 a^3}\big) = \frac{3Q}{4\pi\varepsilon_0 a^3} = \rho_0/\varepsilon_0$ ✓. Outside, $\frac{1}{R^2}\partial_R(\text{const}) = 0$ ✓.

Numbers. $Q = 1$ nC, $a = 1$ cm: peak field $E(a) = 8.988\times10^9 \times 10^{-9}/10^{-4} = 8.99\times10^4$ V/m ≈ 90 kV/m, about 3 % of the breakdown strength of air.



Field of a uniformly charged sphere, normalised to its surface value, against R/a: linear inside (where enclosed charge grows as R^3), inverse-square outside.

Worked Example — Ampère's law: the field in and around a thick wire

A long straight wire of radius a carries current I uniformly ($J = I/(\pi a^2)$, along $\hat{\mathbf{z}}$). Find $\mathbf{H}$ and $\mathbf{B}$ ($\mu = \mu_0$), and verify $\nabla \times \mathbf{H} = \mathbf{J}$.

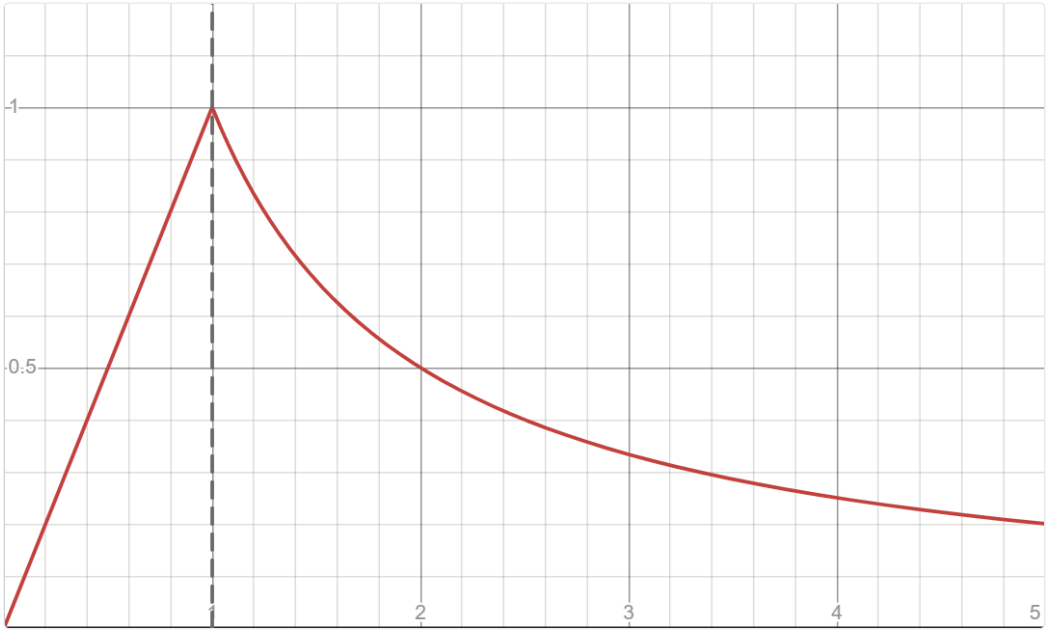
Step 1 — symmetry. $\mathbf{H} = H_\phi(r)\hat{\boldsymbol{\phi}}$. Around a circle of radius r, $\oint \mathbf{H} \cdot d\mathbf{l} = 2\pi r H_\phi$.

Step 2 — enclosed current. $I_{\text{enc}} = I\,r^2/a^2$ for $r < a$, and I for $r \geq a$ (static, so no displacement current).

Step 3 — solve. $H_\phi = \dfrac{Ir}{2\pi a^2}$ inside, $\dfrac{I}{2\pi r}$ outside.

Step 4 — differential check. Inside: $(\nabla \times \mathbf{H})_z = \frac{1}{r}\partial_r\left(r \cdot \frac{Ir}{2\pi a^2}\right) = \frac{I}{\pi a^2} = J$ ✓. Outside: $\frac{1}{r}\partial_r(I/2\pi) = 0$ ✓ — the curl-free wire field of Sections 7.5–7.6, now seen as the field of a current that occupies only $r < a$.

Numbers. $I = 10$ A, $a = 1$ mm: $B(a) = \mu_0 I/(2\pi a) = 2.0$ mT; $B(0.5\text{ mm}) = 1.0$ mT; $B(1\text{ cm}) = 0.20$ mT.



$\|\mathbf{B}\|$ of a thick wire normalised to its surface value, against r/a: linear inside, $1/r$ outside. Compare with the sphere: the outside decay is slower because the source is a line, not a point.

Worked Example — capacitance per metre of a coaxial cable

A coaxial cable has inner radius a, outer radius b, and dielectric ε. Find the capacitance per metre and evaluate it for $a = 0.45$ mm, $b = 1.47$ mm, $\varepsilon_r = 2.25$ (polyethylene).

Step 1 — Gauss. Put charge ρ_ℓ per metre on the inner conductor. A coaxial Gaussian cylinder of radius r and length L ($a < r < b$) has flux only through its curved side: $\varepsilon E_r \cdot 2\pi r L = \rho_\ell L$, so $E_r = \dfrac{\rho_\ell}{2\pi\varepsilon r}$.

Step 2 — line integral for the voltage.

$$V = -\int_b^a E_r\, dr = \frac{\rho_\ell}{2\pi\varepsilon}\int_a^b \frac{dr}{r} = \frac{\rho_\ell}{2\pi\varepsilon}\ln\frac{b}{a}.$$

Step 3 — capacitance. $C' = \rho_\ell / V = \dfrac{2\pi\varepsilon}{\ln(b/a)}$.

Numbers. $\ln(1.47/0.45) = 1.1838$, $2\pi \times 2.25 \times 8.854 \times 10^{-12} = 1.2517 \times 10^{-10}$, so $C' = 105.7$ pF/m — the right order for common 50 Ω cable (about 100 pF/m).

Gauss's law (a surface integral) gave the field; a line integral gave the voltage. That pair of steps solves every symmetric capacitor problem.

Worked Example — Faraday's law: induced EMF and induced field

A uniform field $\mathbf{B} = B_0 \sin(\omega t)\,\hat{\mathbf{z}}$ fills a region. (a) Find the EMF around a circular loop of radius a in the xy-plane centred on the axis. (b) Find the induced electric field and check $\nabla \times \mathbf{E} = -\partial_t \mathbf{B}$. (c) Evaluate the peak EMF for $a = 5$ cm, $B_0 = 10$ mT, $f = 50$ Hz.

(a) Flux $\Phi = \pi a^2 B_0 \sin\omega t$, so EMF $= \oint \mathbf{E}\cdot d\mathbf{l} = -d\Phi/dt = -\pi a^2 B_0 \omega \cos\omega t$.

(b) By symmetry $\mathbf{E} = E_\phi(r)\hat{\boldsymbol{\phi}}$, so the EMF around radius r is $2\pi r E_\phi = -\pi r^2 \dot{B}$, giving $E_\phi = -\frac{r}{2}\dot{B} = -\frac{r}{2}B_0\omega\cos\omega t$. Check: $(\nabla\times\mathbf{E})_z = \frac{1}{r}\partial_r(rE_\phi) = \frac{1}{r}\partial_r\left(-\frac{r^2}{2}\dot{B}\right) = -\dot{B}$ ✓.

(c) Peak EMF $= \pi(0.05)^2(0.01)(2\pi\cdot 50) = 24.7$ mV.

This induced $\mathbf{E}$ has circular field lines and non-zero curl: it is **not** a gradient, and no scalar potential can describe it — Kirchhoff's voltage law fails for a loop around changing flux.

Worked Example — displacement current in a capacitor

A parallel-plate air capacitor has plate area $A = 1$ cm^2 and gap $d = 0.1$ mm, driven by $v(t) = V_0 \sin\omega t$ with $V_0 = 10$ V, $f = 1$ MHz. Show that the displacement current between the plates equals the conduction current in the leads.

Step 1. Between the plates $E = v/d$, so the displacement current density is $\partial D/\partial t = \varepsilon_0 \dot{v}/d$.

Step 2. Its flux through a surface between the plates is $I_d = A\varepsilon_0\dot{v}/d = C\dot{v}$ with $C = \varepsilon_0 A/d$ — exactly the lead current $i = C\,dv/dt$ ✓.

Step 3 — numbers. $C = 8.854\times10^{-12}\times10^{-4}/10^{-4} = 8.854$ pF; peak $I = C\omega V_0 = 8.854\times10^{-12}\times 2\pi\times10^6\times10 = 0.556$ mA.

So a loop around the lead "sees" the same $\oint \mathbf{H}\cdot d\mathbf{l}$ whether the surface it bounds is pierced by the wire (conduction current) or bulges between the plates (displacement current) — Stokes' surface independence restored.

Worked Example — Poynting's theorem for a resistive wire

A straight wire of radius a, length L and conductivity σ carries a DC current I. Show that the Poynting flux into its surface equals I^2R.

Step 1 — fields at the surface. $\mathbf{E} = \mathbf{J}/\sigma = \dfrac{I}{\sigma\pi a^2}\hat{\mathbf{z}}$; tangential $\mathbf{E}$ is continuous, so this is also the field just outside. From the Ampère example, $\mathbf{H} = \dfrac{I}{2\pi a}\hat{\boldsymbol{\phi}}$ at $r = a$.

Step 2 — Poynting vector. $\mathbf{S} = \mathbf{E}\times\mathbf{H} = EH\,(\hat{\mathbf{z}}\times\hat{\boldsymbol{\phi}}) = -EH\,\hat{\mathbf{r}}$: it points **into** the wire.

Step 3 — inward flux. $P = EH\cdot 2\pi aL = \dfrac{I}{\sigma\pi a^2}\cdot\dfrac{I}{2\pi a}\cdot 2\pi aL = I^2\dfrac{L}{\sigma\pi a^2} = I^2R$ ✓.

The energy dissipated in the wire flows in from the surrounding field, not along the inside of the conductor — a striking conclusion reached purely by a cross product and a surface integral.

Common Pitfall

Using Gauss's or Ampère's law to "find" a field without enough symmetry. The integral forms are always true, but they determine the field only when symmetry lets you pull E or H out of the integral as a constant. For a finite wire, a square loop or a charged cube, $\oint \mathbf{H}\cdot d\mathbf{l} = I$ is still correct but does not tell you $\mathbf{H}$ at any point; use Biot–Savart, superposition or a numerical solver instead.

Common Pitfall

Mixing time-domain and phasor forms. In the phasor equations $\mathbf{E}$ is a complex vector and ∂_t has become $j\omega$; quantities like energy and power, which are quadratic, need $\tfrac{1}{2}\,\mathrm{Re}\{\cdot\}$ and conjugates ($\langle \mathbf{S} \rangle = \tfrac{1}{2}\,\mathrm{Re}\{\mathbf{E} \times \mathbf{H}^*\}$), not the time-domain formulas applied to phasors.

Engineering Note

Circuit theory is the low-frequency limit of these equations. KCL is $\nabla \cdot \mathbf{J} = 0$ (continuity with no charge accumulation at nodes, or with capacitor displacement currents counted as branch currents); KVL is $\oint \mathbf{E} \cdot d\mathbf{l} = 0$ (Faraday with flux changes lumped into inductors); $v = L\,di/dt$ and $i = C\,dv/dt$ are Faraday's and the displacement term of Ampère–Maxwell confined to components. When a circuit's dimensions approach a tenth of a wavelength these lumped approximations fail and the full field equations — via transmission-line theory and the wave equation — take over.

Summary

Concept	Key formula
Dot product	$\mathbf{A} \cdot \mathbf{B} = AB\cos\theta = A_xB_x + A_yB_y + A_zB_z$
Cross product	$\lVert \mathbf{A} \times \mathbf{B} \rVert = AB\sin\theta$; determinant with $\hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$
Triple products	$\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C})$ = volume; $\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = \mathbf{B}(\mathbf{A} \cdot \mathbf{C}) - \mathbf{C}(\mathbf{A} \cdot \mathbf{B})$
Arc length, curvature	$s = \int \lVert \mathbf{r}' \rVert dt$, $\kappa = \lVert \mathbf{r}' \times \mathbf{r}'' \rVert / \lVert \mathbf{r}' \rVert^3$
Polar velocity	$\mathbf{v} = \dot{r}\hat{\mathbf{r}} + r\dot{\phi}\hat{\boldsymbol{\phi}} + \dot{z}\hat{\mathbf{z}}$
Field lines	$dx/F_x = dy/F_y = dz/F_z$
Gradient	$\nabla f = \sum \frac{1}{h_i}\partial_{u_i} f\,\hat{\mathbf{u}}_i$; $h = (1, r, 1)$ cyl., $(1, R, R\sin\theta)$ sph.
Divergence (def.)	$\nabla \cdot \mathbf{F} = \lim \frac{1}{\Delta V} \oint \mathbf{F} \cdot d\mathbf{S}$
Divergence (sph.)	$\frac{1}{R^2}\partial_R(R^2F_R) + \frac{1}{R\sin\theta}\partial_\theta(\sin\theta F_\theta) + \frac{1}{R\sin\theta}\partial_\phi F_\phi$
Curl (def.)	$(\nabla \times \mathbf{F}) \cdot \hat{\mathbf{n}} = \lim \frac{1}{\Delta S} \oint \mathbf{F} \cdot d\mathbf{r}$
Curl z-comp. (cyl.)	$\frac{1}{r}[\partial_r(rF_\phi) - \partial_\phi F_r]$
Laplacian (sph.)	$\frac{1}{R^2}\partial_R(R^2\partial_R f) + \frac{1}{R^2\sin\theta}\partial_\theta(\sin\theta\,\partial_\theta f) + \frac{1}{R^2\sin^2\theta}\partial_\phi^2 f$
Zero identities	$\nabla \times \nabla f = \mathbf{0}$, $\nabla \cdot (\nabla \times \mathbf{A}) = 0$
Curl curl	$\nabla \times \nabla \times \mathbf{A} = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2\mathbf{A}$
Line integral	$\int_C \mathbf{F} \cdot d\mathbf{r} = \int_a^b \mathbf{F}(\mathbf{r}(t)) \cdot \mathbf{r}'(t)\,dt$
Fundamental theorem	$\int_C \nabla f \cdot d\mathbf{r} = f(\mathbf{b}) - f(\mathbf{a})$
Surface element	$d\mathbf{S} = \mathbf{r}_u \times \mathbf{r}_v\,du\,dv$; sphere $a^2\sin\theta\,d\theta\,d\phi\,\hat{\mathbf{R}}$
Volume element	$dV = r\,dr\,d\phi\,dz = R^2\sin\theta\,dR\,d\theta\,d\phi$
Green	$\oint (P\,dx + Q\,dy) = \iint (Q_x - P_y)\,dA$; $A = \frac{1}{2}\oint (x\,dy - y\,dx)$
Stokes	$\oint_C \mathbf{F} \cdot d\mathbf{r} = \iint_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S}$
Divergence theorem	$\oint_S \mathbf{F} \cdot d\mathbf{S} = \iiint_V \nabla \cdot \mathbf{F}\,dV$
Continuity	$\nabla \cdot \mathbf{J} + \partial_t \rho = 0$
Point source	$\nabla \cdot (\hat{\mathbf{R}}/R^2) = 4\pi\delta(\mathbf{R})$, $\nabla^2(1/R) = -4\pi\delta(\mathbf{R})$
Maxwell (differential)	$\nabla \cdot \mathbf{D} = \rho$, $\nabla \cdot \mathbf{B} = 0$, $\nabla \times \mathbf{E} = -\partial_t\mathbf{B}$, $\nabla \times \mathbf{H} = \mathbf{J} + \partial_t\mathbf{D}$
Potentials	$\mathbf{B} = \nabla \times \mathbf{A}$, $\mathbf{E} = -\nabla V - \partial_t\mathbf{A}$; $\nabla^2 V = -\rho/\varepsilon$
Wave / Helmholtz	$\nabla^2\mathbf{E} = \mu\varepsilon\,\partial_t^2\mathbf{E}$; $\nabla^2\mathbf{E} + k^2\mathbf{E} = \mathbf{0}$, $k = \omega\sqrt{\mu\varepsilon}$
Poynting	$\mathbf{S} = \mathbf{E} \times \mathbf{H}$; $\langle \mathbf{S} \rangle = \frac{1}{2}\,\mathrm{Re}\{\mathbf{E} \times \mathbf{H}^*\}$

Part III — Linear Algebra

Chapter 8 — Matrices and Linear Systems

> **Prerequisites:** Ch. 1, Ch. 2; the Jacobian matrix of Ch. 6 is helpful but not essential. **Learning outcomes:** After this chapter you can
>
> - manipulate matrices fluently (sums, products, transposes, conjugate transposes, block forms) and read circuit equations as matrix equations;
> - evaluate determinants by cofactor expansion and by row reduction, and use them to test invertibility and to apply Cramer's rule;
> - compute inverses, determine rank, and classify a linear system as having a unique solution, no solution or infinitely many solutions;
> - solve systems by Gaussian elimination with partial pivoting, by Gauss–Jordan elimination, and by $\mathbf{LU}$ and Cholesky factorisation, and count the work each needs;
> - measure the sensitivity of a solution with norms and the condition number, and recognise ill-conditioned problems;
> - exploit sparsity (banded and tridiagonal solvers, compressed storage, iterative methods) in the large systems produced by circuit simulators and field solvers.

A linear circuit with n unknown node voltages produces n linear equations in n unknowns. A finite-difference model of the potential in a capacitor produces ten thousand. A power-flow study of a national grid produces a hundred thousand, solved again at every iteration of Newton's method. Whatever the size, the mathematical object is the same: a **linear system** $\mathbf{A}\mathbf{x} = \mathbf{b}$. This chapter develops the algebra of matrices needed to write such systems compactly, the theory that tells us when they can be solved, and the algorithms — elimination and factorisation — that every circuit simulator, field solver and estimation routine actually runs. Chapter 9 then looks at the same objects geometrically, as vector spaces and linear maps, and Chapter 10 studies their eigenvalues.

Throughout the chapter one small circuit serves as a running example. It has three non-reference nodes and six resistive branches:

Branch	Connects	Conductance
a	node 1 – ground	1 mS
b	node 1 – node 2	2 mS
c	node 2 – node 3	1 mS
d	node 2 – ground	1 mS
e	node 3 – ground	2 mS
f	node 1 – node 3	1 mS

Independent current sources inject 8 mA, 2 mA and 1 mA into nodes 1, 2 and 3. Kirchhoff's current law (KCL) at each node, with currents leaving the node counted positive, gives

$$\begin{aligned} (1+2+1)v_1 - 2v_2 - 1v_3 &= 8,\\ -2v_1 + (2+1+1)v_2 - 1v_3 &= 2,\\ -1v_1 - 1v_2 + (1+2+1)v_3 &= 1, \end{aligned}$$

with conductances in mS, currents in mA and therefore voltages in V (since $\mathrm{mA}/\mathrm{mS} = \mathrm{V}$). In matrix form,

$$\underbrace{\begin{bmatrix} 4 & -2 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}}_{\mathbf{G}} \underbrace{\begin{bmatrix} v_1 \\ v_2 \\ v_3 \end{bmatrix}}_{\mathbf{v}} = \underbrace{\begin{bmatrix} 8 \\ 2 \\ 1 \end{bmatrix}}_{\mathbf{i}_s}.$$

We will find that $\mathbf{v} = (4, 3, 2)^{\mathsf{T}}$ V in at least six different ways before the chapter is over, and each way teaches something different about $\mathbf{G}$.

8.1 Matrix operations

Why matrices

Writing the nodal equations above as three separate lines is fine for three nodes. For three thousand it is hopeless — and, more importantly, it hides structure. The matrix $\mathbf{G}$ is symmetric; its diagonal entries dominate its rows; its off-diagonal entries are non-positive; most of its entries in a large circuit are zero. Each of these properties has a name, a theorem attached to it, and an algorithmic payoff. Matrix notation is what lets us see them.

Definitions

Matrix

An $m \times n$ **matrix** $\mathbf{A}$ is a rectangular array of mn numbers (real or complex) arranged in m rows and n columns. The entry in row i, column j is written a_{ij} or $[\mathbf{A}]_{ij}$:

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix} = [a_{ij}].$$

The pair (m, n) is the **size** (or shape). A matrix with $m = n$ is **square** of **order** n. An $n \times 1$ matrix is a **column vector**, a $1 \times n$ matrix a **row vector**. The set of real $m \times n$ matrices is written $\mathbb{R}^{m \times n}$, the complex ones $\mathbb{C}^{m \times n}$.

Vectors in this book are columns unless stated otherwise: $\mathbf{x} = (x_1, \dots, x_n)^{\mathsf{T}}$ is a convenient way to print a column on one line.

Some square matrices occur so often they have names.

Name	Definition	Example (3×3 pattern)
Diagonal	$a_{ij} = 0$ for $i \neq j$	$\operatorname{diag}(d_1, d_2, d_3)$
Identity $\mathbf{I}$ (or $\mathbf{I}_n$)	diagonal with all $d_i = 1$	δ_{ij} (Kronecker delta)
Zero $\mathbf{0}$	all entries zero	
Upper triangular	$a_{ij} = 0$ for $i > j$	nonzeros on and above diagonal
Lower triangular	$a_{ij} = 0$ for $i < j$	nonzeros on and below diagonal
Tridiagonal	$a_{ij} = 0$ for $\lvert i - j \rvert > 1$	ladder networks, 1-D finite differences
Symmetric	$a_{ij} = a_{ji}$	nodal matrix of a reciprocal circuit
Skew-symmetric	$a_{ij} = -a_{ji}$ (so $a_{ii} = 0$)	gyrator, cross-product matrix
Hermitian	$a_{ij} = a_{ji}^{*}$	power/covariance matrices with complex entries

The **main diagonal** of a square matrix is $a_{11}, a_{22}, \dots, a_{nn}$. The **trace** is the sum of the diagonal entries, $\operatorname{tr}\mathbf{A} = \sum_i a_{ii}$; for $\mathbf{G}$ above, $\operatorname{tr}\mathbf{G} = 12$ mS, which is twice the total conductance of branches b, c, f plus once that of a, d, e (each inter-node branch is counted at both its ends).

Equality, addition and scalar multiplication

Linear operations on matrices

Two matrices are **equal** if they have the same size and all corresponding entries are equal. For $\mathbf{A}, \mathbf{B} \in \mathbb{C}^{m \times n}$ and a scalar c:

$$[\mathbf{A} + \mathbf{B}]_{ij} = a_{ij} + b_{ij}, \qquad [c\mathbf{A}]_{ij} = c\, a_{ij}.$$

Addition of matrices of different sizes is undefined.

These operations inherit every rule of ordinary arithmetic, entry by entry:

$$\begin{aligned} &\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}, && (\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C}), \\ &\mathbf{A} + \mathbf{0} = \mathbf{A}, && \mathbf{A} + (-\mathbf{A}) = \mathbf{0}, \\ &c(\mathbf{A} + \mathbf{B}) = c\mathbf{A} + c\mathbf{B}, && (c + d)\mathbf{A} = c\mathbf{A} + d\mathbf{A}, \quad (cd)\mathbf{A} = c(d\mathbf{A}). \end{aligned}$$

In the language of Chapter 9, $\mathbb{R}^{m \times n}$ is a vector space of dimension mn.

Addition has a direct circuit meaning. Each branch of the running example contributes a small "stamp" to $\mathbf{G}$, and $\mathbf{G}$ is the sum of the stamps. Branch b (2 mS between nodes 1 and 2) contributes

$$\mathbf{G}_b = 2\begin{bmatrix} 1 & -1 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

branch a (1 mS from node 1 to ground) contributes 1 at position $(1,1)$ only, and so on. Summing the six stamps reproduces $\mathbf{G}$. This **stamping** procedure is exactly how SPICE-type simulators assemble their matrices: loop over the elements, add each element's stamp into the global matrix.

Transpose and conjugate transpose

Transpose, conjugate transpose

The **transpose** of $\mathbf{A} \in \mathbb{C}^{m \times n}$ is the $n \times m$ matrix $\mathbf{A}^{\mathsf{T}}$ with $[\mathbf{A}^{\mathsf{T}}]_{ij} = a_{ji}$ (rows become columns). The **conjugate transpose** (Hermitian transpose) is $\mathbf{A}^{\mathsf{H}} = (\mathbf{A}^{*})^{\mathsf{T}}$, i.e. $[\mathbf{A}^{\mathsf{H}}]_{ij} = a_{ji}^{*}$. For real matrices $\mathbf{A}^{\mathsf{H}} = \mathbf{A}^{\mathsf{T}}$.

Properties, each checked entry by entry:

$$(\mathbf{A}^{\mathsf{T}})^{\mathsf{T}} = \mathbf{A}, \qquad (\mathbf{A} + \mathbf{B})^{\mathsf{T}} = \mathbf{A}^{\mathsf{T}} + \mathbf{B}^{\mathsf{T}}, \qquad (c\mathbf{A})^{\mathsf{T}} = c\mathbf{A}^{\mathsf{T}}, \qquad (c\mathbf{A})^{\mathsf{H}} = c^{*}\mathbf{A}^{\mathsf{H}}.$$

The rule for products, $(\mathbf{AB})^{\mathsf{T}} = \mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$, is proved in §8.2.

A square matrix is symmetric exactly when $\mathbf{A}^{\mathsf{T}} = \mathbf{A}$, skew-symmetric when $\mathbf{A}^{\mathsf{T}} = -\mathbf{A}$, and Hermitian when $\mathbf{A}^{\mathsf{H}} = \mathbf{A}$. A Hermitian matrix has a real diagonal, since $a_{ii} = a_{ii}^{*}$.

Symmetric/skew decomposition

Every square matrix splits uniquely into a symmetric and a skew-symmetric part:

$$\mathbf{A} = \underbrace{\tfrac{1}{2}(\mathbf{A} + \mathbf{A}^{\mathsf{T}})}_{\text{symmetric}} + \underbrace{\tfrac{1}{2}(\mathbf{A} - \mathbf{A}^{\mathsf{T}})}_{\text{skew-symmetric}}.$$

Likewise every complex square matrix is a Hermitian part plus j times another Hermitian part: $\mathbf{A} = \mathbf{H}_1 + j\mathbf{H}_2$ with $\mathbf{H}_1 = \tfrac{1}{2}(\mathbf{A} + \mathbf{A}^{\mathsf{H}})$, $\mathbf{H}_2 = \tfrac{1}{2j}(\mathbf{A} - \mathbf{A}^{\mathsf{H}})$.

Proof sketch. Transposing the first bracket returns it unchanged; transposing the second negates it; their sum is $\mathbf{A}$. For uniqueness, if $\mathbf{A} = \mathbf{S} + \mathbf{K}$ with $\mathbf{S}$ symmetric and $\mathbf{K}$ skew, then $\mathbf{A}^{\mathsf{T}} = \mathbf{S} - \mathbf{K}$; adding and subtracting recovers the two brackets. $\square$

Worked Example 8.1 — Basic operations

Let

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 0 \\ 3 & -1 & 4 \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} 0 & 1 & -2 \\ 5 & 2 & 1 \end{bmatrix}.$$

Compute $2\mathbf{A} - 3\mathbf{B}$ and $(\mathbf{A} + \mathbf{B})^{\mathsf{T}}$.

Step 1. Both are 2×3, so linear combinations are defined. Entry by entry,

$$2\mathbf{A} - 3\mathbf{B} = \begin{bmatrix} 2-0 & 4-3 & 0+6 \\ 6-15 & -2-6 & 8-3 \end{bmatrix} = \begin{bmatrix} 2 & 1 & 6 \\ -9 & -8 & 5 \end{bmatrix}.$$

Step 2. $\mathbf{A} + \mathbf{B} = \begin{bmatrix} 1 & 3 & -2 \\ 8 & 1 & 5 \end{bmatrix}$, so

$$(\mathbf{A} + \mathbf{B})^{\mathsf{T}} = \begin{bmatrix} 1 & 8 \\ 3 & 1 \\ -2 & 5 \end{bmatrix},$$

a 3×2 matrix. Check: $\mathbf{A}^{\mathsf{T}} + \mathbf{B}^{\mathsf{T}}$ gives the same thing.

Worked Example 8.2 — A nonreciprocal circuit and its symmetric part

A transistor small-signal model adds a voltage-controlled current source $g_m v_1$ flowing *out* of node 2 to the running example with $g_m = 3$ mS (the source is controlled by v_1). KCL at node 2 gains a term $+3v_1$, so the nodal matrix becomes

$$\mathbf{Y} = \begin{bmatrix} 4 & -2 & -1 \\ 1 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}.$$

Split it into symmetric and skew parts.

Step 1. $\mathbf{Y}^{\mathsf{T}} = \begin{bmatrix} 4 & 1 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}$.

Step 2.

$$\mathbf{S} = \tfrac{1}{2}(\mathbf{Y} + \mathbf{Y}^{\mathsf{T}}) = \begin{bmatrix} 4 & -\frac{1}{2} & -1 \\ -\frac{1}{2} & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}, \qquad \mathbf{K} = \tfrac{1}{2}(\mathbf{Y} - \mathbf{Y}^{\mathsf{T}}) = \begin{bmatrix} 0 & -\frac{3}{2} & 0 \\ \frac{3}{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

Step 3 (check). $\mathbf{S} + \mathbf{K} = \mathbf{Y}$, $\mathbf{S}^{\mathsf{T}} = \mathbf{S}$, $\mathbf{K}^{\mathsf{T}} = -\mathbf{K}$.

Reading. The skew part is entirely due to the controlled source: a passive reciprocal network has a symmetric nodal matrix, and the skew part measures how far a network is from reciprocity. In §8.2 we will see that the power absorbed by the network, $\mathbf{v}^{\mathsf{T}}\mathbf{Y}\mathbf{v}$, depends only on $\mathbf{S}$.

Worked Example 8.3 — Hermitian part of an AC admittance matrix

At angular frequency ω a two-node network has phasor nodal equations $\mathbf{Y}\mathbf{V} = \mathbf{I}$ with

$$\mathbf{Y} = \begin{bmatrix} 2 + j3 & -j3 \\ -j3 & 1 + j4 \end{bmatrix} \text{ mS}.$$

Find $\mathbf{Y}^{\mathsf{H}}$ and the Hermitian part $\mathbf{H}_1 = \tfrac{1}{2}(\mathbf{Y} + \mathbf{Y}^{\mathsf{H}})$.

Step 1. Conjugate every entry, then transpose: $\mathbf{Y}^{*} = \begin{bmatrix} 2 - j3 & j3 \\ j3 & 1 - j4 \end{bmatrix}$, which is already symmetric, so $\mathbf{Y}^{\mathsf{H}} = \mathbf{Y}^{*}$.

Step 2. $\mathbf{H}_1 = \tfrac{1}{2}(\mathbf{Y} + \mathbf{Y}^{*}) = \operatorname{Re}\{\mathbf{Y}\} = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}$ mS.

Reading. For a reciprocal network $\mathbf{Y}$ is complex *symmetric* ($\mathbf{Y}^{\mathsf{T}} = \mathbf{Y}$) but not Hermitian. Its Hermitian part is the conductance matrix: average power is $P = \tfrac{1}{2}\operatorname{Re}\{\mathbf{V}^{\mathsf{H}}\mathbf{I}\} = \tfrac{1}{2}\mathbf{V}^{\mathsf{H}}\mathbf{H}_1\mathbf{V}$, which only involves the resistive branches. The $j3$ susceptance (a capacitor between the nodes) and the extra $j1$ at node 2 (a capacitor to ground) store energy but dissipate none.

Common Pitfall

For complex matrices, $\mathbf{A}^{\mathsf{T}}$ and $\mathbf{A}^{\mathsf{H}}$ are different, and MATLAB's `'` operator is the *conjugate* transpose; `.'` is the plain transpose. Using `'` on a complex symmetric admittance matrix silently conjugates it — a classic source of sign errors in reactive power. NumPy's `.T` is the plain transpose; use `.conj().T` for $\mathbf{A}^{\mathsf{H}}$.

Engineering Note

Matrix symmetry is not a mathematical nicety; it is reciprocity. Tellegen's theorem implies that any network made of resistors, capacitors, inductors and coupled inductors has a symmetric nodal admittance matrix. Simulators check symmetry to choose faster solvers (Cholesky rather than general $\mathbf{LU}$, §8.9), and a non-symmetric matrix in a model that should be passive is a quick bug detector.

8.2 Matrix multiplication

Motivation: composition

Multiplication of matrices is defined the way it is because it represents *composition* of linear maps. If $\mathbf{y} = \mathbf{B}\mathbf{x}$ and $\mathbf{z} = \mathbf{A}\mathbf{y}$, we want a single matrix $\mathbf{C}$ with $\mathbf{z} = \mathbf{C}\mathbf{x}$. Writing out the sums,

$$z_i = \sum_{k} a_{ik} y_k = \sum_{k} a_{ik} \sum_{j} b_{kj} x_j = \sum_{j} \Big(\sum_{k} a_{ik} b_{kj} \Big) x_j,$$

so the right definition is $c_{ij} = \sum_k a_{ik} b_{kj}$. Two-port networks in cascade, coordinate rotations followed by scalings, and a filter followed by a sampler are all compositions, and all become products.

Matrix product

If $\mathbf{A}$ is $m \times p$ and $\mathbf{B}$ is $p \times n$, the product $\mathbf{C} = \mathbf{A}\mathbf{B}$ is the $m \times n$ matrix

$$c_{ij} = \sum_{k=1}^{p} a_{ik} b_{kj}, \qquad i = 1, \dots, m,\ j = 1, \dots, n.$$

The product is defined only when the inner dimensions agree: $(m \times p)(p \times n) \to (m \times n)$.

The entry c_{ij} is the **dot product of row i of $\mathbf{A}$ with column j of $\mathbf{B}$**. Three other readings are equally important:

1. **Column view.** Column j of $\mathbf{A}\mathbf{B}$ is $\mathbf{A}$ times column j of $\mathbf{B}$. In particular $\mathbf{A}\mathbf{x} = x_1 \mathbf{a}_1 + x_2 \mathbf{a}_2 + \cdots + x_n \mathbf{a}_n$ is a **linear combination of the columns** $\mathbf{a}_k$ of $\mathbf{A}$. Solving $\mathbf{A}\mathbf{x} = \mathbf{b}$ means finding the weights that combine the columns into $\mathbf{b}$.
2. **Row view.** Row i of $\mathbf{A}\mathbf{B}$ is row i of $\mathbf{A}$ times $\mathbf{B}$: a linear combination of the rows of $\mathbf{B}$. Row operations in elimination (§8.7) are left-multiplications.
3. **Outer-product view.** $\mathbf{A}\mathbf{B} = \sum_k \mathbf{a}_k \mathbf{b}_k^{\mathsf{T}}$, a sum of rank-one matrices, column k of $\mathbf{A}$ times row k of $\mathbf{B}$. This is the view behind $\mathbf{LU}$ factorisation and the Sherman–Morrison formula.

For the running example the column view reads

$$\mathbf{G}\mathbf{v} = 4 \begin{bmatrix} 4 \\ -2 \\ -1 \end{bmatrix} + 3 \begin{bmatrix} -2 \\ 4 \\ -1 \end{bmatrix} + 2 \begin{bmatrix} -1 \\ -1 \\ 4 \end{bmatrix} = \begin{bmatrix} 16 - 6 - 2 \\ -8 + 12 - 2 \\ -4 - 3 + 8 \end{bmatrix} = \begin{bmatrix} 8 \\ 2 \\ 1 \end{bmatrix},$$

which confirms the claimed solution $\mathbf{v} = (4, 3, 2)^{\mathsf{T}}$. Column k of $\mathbf{G}$ is the vector of currents that must be injected to raise node k to $1\ \mathrm{V}$ with every other node held at $0\ \mathrm{V}$ — the circuit meaning of the column view.

Algebraic rules

Properties of the matrix product

Whenever the sizes allow the products:

1. Associative: $(\mathbf{A}\mathbf{B})\mathbf{C} = \mathbf{A}(\mathbf{B}\mathbf{C})$.
2. Distributive: $\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{A}\mathbf{B} + \mathbf{A}\mathbf{C}$, $(\mathbf{A} + \mathbf{B})\mathbf{C} = \mathbf{A}\mathbf{C} + \mathbf{B}\mathbf{C}$.
3. Scalars commute: $c(\mathbf{A}\mathbf{B}) = (c\mathbf{A})\mathbf{B} = \mathbf{A}(c\mathbf{B})$.
4. Identity: $\mathbf{I}_m \mathbf{A} = \mathbf{A} = \mathbf{A}\mathbf{I}_n$ for $\mathbf{A} \in \mathbb{C}^{m \times n}$.
5. Transpose reverses order: $(\mathbf{A}\mathbf{B})^{\mathsf{T}} = \mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$, $(\mathbf{A}\mathbf{B})^{\mathsf{H}} = \mathbf{B}^{\mathsf{H}}\mathbf{A}^{\mathsf{H}}$.
6. Trace is cyclic: $\operatorname{tr}(\mathbf{A}\mathbf{B}) = \operatorname{tr}(\mathbf{B}\mathbf{A})$ (when both products are square).

But in general $\mathbf{A}\mathbf{B} \neq \mathbf{B}\mathbf{A}$ — matrix multiplication is **not commutative**.

Proofs. (1) The (i,j) entry of both sides is $\sum_k \sum_l a_{ik} b_{kl} c_{lj}$; only the order of summation differs. (5) $[(\mathbf{A}\mathbf{B})^{\mathsf{T}}]_{ij} = [\mathbf{A}\mathbf{B}]_{ji} = \sum_k a_{jk} b_{ki} = \sum_k [\mathbf{B}^{\mathsf{T}}]_{ik} [\mathbf{A}^{\mathsf{T}}]_{kj} = [\mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}]_{ij}$. (6) $\operatorname{tr}(\mathbf{A}\mathbf{B}) = \sum_i \sum_k a_{ik} b_{ki} = \sum_k \sum_i b_{ki} a_{ik} = \operatorname{tr}(\mathbf{B}\mathbf{A})$. $\square$

Other familiar rules of arithmetic also fail:

- $\mathbf{A}\mathbf{B} = \mathbf{0}$ does **not** imply $\mathbf{A} = \mathbf{0}$ or $\mathbf{B} = \mathbf{0}$. Example: $\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} = \mathbf{0}$.
- $\mathbf{A}\mathbf{B} = \mathbf{A}\mathbf{C}$ does **not** imply $\mathbf{B} = \mathbf{C}$ unless $\mathbf{A}$ is invertible (§8.4).
- $(\mathbf{A} + \mathbf{B})^2 = \mathbf{A}^2 + \mathbf{A}\mathbf{B} + \mathbf{B}\mathbf{A} + \mathbf{B}^2$, which equals $\mathbf{A}^2 + 2\mathbf{A}\mathbf{B} + \mathbf{B}^2$ only if $\mathbf{A}$ and $\mathbf{B}$ commute.

Quadratic forms and power

For a square $\mathbf{A}$ and vector $\mathbf{x}$ the scalar $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \sum_i \sum_j a_{ij} x_i x_j$ is a **quadratic form**. Because $\mathbf{x}^{\mathsf{T}}\mathbf{K}\mathbf{x}$ is a scalar equal to its own transpose $\mathbf{x}^{\mathsf{T}}\mathbf{K}^{\mathsf{T}}\mathbf{x} = -\mathbf{x}^{\mathsf{T}}\mathbf{K}\mathbf{x}$ for skew $\mathbf{K}$, it vanishes, and only the symmetric part of $\mathbf{A}$ contributes to a quadratic form. For a resistive network, the total power absorbed is

$$P = \mathbf{v}^{\mathsf{T}} \mathbf{i}_s = \mathbf{v}^{\mathsf{T}} \mathbf{G} \mathbf{v}.$$

For the running example $P = (4, 3, 2) \cdot (8, 2, 1) = 32 + 6 + 2 = 40\ \mathrm{mW}$. Since every resistor absorbs non-negative power, $\mathbf{v}^{\mathsf{T}}\mathbf{G}\mathbf{v} > 0$ for every nonzero $\mathbf{v}$ when the circuit is connected to ground: $\mathbf{G}$ is **positive definite**. That property is studied in Chapter 10 and exploited by the Cholesky factorisation in §8.9.

Incidence matrices: building $\mathbf{G}$ by multiplication

The cleanest derivation of nodal analysis is a matrix product. Number the nodes and branches and give each branch a reference direction (from its first to its second node in the table above).

Reduced incidence matrix

For a network with n non-reference nodes and b branches, the **reduced incidence matrix** $\mathbf{A}$ is $n \times b$ with

$$a_{ik} = \begin{cases} +1 & \text{branch } k \text{ leaves node } i, \\ -1 & \text{branch } k \text{ enters node } i, \\ 0 & \text{otherwise.} \end{cases}$$

The row for the ground node is omitted.

With branch currents $\mathbf{i}_b$, branch voltages $\mathbf{v}_b$ and branch conductances collected in $\mathbf{G}_b = \operatorname{diag}(g_1, \dots, g_b)$, the three laws of circuit theory are three matrix equations:

$$\begin{aligned} &\text{KCL:} && \mathbf{A}\mathbf{i}_b = \mathbf{i}_s, \\ &\text{KVL:} && \mathbf{v}_b = \mathbf{A}^{\mathsf{T}}\mathbf{v}, \\ &\text{Ohm:} && \mathbf{i}_b = \mathbf{G}_b\mathbf{v}_b. \end{aligned}$$

Substituting, $\mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}}\mathbf{v} = \mathbf{i}_s$, so

$$\mathbf{G} = \mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}}.$$

Symmetry is now automatic: $\mathbf{G}^{\mathsf{T}} = (\mathbf{A}^{\mathsf{T}})^{\mathsf{T}}\mathbf{G}_b^{\mathsf{T}}\mathbf{A}^{\mathsf{T}} = \mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}} = \mathbf{G}$. And positivity is automatic too: $\mathbf{v}^{\mathsf{T}}\mathbf{G}\mathbf{v} = \mathbf{v}_b^{\mathsf{T}}\mathbf{G}_b\mathbf{v}_b = \sum_k g_k v_{b,k}^2 \geq 0$.

Worked Example 8.4 — Assembling the running example from its incidence matrix

Branches a, b, c, d, e, f in that order, directed from the first-named node to the second:

$$\mathbf{A} = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & -1 & 1 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 & 1 & -1 \end{bmatrix}, \qquad \mathbf{G}_b = \operatorname{diag}(1, 2, 1, 1, 2, 1).$$

Step 1. $\mathbf{A}\mathbf{G}_b$ scales column k of $\mathbf{A}$ by g_k (right-multiplying by a diagonal matrix scales columns):

$$\mathbf{A}\mathbf{G}_b = \begin{bmatrix} 1 & 2 & 0 & 0 & 0 & 1 \\ 0 & -2 & 1 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 & 2 & -1 \end{bmatrix}.$$

Step 2. Multiply by $\mathbf{A}^{\mathsf{T}}$ (6×3). Entry $(1,1)$ is row 1 of $\mathbf{A}\mathbf{G}_b$ dotted with row 1 of $\mathbf{A}$: $1 + 2 + 1 = 4$. Entry $(1,2)$: row 1 of $\mathbf{A}\mathbf{G}_b$ with row 2 of $\mathbf{A}$: $2 \cdot (-1) = -2$. Entry $(1,3)$: $1 \cdot (-1) = -1$. Entry $(2,2)$: $(-2)(-1) + 1 + 1 = 4$. Entry $(2,3)$: $1 \cdot (-1) = -1$. Entry $(3,3)$: $1 + 2 + 1 = 4$. By symmetry the rest follow:

$$\mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}} = \begin{bmatrix} 4 & -2 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix} = \mathbf{G}. \checkmark$$

Step 3. Branch voltages: $\mathbf{v}_b = \mathbf{A}^{\mathsf{T}}\mathbf{v} = (4,\ 1,\ 1,\ 3,\ 2,\ 2)^{\mathsf{T}}$ V. Branch currents $\mathbf{i}_b = \mathbf{G}_b\mathbf{v}_b = (4, 2, 1, 3, 4, 2)^{\mathsf{T}}$ mA. KCL check: $\mathbf{A}\mathbf{i}_b = (4 + 2 + 2,\ -2 + 1 + 3,\ -1 + 4 - 2)^{\mathsf{T}} = (8, 2, 1)^{\mathsf{T}}$. ✓ Power: $\sum g_k v_{b,k}^2 = 16 + 2 + 1 + 9 + 8 + 4 = 40$ mW, matching $\mathbf{v}^{\mathsf{T}}\mathbf{i}_s$.

Non-commutativity in practice: cascaded two-ports

A two-port is described by its **ABCD (transmission) matrix**, relating input voltage and current to output voltage and current:

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix}.$$

Because the output of one stage is the input of the next, a cascade is a product, taken in the physical order of the stages. A series impedance Z has $\begin{bmatrix} 1 & Z \\ 0 & 1 \end{bmatrix}$, a shunt admittance Y has $\begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix}$.

Worked Example 8.5 — Order matters (an L-section both ways round)

A series resistor $R = 2\ \Omega$ is followed by a shunt conductance $G = 0.5$ S. Find the cascade ABCD matrix, then repeat with the order reversed.

Series then shunt:

$$\begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0.5 & 1 \end{bmatrix} = \begin{bmatrix} 1+1 & 0+2 \\ 0+0.5 & 0+1 \end{bmatrix} = \begin{bmatrix} 2 & 2 \\ 0.5 & 1 \end{bmatrix}.$$

Shunt then series:

$$\begin{bmatrix} 1 & 0 \\ 0.5 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 2 \\ 0.5 & 2 \end{bmatrix}.$$

Reading. The open-circuit voltage gain is $V_2/V_1 = 1/A$ (set $I_2 = 0$): 0.5 in the first case (a divider) and 1 in the second (the shunt element sits across the source and does nothing to V_2). Different physical circuits, different products. Both matrices have determinant $AD - BC = 1$, the hallmark of a reciprocal two-port (§8.3).

Block matrices

Partitioning matrices into blocks and multiplying the blocks as if they were scalars is legitimate provided the partitions are conformable and the order of block factors is kept:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{B}_{11} & \mathbf{B}_{12} \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{11}\mathbf{B}_{11} + \mathbf{A}_{12}\mathbf{B}_{21} & \mathbf{A}_{11}\mathbf{B}_{12} + \mathbf{A}_{12}\mathbf{B}_{22} \\ \mathbf{A}_{21}\mathbf{B}_{11} + \mathbf{A}_{22}\mathbf{B}_{21} & \mathbf{A}_{21}\mathbf{B}_{12} + \mathbf{A}_{22}\mathbf{B}_{22} \end{bmatrix}.$$

Block structure appears naturally in **modified nodal analysis** (MNA), where unknown node voltages $\mathbf{v}$ and unknown voltage-source currents $\mathbf{j}$ are stacked:

$$\begin{bmatrix} \mathbf{G} & \mathbf{B} \\ \mathbf{B}^{\mathsf{T}} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \mathbf{j} \end{bmatrix} = \begin{bmatrix} \mathbf{i}_s \\ \mathbf{e} \end{bmatrix},$$

where $\mathbf{B}$ says which nodes each voltage source connects and $\mathbf{e}$ holds the source voltages. Eliminating one block in terms of the other gives the **Schur complement**, a block version of Gaussian elimination (§8.7).

Worked Example 8.6 — Matrix powers and a recursive network

A ladder of identical L-sections from Worked Example 8.5 (series 2 Ω then shunt 0.5 S) has $\mathbf{T} = \begin{bmatrix} 2 & 2 \\ 0.5 & 1 \end{bmatrix}$. Find the ABCD matrix of three sections and the open-circuit voltage gain.

Step 1. $\mathbf{T}^2 = \begin{bmatrix} 2 & 2 \\ 0.5 & 1 \end{bmatrix} \begin{bmatrix} 2 & 2 \\ 0.5 & 1 \end{bmatrix} = \begin{bmatrix} 4+1 & 4+2 \\ 1+0.5 & 1+1 \end{bmatrix} = \begin{bmatrix} 5 & 6 \\ 1.5 & 2 \end{bmatrix}$.

Step 2. $\mathbf{T}^3 = \mathbf{T}^2\mathbf{T} = \begin{bmatrix} 10+3 & 10+6 \\ 3+1 & 3+2 \end{bmatrix} = \begin{bmatrix} 13 & 16 \\ 4 & 5 \end{bmatrix}$.

Step 3. Gain $V_2/V_1 = 1/A = 1/13 \approx 0.0769$. Check reciprocity: $\det \mathbf{T}^3 = 65 - 64 = 1$. ✓

Powers of a matrix are computed far more cleverly via eigenvalues (Chapter 10); here the attenuation per section tends to the reciprocal of the larger eigenvalue of $\mathbf{T}$, which is $(3 + \sqrt{5})/2 \approx 2.618$.

Cost of multiplication

Each entry of an $m \times p$ by $p \times n$ product costs p multiplications and $p - 1$ additions, so the whole product costs about $2mpn$ floating-point operations (**flops**). For two $n \times n$ matrices this is $2n^3$; a matrix–vector product is $2n^2$. These counts set the scale for everything in §§8.7–8.11: a dense $n = 10^4$ matrix–matrix product is 2×10^{12} flops, a couple of seconds on a modern CPU core with vector units, while a dense $n = 10^6$ problem is out of reach — which is why sparsity (§8.11) matters.

Associativity lets us choose the cheapest bracketing. For $\mathbf{A} \in \mathbb{R}^{n\times n}$, $\mathbf{B} \in \mathbb{R}^{n\times n}$ and $\mathbf{x} \in \mathbb{R}^n$, $(\mathbf{AB})\mathbf{x}$ costs $2n^3 + 2n^2$ but $\mathbf{A}(\mathbf{Bx})$ costs only $4n^2$.

Common Pitfall

"Multiplying matrices entry by entry" (the **Hadamard product** $\mathbf{A} \odot \mathbf{B}$, MATLAB `.*`, NumPy `*`) is a different operation from the matrix product (MATLAB `*`, NumPy `@`). In NumPy, `A*x` with a 2-D array `A` and 1-D `x` silently broadcasts and returns a matrix, not $\mathbf{Ax}$. Always check the shape of the result.

Engineering Note

Chain matrices (ABCD), scattering-transfer matrices (T-parameters) in RF design, Jones matrices in optics and the ray-transfer matrices of lens systems are all multiplied in the physical order in which the signal meets the elements. Write the product from left to right in the order the wave travels from input to output, and check the first and last factors against a sketch.

8.3 Determinants

Motivation

The determinant is a single number computed from a square matrix that answers the most important yes/no question about it: *is the matrix invertible?* — equivalently, does $\mathbf{A}\mathbf{x} = \mathbf{b}$ have exactly one solution for every $\mathbf{b}$? It also measures how the linear map $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ scales areas and volumes (the Jacobian determinant of Chapter 6 is exactly this, applied to the local linearisation of a nonlinear map), it gives closed-form solutions of small systems (Cramer's rule), and its vanishing defines the eigenvalues of Chapter 10 through $\det(\mathbf{A} - \lambda\mathbf{I}) = 0$. In circuit theory the determinant of the nodal or mesh matrix is the denominator of every network function, so its zeros as a function of s are the natural frequencies (poles) of the network.

Definition

For small matrices:

$$\det \begin{bmatrix} a & b \\ c & d \end{bmatrix} = ad - bc,$$

$$\det \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} = a_{11}(a_{22}a_{33} - a_{23}a_{32}) - a_{12}(a_{21}a_{33} - a_{23}a_{31}) + a_{13}(a_{21}a_{32} - a_{22}a_{31}).$$

The 3×3 formula is a pattern that generalises.

Minor, cofactor, determinant

Let $\mathbf{A}$ be $n \times n$. The **minor** M_{ij} is the determinant of the $(n-1) \times (n-1)$ matrix obtained by deleting row i and column j. The **cofactor** is $C_{ij} = (-1)^{i+j} M_{ij}$. The **determinant** is defined recursively by $\det[a] = a$ for 1×1 and, for $n \geq 2$, by **cofactor (Laplace) expansion along the first row**:

$$\det \mathbf{A} = \sum_{j=1}^{n} a_{1j} C_{1j}.$$

We also write $|\mathbf{A}|$ or Δ.

The sign factor $(-1)^{i+j}$ follows a chessboard pattern beginning with $+$ in the top-left corner:

$$\begin{bmatrix} + & - & + & \cdots \\ - & + & - & \cdots \\ + & - & + & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

Laplace expansion along any row or column

For any fixed row i or any fixed column j,

$$\det \mathbf{A} = \sum_{k=1}^{n} a_{ik} C_{ik} = \sum_{k=1}^{n} a_{kj} C_{kj}.$$

Moreover, expanding a row against the cofactors of a *different* row gives zero: $\sum_k a_{ik} C_{lk} = 0$ for $i \neq l$.

The equivalent closed form, which makes the theorem transparent, is the **Leibniz formula**

$$\det \mathbf{A} = \sum_{\sigma} \operatorname{sgn}(\sigma)\, a_{1\sigma(1)} a_{2\sigma(2)} \cdots a_{n\sigma(n)},$$

summed over all $n!$ permutations σ of $\{1, \dots, n\}$, with $\operatorname{sgn}\sigma = \pm 1$ according to whether σ is an even or odd number of swaps. Each term takes exactly one entry from every row and every column. Expanding along any row or column just groups these $n!$ terms differently. The "different row gives zero" statement holds because $\sum_k a_{ik} C_{lk}$ is the determinant of a matrix whose row l has been replaced by a copy of row i — a matrix with two equal rows, whose determinant is zero (property 3 below).

The $n!$ terms make the definition useless for computation beyond $n \approx 5$: for $n = 25$, $25! \approx 1.6 \times 10^{25}$ products would take longer than the age of the universe at 10^9 products per second. Row reduction (below) needs only about $\tfrac{2}{3}n^3$ flops.

Properties

Properties of determinants

For $n \times n$ matrices $\mathbf{A}, \mathbf{B}$ and scalar c:

1. $\det \mathbf{A}^{\mathsf{T}} = \det \mathbf{A}$; $\det \mathbf{A}^{\mathsf{H}} = (\det \mathbf{A})^{*}$.
2. **Row swap** changes the sign of the determinant.
3. If two rows (or columns) are equal, or a row is all zeros, $\det \mathbf{A} = 0$.
4. **Row scaling**: multiplying one row by c multiplies the determinant by c. Hence $\det(c\mathbf{A}) = c^{n} \det \mathbf{A}$.
5. **Row replacement**: adding a multiple of one row to another leaves the determinant unchanged.
6. The determinant of a triangular (in particular diagonal) matrix is the product of its diagonal entries.
7. **Product rule**: $\det(\mathbf{AB}) = \det \mathbf{A} \, \det \mathbf{B}$.
8. $\mathbf{A}$ is invertible if and only if $\det \mathbf{A} \neq 0$, and then $\det(\mathbf{A}^{-1}) = 1/\det \mathbf{A}$.
9. The determinant is linear in each row separately (multilinearity).

Proof sketches. (1) Transposing maps each Leibniz term to a term of the same sign. (2) Swapping two rows composes every permutation with a transposition, flipping every sign. (3) Swapping two equal rows leaves $\mathbf{A}$ unchanged but negates $\det \mathbf{A}$, so $\det \mathbf{A} = -\det \mathbf{A} = 0$; a zero row puts a zero factor in every Leibniz term. (4) and (9) Each Leibniz term contains exactly one factor from each row. (5) By multilinearity, $\det(\dots, \mathbf{r}_i + c\mathbf{r}_l, \dots) = \det(\dots, \mathbf{r}_i, \dots) + c \det(\dots, \mathbf{r}_l, \dots)$, and the second determinant has two equal rows. (6) Expand repeatedly down the first column: only the diagonal entry survives each time. (7) Row-reduce $\mathbf{A}$ with elementary matrices whose determinants are known (§8.4), then use (6). (8) follows from (7), $\det \mathbf{I} = 1$, and the fact that row reduction of a singular matrix produces a zero row. □

Properties 2, 4 and 5 are exactly the three row operations of Gaussian elimination. That gives the practical algorithm:

> **Determinant by elimination.** Reduce $\mathbf{A}$ to upper triangular $\mathbf{U}$ using row replacements and s row swaps (no scaling). Then $\det \mathbf{A} = (-1)^{s} \, u_{11} u_{22} \cdots u_{nn}$, the signed product of the pivots.

Geometric meaning

For a 2×2 matrix with columns $\mathbf{a}_1 = (a, c)^{\mathsf{T}}$ and $\mathbf{a}_2 = (b, d)^{\mathsf{T}}$, $|ad - bc|$ is the area of the parallelogram spanned by the columns; the sign records orientation (positive if $\mathbf{a}_1$ turns anticlockwise to reach $\mathbf{a}_2$). For 3×3, $|\det \mathbf{A}|$ is the volume of the parallelepiped spanned by the columns — the scalar triple product $\mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3)$ of Chapter 7. In general the linear map $\mathbf{x} \mapsto \mathbf{Ax}$ multiplies every n-dimensional volume by $|\det \mathbf{A}|$. A zero determinant means the columns are squashed into a lower-dimensional set — they are linearly dependent — and information is lost; no inverse map can recover it. This is the geometric content of property 8, and it also explains the product rule: applying $\mathbf{B}$ then $\mathbf{A}$ scales volumes by $|\det \mathbf{B}|$ and then by $|\det \mathbf{A}|$.

Cramer's rule

Cramer's rule

If $\det \mathbf{A} \neq 0$, the unique solution of $\mathbf{Ax} = \mathbf{b}$ is

$$x_k = \frac{\det \mathbf{A}_k}{\det \mathbf{A}}, \qquad k = 1, \dots, n,$$

where $\mathbf{A}_k$ is $\mathbf{A}$ with column k replaced by $\mathbf{b}$.

Proof. Write $\mathbf{b} = \sum_j x_j \mathbf{a}_j$ (column view). Replace column k of $\mathbf{A}$ by this sum and use multilinearity in columns: $\det \mathbf{A}_k = \sum_j x_j \det(\mathbf{a}_1, \dots, \mathbf{a}_j, \dots, \mathbf{a}_n)$ with $\mathbf{a}_j$ in slot k. Every term with $j \neq k$ has a repeated column and vanishes, leaving $\det \mathbf{A}_k = x_k \det \mathbf{A}$. □

Cramer's rule is the right tool for 2×2 and 3×3 systems with symbolic entries — for example, to obtain a transfer function in terms of s and component values — and the wrong tool for numerical systems larger than that, where it costs $n + 1$ determinants and is numerically inferior to elimination.

Worked Example 8.7 — Determinant of the running example, two ways

Find $\det \mathbf{G}$ for $\mathbf{G} = \begin{bmatrix} 4 & -2 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}$.

Method 1: cofactor expansion along row 1.

$$\begin{aligned} \det \mathbf{G} &= 4 \begin{vmatrix} 4 & -1 \\ -1 & 4 \end{vmatrix} - (-2) \begin{vmatrix} -2 & -1 \\ -1 & 4 \end{vmatrix} + (-1) \begin{vmatrix} -2 & 4 \\ -1 & -1 \end{vmatrix} \\ &= 4(16 - 1) + 2(-8 - 1) - (2 + 4) = 60 - 18 - 6 = 36. \end{aligned}$$

Method 2: elimination. $R_2 \leftarrow R_2 + \tfrac{1}{2} R_1$ and $R_3 \leftarrow R_3 + \tfrac{1}{4} R_1$ give rows $(0, 3, -\tfrac{3}{2})$ and $(0, -\tfrac{3}{2}, \tfrac{15}{4})$. Then $R_3 \leftarrow R_3 + \tfrac{1}{2} R_2$ gives $(0, 0, 3)$. No swaps, so

$$\det \mathbf{G} = 4 \cdot 3 \cdot 3 = 36.$$

The units are mS^3. Method 2 is the one that scales.

Worked Example 8.8 — A determinant needing a row swap

The modified nodal formulation of §8.7 (Worked Example 8.22) leads to

$$\mathbf{M} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 4 & -2 & -1 \\ 0 & -2 & 4 & -1 \\ 0 & -1 & -1 & 4 \end{bmatrix}.$$

Find $\det \mathbf{M}$.

Step 1. $m_{11} = 0$, so swap $R_1 \leftrightarrow R_2$ ($s = 1$):

$$\begin{bmatrix} 1 & 4 & -2 & -1 \\ 0 & 1 & 0 & 0 \\ 0 & -2 & 4 & -1 \\ 0 & -1 & -1 & 4 \end{bmatrix}.$$

Step 2. $R_3 \leftarrow R_3 + 2R_2$, $R_4 \leftarrow R_4 + R_2$: rows 3 and 4 become $(0, 0, 4, -1)$ and $(0, 0, -1, 4)$.

Step 3. $R_4 \leftarrow R_4 + \tfrac{1}{4} R_3$: row 4 becomes $(0, 0, 0, \tfrac{15}{4})$.

Step 4. $\det \mathbf{M} = (-1)^1 \cdot 1 \cdot 1 \cdot 4 \cdot \tfrac{15}{4} = -15$.

Check by expansion along row 1: only $m_{12} = 1$ is nonzero, so $\det \mathbf{M} = (-1)^{1+2} M_{12}$, and $M_{12} = \det \begin{bmatrix} 1 & -2 & -1 \\ 0 & 4 & -1 \\ 0 & -1 & 4 \end{bmatrix} = 1 \cdot (16 - 1) = 15$. Hence -15. ✓

(Choosing the sparsest row for the expansion is always worth a glance.)

Two-mesh example and its geometry

Consider a two-mesh resistive circuit: mesh 1 contains a 2 kΩ resistor and a 7 V source, mesh 2 contains a 4 kΩ resistor and a 1 V source, and the two meshes share a 3 kΩ resistor. With clockwise mesh currents i_1, i_2 in mA, KVL gives the **mesh equations** $\mathbf{R}\mathbf{i} = \mathbf{v}_s$:

$$\begin{bmatrix} 5 & -3 \\ -3 & 7 \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 7 \\ 1 \end{bmatrix}.$$

The diagonal entries are the total resistance around each mesh, the off-diagonal entries minus the shared resistance — the mesh-analysis mirror image of the nodal rule. Units: $\text{k}\Omega \times \text{mA} = \text{V}$.

Worked Example 8.9 — Cramer's rule for the two-mesh circuit

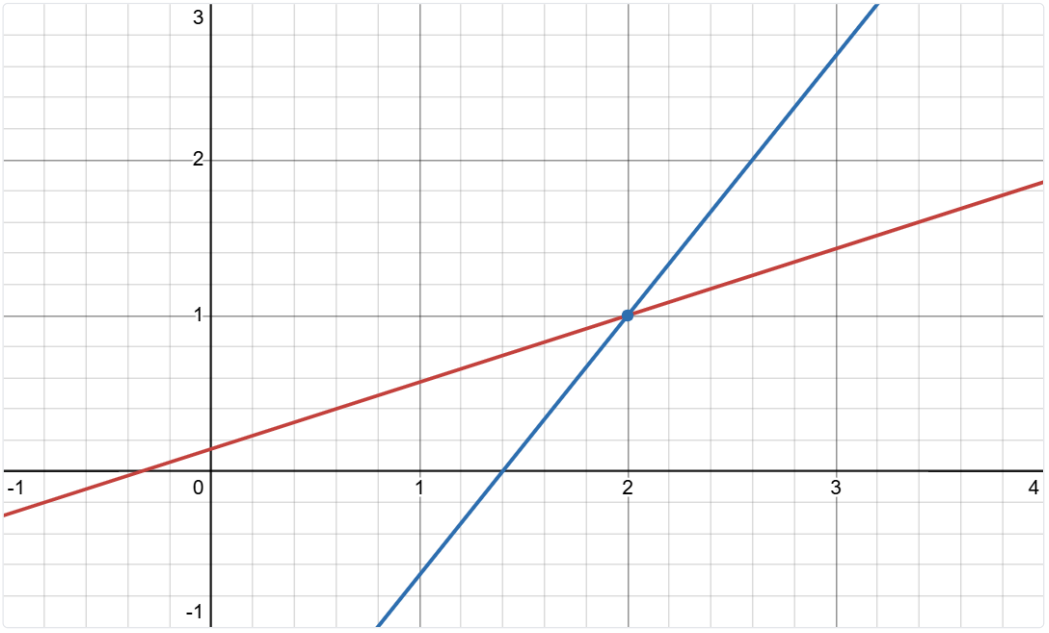
Step 1. $\det \mathbf{R} = 5 \cdot 7 - (-3)(-3) = 35 - 9 = 26\ \text{k}\Omega^2$.

Step 2.

$$i_1 = \frac{\begin{vmatrix} 7 & -3 \\ 1 & 7 \end{vmatrix}}{26} = \frac{49 + 3}{26} = 2\ \text{mA}, \qquad i_2 = \frac{\begin{vmatrix} 5 & 7 \\ -3 & 1 \end{vmatrix}}{26} = \frac{5 + 21}{26} = 1\ \text{mA}.$$

Step 3 (check). $5(2) - 3(1) = 7$ ✓, $-3(2) + 7(1) = 1$ ✓. The shared resistor carries $i_1 - i_2 = 1$ mA.

Geometry. Each equation is a straight line in the (i_1, i_2) plane; the solution is their intersection. Because $\det \mathbf{R} \neq 0$ the lines are not parallel and meet in exactly one point.



The two mesh equations as lines in the (i_1, i_2) plane (horizontal axis i_1, vertical axis i_2, both in mA). They cross at the unique solution $(2, 1)$; a nonzero determinant guarantees the slopes $5/3$ and $3/7$ differ.

Worked Example 8.10 — Cramer's rule for one node voltage, symbolically

In the running example, suppose only node 1 is driven, by a current I, and we want the transfer resistance v_3/I.

Step 1. $\mathbf{i}_s = (I, 0, 0)^{\mathsf{T}}$. Replace column 3 of $\mathbf{G}$:

$$\det \mathbf{G}_3 = \begin{vmatrix} 4 & -2 & I \\ -2 & 4 & 0 \\ -1 & -1 & 0 \end{vmatrix} = I \begin{vmatrix} -2 & 4 \\ -1 & -1 \end{vmatrix} = I(2 + 4) = 6I,$$

expanding along column 3, where only the top entry is nonzero and its sign factor is $(-1)^{1+3} = +1$.

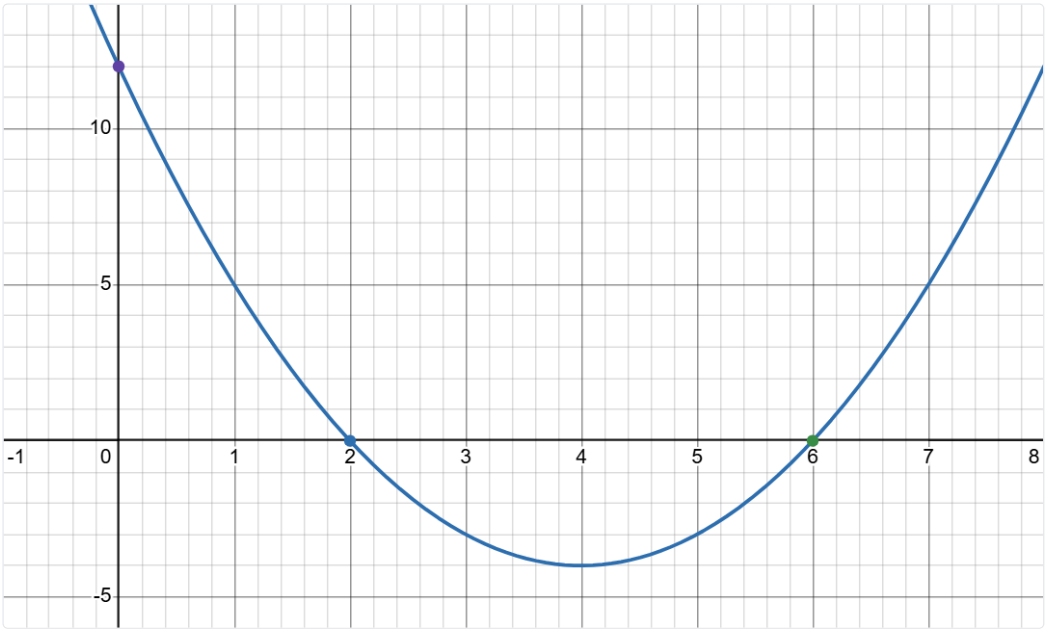
Step 2. $v_3 = 6I/36 = I/6$, so the transfer resistance is $v_3/I = 1/6\ \text{k}\Omega \approx 167\ \Omega$ (since $1/\text{mS} = \text{k}\Omega$).

Step 3 (full solution check). With the original sources $(8, 2, 1)$, Cramer gives $\det \mathbf{G}_1 = 144$, $\det \mathbf{G}_2 = 108$, $\det \mathbf{G}_3 = 72$, so $\mathbf{v} = (144, 108, 72)/36 = (4, 3, 2)\ \text{V}$. ✓

Determinant as a function of a parameter

When a component value varies, the determinant becomes a polynomial in that value, and its zeros mark the values at which the circuit equations become singular. Consider $\mathbf{A} - \lambda\mathbf{I}$ with $\mathbf{A} = \begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix}$ (the nodal matrix of nodes 1 and 2 of a circuit like the running example with node 3 tied to ground):

$$p(\lambda) = \det \begin{bmatrix} 4 - \lambda & -2 \\ -2 & 4 - \lambda \end{bmatrix} = (4 - \lambda)^2 - 4 = \lambda^2 - 8\lambda + 12 = (\lambda - 2)(\lambda - 6).$$



$\det(\mathbf{A} - \lambda\mathbf{I})$ as a function of λ (horizontal axis). At $\lambda = 0$ it equals $\det \mathbf{A} = 12$; it vanishes at $\lambda = 2$ and $\lambda = 6$, where $\mathbf{A} - \lambda\mathbf{I}$ is singular. These are the eigenvalues of $\mathbf{A}$ (Chapter 10).

Common Pitfall

A small determinant does **not** mean a matrix is nearly singular. $\det(10^{-3}\mathbf{I}_{10}) = 10^{-30}$, yet $10^{-3}\mathbf{I}$ is perfectly conditioned; and the determinant changes with units ($\mathbf{G}$ in S instead of mS has a determinant 10^9 times smaller, with no change in the difficulty of solving the system). Use the condition number (§8.10), not the determinant, to judge numerical near-singularity.

Engineering Note

For a network with impedances depending on s, $\Delta(s) = \det \mathbf{Y}(s)$ is, up to a factor, the characteristic polynomial of the network; its roots are the natural frequencies. Every node voltage is $\Delta_k(s)/\Delta(s)$ by Cramer's rule, which is why all transfer functions of a network share the same denominator. Mason's gain formula for signal-flow graphs is a combinatorial way of evaluating these same determinants.

8.4 Matrix inverse

Motivation

For a scalar equation $ax = b$ we write $x = a^{-1}b$ provided $a \neq 0$. The matrix analogue $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$ is the natural way to *express* the solution of a linear system and to reason about it, even though (as we shall stress) it is rarely the way to *compute* it. The inverse also has direct physical meaning: the inverse of a nodal conductance matrix is the **nodal resistance (impedance) matrix**, whose entries are driving-point and transfer resistances; the inverse of a mesh resistance matrix is a conductance matrix; the inverse of a two-port's $\mathbf{Z}$-parameter matrix is its $\mathbf{Y}$-parameter matrix.

Definition and uniqueness

Inverse

A square matrix $\mathbf{A}$ is **invertible** (nonsingular) if there is a matrix $\mathbf{A}^{-1}$ with

$$\mathbf{A}\mathbf{A}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}.$$

A square matrix with no inverse is **singular**.

The inverse, when it exists, is unique: if $\mathbf{B}$ and $\mathbf{C}$ are both inverses then $\mathbf{B} = \mathbf{B}\mathbf{I} = \mathbf{B}(\mathbf{A}\mathbf{C}) = (\mathbf{B}\mathbf{A})\mathbf{C} = \mathbf{I}\mathbf{C} = \mathbf{C}$. For square matrices a one-sided inverse is automatically two-sided: if $\mathbf{B}\mathbf{A} = \mathbf{I}$ then $\mathbf{A}\mathbf{B} = \mathbf{I}$ too (this follows from the rank arguments of §8.5). Non-square matrices never have two-sided inverses; their one-sided and generalised inverses (the pseudo-inverse) belong to least-squares theory in Chapter 9.

If $\mathbf{A}$ is invertible, $\mathbf{A}\mathbf{x} = \mathbf{b}$ has the unique solution $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$: it is a solution because $\mathbf{A}(\mathbf{A}^{-1}\mathbf{b}) = \mathbf{b}$, and it is the only one because any solution satisfies $\mathbf{x} = \mathbf{A}^{-1}\mathbf{A}\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$.

Formulas

For a 2×2 matrix the inverse is: *swap the diagonal, negate the off-diagonal, divide by the determinant*,

$$\begin{bmatrix} a & b \\ c & d \end{bmatrix}^{-1} = \frac{1}{ad - bc}\begin{bmatrix} d & -b \\ -c & a \end{bmatrix}, \qquad ad - bc \neq 0.$$

In general:

Adjugate formula

Let $\mathbf{C} = [C_{ij}]$ be the matrix of cofactors of $\mathbf{A}$ and define the **adjugate** $\operatorname{adj}\mathbf{A} = \mathbf{C}^{\mathsf{T}}$. Then

$$\mathbf{A}\,\operatorname{adj}\mathbf{A} = \operatorname{adj}\mathbf{A}\,\mathbf{A} = (\det\mathbf{A})\,\mathbf{I},$$

so if $\det\mathbf{A} \neq 0$,

$$\mathbf{A}^{-1} = \frac{1}{\det\mathbf{A}}\operatorname{adj}\mathbf{A}.$$

Proof. The (i,l) entry of $\mathbf{A}\operatorname{adj}\mathbf{A}$ is $\sum_k a_{ik}C_{lk}$. By the Laplace expansion theorem of §8.3 this equals $\det\mathbf{A}$ when $i = l$ and 0 when $i \neq l$. $\square$

The adjugate formula is the matrix version of Cramer's rule — indeed $(\operatorname{adj}\mathbf{A}\,\mathbf{b})_k = \det\mathbf{A}_k$ — and has the same uses (symbolic 2×2 and 3×3 work, theory) and the same drawback (cost) for anything larger.

Algebra of inverses

If $\mathbf{A}$ and $\mathbf{B}$ are invertible $n \times n$ matrices and $c \neq 0$:

1. $(\mathbf{A}^{-1})^{-1} = \mathbf{A}$.
2. $(\mathbf{A}\mathbf{B})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$ (order reverses — "socks and shoes").
3. $(\mathbf{A}^{\mathsf{T}})^{-1} = (\mathbf{A}^{-1})^{\mathsf{T}}$ and $(\mathbf{A}^{\mathsf{H}})^{-1} = (\mathbf{A}^{-1})^{\mathsf{H}}$; hence the inverse of a symmetric matrix is symmetric.
4. $(c\mathbf{A})^{-1} = c^{-1}\mathbf{A}^{-1}$.
5. $\mathbf{A}^{-1}$ of a diagonal matrix is the diagonal matrix of reciprocals; the inverse of an upper (lower) triangular matrix is upper (lower) triangular.

Proof of 2 and 3. $(\mathbf{A}\mathbf{B})(\mathbf{B}^{-1}\mathbf{A}^{-1}) = \mathbf{A}\mathbf{I}\mathbf{A}^{-1} = \mathbf{I}$. Transposing $\mathbf{A}\mathbf{A}^{-1} = \mathbf{I}$ gives $(\mathbf{A}^{-1})^{\mathsf{T}}\mathbf{A}^{\mathsf{T}} = \mathbf{I}$. $\square$

Elementary matrices

Each row operation of elimination is a left-multiplication by an **elementary matrix**, obtained by doing that operation to $\mathbf{I}$:

Row operation	Elementary matrix (3×3 example)	Inverse	Determinant
$R_2 \leftarrow R_2 + mR_1$	$\mathbf{E} = \begin{bmatrix} 1 & 0 & 0 \\ m & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$	same with $-m$	1
$R_2 \leftarrow cR_2$	$\operatorname{diag}(1, c, 1)$	$\operatorname{diag}(1, 1/c, 1)$	c
$R_1 \leftrightarrow R_2$	$\mathbf{P} = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}$	$\mathbf{P}$ itself	-1

Every elementary matrix is invertible, and its inverse undoes the operation. If a sequence of row operations reduces $\mathbf{A}$ to $\mathbf{I}$, say $\mathbf{E}_k \cdots \mathbf{E}_2 \mathbf{E}_1 \mathbf{A} = \mathbf{I}$, then $\mathbf{A}^{-1} = \mathbf{E}_k \cdots \mathbf{E}_1$ — the same operations applied to $\mathbf{I}$. This is the Gauss–Jordan method for the inverse (§8.8), and it also proves the product rule for determinants claimed in §8.3.

The invertible matrix theorem

Invertible matrix theorem

For an $n \times n$ matrix $\mathbf{A}$ the following are equivalent:

1. $\mathbf{A}$ is invertible.
2. $\det \mathbf{A} \neq 0$.
3. $\mathbf{A}\mathbf{x} = \mathbf{b}$ has a unique solution for every $\mathbf{b}$.
4. $\mathbf{A}\mathbf{x} = \mathbf{0}$ has only the trivial solution $\mathbf{x} = \mathbf{0}$.
5. $\operatorname{rank} \mathbf{A} = n$ (§8.5); the columns (and rows) are linearly independent.
6. Gaussian elimination produces n nonzero pivots (with row swaps if needed).
7. $\mathbf{A}$ is a product of elementary matrices.
8. 0 is not an eigenvalue of $\mathbf{A}$ (Chapter 10).

For circuits, statement 4 has a direct reading: the nodal equations with all independent sources switched off have only the zero solution. A network in which some node "floats" (no DC path to ground) violates it — the floating part can sit at any voltage — and its nodal matrix is singular (§8.5, Worked Example 8.17).

Worked Example 8.11 — Inverse of the mesh matrix

For $\mathbf{R} = \begin{bmatrix} 5 & -3 \\ -3 & 7 \end{bmatrix}$ kΩ (§8.3), find $\mathbf{R}^{-1}$ and use it to solve $\mathbf{R}\mathbf{i} = (7, 1)^{\mathsf{T}}$.

Step 1. $\det \mathbf{R} = 26$. Swap diagonal, negate off-diagonal:

$$\mathbf{R}^{-1} = \frac{1}{26}\begin{bmatrix} 7 & 3 \\ 3 & 5 \end{bmatrix} \text{ mS}.$$

Step 2. $\mathbf{i} = \mathbf{R}^{-1}\mathbf{v}_s = \frac{1}{26}(49 + 3,\ 21 + 5)^{\mathsf{T}} = (2, 1)^{\mathsf{T}}$ mA. ✓

Step 3 (check). $\mathbf{R}\mathbf{R}^{-1} = \frac{1}{26}\begin{bmatrix} 35 - 9 & 15 - 15 \\ -21 + 21 & -9 + 35 \end{bmatrix} = \mathbf{I}$. ✓

Reading. $[\mathbf{R}^{-1}]_{12} = 3/26$ mS is the current in mesh 1 per volt of source in mesh 2. Its equality with $[\mathbf{R}^{-1}]_{21}$ is reciprocity, and it follows from property 3 of the inverse.

Worked Example 8.12 — The nodal resistance matrix of the running example

Find $\mathbf{Z} = \mathbf{G}^{-1}$ by the adjugate formula and interpret its entries.

Step 1 (cofactors). Using $\mathbf{G} = \begin{bmatrix} 4 & -2 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix}$:

$$C_{11} = +\begin{vmatrix} 4 & -1 \\ -1 & 4 \end{vmatrix} = 15, \quad C_{12} = -\begin{vmatrix} -2 & -1 \\ -1 & 4 \end{vmatrix} = 9, \quad C_{13} = +\begin{vmatrix} -2 & 4 \\ -1 & -1 \end{vmatrix} = 6,$$
$$C_{22} = +\begin{vmatrix} 4 & -1 \\ -1 & 4 \end{vmatrix} = 15, \quad C_{23} = -\begin{vmatrix} 4 & -2 \\ -1 & -1 \end{vmatrix} = 6, \quad C_{33} = +\begin{vmatrix} 4 & -2 \\ -2 & 4 \end{vmatrix} = 12,$$

and by symmetry $C_{21} = 9$, $C_{31} = 6$, $C_{32} = 6$.

Step 2. $\det \mathbf{G} = 36$ (Worked Example 8.7), so

$$\mathbf{Z} = \mathbf{G}^{-1} = \frac{1}{36}\begin{bmatrix} 15 & 9 & 6 \\ 9 & 15 & 6 \\ 6 & 6 & 12 \end{bmatrix} = \begin{bmatrix} \frac{5}{12} & \frac{1}{4} & \frac{1}{6} \\ \frac{1}{4} & \frac{5}{12} & \frac{1}{6} \\ \frac{1}{6} & \frac{1}{6} & \frac{1}{3} \end{bmatrix} \text{ kΩ}.$$

Step 3 (check). Row 1 of $\mathbf{G}$ times column 1 of $\operatorname{adj}\mathbf{G}$: $4(15) - 2(9) - 1(6) = 36$ ✓; row 1 times column 2: $4(9) - 2(15) - 6 = 0$ ✓.

Step 4 (solve). $\mathbf{v} = \mathbf{Z}\mathbf{i}_s = \frac{1}{36}(120 + 18 + 6,\ 72 + 30 + 6,\ 48 + 12 + 12)^{\mathsf{T}} = (4, 3, 2)^{\mathsf{T}}$ V. ✓

Reading. $Z_{11} = 5/12$ kΩ ≈ 417 Ω is the resistance seen looking into node 1 from ground (the Thévenin resistance at node 1); $Z_{31} = 1/6$ kΩ is the transfer resistance found by Cramer's rule in Worked Example 8.10. All entries are positive and each diagonal entry is the largest in its column — typical of resistive networks: injecting current at a node raises that node most.

Updating an inverse: Sherman–Morrison

Design work often changes one component and re-solves. Changing a conductance g between nodes p and q by δ changes $\mathbf{G}$ by a **rank-one** matrix $\delta\,\mathbf{u}\mathbf{u}^{\mathsf{T}}$ with $\mathbf{u} = \mathbf{e}_p - \mathbf{e}_q$ (or $\mathbf{u} = \mathbf{e}_p$ for a branch to ground), where $\mathbf{e}_k$ is column k of $\mathbf{I}$.

Sherman–Morrison formula

If $\mathbf{A}$ is invertible and $1 + \mathbf{v}^{\mathsf T}\mathbf{A}^{-1}\mathbf{u} \neq 0$, then

$$(\mathbf{A} + \mathbf{u}\mathbf{v}^{\mathsf T})^{-1} = \mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{u}\,\mathbf{v}^{\mathsf T}\mathbf{A}^{-1}}{1 + \mathbf{v}^{\mathsf T}\mathbf{A}^{-1}\mathbf{u}}.$$

Consequently the new solution of $(\mathbf{A} + \mathbf{u}\mathbf{v}^{\mathsf T})\mathbf{x}' = \mathbf{b}$ is

$$\mathbf{x}' = \mathbf{x} - \frac{\mathbf{v}^{\mathsf T}\mathbf{x}}{1 + \mathbf{v}^{\mathsf T}\mathbf{w}}\,\mathbf{w}, \qquad \mathbf{x} = \mathbf{A}^{-1}\mathbf{b},\ \ \mathbf{w} = \mathbf{A}^{-1}\mathbf{u}.$$

Proof. Multiply $\mathbf{A} + \mathbf{u}\mathbf{v}^{\mathsf T}$ by the claimed inverse. With $\beta = \mathbf{v}^{\mathsf T}\mathbf{A}^{-1}\mathbf{u}$ (a scalar),

$$(\mathbf{A} + \mathbf{u}\mathbf{v}^{\mathsf T})\Big(\mathbf{A}^{-1} - \frac{\mathbf{A}^{-1}\mathbf{u}\mathbf{v}^{\mathsf T}\mathbf{A}^{-1}}{1+\beta}\Big) = \mathbf{I} + \mathbf{u}\mathbf{v}^{\mathsf T}\mathbf{A}^{-1} - \frac{\mathbf{u}\mathbf{v}^{\mathsf T}\mathbf{A}^{-1} + \beta\,\mathbf{u}\mathbf{v}^{\mathsf T}\mathbf{A}^{-1}}{1+\beta} = \mathbf{I}. \qquad \square$$

The update costs $O(n^2)$ given $\mathbf{w}$ (one extra solve with the existing factorisation), instead of $O(n^3)$ for a fresh solve. Its generalisation to rank-k changes is the **Woodbury identity** $(\mathbf{A} + \mathbf{U}\mathbf{C}\mathbf{V}^{\mathsf T})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{U}(\mathbf{C}^{-1} + \mathbf{V}^{\mathsf T}\mathbf{A}^{-1}\mathbf{U})^{-1}\mathbf{V}^{\mathsf T}\mathbf{A}^{-1}$, used in Kalman filtering and in contingency analysis of power networks (removing a line is a rank-one change with $\delta = -g$).

Worked Example 8.13 — Doubling one resistor's conductance

In the running example, branch f (between nodes 1 and 3) is changed from 1 mS to 2 mS. Find the new node voltages without re-solving.

Step 1. $\delta = 1$, $\mathbf{u} = \mathbf{v} = \mathbf{e}_1 - \mathbf{e}_3 = (1, 0, -1)^{\mathsf T}$, so $\mathbf{G}' = \mathbf{G} + \mathbf{u}\mathbf{u}^{\mathsf T}$.

Step 2. $\mathbf{w} = \mathbf{Z}\mathbf{u} =$ column 1 minus column 3 of $\mathbf{Z} = (\tfrac{5}{12} - \tfrac{1}{6},\ \tfrac{1}{4} - \tfrac{1}{6},\ \tfrac{1}{6} - \tfrac{1}{3})^{\mathsf T} = (\tfrac{1}{4},\ \tfrac{1}{12},\ -\tfrac{1}{6})^{\mathsf T}$.

Step 3. $\mathbf{u}^{\mathsf T}\mathbf{w} = \tfrac{1}{4} + \tfrac{1}{6} = \tfrac{5}{12}$ — this is the resistance (in kΩ) seen by the branch between nodes 1 and 3 — and $\mathbf{u}^{\mathsf T}\mathbf{v}_{\text{old}} = 4 - 2 = 2$ V.

Step 4.

$$\mathbf{v}' = \begin{bmatrix}4\\3\\2\end{bmatrix} - \frac{2}{1 + \frac{5}{12}}\begin{bmatrix}\frac{1}{4}\\ \frac{1}{12}\\ -\frac{1}{6}\end{bmatrix} = \begin{bmatrix}4\\3\\2\end{bmatrix} - \frac{24}{17}\begin{bmatrix}\frac{1}{4}\\ \frac{1}{12}\\ -\frac{1}{6}\end{bmatrix} = \frac{1}{17}\begin{bmatrix}62\\49\\38\end{bmatrix} \approx \begin{bmatrix}3.647\\2.882\\2.235\end{bmatrix}\ \text{V}.$$

Step 5 (check). $\mathbf{G}' = \begin{bmatrix}5 & -2 & -2\\ -2 & 4 & -1\\ -2 & -1 & 5\end{bmatrix}$; row 1 times $(62, 49, 38)/17$ is $(310 - 98 - 76)/17 = 136/17 = 8$ ✓; row 3: $(-124 - 49 + 190)/17 = 17/17 = 1$ ✓.

Reading. Stiffening the link between nodes 1 and 3 pulls their voltages together: the difference falls from 2 V to $24/17 \approx 1.41$ V.

Block inverses, Schur complements and Kron reduction

Partition a system into the unknowns we care about ($\mathbf{x}_1$) and those we would like to eliminate ($\mathbf{x}_2$):

$$\begin{bmatrix}\mathbf{A}_{11} & \mathbf{A}_{12}\\ \mathbf{A}_{21} & \mathbf{A}_{22}\end{bmatrix}\begin{bmatrix}\mathbf{x}_1\\ \mathbf{x}_2\end{bmatrix} = \begin{bmatrix}\mathbf{b}_1\\ \mathbf{b}_2\end{bmatrix}.$$

If $\mathbf{A}_{22}$ is invertible, the second block row gives $\mathbf{x}_2 = \mathbf{A}_{22}^{-1}(\mathbf{b}_2 - \mathbf{A}_{21}\mathbf{x}_1)$; substituting into the first,

$$\underbrace{(\mathbf{A}_{11} - \mathbf{A}_{12}\mathbf{A}_{22}^{-1}\mathbf{A}_{21})}_{\mathbf{S},\ \text{Schur complement}}\mathbf{x}_1 = \mathbf{b}_1 - \mathbf{A}_{12}\mathbf{A}_{22}^{-1}\mathbf{b}_2.$$

Moreover $\det\mathbf{A} = \det\mathbf{A}_{22}\,\det\mathbf{S}$. In network theory this is **Kron reduction**: eliminating internal nodes leaves an equivalent network seen from the retained nodes. The star–delta transformation is the special case of eliminating a single node with three neighbours.

Worked Example 8.14 — Kron reduction of node 3

Eliminate v_3 from the running example and solve the reduced 2×2 system.

Step 1. $\mathbf{A}_{11} = \begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix}$, $\mathbf{A}_{12} = \begin{bmatrix} -1 \\ -1 \end{bmatrix} = \mathbf{A}_{21}^{\mathsf{T}}$, $\mathbf{A}_{22} = [4]$, $\mathbf{b}_1 = (8, 2)^{\mathsf{T}}$, $b_2 = 1$.

Step 2.

$$\mathbf{S} = \begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix} - \frac{1}{4}\begin{bmatrix} -1 \\ -1 \end{bmatrix}\begin{bmatrix} -1 & -1 \end{bmatrix} = \begin{bmatrix} 3.75 & -2.25 \\ -2.25 & 3.75 \end{bmatrix}, \qquad \mathbf{b}_1' = \begin{bmatrix} 8 \\ 2 \end{bmatrix} - \frac{1}{4}\begin{bmatrix} -1 \\ -1 \end{bmatrix}(1) = \begin{bmatrix} 8.25 \\ 2.25 \end{bmatrix}.$$

Step 3. $\det \mathbf{S} = 3.75^2 - 2.25^2 = 9$, and $\det \mathbf{A}_{22} \det \mathbf{S} = 4 \cdot 9 = 36 = \det \mathbf{G}$ ✓. Then

$$v_1 = \frac{8.25(3.75) + 2.25(2.25)}{9} = \frac{36}{9} = 4, \qquad v_2 = \frac{3.75(2.25) + 2.25(8.25)}{9} = \frac{27}{9} = 3 \text{ V}.$$

Step 4. Back-substitute: $v_3 = \frac{1}{4}(1 + v_1 + v_2) = \frac{1}{4}(8) = 2$ V. ✓

Reading. $\mathbf{S}$ is the nodal matrix of an equivalent two-node network: the off-diagonal -2.25 says the direct 2 mS link between nodes 1 and 2 is supplemented by an effective 0.25 mS through the eliminated node (the series combination of the two 1 mS branches meeting there, weighted by node 3's 4 mS total — exactly the star–delta rule $g_1 g_2 / \sum g$). The modified source vector shows that node 3's 1 mA source is redistributed as 0.25 mA into each of nodes 1 and 2.

Common Pitfall

Do not compute $\mathbf{A}^{-1}$ in order to solve $\mathbf{A}\mathbf{x} = \mathbf{b}$. Forming the inverse costs about $2n^3$ flops versus $\frac{2}{3}n^3$ for an $\mathbf{LU}$ solve, is less accurate in floating point, and for sparse matrices is catastrophic: the inverse of a sparse nodal matrix is typically completely full (every entry of $\mathbf{Z}$ above is nonzero although $\mathbf{G}$ could be sparse). Write $\mathbf{A}^{-1}\mathbf{b}$ in formulas; compute it as `A\b` (MATLAB) or `numpy.linalg.solve(A, b)`.

Engineering Note

The nodal resistance matrix $\mathbf{Z} = \mathbf{G}^{-1}$ is the natural object in **sensitivity analysis**. By differentiating $\mathbf{G}\mathbf{v} = \mathbf{i}_s$, $\partial \mathbf{v}/\partial g = -\mathbf{Z}(\partial \mathbf{G}/\partial g)\mathbf{v}$; with the stamp $\partial \mathbf{G}/\partial g = \mathbf{u}\mathbf{u}^{\mathsf{T}}$ this is the derivative form of Sherman–Morrison. Circuit simulators compute such sensitivities with one extra *adjoint* solve using $\mathbf{G}^{\mathsf{T}}$, reusing the factorisation — the same trick that underlies back-propagation in neural networks.

8.5 Rank

Motivation

A square matrix is either invertible or not; the determinant is a yes/no test. But engineers constantly meet matrices that are rectangular (more measurements than unknowns, more branches than nodes) or singular for structural reasons (a floating subcircuit, a redundant sensor, a dependent equation written twice). The **rank** is the single number that says how much independent information a matrix carries. It decides whether a linear system is solvable, how many free parameters its solution has, how many independent KCL or KVL equations a network supplies, and — in Chapter 9 — the dimensions of the column space and null space.

Echelon form

Row echelon form, pivots

A matrix is in **row echelon form (REF)** if

1. all zero rows are at the bottom, and
2. the first nonzero entry (the **pivot** or leading entry) of each nonzero row lies strictly to the right of the pivot of the row above.

The columns containing pivots are **pivot columns**; the others are **free columns**.

A typical REF pattern, with ■ a nonzero pivot and $*$ anything:

$$\begin{bmatrix} \blacksquare & * & * & * & * \\ 0 & 0 & \blacksquare & * & * \\ 0 & 0 & 0 & \blacksquare & * \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

Gaussian elimination (§8.7) reduces every matrix to an REF using row operations. The REF itself is not unique (it depends on the operations chosen), but the *number* of pivots and the *positions* of the pivot columns are.

Rank

The **rank** of $\mathbf{A}$, written $\operatorname{rank} \mathbf{A}$, is the number of pivots in any row echelon form of $\mathbf{A}$. Equivalently, it is

- the maximum number of linearly independent rows of $\mathbf{A}$ (the **row rank**);
- the maximum number of linearly independent columns of $\mathbf{A}$ (the **column rank**);
- the order of the largest square submatrix with nonzero determinant (the largest nonzero **minor**).

A set of vectors $\mathbf{a}_1, \dots, \mathbf{a}_k$ is **linearly independent** if $c_1\mathbf{a}_1 + \cdots + c_k\mathbf{a}_k = \mathbf{0}$ forces $c_1 = \cdots = c_k = 0$; otherwise one of them is a linear combination of the others. Chapter 9 develops this notion fully; here we need only the computational test supplied by elimination.

Why the characterisations agree (sketch). Row operations replace rows by combinations of rows and are reversible, so they preserve the set of all combinations of rows and hence the row rank; in an REF the nonzero rows are visibly independent, so row rank equals the number of pivots. Row operations also preserve every linear relation among the columns (if $\mathbf{Ac} = \mathbf{0}$ then $\mathbf{EAc} = \mathbf{0}$, and conversely since $\mathbf{E}$ is invertible), so the pivot columns of $\mathbf{A}$ are independent and every free column is a combination of them: column rank equals the number of pivots too. Finally, a nonzero $r \times r$ minor exists in the REF (the pivot rows and columns form a triangular block with nonzero diagonal), and no larger one can, since any larger set of rows is dependent. $\square$

The equality of row rank and column rank is one of the genuinely surprising facts of linear algebra: a 3×100 matrix cannot have more than three independent columns, because it has only three rows.

Properties

Properties of rank

For $\mathbf{A} \in \mathbb{C}^{m\times n}$:

1. $0 \le \operatorname{rank}\mathbf{A} \le \min(m,n)$; $\operatorname{rank}\mathbf{A} = 0$ only for $\mathbf{A} = \mathbf{0}$. If $\operatorname{rank}\mathbf{A} = \min(m,n)$, $\mathbf{A}$ has **full rank**.
2. $\operatorname{rank}\mathbf{A}^{\mathsf{T}} = \operatorname{rank}\mathbf{A}^{\mathsf{H}} = \operatorname{rank}\mathbf{A}$.
3. $\operatorname{rank}(\mathbf{AB}) \le \min(\operatorname{rank}\mathbf{A}, \operatorname{rank}\mathbf{B})$.
4. If $\mathbf{P}$ and $\mathbf{Q}$ are invertible, $\operatorname{rank}(\mathbf{PAQ}) = \operatorname{rank}\mathbf{A}$.
5. A nonzero outer product $\mathbf{uv}^{\mathsf{T}}$ has rank 1; conversely every rank-1 matrix is an outer product.
6. $\operatorname{rank}(\mathbf{A}+\mathbf{B}) \le \operatorname{rank}\mathbf{A} + \operatorname{rank}\mathbf{B}$.
7. **Rank–nullity:** the solutions of $\mathbf{Ax} = \mathbf{0}$ form a set described by exactly $n - \operatorname{rank}\mathbf{A}$ free parameters (the *nullity*; see Chapter 9).
8. A square $n \times n$ matrix is invertible if and only if its rank is n.

Property 3 follows from the column view: every column of $\mathbf{AB}$ is a combination of the columns of $\mathbf{A}$, and (transposing) every row of $\mathbf{AB}$ is a combination of the rows of $\mathbf{B}$. It explains why $\mathbf{G} = \mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}}$ can be no better than the incidence matrix $\mathbf{A}$ it is built from.

Worked Example 8.15 — Rank of a rectangular matrix

Find the rank of

$$\mathbf{M} = \begin{bmatrix} 1 & 2 & 1 & 3 \\ 2 & 4 & 0 & 2 \\ 3 & 6 & 1 & 5 \end{bmatrix}$$

and express the free columns in terms of the pivot columns.

Step 1. $R_2 \leftarrow R_2 - 2R_1$, $R_3 \leftarrow R_3 - 3R_1$:

$$\begin{bmatrix} 1 & 2 & 1 & 3 \\ 0 & 0 & -2 & -4 \\ 0 & 0 & -2 & -4 \end{bmatrix}.$$

Step 2. $R_3 \leftarrow R_3 - R_2$ gives a zero third row. The REF has pivots in columns 1 and 3, so $\operatorname{rank}\mathbf{M} = 2$.

Step 3. Row 3 of $\mathbf{M}$ is row 1 plus row 2 — the dependency the elimination discovered. Columns: $\mathbf{m}_2 = 2\mathbf{m}_1$ by inspection; for $\mathbf{m}_4 = \alpha\mathbf{m}_1 + \beta\mathbf{m}_3$, the second component gives $2\alpha = 2$, so $\alpha = 1$, and the first gives $1 + \beta = 3$, so $\beta = 2$. Check the third: $3 + 2(1) = 5$ ✓.

Reading. Although $\mathbf{M}$ has four columns in $\mathbb{R}^3$, they span only a plane. A system $\mathbf{Mx} = \mathbf{b}$ can be solved only for $\mathbf{b}$ in that plane (those with $b_3 = b_1 + b_2$), and then with $4 - 2 = 2$ free parameters.

Worked Example 8.16 — Rank depending on a parameter

For which k does $\mathbf{B} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 3 & k \end{bmatrix}$ have rank 3? What is the rank otherwise?

Step 1. $R_2 \leftarrow R_2 - R_1$, $R_3 \leftarrow R_3 - R_1$: rows $(0,1,2)$ and $(0,2,k-1)$.

Step 2. $R_3 \leftarrow R_3 - 2R_2$: row $(0,0,k-5)$.

Step 3. The pivots are $1, 1, k-5$, so $\det\mathbf{B} = k - 5$. For $k \neq 5$, $\operatorname{rank}\mathbf{B} = 3$; for $k = 5$ the third row vanishes and $\operatorname{rank}\mathbf{B} = 2$ (the 2×2 minor $\begin{vmatrix} 1 & 1 \\ 1 & 2 \end{vmatrix} = 1 \neq 0$ confirms it is not lower). At $k = 5$, row 3 $=$ 2 row 2 $-$ row 1. We use this matrix again in §8.6.

Rank in network topology

For a connected network with N nodes (including ground) and b branches, the full $N \times b$ incidence matrix has every column containing one $+1$ and one -1, so its rows sum to zero: the rows are dependent and the rank is at most $N - 1$. In fact it is exactly $N - 1$ for a connected graph — which is why we delete the ground row and keep the $(N-1)\times b$ **reduced** incidence matrix, of full row rank. The number of independent KCL equations is therefore $N - 1$, and the number of independent KVL (loop/mesh) equations is $b - (N - 1)$, the nullity of the reduced incidence matrix. For the running example $N = 4$, $b = 6$: three nodal equations, three independent loops.

Worked Example 8.17 — A floating network has a singular nodal matrix

Remove the three branches to ground (a, d, e) from the running example, leaving branches b (2 mS, 1–2), c (1 mS, 2–3), f (1 mS, 1–3), with no connection to ground. Write the nodal matrix and find its rank.

Step 1. Stamping the three branches:

$$\mathbf{L} = \begin{bmatrix} 3 & -2 & -1 \\ -2 & 3 & -1 \\ -1 & -1 & 2 \end{bmatrix}.$$

Step 2. Every row sums to zero: $\mathbf{L}(1,1,1)^{\mathsf{T}} = \mathbf{0}$. A nonzero solution of $\mathbf{L}\mathbf{x} = \mathbf{0}$ exists, so $\mathbf{L}$ is singular and $\operatorname{rank}\mathbf{L} \le 2$.

Step 3. Elimination: $R_2 \leftarrow R_2 + \tfrac{2}{3}R_1$ gives $(0, \tfrac{5}{3}, -\tfrac{5}{3})$; $R_3 \leftarrow R_3 + \tfrac{1}{3}R_1$ gives $(0, -\tfrac{5}{3}, \tfrac{5}{3})$; then $R_3 \leftarrow R_3 + R_2$ gives $\mathbf{0}$. Two pivots: $\operatorname{rank}\mathbf{L} = 2$.

Reading. Physically, adding the same voltage to every node of a floating network changes no branch voltage and therefore no current; the solution can only ever be determined up to that common offset. Choosing any node as the reference (deleting its row and column) restores full rank. Matrices with zero row sums and non-positive off-diagonals like $\mathbf{L}$ are **graph Laplacians**; their rank is $N - c$ where c is the number of connected pieces.

Numerical rank

In exact arithmetic rank is an integer and elimination finds it. In floating point, or with measured data, "zero" pivots come out as 10^{-14} or as noise, and the question becomes *how close is the matrix to one of lower rank?* The matrix $\begin{bmatrix} 1 & 1 \\ 1 & 1.0001 \end{bmatrix}$ has rank 2, but a perturbation of size 10^{-4} in one entry makes it rank 1; for most engineering purposes it behaves like a rank-1 matrix. The robust tool is the singular value decomposition (Chapter 10): the singular values of this matrix are about 2.00005 and 5.0×10^{-5}, and the **numerical rank** is the number of singular values above a tolerance tied to the data accuracy. The ratio of the largest to the smallest singular value is the 2-norm condition number of §8.10.

Common Pitfall

Rank is not the number of nonzero rows of the *original* matrix, nor the number of nonzero entries on its diagonal. $\begin{bmatrix} 1 & 2 \\ 2 & 4 \end{bmatrix}$ has no zero rows and a nonzero diagonal but rank 1. Always reduce to echelon form (or use singular values) before counting.

Engineering Note

Rank deficiency in a circuit simulator usually means a modelling error, and SPICE reports it as a "singular matrix" error. The usual culprits: a node with no DC path to ground (e.g. the junction of two series capacitors), a loop consisting only of ideal voltage sources and inductors (KVL makes one of the source equations redundant or contradictory), or a cut-set of only current sources and capacitors. Each is a rank defect of a structural submatrix and can be detected from the network topology before any number is computed.

8.6 Systems of linear equations

Formulation

Linear system

A system of m linear equations in n unknowns,

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n &= b_1, \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n &= b_m, \end{aligned}$$

is written $\mathbf{A}\mathbf{x} = \mathbf{b}$ with **coefficient matrix** $\mathbf{A} \in \mathbb{C}^{m\times n}$ and **right-hand side** $\mathbf{b} \in \mathbb{C}^m$. The **augmented matrix** is $[\mathbf{A} \mid \mathbf{b}]$. The system is **homogeneous** if $\mathbf{b} = \mathbf{0}$. It is **consistent** if it has at least one solution, **inconsistent** otherwise.

Systems are classified by shape: **square** ($m = n$, the usual case for well-posed circuit equations), **overdetermined** ($m > n$, typical of measurements; usually inconsistent and solved in the least-squares sense of Chapter 9) and **underdetermined** ($m < n$; consistent systems have infinitely many solutions, and a particular one is chosen by an extra criterion such as minimum norm).

Existence and uniqueness

Rouché–Capelli (Kronecker–Capelli) theorem

Let $\mathbf{A}$ be $m \times n$ and $r = \operatorname{rank}\mathbf{A}$.

1. $\mathbf{A}\mathbf{x} = \mathbf{b}$ is consistent if and only if $\operatorname{rank}[\mathbf{A} \mid \mathbf{b}] = \operatorname{rank}\mathbf{A}$.
2. If it is consistent and $r = n$, the solution is unique.
3. If it is consistent and $r < n$, there are infinitely many solutions, described by $n - r$ free parameters.

Proof sketch. Reduce $[\mathbf{A} \mid \mathbf{b}]$ to echelon form. If the augmented column contains a pivot, some row reads $0 = c$ with $c \neq 0$: inconsistent, and the augmented rank exceeds r. Otherwise the r nonzero rows can be solved by back substitution for the r pivot variables in terms of the $n - r$ free variables, which may be chosen arbitrarily. □

In terms of the column view: $\mathbf{A}\mathbf{x} = \mathbf{b}$ is solvable exactly when $\mathbf{b}$ is a combination of the columns of $\mathbf{A}$, and appending such a $\mathbf{b}$ cannot raise the rank.

Structure of the solution set

If $\mathbf{x}_p$ is any one solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$, every solution has the form

$$\mathbf{x} = \mathbf{x}_p + \mathbf{x}_h,$$

where $\mathbf{x}_h$ ranges over all solutions of the homogeneous system $\mathbf{A}\mathbf{x}_h = \mathbf{0}$.

Proof. If $\mathbf{A}\mathbf{x} = \mathbf{b}$ then $\mathbf{A}(\mathbf{x} - \mathbf{x}_p) = \mathbf{b} - \mathbf{b} = \mathbf{0}$; conversely $\mathbf{A}(\mathbf{x}_p + \mathbf{x}_h) = \mathbf{b} + \mathbf{0}$. □

This "particular plus homogeneous" structure reappears verbatim for linear differential equations (Chapters 11–12), where it is the split into forced and natural response. Its companion is **superposition**: if $\mathbf{A}\mathbf{x}_1 = \mathbf{b}_1$ and $\mathbf{A}\mathbf{x}_2 = \mathbf{b}_2$ then $\mathbf{A}(\alpha\mathbf{x}_1 + \beta\mathbf{x}_2) = \alpha\mathbf{b}_1 + \beta\mathbf{b}_2$. A circuit's response to several sources is the sum of its responses to each — which is just the linearity of $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$ in $\mathbf{b}$.

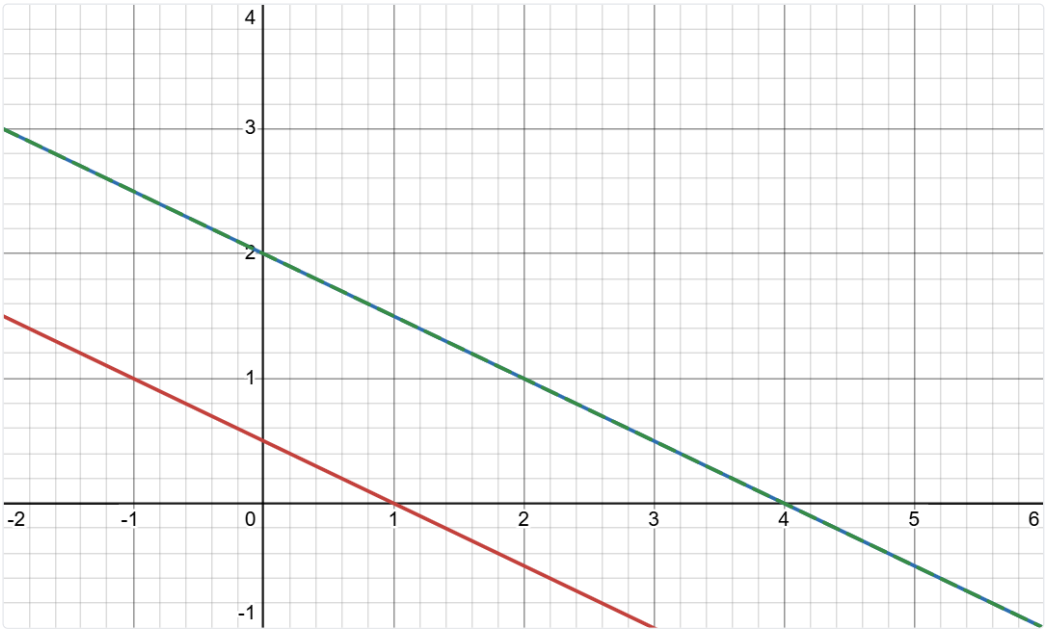
Homogeneous systems

A homogeneous system always has the **trivial solution** $\mathbf{x} = \mathbf{0}$. By Rouché–Capelli it has nontrivial solutions if and only if $\operatorname{rank}\mathbf{A} < n$. Two consequences:

- A homogeneous system with **more unknowns than equations** ($n > m$) always has nontrivial solutions, since $r \leq m < n$.
- A **square** homogeneous system has nontrivial solutions if and only if $\det\mathbf{A} = 0$. This is how eigenvalue problems $(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = \mathbf{0}$ lead to the characteristic equation $\det(\mathbf{A} - \lambda\mathbf{I}) = 0$ (Chapter 10), and how a circuit's natural frequencies arise from $\det\mathbf{Y}(s) = 0$: a nonzero response with no sources needs a singular system matrix.

Geometry

With two unknowns, each equation $a_{i1}x + a_{i2}y = b_i$ is a line in the plane. Two lines either cross at one point (unique solution, $\det\mathbf{A} \neq 0$, the case drawn in §8.3), are parallel and distinct (no solution), or coincide (infinitely many). With three unknowns each equation is a plane in space; three planes in general position meet in a single point, but they may also share a common line (rank 2, consistent), be arranged like the faces of a triangular prism with no common point (rank 2, inconsistent), contain two parallel planes, or all coincide (rank 1).



Singular 2×2 systems. The blue line $x + 2y = 4$ and red line $x + 2y = 1$ are parallel: the system has no solution ($\operatorname{rank}\mathbf{A} = 1$, $\operatorname{rank}[\mathbf{A} \mid \mathbf{b}] = 2$). The dashed green line $2x + 4y = 8$ lies exactly on the blue one: together they give infinitely many solutions (both ranks 1, one free parameter).

Worked Example 8.18 — The three cases for two unknowns

Classify (a) $x + 2y = 4,\ 3x - y = 5$; (b) $x + 2y = 4,\ x + 2y = 1$; (c) $x + 2y = 4,\ 2x + 4y = 8$.

(a) $\det\begin{bmatrix} 1 & 2 \\ 3 & -1 \end{bmatrix} = -7 \neq 0$: unique solution. Cramer: $x = \dfrac{-4 - 10}{-7} = 2$, $y = \dfrac{5 - 12}{-7} = 1$.

(b) $R_2 \leftarrow R_2 - R_1$ gives $[\,0 \;\; 0 \mid -3\,]$, i.e. $0 = -3$. $\operatorname{rank}\mathbf{A} = 1 < \operatorname{rank}[\mathbf{A} \mid \mathbf{b}] = 2$: inconsistent.

(c) $R_2 \leftarrow R_2 - 2R_1$ gives $[\,0 \;\; 0 \mid 0\,]$. Both ranks are 1, $n - r = 1$ free parameter. Let $y = t$; then $x = 4 - 2t$, so $(x, y) = (4, 0) + t(-2, 1)$ — a particular solution plus any multiple of the homogeneous solution $(-2, 1)$, which satisfies $x + 2y = 0$.

Worked Example 8.19 — A system with parameters

Discuss, in terms of k and m, the solutions of

$$\begin{aligned} x + y + z &= 3, \\ x + 2y + 3z &= 6, \\ x + 3y + kz &= m. \end{aligned}$$

Step 1. The coefficient matrix is $\mathbf{B}$ of Worked Example 8.16. Apply the same row operations to the augmented matrix:

$$\left[\begin{array}{ccc|c} 1 & 1 & 1 & 3 \\ 1 & 2 & 3 & 6 \\ 1 & 3 & k & m \end{array}\right] \to \left[\begin{array}{ccc|c} 1 & 1 & 1 & 3 \\ 0 & 1 & 2 & 3 \\ 0 & 2 & k-1 & m-3 \end{array}\right] \to \left[\begin{array}{ccc|c} 1 & 1 & 1 & 3 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & k-5 & m-9 \end{array}\right].$$

Step 2 (classify).

- $k \neq 5$: three pivots, rank $3 = n$: unique solution $z = \dfrac{m-9}{k-5}$, $y = 3 - 2z$, $x = 3 - y - z = z$.
- $k = 5$, $m \neq 9$: last row reads $0 = m - 9 \neq 0$; rank $\mathbf{A} = 2 <$ rank$[\mathbf{A} \mid \mathbf{b}] = 3$: no solution.
- $k = 5$, $m = 9$: both ranks 2, one free parameter. With $z = t$: $y = 3 - 2t$, $x = 3 - (3 - 2t) - t = t$, so $(x, y, z) = (0, 3, 0) + t(1, -2, 1)$.

Step 3 (check). For $k = 6$, $m = 10$: $z = 1$, $y = 1$, $x = 1$; indeed $1 + 1 + 1 = 3$, $1 + 2 + 3 = 6$, $1 + 3 + 6 = 10$ ✓. For the infinite family, $(t, 3 - 2t, t)$ in the third equation with $k = 5$: $t + 9 - 6t + 5t = 9$ ✓.

Geometry. For $k = 5$ the three planes share a common line when $m = 9$ and form a "prism" (pairwise intersecting lines, no common point) when $m \neq 9$.

Worked Example 8.20 — Solving the floating network: offsets and superposition

For the floating network $\mathbf{L}$ of Worked Example 8.17, inject 1 mA into node 1 and extract it from node 3: $\mathbf{L}\mathbf{v} = (1, 0, -1)^{\mathsf{T}}$. Find all solutions.

Step 1 (consistency). Since every column of $\mathbf{L}$ sums to zero, so does every vector $\mathbf{L}\mathbf{v}$: the system is solvable only if the injected currents sum to zero. Here $1 + 0 - 1 = 0$ — physically, current into a floating network must also leave it. Reduction of $[\mathbf{L} \mid \mathbf{b}]$ confirms both ranks are 2.

Step 2 (particular solution). Fix the free variable by grounding node 3, $v_3 = 0$; the first two equations become $3v_1 - 2v_2 = 1$, $-2v_1 + 3v_2 = 0$, with solution $v_1 = \frac{3}{5}$, $v_2 = \frac{2}{5}$ V. Check row 3: $-\frac{3}{5} - \frac{2}{5} + 0 = -1$ ✓.

Step 3 (general solution). The homogeneous solutions are $t(1, 1, 1)^{\mathsf{T}}$, so

$$\mathbf{v} = \begin{bmatrix} 0.6 \\ 0.4 \\ 0 \end{bmatrix} + t \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}, \qquad t \in \mathbb{R}.$$

Every physically meaningful quantity — the branch voltages $v_1 - v_2 = 0.2$, $v_2 - v_3 = 0.4$, $v_1 - v_3 = 0.6$ V — is independent of t. The resistance between nodes 1 and 3 is $0.6\ \text{V} / 1\ \text{mA} = 0.6\ \text{k}\Omega$, which matches the series–parallel calculation: $(\frac{1}{2} + 1)\ \text{k}\Omega$ in parallel with $1\ \text{k}\Omega$ is $\frac{1.5}{2.5} = 0.6\ \text{k}\Omega$ ✓.

Step 4 (superposition). Adding a second injection pattern $(0, 1, -1)^{\mathsf{T}}$ (with solution $(0.4, 0.6, 0)^{\mathsf{T}} + t(1, 1, 1)^{\mathsf{T}}$ by the same method — check: $3(0.4) - 2(0.6) = 0$, $-2(0.4) + 3(0.6) = 1$ ✓) gives the response to $(1, 1, -2)^{\mathsf{T}}$ as the sum $(1, 1, 0)^{\mathsf{T}} + t(1, 1, 1)^{\mathsf{T}}$.

Common Pitfall

Counting equations and unknowns does not settle solvability. Three equations in three unknowns may have no solution or infinitely many (Worked Example 8.19 with $k = 5$); five equations in three unknowns may have exactly one (if two are redundant). Only the ranks of $\mathbf{A}$ and $[\mathbf{A} \mid \mathbf{b}]$ decide.

Engineering Note

Well-posed circuit formulations (nodal, mesh, modified nodal) are constructed to give square nonsingular systems when the circuit itself is well-posed. Overdetermined systems arise on purpose in **state estimation**: a power-system control centre measures more line flows and voltages than there are unknown bus voltages, precisely so that bad measurements can be detected from the inconsistency, and solves the system in the weighted least-squares sense. Underdetermined systems arise in **compressed sensing** and in redundant actuator allocation, where the extra freedom is spent on minimising energy or sparsity.

8.7 Gaussian elimination

Motivation

Gaussian elimination is the workhorse algorithm of computational linear algebra. Every dense linear solver — MATLAB's backslash, LAPACK's `dgesv`, the DC operating-point and transient solvers inside SPICE — is a carefully engineered version of it. The idea is the one taught in school for two equations: use one equation to eliminate a variable from the others, repeat until one equation in one unknown remains, then substitute back. Doing this systematically turns $\mathbf{A}\mathbf{x} = \mathbf{b}$ into an equivalent **upper triangular** system $\mathbf{U}\mathbf{x} = \mathbf{c}$, which is trivial to solve.

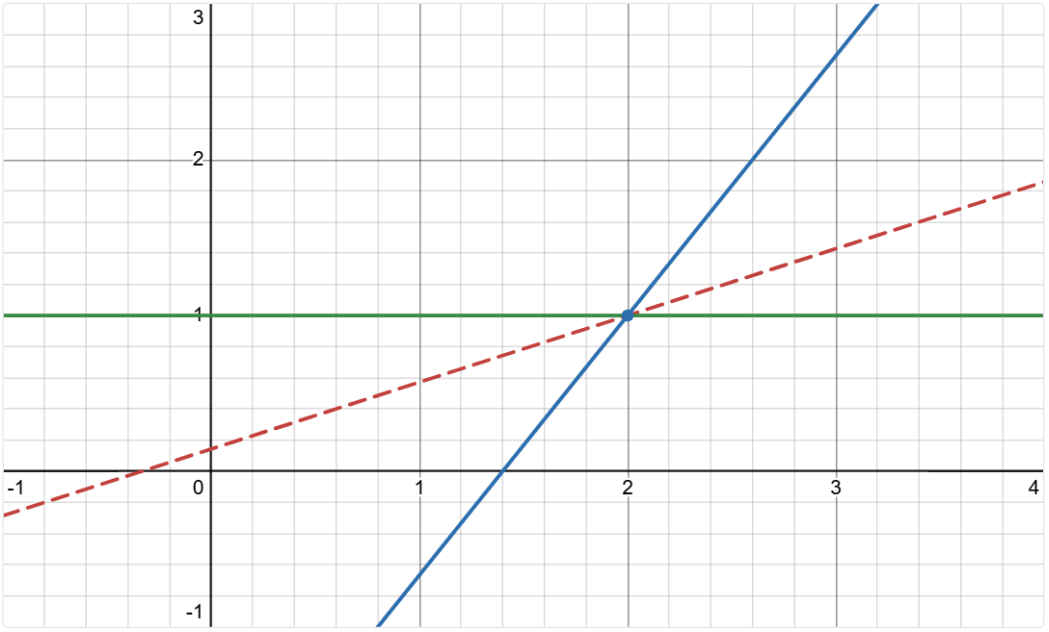
Elementary row operations and equivalence

Elementary row operations

1. **Replacement:** add a multiple of one row to another, $R_i \leftarrow R_i + cR_k$.
2. **Interchange:** swap two rows, $R_i \leftrightarrow R_k$.
3. **Scaling:** multiply a row by a nonzero constant, $R_i \leftarrow cR_i$.

Applied to the augmented matrix $[\mathbf{A} \mid \mathbf{b}]$, they produce an **equivalent** system: one with exactly the same solution set.

Equivalence holds because each operation is a left-multiplication by an invertible elementary matrix $\mathbf{E}$ (§8.4): $\mathbf{Ax} = \mathbf{b} \iff \mathbf{EAx} = \mathbf{Eb}$. In the plane, a replacement swaps one line for a different line through the *same* intersection point — the solution never moves.



Elimination in pictures for the mesh system of §8.3. The replacement $R_2 \leftarrow R_2 + \frac{3}{5}R_1$ turns the red dashed line $-3x + 7y = 1$ into the green line $\frac{26}{5}y = \frac{26}{5}$, i.e. $y = 1$, which passes through the same point $(2, 1)$ but no longer involves x. Back substitution then reads off x from the blue line.

The algorithm

Forward elimination. For $k = 1, 2, \dots, n-1$ (the current pivot column):

1. The **pivot** is $a_{kk}^{(k)}$, the current (k, k) entry. (If it is zero, or small, interchange rows first — see pivoting below.)
2. For each row $i = k+1, \dots, n$ compute the **multiplier** $m_{ik} = a_{ik}^{(k)} / a_{kk}^{(k)}$.
3. Replace $R_i \leftarrow R_i - m_{ik} R_k$, which makes $a_{ik}^{(k+1)} = 0$:

$$a_{ij}^{(k+1)} = a_{ij}^{(k)} - m_{ik} a_{kj}^{(k)}, \quad j = k+1, \dots, n, \qquad b_i^{(k+1)} = b_i^{(k)} - m_{ik} b_k^{(k)}.$$

After $n-1$ stages the matrix is upper triangular, $\mathbf{U} = [u_{ij}]$ with $u_{ij} = a_{ij}^{(i)}$, and the right-hand side has become $\mathbf{c}$.

Back substitution. Solve $\mathbf{Ux} = \mathbf{c}$ from the bottom up:

$$x_n = \frac{c_n}{u_{nn}}, \qquad x_i = \frac{1}{u_{ii}}\Big(c_i - \sum_{j=i+1}^{n} u_{ij} x_j\Big), \quad i = n-1, \dots, 1.$$

The process succeeds — in exact arithmetic, with row interchanges allowed — exactly when $\mathbf{A}$ is nonsingular, and the pivots $u_{11}, \dots, u_{nn}$ multiply to $\pm \det \mathbf{A}$.

Operation count

At stage k there are $n-k$ rows to update, each with $n-k$ matrix entries (plus one right-hand-side entry), each costing one multiply and one subtract. Ignoring lower-order terms,

$$\text{forward elimination} \approx \sum_{k=1}^{n-1} 2(n-k)^2 = 2\sum_{p=1}^{n-1} p^2 \approx \frac{2n^3}{3} \text{ flops},$$

while back substitution costs $\sum_i 2(n-i) \approx n^2$ flops, as does applying the elimination to one extra right-hand side. Doubling n multiplies the elimination time by eight. For $n = 1000$, $\frac{2}{3}n^3 \approx 6.7 \times 10^8$ flops: well under a second. For $n = 10^5$ dense it is 6.7×10^{14} — minutes to hours, and 80 GB just to store the matrix in double precision. Large problems are only tractable because they are sparse (§8.11).

Worked Example 8.21 — The running example by Gaussian elimination

Solve $\mathbf{G}\mathbf{v} = \mathbf{i}_s$ with the augmented matrix

$$\left[\begin{array}{ccc|c} 4 & -2 & -1 & 8 \\ -2 & 4 & -1 & 2 \\ -1 & -1 & 4 & 1 \end{array}\right].$$

Stage 1 (pivot 4). Multipliers $m_{21} = -2/4 = -\tfrac{1}{2}$, $m_{31} = -\tfrac{1}{4}$.

$$\begin{aligned} R_2 \leftarrow R_2 + \tfrac{1}{2}R_1: &\quad (0,\ 4-1,\ -1-\tfrac{1}{2} \mid 2+4) = (0,\ 3,\ -\tfrac{3}{2} \mid 6), \\ R_3 \leftarrow R_3 + \tfrac{1}{4}R_1: &\quad (0,\ -1-\tfrac{1}{2},\ 4-\tfrac{1}{4} \mid 1+2) = (0,\ -\tfrac{3}{2},\ \tfrac{15}{4} \mid 3). \end{aligned}$$

Stage 2 (pivot 3). Multiplier $m_{32} = (-\tfrac{3}{2})/3 = -\tfrac{1}{2}$.

$$R_3 \leftarrow R_3 + \tfrac{1}{2}R_2: \quad (0,\ 0,\ \tfrac{15}{4} - \tfrac{3}{4} \mid 3+3) = (0,\ 0,\ 3 \mid 6).$$

Triangular system.

$$\left[\begin{array}{ccc|c} 4 & -2 & -1 & 8 \\ 0 & 3 & -\frac{3}{2} & 6 \\ 0 & 0 & 3 & 6 \end{array}\right].$$

Back substitution. $v_3 = 6/3 = 2$; $v_2 = (6 + \tfrac{3}{2}\cdot 2)/3 = 9/3 = 3$; $v_1 = (8 + 2\cdot 3 + 1\cdot 2)/4 = 16/4 = 4$. So $\mathbf{v} = (4, 3, 2)^{\mathsf{T}}$ V. ✓

By-products. $\det \mathbf{G} = 4 \cdot 3 \cdot 3 = 36$. The multipliers $-\tfrac{1}{2}, -\tfrac{1}{4}, -\tfrac{1}{2}$ will reappear as the entries of $\mathbf{L}$ in §8.9.

Circuit reading. Stage 1 is Kron reduction of node 1: the 2×2 block $\begin{bmatrix} 3 & -\frac{3}{2} \\ -\frac{3}{2} & \frac{15}{4} \end{bmatrix}$ is the nodal matrix, seen from nodes 2 and 3, of the network with node 1 eliminated, and $(6, 3)$ are the correspondingly redistributed source currents. Gaussian elimination *is* repeated node elimination.

Pivoting

If a pivot is zero the algorithm cannot proceed as written, even though the matrix may be perfectly nonsingular; if a pivot is merely small, the multipliers are large and rounding errors are amplified.

Partial pivoting

At stage k, choose the row $p \geq k$ for which $|a_{pk}^{(k)}|$ is largest, and interchange rows p and k before eliminating. Then every multiplier satisfies $|m_{ik}| \leq 1$.

Complete pivoting searches the whole remaining submatrix and swaps columns as well as rows; it is more stable in theory but rarely needed. The quantity that controls stability is the **growth factor** $\rho = \max_{i,j,k} |a_{ij}^{(k)}| / \max_{i,j} |a_{ij}|$: backward error analysis (Wilkinson) shows that the computed solution is the exact solution of a nearby system $(\mathbf{A} + \delta\mathbf{A})\hat{\mathbf{x}} = \mathbf{b}$ with $\|\delta\mathbf{A}\| \lesssim c\, n\, \rho\, u \|\mathbf{A}\|$, where $u \approx 1.1 \times 10^{-16}$ is the double-precision unit roundoff. With partial pivoting $\rho \leq 2^{n-1}$ in the worst case, but in practice ρ is almost always small, which is why partial pivoting is the universal default.

When pivoting is unnecessary

If $\mathbf{A}$ is **strictly diagonally dominant by columns** ($|a_{jj}| > \sum_{i \neq j} |a_{ij}|$ for every j), or **symmetric positive definite**, then Gaussian elimination without interchanges never meets a zero pivot, the growth factor is bounded ($\rho \leq 2$ and $\rho \leq 1$ respectively), and the matrix is nonsingular. Diagonal dominance by rows also guarantees nonsingularity and nonzero pivots.

Sketch for diagonal dominance. After one elimination stage, the reduced $(n-1) \times (n-1)$ block is again diagonally dominant (a short calculation with the triangle inequality), so induction shows every pivot is nonzero. □

Nodal matrices of resistive networks with at least one branch to ground at every node are strictly diagonally dominant (diagonal = sum of all conductances at the node, off-diagonal magnitudes = the conductances to other nodes) and symmetric positive definite, so they can be eliminated in any order without pivoting for stability. Simulators exploit this freedom to choose an elimination order that preserves sparsity (§8.11).

Worked Example 8.22 — A zero pivot from a voltage source

Replace the 8 mA source at node 1 of the running example by an ideal 4 V voltage source from ground to node 1, and let j be the current (mA) flowing from node 1 into the source. With unknowns ordered (j, v_1, v_2, v_3) and the source equation written first, modified nodal analysis gives

$$\left[\begin{array}{cccc|c} 0 & 1 & 0 & 0 & 4 \\ 1 & 4 & -2 & -1 & 0 \\ 0 & -2 & 4 & -1 & 2 \\ 0 & -1 & -1 & 4 & 1 \end{array}\right].$$

Step 1. The $(1,1)$ pivot is 0. Interchange $R_1 \leftrightarrow R_2$:

$$\left[\begin{array}{cccc|c} 1 & 4 & -2 & -1 & 0 \\ 0 & 1 & 0 & 0 & 4 \\ 0 & -2 & 4 & -1 & 2 \\ 0 & -1 & -1 & 4 & 1 \end{array}\right].$$

Column 1 is already clear below the pivot.

Step 2 (pivot 1 in column 2; strict partial pivoting would pick the -2 in row 3, which gives the same exact answer). $R_3 \leftarrow R_3 + 2R_2$, $R_4 \leftarrow R_4 + R_2$: rows 3, 4 become $(0, 0, 4, -1 \mid 10)$ and $(0, 0, -1, 4 \mid 5)$.

Step 3. $R_4 \leftarrow R_4 + \tfrac{1}{4}R_3$: $(0, 0, 0, \tfrac{15}{4} \mid 7.5)$.

Step 4 (back substitution). $v_3 = 7.5/3.75 = 2$; row 3 reads $4v_2 - v_3 = 10$, so $v_2 = 3$; row 2 gives $v_1 = 4$; and $j + 4(4) - 2(3) - 1(2) = 0 \Rightarrow j = -8$ mA.

Reading. The node voltages are unchanged, as they must be: the voltage source holds node 1 at exactly the voltage the current source produced. The source current $j = -8$ mA means 8 mA flows *out* of the source into node 1 — the same 8 mA the current source injected. The determinant is $(-1)^1 \cdot 1 \cdot 1 \cdot 4 \cdot \tfrac{15}{4} = -15$, agreeing with Worked Example 8.8. MNA matrices are symmetric but **indefinite** (zero diagonal blocks), so they need pivoting where pure nodal matrices do not.

Worked Example 8.23 — Why small pivots are dangerous

Solve

$$\begin{aligned} 0.0001\,x_1 + x_2 &= 1, \\ x_1 + x_2 &= 2 \end{aligned}$$

in **three-significant-figure** arithmetic (each result rounded to 3 significant figures), first without and then with pivoting. The exact solution is $x_1 = 1/0.9999 = 1.00010\ldots$, $x_2 = 0.9998/0.9999 = 0.99990\ldots$.

Without pivoting. $m_{21} = 1/0.0001 = 10000$. Then $a_{22} = 1 - 10000 = -9999 \to -1.00 \times 10^4$ and $b_2 = 2 - 10000 = -9998 \to -1.00 \times 10^4$. So $x_2 = 1.00$, and $x_1 = (1 - x_2)/0.0001 = 0/0.0001 = 0$. The answer $x_1 = 0$ is completely wrong: the information in the second equation ("$x_1 + x_2 = 2$") was swamped by the huge multiple of the first.

With partial pivoting. $|1| > |0.0001|$, so swap the equations. Now $m_{21} = 0.0001$, $a_{22} = 1 - 0.0001 = 0.9999 \to 1.00$, $b_2 = 1 - 0.0002 = 0.9998 \to 1.00$. So $x_2 = 1.00$ and $x_1 = 2 - 1.00 = 1.00$. Both components are correct to the working precision.

Moral. The matrix is well conditioned (condition number about 4, §8.10); the failure without pivoting is entirely the algorithm's fault. In double precision the same thing happens with a pivot of 10^{-20}.

Worked Example 8.24 — Elimination with complex (phasor) entries

A two-node AC network has a 1 S conductance from each node to ground and a capacitive susceptance $j1$ S between the nodes. A phasor current $1\angle 0^\circ$ A is injected at node 1. Find V_1 and V_2.

Step 1. $\mathbf{Y} = \begin{bmatrix} 1+j & -j \\ -j & 1+j \end{bmatrix}$, $\mathbf{I} = (1, 0)^{\mathsf{T}}$.

Step 2. $m_{21} = \dfrac{-j}{1+j} = \dfrac{-j(1-j)}{2} = \dfrac{-1-j}{2}$. Then

$$u_{22} = (1+j) - m_{21}(-j) = (1+j) + \frac{(-1-j)j}{2} = (1+j) + \frac{1-j}{2} = \frac{3+j}{2}, \qquad c_2 = 0 - m_{21} \cdot 1 = \frac{1+j}{2}.$$

Step 3.

$$V_2 = \frac{(1+j)/2}{(3+j)/2} = \frac{(1+j)(3-j)}{10} = \frac{4+2j}{10} = 0.4 + j0.2 \text{ V},$$

$$V_1 = \frac{1 + jV_2}{1+j} = \frac{1 + j0.4 - 0.2}{1+j} = \frac{(0.8 + j0.4)(1-j)}{2} = 0.6 - j0.2 \text{ V}.$$

Step 4 (check). $(1+j)(0.6 - j0.2) - j(0.4 + j0.2) = (0.8 + j0.4) + (0.2 - j0.4) = 1$ ✓; $-j(0.6 - j0.2) + (1+j)(0.4 + j0.2) = (-0.2 - j0.6) + (0.2 + j0.6) = 0$ ✓.

Reading. Complex arithmetic changes nothing in the algorithm; each complex flop costs about four real ones. $|V_2| \approx 0.447$ V with phase $+26.6^\circ$: the capacitor couples a leading current into node 2.

Common Pitfall

When doing elimination by hand, apply every row operation to the right-hand side as well (or carry the augmented matrix), and do **not** scale rows by convenience factors in the middle of a determinant calculation without tracking the factor. Scaling is harmless for solving but changes the determinant.

Engineering Note

Elimination order has a physical meaning in circuits: eliminating a node is Kron reduction, and the "fill-in" it creates is the set of new branches the star–mesh transformation adds between the node's neighbours. A node with many neighbours (a ground plane, a power rail) creates a dense clique when eliminated, which is why simulators eliminate such nodes last.

8.8 Gauss–Jordan elimination

Motivation

Gaussian elimination stops at a triangular matrix and finishes with back substitution. **Gauss–Jordan elimination** keeps going: it scales every pivot to 1 and clears the entries *above* each pivot as well as below, until the coefficient part is as simple as possible. For a nonsingular square system that simplest form is the identity, and the solution can be read off directly. The method costs more than Gaussian elimination for a single solve, but it has three uses that make it indispensable: it computes inverses (by reducing $[\mathbf{A} \mid \mathbf{I}]$), it produces the unique **reduced row echelon form** that settles questions of rank and dependence unambiguously, and it writes the complete solution of an underdetermined system in terms of free parameters.

Reduced row echelon form

Reduced row echelon form (RREF)

A matrix is in **reduced row echelon form** if it is in row echelon form and, in addition,

1. every pivot equals 1, and
2. every pivot is the only nonzero entry in its column.

For example,

$$\begin{bmatrix} 1 & 2 & 0 & 1 & 0 \\ 0 & 0 & 1 & 2 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

is in RREF, with pivot columns 1, 3, 5.

Uniqueness of the RREF

Every matrix is row-equivalent to exactly one matrix in reduced row echelon form, written $\operatorname{rref}(\mathbf{A})$.

Proof sketch. Row operations preserve all linear relations among columns (§8.5). In an RREF those relations are visible: each pivot column is a standard basis vector $\mathbf{e}_1, \mathbf{e}_2, \dots$ (in order) and each free column lists the coefficients expressing it in terms of the earlier pivot columns. Since the relations are determined by $\mathbf{A}$, so is the RREF. $\square$

Uniqueness is what makes the RREF a reliable bookkeeping device: two people reducing the same matrix in different orders reach the same answer (whereas their REFs may differ).

The algorithm

For each column from left to right:

1. Find a row at or below the current row with a nonzero entry in this column (with partial pivoting, the one of largest magnitude); swap it into the current row. If there is none, the column is free: move to the next column, staying on the same row.
2. **Normalise:** divide the current row by its pivot so the pivot becomes 1.
3. **Eliminate:** subtract multiples of the current row from *every other row*, above and below, to make the rest of the column zero.
4. Move to the next row and column.

Applied to $[\mathbf{A} \mid \mathbf{b}]$ with $\mathbf{A}$ nonsingular, the result is $[\mathbf{I} \mid \mathbf{x}]$.

Cost. Clearing above as well as below the pivots roughly doubles the work in the elimination phase: about n^3 flops for one right-hand side, versus $\tfrac{2}{3}n^3 + n^2$ for Gaussian elimination with back substitution. For solving a single system Gauss–Jordan is therefore 50% more expensive and is not used in production solvers; its value is conceptual and for the special tasks below.

Worked Example 8.25 — The running example by Gauss–Jordan

Reduce $\left[\begin{array}{ccc|c} 4 & -2 & -1 & 8 \\ -2 & 4 & -1 & 2 \\ -1 & -1 & 4 & 1 \end{array}\right]$ to RREF.

Column 1. $R_1 \leftarrow \tfrac14 R_1$: $(1, -\tfrac12, -\tfrac14 \mid 2)$. Then $R_2 \leftarrow R_2 + 2R_1$: $(0, 3, -\tfrac32 \mid 6)$; $R_3 \leftarrow R_3 + R_1$: $(0, -\tfrac32, \tfrac{15}{4} \mid 3)$.

Column 2. $R_2 \leftarrow \tfrac13 R_2$: $(0, 1, -\tfrac12 \mid 2)$. Then $R_1 \leftarrow R_1 + \tfrac12 R_2$: $(1, 0, -\tfrac12 \mid 3)$; $R_3 \leftarrow R_3 + \tfrac32 R_2$: $(0, 0, 3 \mid 6)$.

Column 3. $R_3 \leftarrow \tfrac13 R_3$: $(0, 0, 1 \mid 2)$. Then $R_1 \leftarrow R_1 + \tfrac12 R_3$: $(1, 0, 0 \mid 4)$; $R_2 \leftarrow R_2 + \tfrac12 R_3$: $(0, 1, 0 \mid 3)$.

Result. $\left[\begin{array}{ccc|c} 1 & 0 & 0 & 4 \\ 0 & 1 & 0 & 3 \\ 0 & 0 & 1 & 2 \end{array}\right]$, so $\mathbf{v} = (4, 3, 2)^{\mathsf T}$ V with no back substitution. ✓

Computing the inverse

Since $\mathbf{A}\mathbf{X} = \mathbf{I}$ is n systems $\mathbf{A}\mathbf{x}_j = \mathbf{e}_j$ sharing one matrix, reduce them all at once:

$$[\,\mathbf{A} \mid \mathbf{I}\,] \xrightarrow{\text{Gauss–Jordan}} [\,\mathbf{I} \mid \mathbf{A}^{-1}\,].$$

If the left block cannot be reduced to $\mathbf{I}$ (a zero row appears), $\mathbf{A}$ is singular. In terms of elementary matrices: the operations that turn $\mathbf{A}$ into $\mathbf{I}$, accumulated, are $\mathbf{E}_k \cdots \mathbf{E}_1 = \mathbf{A}^{-1}$, and the right block records exactly that product applied to $\mathbf{I}$. The cost is about $2n^3$ flops (fewer if one exploits the zeros of $\mathbf{I}$).

Worked Example 8.26 — Inverting $\mathbf{G}$ by Gauss–Jordan

Reduce $[\mathbf{G} \mid \mathbf{I}]$.

Start.

$$\left[\begin{array}{ccc|ccc} 4 & -2 & -1 & 1 & 0 & 0 \\ -2 & 4 & -1 & 0 & 1 & 0 \\ -1 & -1 & 4 & 0 & 0 & 1 \end{array}\right]$$

Column 1. $R_1 \leftarrow \tfrac14 R_1$, $R_2 \leftarrow R_2 + 2R_1$, $R_3 \leftarrow R_3 + R_1$:

$$\left[\begin{array}{ccc|ccc} 1 & -\tfrac12 & -\tfrac14 & \tfrac14 & 0 & 0 \\ 0 & 3 & -\tfrac32 & \tfrac12 & 1 & 0 \\ 0 & -\tfrac32 & \tfrac{15}{4} & \tfrac14 & 0 & 1 \end{array}\right]$$

Column 2. $R_2 \leftarrow \tfrac13 R_2$, $R_1 \leftarrow R_1 + \tfrac12 R_2$, $R_3 \leftarrow R_3 + \tfrac32 R_2$:

$$\left[\begin{array}{ccc|ccc} 1 & 0 & -\tfrac12 & \tfrac13 & \tfrac16 & 0 \\ 0 & 1 & -\tfrac12 & \tfrac16 & \tfrac13 & 0 \\ 0 & 0 & 3 & \tfrac12 & \tfrac12 & 1 \end{array}\right]$$

Column 3. $R_3 \leftarrow \tfrac13 R_3$, $R_1 \leftarrow R_1 + \tfrac12 R_3$, $R_2 \leftarrow R_2 + \tfrac12 R_3$:

$$\left[\begin{array}{ccc|ccc} 1 & 0 & 0 & \tfrac{5}{12} & \tfrac14 & \tfrac16 \\ 0 & 1 & 0 & \tfrac14 & \tfrac{5}{12} & \tfrac16 \\ 0 & 0 & 1 & \tfrac16 & \tfrac16 & \tfrac13 \end{array}\right]$$

The right block is $\mathbf{Z} = \mathbf{G}^{-1}$, agreeing with the adjugate calculation of Worked Example 8.12. ✓ Each column of $\mathbf{Z}$ is the vector of node voltages produced by a 1 mA source at one node.

Several right-hand sides

Gauss–Jordan (and Gaussian elimination) can process any number of right-hand sides in one pass: reduce $[\mathbf{A} \mid \mathbf{b}_1\ \mathbf{b}_2\ \cdots\ \mathbf{b}_k]$. Each extra column costs only $O(n^2)$. In circuit terms this computes the response to several source patterns at once. In production codes the same economy is obtained more flexibly by storing an $\mathbf{LU}$ factorisation (§8.9), since the right-hand sides are often not all known in advance.

General solutions of consistent singular systems

When $\operatorname{rank}\mathbf{A} = r < n$, the RREF of $[\mathbf{A} \mid \mathbf{b}]$ splits the unknowns into r **basic** (pivot) variables and $n - r$ **free** variables. Each nonzero row of the RREF contains exactly one basic variable, so it expresses that variable directly in terms of the free ones. Setting the free variables to parameters $s, t, \ldots$ gives the solution in the form

$$\mathbf{x} = \mathbf{x}_p + s\,\mathbf{n}_1 + t\,\mathbf{n}_2 + \cdots,$$

where $\mathbf{x}_p$ (all free variables zero) is a particular solution and $\mathbf{n}_1, \mathbf{n}_2, \ldots$ are homogeneous solutions forming a basis of the **null space** of $\mathbf{A}$ (Chapter 9). This is the constructive content of the Rouché–Capelli theorem.

Worked Example 8.27 — An underdetermined system

Solve $\mathbf{M}\mathbf{x} = \mathbf{b}$ with $\mathbf{M}$ from Worked Example 8.15 and $\mathbf{b} = (2, 2, 4)^{\mathsf{T}}$.

Step 1 (consistency). $\mathbf{b}$ satisfies $b_3 = b_1 + b_2$, the compatibility condition found in Worked Example 8.15, so a solution exists.

Step 2 (reduce).

$$\left[\begin{array}{cccc|c} 1 & 2 & 1 & 3 & 2 \\ 2 & 4 & 0 & 2 & 2 \\ 3 & 6 & 1 & 5 & 4 \end{array}\right] \to \left[\begin{array}{cccc|c} 1 & 2 & 1 & 3 & 2 \\ 0 & 0 & -2 & -4 & -2 \\ 0 & 0 & 0 & 0 & 0 \end{array}\right] \to \left[\begin{array}{cccc|c} 1 & 2 & 0 & 1 & 1 \\ 0 & 0 & 1 & 2 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{array}\right].$$

(The last step is $R_2 \leftarrow -\tfrac{1}{2}R_2$, then $R_1 \leftarrow R_1 - R_2$.)

Step 3 (read off). Basic variables x_1, x_3; free variables $x_2 = s$, $x_4 = t$:

$$x_1 = 1 - 2s - t, \qquad x_3 = 1 - 2t,$$

$$\mathbf{x} = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} + s \begin{bmatrix} -2 \\ 1 \\ 0 \\ 0 \end{bmatrix} + t \begin{bmatrix} -1 \\ 0 \\ -2 \\ 1 \end{bmatrix}.$$

Step 4 (check). $\mathbf{M}(1,0,1,0)^{\mathsf{T}} = (2,2,4)^{\mathsf{T}}$ ✓; $\mathbf{M}(-2,1,0,0)^{\mathsf{T}} = (0,0,0)^{\mathsf{T}}$ ✓; $\mathbf{M}(-1,0,-2,1)^{\mathsf{T}} = (-1-2+3,\ -2+0+2,\ -3-2+5)^{\mathsf{T}} = \mathbf{0}$ ✓. The two free parameters match $n - r = 4 - 2$.

Reading. The RREF also displays the column relations of Worked Example 8.15: the free column 2 reads $(2, 0)$, i.e. $\mathbf{m}_2 = 2\mathbf{m}_1$; the free column 4 reads $(1, 2)$, i.e. $\mathbf{m}_4 = \mathbf{m}_1 + 2\mathbf{m}_3$.

Common Pitfall

Inverting by Gauss–Jordan in floating point still needs pivoting. And having $\mathbf{A}^{-1}$ in hand is rarely useful by itself: if you need $\mathbf{A}^{-1}\mathbf{B}$, solve $\mathbf{A}\mathbf{X} = \mathbf{B}$; if you need one entry of the inverse (say a transfer impedance), solve for one column. Compute the full inverse only when its entries are themselves the deliverable — a nodal impedance matrix for a short-circuit study, or a covariance matrix.

Engineering Note

In power-system fault analysis the **bus impedance matrix** $\mathbf{Z}_{\text{bus}} = \mathbf{Y}_{\text{bus}}^{-1}$ is genuinely wanted: its diagonal entries are the Thévenin impedances at each bus, which set the short-circuit currents. For large networks it is built not by Gauss–Jordan but by adding one branch at a time with rank-one updates — Sherman–Morrison again — or only the needed columns are computed from an $\mathbf{LU}$ factorisation.

8.9 LU decomposition

Motivation

In practice the same coefficient matrix meets many right-hand sides. A transient simulation with fixed time step solves $(\mathbf{G} + \mathbf{C}/h)\mathbf{v}_{k+1} = \mathbf{i}_{k+1} + (\mathbf{C}/h)\mathbf{v}_k$ at every step with the *same* matrix; a sweep over source positions, a Newton iteration with a frozen Jacobian, or an adjoint sensitivity computation all have the same pattern. Gaussian elimination spends $\tfrac{2}{3}n^3$ flops on the matrix and only $O(n^2)$ on each right-hand side. **LU decomposition** packages the expensive part — the record of the elimination — so it can be stored and reused.

Elimination as factorisation

Each stage of Gaussian elimination without interchanges is a left-multiplication by a unit lower triangular matrix. For $n = 3$:

$$\mathbf{L}_1 = \begin{bmatrix} 1 & 0 & 0 \\ -m_{21} & 1 & 0 \\ -m_{31} & 0 & 1 \end{bmatrix}, \qquad \mathbf{L}_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -m_{32} & 1 \end{bmatrix}, \qquad \mathbf{L}_2\mathbf{L}_1\mathbf{A} = \mathbf{U}.$$

Inverting, $\mathbf{A} = \mathbf{L}_1^{-1}\mathbf{L}_2^{-1}\mathbf{U}$. The inverses simply flip the signs of the multipliers, and — the pleasant surprise — their product just collects the multipliers in place:

$$\mathbf{L} = \mathbf{L}_1^{-1}\mathbf{L}_2^{-1} = \begin{bmatrix} 1 & 0 & 0 \\ m_{21} & 1 & 0 \\ m_{31} & m_{32} & 1 \end{bmatrix}.$$

LU factorisation

If Gaussian elimination on $\mathbf{A}$ ($n \times n$) succeeds without row interchanges, then

$$\mathbf{A} = \mathbf{L}\mathbf{U},$$

where $\mathbf{L}$ is **unit lower triangular** (ones on the diagonal) with $\ell_{ik} = m_{ik}$, the elimination multipliers, and $\mathbf{U}$ is the upper triangular result of elimination. This happens if and only if the leading principal minors $\det \mathbf{A}_{1:k,1:k}$, $k = 1, \dots, n-1$, are nonzero, and then (for nonsingular $\mathbf{A}$) the factorisation is unique.

For **any** nonsingular $\mathbf{A}$ there is a permutation matrix $\mathbf{P}$ (recording the row interchanges) such that

$$\mathbf{P}\mathbf{A} = \mathbf{L}\mathbf{U}.$$

With partial pivoting, all $|\ell_{ik}| \le 1$.

Why the leading minors. The pivots satisfy $u_{11}u_{22}\cdots u_{kk} = \det \mathbf{A}_{1:k,1:k}$, because row replacements using rows $1, \dots, k$ do not change the leading $k \times k$ determinant. So the k-th pivot is nonzero exactly when the k-th leading minor is. Uniqueness: if $\mathbf{L}_1\mathbf{U}_1 = \mathbf{L}_2\mathbf{U}_2$ then $\mathbf{L}_2^{-1}\mathbf{L}_1 = \mathbf{U}_2\mathbf{U}_1^{-1}$ is both unit lower and upper triangular, hence $\mathbf{I}$. $\square$

Solving with the factors

With $\mathbf{P}\mathbf{A} = \mathbf{L}\mathbf{U}$, the system $\mathbf{A}\mathbf{x} = \mathbf{b}$ becomes $\mathbf{L}\mathbf{U}\mathbf{x} = \mathbf{P}\mathbf{b}$, solved in two triangular sweeps:

$$\begin{aligned} &\text{forward substitution:} && \mathbf{L}\mathbf{y} = \mathbf{P}\mathbf{b}, && y_i = (\mathbf{P}\mathbf{b})_i - \sum_{j<i} \ell_{ij} y_j, \\ &\text{back substitution:} && \mathbf{U}\mathbf{x} = \mathbf{y}, && x_i = \frac{1}{u_{ii}}\Big(y_i - \sum_{j>i} u_{ij} x_j\Big). \end{aligned}$$

Each sweep costs about n^2 flops. So: **factor once for $\tfrac{2}{3}n^3$, then solve each right-hand side for $2n^2$.** For $n = 1000$ that is 6.7×10^8 flops for the factorisation and 2×10^6 per solve — a ratio of over 300. The determinant also comes free: $\det \mathbf{A} = \det \mathbf{P}^{-1} \det \mathbf{L} \det \mathbf{U} = \pm \prod_i u_{ii}$.

Direct (Doolittle) formulas

Equating entries of $\mathbf{A} = \mathbf{L}\mathbf{U}$ row by row gives the factors without writing out elimination steps. For $k = 1, \dots, n$:

$$u_{kj} = a_{kj} - \sum_{p=1}^{k-1} \ell_{kp} u_{pj} \quad (j \ge k), \qquad \ell_{ik} = \frac{1}{u_{kk}}\Big(a_{ik} - \sum_{p=1}^{k-1} \ell_{ip} u_{pk}\Big) \quad (i > k).$$

This is the **Doolittle** algorithm ($\mathbf{L}$ unit diagonal). **Crout**'s variant puts the ones on the diagonal of $\mathbf{U}$ instead. Both perform the same arithmetic as elimination in a different order, which matters for memory access patterns on real hardware but not for the result.

Worked Example 8.28 — LU of the running example and reuse

Step 1 (factor). From Worked Example 8.21 the multipliers are $m_{21} = -\tfrac{1}{2}$, $m_{31} = -\tfrac{1}{4}$, $m_{32} = -\tfrac{1}{2}$ and the final triangle is $\mathbf{U}$:

$$\mathbf{G} = \underbrace{\begin{bmatrix} 1 & 0 & 0 \\ -\tfrac{1}{2} & 1 & 0 \\ -\tfrac{1}{4} & -\tfrac{1}{2} & 1 \end{bmatrix}}_{\mathbf{L}} \underbrace{\begin{bmatrix} 4 & -2 & -1 \\ 0 & 3 & -\tfrac{3}{2} \\ 0 & 0 & 3 \end{bmatrix}}_{\mathbf{U}}.$$

Check row 3: $-\tfrac{1}{4}(4,-2,-1) - \tfrac{1}{2}(0,3,-\tfrac{3}{2}) + (0,0,3) = (-1,\ \tfrac{1}{2} - \tfrac{3}{2},\ \tfrac{1}{4} + \tfrac{3}{4} + 3) = (-1,-1,4)$ ✓.

Step 2 (solve for the original sources). $\mathbf{L}\mathbf{y} = (8,2,1)^{\mathsf{T}}$: $y_1 = 8$, $y_2 = 2 + \tfrac{1}{2}(8) = 6$, $y_3 = 1 + \tfrac{1}{4}(8) + \tfrac{1}{2}(6) = 6$. Then $\mathbf{U}\mathbf{v} = \mathbf{y}$ gives $v_3 = 2$, $v_2 = (6 + 3)/3 = 3$, $v_1 = (8 + 6 + 2)/4 = 4$ ✓ — the same arithmetic as before, now split into two clean sweeps.

Step 3 (reuse for a new source pattern). A 1 mA source at node 1 only: $\mathbf{L}\mathbf{y} = (1,0,0)^{\mathsf{T}}$ gives $y = (1, \tfrac{1}{2}, \tfrac{1}{4} + \tfrac{1}{4}) = (1, \tfrac{1}{2}, \tfrac{1}{2})$. Then $v_3 = \tfrac{1}{2}/3 = \tfrac{1}{6}$, $v_2 = (\tfrac{1}{2} + \tfrac{3}{2}\cdot\tfrac{1}{6})/3 = (\tfrac{1}{2} + \tfrac{1}{4})/3 = \tfrac{1}{4}$, $v_1 = (1 + 2\cdot\tfrac{1}{4} + \tfrac{1}{6})/4 = \tfrac{5/3}{4} = \tfrac{5}{12}$. This is the first column of $\mathbf{Z}$ from Worked Example 8.12 ✓, obtained for about $2n^2$ operations.

Step 4. $\det \mathbf{G} = 4 \cdot 3 \cdot 3 = 36$ ✓.

Worked Example 8.29 — A factorisation that needs a permutation

Factor $\mathbf{A} = \begin{bmatrix} 1 & 1 & 1 \\ 2 & 2 & 5 \\ 4 & 6 & 8 \end{bmatrix}$.

Step 1. Eliminate column 1 with $m_{21} = 2$, $m_{31} = 4$: rows 2 and 3 become $(0, 0, 3)$ and $(0, 2, 4)$.

Step 2. The $(2,2)$ pivot is 0, so no $\mathbf{LU}$ factorisation of $\mathbf{A}$ exists (indeed the leading minor $\begin{vmatrix} 1 & 1 \\ 2 & 2 \end{vmatrix} = 0$). Interchange rows 2 and 3 — together with their stored multipliers — to get pivot 2; column 2 is then already clear below it.

Step 3. With $\mathbf{P}$ swapping rows 2 and 3,

$$\mathbf{PA} = \begin{bmatrix} 1 & 1 & 1 \\ 4 & 6 & 8 \\ 2 & 2 & 5 \end{bmatrix} = \underbrace{\begin{bmatrix} 1 & 0 & 0 \\ 4 & 1 & 0 \\ 2 & 0 & 1 \end{bmatrix}}_{\mathbf{L}} \underbrace{\begin{bmatrix} 1 & 1 & 1 \\ 0 & 2 & 4 \\ 0 & 0 & 3 \end{bmatrix}}_{\mathbf{U}}.$$

Check row 2: $4(1,1,1) + (0,2,4) = (4,6,8)$ ✓; row 3: $2(1,1,1) + (0,0,3) = (2,2,5)$ ✓.

Step 4. $\det \mathbf{A} = (-1)^1 \cdot 1 \cdot 2 \cdot 3 = -6$. Direct check by cofactors: $1(16-30) - 1(16-20) + 1(12-8) = -14 + 4 + 4 = -6$ ✓.

(A library routine with partial pivoting would instead start by swapping row 3, whose entry 4 is the largest in column 1, to the top; it produces different but equally valid $\mathbf{P}, \mathbf{L}, \mathbf{U}$ with all $|\ell_{ik}| \le 1$.)

Symmetric matrices: $\mathbf{LDL}^{\mathsf{T}}$ and Cholesky

If $\mathbf{A}$ is symmetric and has an $\mathbf{LU}$ factorisation, write $\mathbf{U} = \mathbf{D}\tilde{\mathbf{U}}$ with $\mathbf{D} = \operatorname{diag}(u_{11}, \dots, u_{nn})$ and $\tilde{\mathbf{U}}$ unit upper triangular. Then $\mathbf{A} = \mathbf{L}\mathbf{D}\tilde{\mathbf{U}}$, and symmetry plus uniqueness force $\tilde{\mathbf{U}} = \mathbf{L}^{\mathsf{T}}$:

$$\mathbf{A} = \mathbf{L}\mathbf{D}\mathbf{L}^{\mathsf{T}}.$$

If moreover $\mathbf{A}$ is **symmetric positive definite** (SPD: $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$), all pivots are positive and we can split $\mathbf{D} = \mathbf{D}^{1/2}\mathbf{D}^{1/2}$.

Cholesky factorisation

A real symmetric matrix $\mathbf{A}$ is positive definite if and only if it can be written

$$\mathbf{A} = \mathbf{R}\mathbf{R}^{\mathsf{T}}$$

with $\mathbf{R}$ lower triangular with positive diagonal entries; $\mathbf{R}$ is then unique. (For complex Hermitian positive definite $\mathbf{A}$, $\mathbf{A} = \mathbf{R}\mathbf{R}^{\mathsf{H}}$.) The entries are computed column by column:

$$r_{kk} = \sqrt{a_{kk} - \sum_{p<k} r_{kp}^2}, \qquad r_{ik} = \frac{1}{r_{kk}}\Big(a_{ik} - \sum_{p<k} r_{ip} r_{kp}\Big) \quad (i > k).$$

Cholesky needs about $\tfrac{1}{3}n^3$ flops — half of $\mathbf{LU}$ — and half the storage, requires no pivoting for stability, and doubles as a **test for positive definiteness**: if a square root of a non-positive number is ever requested, $\mathbf{A}$ is not SPD. Nodal matrices of passive resistive networks with a ground connection are SPD (§8.2), so Cholesky is the natural direct solver for them.

Worked Example 8.30 — $\mathbf{LDL}^{\mathsf{T}}$ and Cholesky for $\mathbf{G}$

Step 1 ($\mathbf{LDL}^{\mathsf{T}}$). From Worked Example 8.28, the pivots are $4, 3, 3$, so

$$\mathbf{G} = \begin{bmatrix} 1 & 0 & 0 \\ -\frac{1}{2} & 1 & 0 \\ -\frac{1}{4} & -\frac{1}{2} & 1 \end{bmatrix} \begin{bmatrix} 4 & 0 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & 3 \end{bmatrix} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{4} \\ 0 & 1 & -\frac{1}{2} \\ 0 & 0 & 1 \end{bmatrix}.$$

Indeed $\mathbf{D}\mathbf{L}^{\mathsf{T}} = \mathbf{U}$: row 2 of $\mathbf{D}\mathbf{L}^{\mathsf{T}}$ is $3(0, 1, -\tfrac{1}{2}) = (0, 3, -\tfrac{3}{2})$ ✓.

Step 2 (Cholesky by the formulas).

$$\begin{aligned} r_{11} &= \sqrt{4} = 2, & r_{21} &= -2/2 = -1, & r_{31} &= -1/2, \\ r_{22} &= \sqrt{4 - (-1)^2} = \sqrt{3}, & r_{32} &= \frac{-1 - (-\tfrac{1}{2})(-1)}{\sqrt{3}} = -\frac{3/2}{\sqrt{3}} = -\frac{\sqrt{3}}{2}, \\ r_{33} &= \sqrt{4 - \tfrac{1}{4} - \tfrac{3}{4}} = \sqrt{3}. \end{aligned}$$

$$\mathbf{R} = \begin{bmatrix} 2 & 0 & 0 \\ -1 & \sqrt{3} & 0 \\ -\frac{1}{2} & -\frac{\sqrt{3}}{2} & \sqrt{3} \end{bmatrix} = \mathbf{L}\mathbf{D}^{1/2}.$$

Step 3 (check). Row 3 of $\mathbf{R}$ dotted with itself: $\frac{1}{4} + \frac{3}{4} + 3 = 4 = g_{33}$ ✓; row 3 with row 2: $\frac{1}{2} - \frac{3}{2} + 0 = -1 = g_{32}$ ✓.

Reading. All square-root arguments were positive, confirming $\mathbf{G}$ is positive definite — the algebraic face of "every resistor absorbs power". Units: $\mathbf{R}$ has units $\mathrm{mS}^{1/2}$.

Worked Example 8.31 — Factor once, step many times

A node with conductance $G = 1$ mS to ground and capacitance $C = 1\ \mu$F to ground, coupled through 2 mS to a second identical node, is simulated with backward Euler at step $h = 1$ ms. Find the system matrix and explain the cost per step.

Step 1. Backward Euler replaces $\mathbf{C}\dot{\mathbf{v}}$ by $\mathbf{C}(\mathbf{v}_{k+1} - \mathbf{v}_k)/h$, giving $(\mathbf{G} + \mathbf{C}/h)\mathbf{v}_{k+1} = \mathbf{i}_{k+1} + (\mathbf{C}/h)\mathbf{v}_k$. Here $C/h = 10^{-6}/10^{-3} = 1$ mS, so

$$\mathbf{G} + \mathbf{C}/h = \begin{bmatrix} 1+2+1 & -2 \\ -2 & 1+2+1 \end{bmatrix} = \begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix} \text{ mS}.$$

Step 2. Factor once: $\ell_{21} = -\tfrac{1}{2}$, $u_{22} = 4 - 1 = 3$, so $\mathbf{L} = \begin{bmatrix} 1 & 0 \\ -\tfrac{1}{2} & 1 \end{bmatrix}$, $\mathbf{U} = \begin{bmatrix} 4 & -2 \\ 0 & 3 \end{bmatrix}$.

Step 3. Each time step is now one forward and one back substitution. With a 3 mA step input at node 1 and $\mathbf{v}_0 = \mathbf{0}$: the right-hand side is $(3, 0)$; $\mathbf{y} = (3, 1.5)$; $v_2 = 0.5$, $v_1 = (3 + 1)/4 = 1$ V. Next step, right-hand side $(3, 0) + 1 \cdot (1, 0.5) = (4, 0.5)$, $\mathbf{y} = (4, 2.5)$, $v_2 = \tfrac{5}{6} \approx 0.833$, $v_1 = (4 + \tfrac{5}{3})/4 = \tfrac{17}{12} \approx 1.417$ V. The voltages approach the DC solution of $\begin{bmatrix} 3 & -2 \\ -2 & 3 \end{bmatrix}\mathbf{v} = (3, 0)^{\mathsf{T}}$, namely $(1.8, 1.2)$ V.

Cost. For an n-node circuit simulated over N steps the work is $\tfrac{2}{3}n^3 + 2Nn^2$ instead of $N \cdot \tfrac{2}{3}n^3$. Changing h changes the matrix and forces a refactorisation — one reason adaptive-step simulators change h reluctantly.

Common Pitfall

The $\mathbf{L}$ and $\mathbf{U}$ returned by a library are tied to its permutation: `scipy.linalg.lu` returns $\mathbf{P}, \mathbf{L}, \mathbf{U}$ with $\mathbf{A} = \mathbf{PLU}$, while MATLAB's `[L,U,P]=lu(A)` satisfies $\mathbf{PA} = \mathbf{LU}$. Forgetting to apply the permutation to $\mathbf{b}$ gives a wrong answer with no error message. Use the library's paired factor/solve routines (`lu_factor` / `lu_solve`, `decomposition`) rather than handling $\mathbf{P}$ yourself.

Engineering Note

SPICE's inner loop is: stamp the linearised companion models into the MNA matrix, $\mathbf{LU}$-factor it (sparse, §8.11), forward/back substitute, update the nonlinear devices, repeat until Newton converges, then advance time. Because the sparsity *pattern* never changes, the symbolic part of the factorisation (which entries will be nonzero, which pivot order to use) is computed once at the start of the run, and only the numerical values are refactored at each iteration.

8.10 Numerical conditioning

Motivation

Every number that enters a real linear system carries an error. Component values have tolerances of 1% or 5%; measured data carry noise; and even exact inputs are rounded to about 16 significant digits when stored in double precision. The question is how much those small input errors can change the solution. For some systems the answer is "about as much as the inputs changed"; for others a change in the fifth digit of the data changes the first digit of the answer. This sensitivity is a property of the *problem*, not of the algorithm used to solve it, and it is measured by the **condition number**. Distinguishing an ill-conditioned problem from an unstable algorithm (Worked Example 8.23 was the latter) is the central skill of numerical linear algebra.

Vector and matrix norms

To talk about "small" errors in vectors and matrices we need sizes.

Vector norms

For $\mathbf{x} \in \mathbb{C}^n$:

$$\|\mathbf{x}\|_1 = \sum_i |x_i|, \qquad \|\mathbf{x}\|_2 = \Big(\sum_i |x_i|^2\Big)^{1/2}, \qquad \|\mathbf{x}\|_\infty = \max_i |x_i|.$$

Each satisfies $\|\mathbf{x}\| \geq 0$ with equality only for $\mathbf{x} = \mathbf{0}$, $\|c\mathbf{x}\| = |c|\|\mathbf{x}\|$, and the triangle inequality $\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$.

Induced matrix norm

Given a vector norm, the **induced** (operator) norm of $\mathbf{A}$ is the largest factor by which $\mathbf{A}$ can stretch a vector:

$$\|\mathbf{A}\| = \max_{\mathbf{x} \neq \mathbf{0}} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|}.$$

For the three common vector norms this gives

$$\|\mathbf{A}\|_1 = \max_j \sum_i |a_{ij}| \ \text{(max column sum)}, \qquad \|\mathbf{A}\|_\infty = \max_i \sum_j |a_{ij}| \ \text{(max row sum)},$$

$$\|\mathbf{A}\|_2 = \sigma_{\max}(\mathbf{A}) = \sqrt{\lambda_{\max}(\mathbf{A}^{\mathsf{H}}\mathbf{A})} \ \text{(spectral norm)}.$$

The **Frobenius norm** $\|\mathbf{A}\|_F = \big(\sum_{i,j} |a_{ij}|^2\big)^{1/2}$ is not induced but is easy to compute and satisfies $\|\mathbf{A}\|_2 \leq \|\mathbf{A}\|_F$.

Why the max-row-sum formula. For $\|\mathbf{x}\|_\infty = 1$, $|(\mathbf{A}\mathbf{x})_i| \le \sum_j |a_{ij}||x_j| \le \sum_j |a_{ij}|$, so $\|\mathbf{A}\|_\infty \le \max_i \sum_j |a_{ij}|$; and choosing $x_j = \operatorname{sgn} a_{pj}$ for the row p attaining the maximum achieves it. The 1-norm case is the same argument on columns. □

Induced norms satisfy $\|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$ and are **submultiplicative**, $\|\mathbf{A}\mathbf{B}\| \le \|\mathbf{A}\|\|\mathbf{B}\|$, with $\|\mathbf{I}\| = 1$. For the running example $\|\mathbf{G}\|_1 = \|\mathbf{G}\|_\infty = 4 + 2 + 1 = 7$ mS and, $\mathbf{G}$ being symmetric, $\|\mathbf{G}\|_2$ equals its largest eigenvalue, 6 mS.

The condition number

Condition number

For a nonsingular square matrix,

$$\kappa(\mathbf{A}) = \|\mathbf{A}\|\,\|\mathbf{A}^{-1}\|,$$

with a subscript naming the norm used ($\kappa_1, \kappa_2, \kappa_\infty$). For singular $\mathbf{A}$ one sets $\kappa = \infty$.

Basic facts: $\kappa(\mathbf{A}) \ge \|\mathbf{A}\mathbf{A}^{-1}\| = 1$; $\kappa(c\mathbf{A}) = \kappa(\mathbf{A})$, so unlike the determinant it is **independent of overall scale and units**; $\kappa_2(\mathbf{A}) = \sigma_{\max}/\sigma_{\min}$, the ratio of the largest to smallest singular values; for symmetric positive definite $\mathbf{A}$, $\kappa_2 = \lambda_{\max}/\lambda_{\min}$. Geometrically, $\mathbf{A}$ maps the unit sphere to an ellipsoid, and κ_2 is the ratio of its longest to shortest axis: a very flat ellipsoid means some directions are almost annihilated, and recovering them (inverting) amplifies errors enormously. Moreover $1/\kappa(\mathbf{A})$ is the relative distance from $\mathbf{A}$ to the nearest singular matrix: $\min\{\|\delta\mathbf{A}\|/\|\mathbf{A}\| : \ \mathbf{A} + \delta\mathbf{A} \text{ singular}\} = 1/\kappa(\mathbf{A})$ in the 2-norm.

Perturbation theorems

Sensitivity to the right-hand side

If $\mathbf{A}\mathbf{x} = \mathbf{b}$ with $\mathbf{b} \neq \mathbf{0}$ and $\mathbf{A}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b} + \delta\mathbf{b}$, then

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A})\,\frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|},$$

and for every $\mathbf{A}$ there are $\mathbf{b}, \delta\mathbf{b}$ for which equality holds.

Proof. Subtracting, $\mathbf{A}\,\delta\mathbf{x} = \delta\mathbf{b}$, so $\|\delta\mathbf{x}\| = \|\mathbf{A}^{-1}\delta\mathbf{b}\| \le \|\mathbf{A}^{-1}\|\|\delta\mathbf{b}\|$. Also $\|\mathbf{b}\| = \|\mathbf{A}\mathbf{x}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$, i.e. $1/\|\mathbf{x}\| \le \|\mathbf{A}\|/\|\mathbf{b}\|$. Multiply the two inequalities. Equality needs $\mathbf{x}$ to be a direction that $\mathbf{A}$ stretches most and $\delta\mathbf{b}$ a direction that $\mathbf{A}^{-1}$ stretches most. □

Sensitivity to the matrix

If $(\mathbf{A} + \delta\mathbf{A})(\mathbf{x} + \delta\mathbf{x}) = \mathbf{b}$ and $\kappa(\mathbf{A})\|\delta\mathbf{A}\|/\|\mathbf{A}\| < 1$, then

$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \frac{\kappa(\mathbf{A})\,\|\delta\mathbf{A}\|/\|\mathbf{A}\|}{1 - \kappa(\mathbf{A})\,\|\delta\mathbf{A}\|/\|\mathbf{A}\|} \approx \kappa(\mathbf{A})\frac{\|\delta\mathbf{A}\|}{\|\mathbf{A}\|}.$$

Sketch. Expand: $\mathbf{A}\,\delta\mathbf{x} = -\delta\mathbf{A}(\mathbf{x} + \delta\mathbf{x})$, so $\|\delta\mathbf{x}\| \le \|\mathbf{A}^{-1}\|\|\delta\mathbf{A}\|(\|\mathbf{x}\| + \|\delta\mathbf{x}\|)$; collect the $\|\delta\mathbf{x}\|$ terms and divide by $\|\mathbf{x}\|$. □

Rule of thumb. If the data are accurate to d significant digits and $\kappa \approx 10^k$, expect the solution to be accurate to about $d - k$ digits. With double precision ($d \approx 16$) a system with $\kappa = 10^{10}$ still yields about 6 good digits; with component values known to 1% ($d = 2$) even $\kappa = 100$ leaves nothing trustworthy in the worst case.

Residual versus error

Having computed $\hat{\mathbf{x}}$, we can always evaluate the **residual** $\mathbf{r} = \mathbf{b} - \mathbf{A}\hat{\mathbf{x}}$, but not the **error** $\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}$ (we do not know $\mathbf{x}$). Since $\mathbf{A}\mathbf{e} = \mathbf{r}$, the first perturbation theorem applies with $\delta\mathbf{b} = \mathbf{r}$:

$$\frac{\|\mathbf{e}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A})\frac{\|\mathbf{r}\|}{\|\mathbf{b}\|}.$$

A small residual guarantees a small error only when κ is modest. Gaussian elimination with partial pivoting is **backward stable**: it always produces a small residual, $\|\mathbf{r}\| \lesssim n\rho u\|\mathbf{A}\|\|\hat{\mathbf{x}}\|$. So for a well-conditioned system its answer is accurate, and for an ill-conditioned one its answer is as accurate as the problem allows — no algorithm can do substantially better with the same data.

An ill-conditioned 2×2 system: nearly parallel lines $x + y = 2$ (blue) and $x + 1.05y = 2.05$ (red) meet at $(1, 1)$. Raising the second right-hand side by only 0.05 (dashed red) slides the intersection along the blue line to $(0, 2)$. The narrow angle between the lines is what a large condition number looks like.

Worked Example 8.32 — Condition number of the running example

Compute $\kappa_1(\mathbf{G})$ and $\kappa_2(\mathbf{G})$.

Step 1. $\|\mathbf{G}\|_1 = \max(4 + 2 + 1,\ 2 + 4 + 1,\ 1 + 1 + 4) = 7$.

Step 2. From Worked Example 8.12, the column sums of $|\mathbf{Z}|$ are $\frac{30}{36}, \frac{30}{36}, \frac{24}{36}$, so $\|\mathbf{Z}\|_1 = \frac{5}{6}$.

Step 3. $\kappa_1(\mathbf{G}) = 7 \cdot \frac{5}{6} = \frac{35}{6} \approx 5.83$.

Step 4 (2-norm). $\mathbf{G}$ is symmetric positive definite with eigenvalues $3 - \sqrt{3} \approx 1.268$, $3 + \sqrt{3} \approx 4.732$ and 6 (Chapter 10). So $\kappa_2 = 6/(3 - \sqrt{3}) = 3 + \sqrt{3} \approx 4.73$.

Reading. $\kappa \approx 5$: a 1% uncertainty in the source currents produces at most about 5% relative uncertainty in the node voltages. Diagonally dominant nodal matrices of modest size are typically this benign.

Worked Example 8.33 — Nearly parallel lines

For $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.05 \end{bmatrix}$, $\mathbf{b} = (2,\ 2.05)^{\mathsf{T}}$, verify the perturbation bound in the ∞-norm for $\delta\mathbf{b} = (0,\ 0.05)^{\mathsf{T}}$, and show that a small residual can hide a large error.

Step 1. $\det \mathbf{A} = 0.05$, $\mathbf{A}^{-1} = \dfrac{1}{0.05}\begin{bmatrix} 1.05 & -1 \\ -1 & 1 \end{bmatrix} = \begin{bmatrix} 21 & -20 \\ -20 & 20 \end{bmatrix}$.

Step 2. $\|\mathbf{A}\|_\infty = 2.05$, $\|\mathbf{A}^{-1}\|_\infty = 41$, so $\kappa_\infty = 84.05$.

Step 3. $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} = (42 - 41,\ -40 + 41)^{\mathsf{T}} = (1, 1)^{\mathsf{T}}$. $\delta\mathbf{x} = \mathbf{A}^{-1}\delta\mathbf{b} = (-1,\ 1)^{\mathsf{T}}$, so $\mathbf{x} + \delta\mathbf{x} = (0, 2)^{\mathsf{T}}$.

Step 4 (bound). Relative input change $\|\delta\mathbf{b}\|_\infty / \|\mathbf{b}\|_\infty = 0.05/2.05 \approx 0.0244$; relative output change $\|\delta\mathbf{x}\|_\infty / \|\mathbf{x}\|_\infty = 1$, i.e. 100%. The amplification is $1/0.0244 = 41$, within the bound 84.05 ✓.

Step 5 (residual). Suppose some method returned $\hat{\mathbf{x}} = (0, 2)^{\mathsf{T}}$ for the original system. Its residual $\mathbf{b} - \mathbf{A}\hat{\mathbf{x}} = (2 - 2,\ 2.05 - 2.1)^{\mathsf{T}} = (0, -0.05)^{\mathsf{T}}$ is about 2% of $\|\mathbf{b}\|$, yet the error is 100%. Checking that "the answer satisfies the equations" is not enough for an ill-conditioned system.

Worked Example 8.34 — Wide spread of conductances

Two nodes are joined by a low-resistance strap of 1000 mS (1 Ω), and each has 1 mS to ground. Analyse

$$\mathbf{G}_s = \begin{bmatrix} 1001 & -1000 \\ -1000 & 1001 \end{bmatrix} \text{ mS}.$$

Step 1. The eigenvalues are 1001 ∓ 1000, i.e. 1 and 2001, with eigenvectors $(1,1)$ (both nodes moving together, opposed only by the ground conductances) and $(1,-1)$ (the nodes moving apart, opposed by the strap). Hence $\kappa_2 = 2001$.

Step 2. With 1 mA into node 1, $\mathbf{v} = \frac{1}{2001}(1001, 1000)^{\mathsf{T}} \approx (0.50025,\ 0.49975)$ V.

Step 3. The *sum* $v_1 + v_2$ is well determined, but the *difference* $v_1 - v_2 = 1/2001 \approx 0.5$ mV — the voltage across the strap — is the small result of subtracting two nearly equal numbers. A 1% change in the strap conductance changes $v_1 - v_2$ by about 1%, while a 10^{-6} relative rounding error in v_1 and v_2 changes it by about 0.1%: the relative accuracy lost is roughly the factor κ.

Reading. Circuits with conductances spanning many decades (milliohm interconnect next to megaohm bias resistors, or the GΩ "gmin" conductances SPICE adds to ground) have large condition numbers. Engineers often replace an extremely stiff element by an ideal short (merging the nodes), which removes the ill-conditioning analytically.

Worked Example 8.35 — Scaling can remove apparent ill-conditioning

The system of Worked Example 8.23, with its first equation multiplied by 10^4, reads

$$\begin{bmatrix} 1 & 10^4 \\ 1 & 1 \end{bmatrix} \mathbf{x} = \begin{bmatrix} 10^4 \\ 2 \end{bmatrix}.$$

Step 1. $\|\mathbf{A}\|_\infty = 10001$, $\mathbf{A}^{-1} = \dfrac{1}{1-10^4}\begin{bmatrix} 1 & -10^4 \\ -1 & 1 \end{bmatrix}$, $\|\mathbf{A}^{-1}\|_\infty = 10001/9999 \approx 1.0002$, so $\kappa_\infty \approx 1.0 \times 10^4$.

Step 2. Dividing row 1 by 10^4 (**row equilibration**, making the largest entry in each row equal to 1) gives back $\begin{bmatrix} 10^{-4} & 1 \\ 1 & 1 \end{bmatrix}$ with $\kappa_\infty \approx 4.0$.

Reading. The solution $(1.0001,\ 0.9999)$ is the same either way; only the bookkeeping changed. Part of a large condition number may therefore come from poor scaling — for example, MNA equations mixing currents in amperes with voltage constraints in volts, or conductances in siemens next to capacitances in farads — and is cured by rescaling rows or columns (equilibration), which good solvers do automatically. The part that survives every scaling, as in Worked Example 8.33, is intrinsic to the problem.

A notoriously ill-conditioned family

The **Hilbert matrix** $\mathbf{H}_n$, with $h_{ij} = 1/(i+j-1)$, arises in least-squares fitting of polynomials $1, t, t^2, \dots$ on $[0,1]$ — a reason never to fit high-degree polynomials in the monomial basis. Its condition numbers grow explosively:

n	3	5	8	10
$\kappa_2(\mathbf{H}_n)$	5.2×10^2	4.8×10^5	1.5×10^{10}	1.6×10^{13}

At $n = 10$ a double-precision solve keeps only about three correct digits. The cure is a better-conditioned formulation (orthogonal polynomials, QR factorisation — Chapter 9), not a cleverer elimination.

Common Pitfall

Do not judge conditioning by the determinant (§8.3) or by the size of the entries. And do not confuse an **ill-conditioned problem** (large κ: every method struggles) with an **unstable algorithm** (elimination without pivoting on Worked Example 8.23: a good method would have succeeded). The remedies are different: reformulate or measure better for the first; pivot or use a stable factorisation for the second.

Engineering Note

Libraries estimate κ_1 cheaply from an existing $\mathbf{LU}$ factorisation (LAPACK `dgecon`, MATLAB `rcond`, which returns $1/\kappa_1$); MATLAB's warning "Matrix is close to singular or badly scaled. RCOND = 1e-17" is this estimate. In tolerance analysis the condition number gives a quick worst-case bound before running a Monte Carlo study: if $\kappa \approx 10^3$ and components are 1% parts, some outputs may be completely unreliable, and the design should be changed (for instance, a bridge measurement should be read as a difference directly rather than computed from two large node voltages).

8.11 Sparse matrices

Motivation

A circuit with n nodes has an $n \times n$ nodal matrix, but each node connects to only a few others — typically three to five. The matrix therefore has about $5n$ nonzero entries out of n^2. For a post-layout simulation with $n = 10^6$ nodes, the dense matrix would have 10^{12} entries (8 terabytes) and dense elimination would need $\frac{2}{3} \times 10^{18}$ flops; the sparse matrix has perhaps 5×10^6 nonzeros (tens of megabytes) and can be factored in seconds. Finite-difference and finite-element field solvers, power-grid models and the normal equations of large estimation problems are all sparse in the same way. **Sparse matrix methods** store and operate on only the nonzeros, and choose algorithms that keep it that way.

Sparse matrix

A matrix is **sparse** when the number of nonzero entries, $\operatorname{nnz}(\mathbf{A})$, is small enough compared with mn that exploiting the zeros pays off — in practice $\operatorname{nnz} = O(n)$ for an $n \times n$ matrix. The **sparsity pattern** is the set of positions of the nonzeros. A matrix is **banded** with bandwidth w if $a_{ij} = 0$ for $|i-j| > w$; **tridiagonal** is $w = 1$.

The sparsity pattern of a nodal matrix *is* the circuit graph: $g_{ij} \neq 0$ ($i \neq j$) exactly when nodes i and j are joined by a branch.

Storage formats

- **Coordinate (COO, "triplet")**: three arrays of length nnz holding (row, column, value). Easy to build by stamping — duplicates are simply summed afterwards — and the usual assembly format.
- **Compressed sparse row (CSR)**: the values and column indices row by row, plus a row-pointer array of length $n+1$ marking where each row starts. Storage $2\,\text{nnz} + n + 1$; matrix–vector products touch each nonzero once ($2\,\text{nnz}$ flops).
- **Compressed sparse column (CSC)**: the same by columns; the native format of MATLAB and most direct solvers.
- **Banded storage**: the $2w+1$ diagonals as dense vectors — ideal for ladder networks and 1-D discretisations.

Worked Example 8.36 — CSR storage of a ladder network

A four-node resistive ladder has 1 S series links between consecutive nodes and 1 S to ground at every node, with the left end driven through a further 1 S from a 10 V source (Norton equivalent: 10 A into node 1). Its nodal matrix is

$$\mathbf{T} = \begin{bmatrix} 3 & -1 & 0 & 0 \\ -1 & 3 & -1 & 0 \\ 0 & -1 & 3 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix}, \qquad \mathbf{b} = \begin{bmatrix} 10 \\ 0 \\ 0 \\ 0 \end{bmatrix}.$$

Give its CSR representation (0-based indices).

Solution. Reading row by row,

Array	Contents
values	$3, -1,\ -1, 3, -1,\ -1, 3, -1,\ -1, 2$
column index	$0, 1,\ 0, 1, 2,\ 1, 2, 3,\ 2, 3$
row pointer	$0, 2, 5, 8, 10$

Row i occupies positions $\text{ptr}[i]$ to $\text{ptr}[i+1]-1$; e.g. row 2 is positions 5–7: values $-1, 3, -1$ in columns $1, 2, 3$. Ten nonzeros out of sixteen entries here; for a 1000-node ladder it would be 2998 out of 10^6.

Fill-in and ordering

Eliminating a variable creates nonzeros wherever two of its neighbours were not already connected: the update $a_{ij} \leftarrow a_{ij} - a_{ik}a_{kj}/a_{kk}$ makes a_{ij} nonzero whenever a_{ik} and a_{kj} are. In graph terms, eliminating node k joins all its neighbours into a clique — exactly the star–mesh transformation of circuit theory. These new nonzeros are **fill-in**. The factors $\mathbf{L}$ and $\mathbf{U}$ can be far denser than $\mathbf{A}$, and the amount of fill depends dramatically on the **elimination order** (the symmetric permutation $\mathbf{P}\mathbf{A}\mathbf{P}^{\mathsf{T}}$).

Worked Example 8.37 — A star network: order is everything

A hub node connects through 1 S to each of four leaf nodes, and each leaf has 1 S to ground. Compare elimination with the hub numbered first and last.

Hub first.

$$\mathbf{A} = \begin{bmatrix} 4 & -1 & -1 & -1 & -1 \\ -1 & 2 & 0 & 0 & 0 \\ -1 & 0 & 2 & 0 & 0 \\ -1 & 0 & 0 & 2 & 0 \\ -1 & 0 & 0 & 0 & 2 \end{bmatrix}.$$

Eliminating the hub replaces the leaf block by $2\mathbf{I} - \tfrac{1}{4}\mathbf{1}\mathbf{1}^{\mathsf{T}}$ (where $\mathbf{1}$ is the all-ones vector): every one of its 12 off-diagonal zeros becomes $-\tfrac{1}{4}$. The factor $\mathbf{L}$ is completely full — the eliminated hub has "meshed" all four leaves together.

Hub last. The matrix is the "arrowhead" $\begin{bmatrix} 2\mathbf{I}_4 & -\mathbf{1} \\ -\mathbf{1}^{\mathsf{T}} & 4 \end{bmatrix}$. Eliminating leaf k affects only the hub's diagonal: $4 \leftarrow 4 - (-1)(-1)/2$. After all four leaves the hub pivot is $4 - 4 \cdot \tfrac{1}{2} = 2$, and **no fill-in** occurs: $\mathbf{L}$ has exactly the nonzeros of the lower triangle of $\mathbf{A}$.

Check. Both orders must give the same determinant: hub last, $2^4 \cdot 2 = 32$; hub first, $4 \cdot \det(2\mathbf{I} - \tfrac{1}{4}\mathbf{1}\mathbf{1}^{\mathsf{T}}) = 4 \cdot 2^3(2 - \tfrac{4}{4}) = 4 \cdot 8 \cdot 1 = 32$ ✓ (using $\det(c\mathbf{I} - \alpha\mathbf{1}\mathbf{1}^{\mathsf{T}}) = c^{n-1}(c - n\alpha)$).

Reading. Eliminate low-degree nodes first and high-degree nodes (hubs, supply rails) last. This greedy rule is the **minimum-degree** ordering; its refinements (approximate minimum degree, AMD) and **nested dissection** (recursively cutting the graph with small separators, which are numbered last) are what production sparse solvers use.

For a nodal matrix that is SPD and diagonally dominant, any symmetric ordering is numerically safe, so the ordering can be chosen purely to minimise fill. For MNA and other indefinite matrices the solver must balance sparsity against pivoting for stability (threshold pivoting: accept a pivot if it is not much smaller than the largest candidate).

Banded and tridiagonal systems

If $\mathbf{A}$ has bandwidth w, elimination without pivoting creates no fill outside the band, and the factorisation costs about $2nw^2$ flops instead of $\tfrac{2}{3}n^3$. The tridiagonal case ($w = 1$) is the **Thomas algorithm**: for the system with subdiagonal a_i, diagonal d_i, superdiagonal c_i, right-hand side b_i,

$$\begin{aligned} &\text{forward:} \quad c'_1 = \frac{c_1}{d_1}, \quad b'_1 = \frac{b_1}{d_1}, \quad c'_i = \frac{c_i}{d_i - a_i c'_{i-1}}, \quad b'_i = \frac{b_i - a_i b'_{i-1}}{d_i - a_i c'_{i-1}}, \\ &\text{backward:} \quad x_n = b'_n, \quad x_i = b'_i - c'_i x_{i+1}. \end{aligned}$$

About $8n$ flops in total — linear in n. It is stable without pivoting when the matrix is diagonally dominant.

Worked Example 8.38 — Solving the ladder by the Thomas algorithm

Solve $\mathbf{T}\mathbf{v} = \mathbf{b}$ from Worked Example 8.36. Here $d = (3, 3, 3, 2)$, $a_i = c_i = -1$.

Forward sweep.

$$\begin{aligned} c'_1 &= -\tfrac{1}{3}, & b'_1 &= \tfrac{10}{3}, \\ d_2 - a_2 c'_1 &= 3 - \tfrac{1}{3} = \tfrac{8}{3}, & c'_2 &= -\tfrac{3}{8}, & b'_2 &= \frac{0 + \frac{10}{3}}{8/3} = \tfrac{5}{4}, \\ d_3 - a_3 c'_2 &= 3 - \tfrac{3}{8} = \tfrac{21}{8}, & c'_3 &= -\tfrac{8}{21}, & b'_3 &= \frac{0 + \frac{5}{4}}{21/8} = \tfrac{10}{21}, \\ d_4 - a_4 c'_3 &= 2 - \tfrac{8}{21} = \tfrac{34}{21}, & & & b'_4 &= \frac{0 + \frac{10}{21}}{34/21} = \tfrac{5}{17}. \end{aligned}$$

Backward sweep. $v_4 = \tfrac{5}{17}$; $v_3 = \tfrac{10}{21} + \tfrac{8}{21} \cdot \tfrac{5}{17} = \tfrac{210}{357} = \tfrac{10}{17}$; $v_2 = \tfrac{5}{4} + \tfrac{3}{8} \cdot \tfrac{10}{17} = \tfrac{25}{17}$; $v_1 = \tfrac{10}{3} + \tfrac{1}{3} \cdot \tfrac{25}{17} = \tfrac{65}{17}$.

So $\mathbf{v} = \tfrac{1}{17}(65, 25, 10, 5)^{\mathsf{T}} \approx (3.824,\ 1.471,\ 0.588,\ 0.294)$ V.

Check. Row 1: $3 \cdot 65 - 25 = 170 = 17 \cdot 10$ ✓. Row 4: $-10 + 2 \cdot 5 = 0$ ✓. The pivots $3, \tfrac{8}{3}, \tfrac{21}{8}, \tfrac{34}{21}$ multiply to $\det \mathbf{T} = 34$. Successive node voltages fall by factors 2.6, 2.5 and 2 (the last is an end effect of the open termination); far from the ends of a long ladder the ratio approaches r with $r + 1/r = 3$, i.e. $(3 + \sqrt{5})/2 \approx 2.618$ of an infinite ladder, the same number met in Worked Example 8.6.

Iterative methods

For very large sparse systems — especially 3-D field problems, where even the best ordering produces heavy fill — **iterative methods** replace factorisation by repeated cheap matrix–vector products. Split $\mathbf{A} = \mathbf{D} + \mathbf{L}_A + \mathbf{U}_A$ into diagonal, strictly lower and strictly upper parts.

Jacobi and Gauss–Seidel iterations

Starting from a guess $\mathbf{x}^{(0)}$,

$$\text{Jacobi:} \quad x_i^{(k+1)} = \frac{1}{a_{ii}}\Big(b_i - \sum_{j \neq i} a_{ij} x_j^{(k)}\Big),$$

$$\text{Gauss–Seidel:} \quad x_i^{(k+1)} = \frac{1}{a_{ii}}\Big(b_i - \sum_{j<i} a_{ij} x_j^{(k+1)} - \sum_{j>i} a_{ij} x_j^{(k)}\Big).$$

In matrix form $\mathbf{x}^{(k+1)} = \mathbf{M}\mathbf{x}^{(k)} + \mathbf{c}$ with $\mathbf{M}_J = -\mathbf{D}^{-1}(\mathbf{L}_A + \mathbf{U}_A)$ or $\mathbf{M}_{GS} = -(\mathbf{D} + \mathbf{L}_A)^{-1}\mathbf{U}_A$.

Gauss–Seidel uses each new value as soon as it is available. In circuit terms, Jacobi sets every node voltage to the conductance-weighted average of its neighbours' old voltages plus its source contribution — a relaxation process.

Convergence of stationary iterations

The iteration $\mathbf{x}^{(k+1)} = \mathbf{M}\mathbf{x}^{(k)} + \mathbf{c}$ converges for every starting vector if and only if the **spectral radius** $\rho(\mathbf{M}) = \max|\lambda_i(\mathbf{M})| < 1$; the error then shrinks asymptotically by the factor $\rho(\mathbf{M})$ per iteration. Sufficient conditions: if $\mathbf{A}$ is strictly diagonally dominant, both Jacobi and Gauss–Seidel converge; if $\mathbf{A}$ is symmetric positive definite, Gauss–Seidel converges.

Sketch. The error $\mathbf{e}^{(k)} = \mathbf{x}^{(k)} - \mathbf{x}$ obeys $\mathbf{e}^{(k+1)} = \mathbf{M}\mathbf{e}^{(k)}$, so $\mathbf{e}^{(k)} = \mathbf{M}^k \mathbf{e}^{(0)}$, and $\mathbf{M}^k \to \mathbf{0}$ exactly when $\rho(\mathbf{M}) < 1$ (Chapter 10). For diagonal dominance, $\|\mathbf{M}_J\|_\infty = \max_i \sum_{j \neq i} |a_{ij}|/|a_{ii}| < 1$ directly. $\square$

Worked Example 8.39 — Jacobi and Gauss–Seidel on the running example

Solve $\mathbf{G}\mathbf{v} = (8, 2, 1)^{\mathsf{T}}$ from $\mathbf{v}^{(0)} = \mathbf{0}$.

Jacobi, iteration 1. $v_1 = \tfrac{1}{4}(8 + 2\cdot 0 + 0) = 2$, $v_2 = \tfrac{1}{4}(2 + 0 + 0) = 0.5$, $v_3 = \tfrac{1}{4}(1 + 0 + 0) = 0.25$.

Jacobi, iteration 2. $v_1 = \tfrac{1}{4}(8 + 2(0.5) + 0.25) = 2.3125$, $v_2 = \tfrac{1}{4}(2 + 2(2) + 0.25) = 1.5625$, $v_3 = \tfrac{1}{4}(1 + 2 + 0.5) = 0.875$.

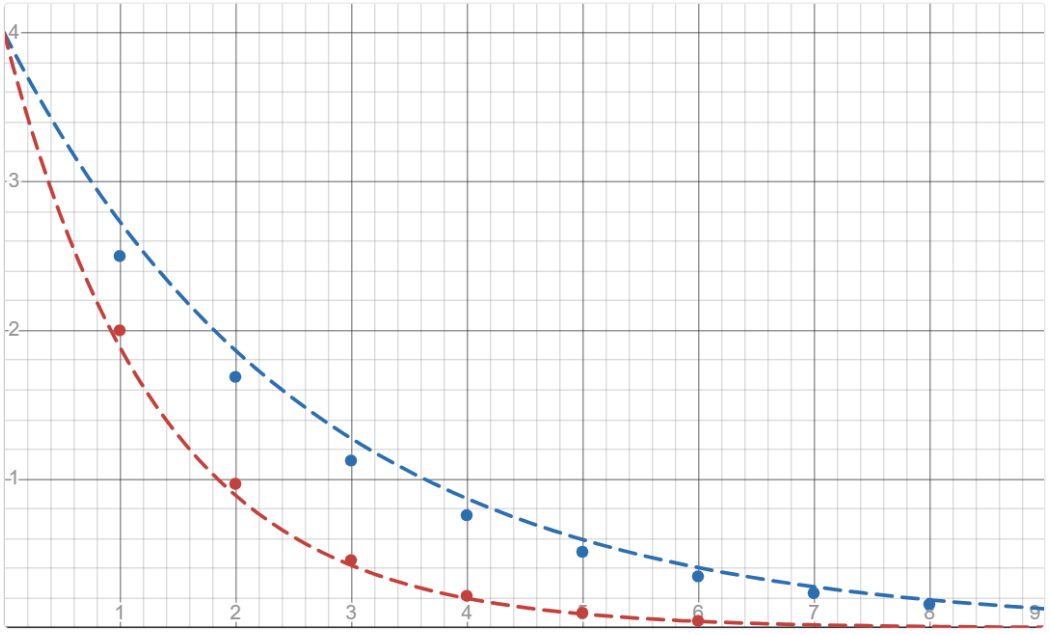
Gauss–Seidel, iteration 1. $v_1 = \tfrac{1}{4}(8) = 2$; then, using the new v_1, $v_2 = \tfrac{1}{4}(2 + 2\cdot 2 + 0) = 1.5$; then $v_3 = \tfrac{1}{4}(1 + 2 + 1.5) = 1.125$.

Gauss–Seidel, iteration 2. $v_1 = \tfrac{1}{4}(8 + 3 + 1.125) = 3.03125$, $v_2 = \tfrac{1}{4}(2 + 6.0625 + 1.125) = 2.296875$, $v_3 = \tfrac{1}{4}(1 + 3.03125 + 2.296875) = 1.58203$.

Progress. Maximum error $\|\mathbf{v}^{(k)} - (4, 3, 2)^{\mathsf{T}}\|_\infty$:

k	1	2	3	4	5	6
Jacobi	2.500	1.688	1.125	0.758	0.512	0.347
Gauss–Seidel	2.000	0.969	0.456	0.216	0.102	0.048

Rates. $\rho(\mathbf{M}_J) = (1 + \sqrt{3})/4 \approx 0.683$ and $\rho(\mathbf{M}_{GS}) \approx 0.472$: Gauss–Seidel removes roughly twice as many digits per iteration. Reaching 10^{-6} accuracy takes about $\ln(10^{-6}/4)/\ln 0.683 \approx 40$ Jacobi or 21 Gauss–Seidel iterations — far more work than a 3×3 elimination, which is why iterative methods are only worthwhile for large sparse systems.



Maximum error against iteration number k for Jacobi (blue) and Gauss–Seidel (red) on the running example. The dashed curves $4\rho^k$ with $\rho = 0.683$ and 0.472 show the geometric decay set by the spectral radius of each iteration matrix.

Modern practice goes well beyond these classical methods. **Successive over-relaxation** (SOR) extrapolates the Gauss–Seidel step by a factor $1 < \omega < 2$; the **conjugate gradient** method (for SPD matrices) and **GMRES** (general matrices) are Krylov-subspace methods that converge in a number of iterations governed by $\sqrt{\kappa}$ or by the eigenvalue distribution; and **preconditioning** — solving $\mathbf{P}^{-1}\mathbf{A}\mathbf{x} = \mathbf{P}^{-1}\mathbf{b}$ with $\mathbf{P} \approx \mathbf{A}$ cheap to invert, such as an incomplete $\mathbf{LU}$ factorisation that discards fill — is what makes them fast. These are treated in Chapter 22.

Common Pitfall

Never form the inverse, or any dense intermediate, of a sparse matrix: $\mathbf{A}^{-1}$ is generally full (Worked Example 8.12 shows a dense $\mathbf{Z}$). Likewise, building a sparse matrix by inserting entries one at a time into a CSR/CSC structure is quadratic in cost; assemble in COO (triplet) form and convert once. And beware of accidental densification: in NumPy/SciPy, `A + 0` or `A * dense_array` may silently return a dense result.

Engineering Note

SPICE-class simulators use sparse $\mathbf{LU}$ with a Markowitz-type ordering chosen once per circuit (KLU, designed specifically for circuit matrices, exploits their near-block-triangular structure). Field solvers using finite elements produce SPD sparse matrices solved by preconditioned conjugate gradients or multigrid. Power-system load flow uses sparse $\mathbf{LU}$ of the Jacobian with ordering by minimum degree — introduced for exactly this purpose by Tinney and Walker in 1967. In every case the decisive step is the same: recognise the graph behind the matrix and order the unknowns to keep the factors sparse.

Summary

Concept	Key formula or fact
Product	$c_{ij} = \sum_k a_{ik}b_{kj}$; $\mathbf{Ax} = \sum_k x_k \mathbf{a}_k$; $\mathbf{AB} \neq \mathbf{BA}$ in general

Concept	Key formula or fact
Transpose rules	$(\mathbf{AB})^{\mathsf{T}} = \mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$, $(\mathbf{AB})^{\mathsf{H}} = \mathbf{B}^{\mathsf{H}}\mathbf{A}^{\mathsf{H}}$
Nodal matrix	$\mathbf{G} = \mathbf{A}\mathbf{G}_b\mathbf{A}^{\mathsf{T}}$ (symmetric, positive definite if grounded)
2×2 determinant / inverse	$ad - bc$; $\dfrac{1}{ad-bc}\begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$
Cofactor expansion	$\det \mathbf{A} = \sum_k a_{ik}C_{ik}$, $C_{ik} = (-1)^{i+k}M_{ik}$
Determinant rules	$\det(\mathbf{AB}) = \det \mathbf{A} \det \mathbf{B}$; swap $\to -$; replacement $\to$ unchanged; $\det = \pm \prod u_{ii}$
Cramer's rule	$x_k = \det \mathbf{A}_k / \det \mathbf{A}$
Adjugate inverse	$\mathbf{A}^{-1} = \operatorname{adj} \mathbf{A} / \det \mathbf{A}$
Product inverse	$(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$
Sherman–Morrison	$(\mathbf{A} + \mathbf{uv}^{\mathsf{T}})^{-1} = \mathbf{A}^{-1} - \dfrac{\mathbf{A}^{-1}\mathbf{uv}^{\mathsf{T}}\mathbf{A}^{-1}}{1 + \mathbf{v}^{\mathsf{T}}\mathbf{A}^{-1}\mathbf{u}}$
Schur complement (Kron)	$\mathbf{S} = \mathbf{A}_{11} - \mathbf{A}_{12}\mathbf{A}_{22}^{-1}\mathbf{A}_{21}$, $\det \mathbf{A} = \det \mathbf{A}_{22} \det \mathbf{S}$
Rank	number of pivots = independent rows = independent columns
Rouché–Capelli	consistent $\iff \operatorname{rank} \mathbf{A} = \operatorname{rank}[\mathbf{A} \mid \mathbf{b}]$; $n - r$ free parameters
Solution structure	$\mathbf{x} = \mathbf{x}_p + \mathbf{x}_h$, $\mathbf{A}\mathbf{x}_h = \mathbf{0}$
Gaussian elimination	$m_{ik} = a_{ik}/a_{kk}$; cost $\frac{2}{3}n^3$; back substitution n^2
Partial pivoting	largest $\lvert a_{pk}\rvert$ as pivot; $\lvert m_{ik}\rvert \le 1$
Gauss–Jordan	$[\mathbf{A} \mid \mathbf{I}] \to [\mathbf{I} \mid \mathbf{A}^{-1}]$; cost $\approx n^3$ per solve
LU	$\mathbf{PA} = \mathbf{LU}$; $\mathbf{Ly} = \mathbf{Pb}$, $\mathbf{Ux} = \mathbf{y}$; $2n^2$ per extra right-hand side
Cholesky	$\mathbf{A} = \mathbf{R}\mathbf{R}^{\mathsf{T}}$ for SPD; $r_{kk} = \sqrt{a_{kk} - \sum_{p<k} r_{kp}^2}$; cost $\frac{1}{3}n^3$
Induced norms	$\lVert\mathbf{A}\rVert_1$ = max column sum, $\lVert\mathbf{A}\rVert_\infty$ = max row sum, $\lVert\mathbf{A}\rVert_2 = \sigma_{\max}$
Condition number	$\kappa = \lVert\mathbf{A}\rVert\lVert\mathbf{A}^{-1}\rVert$; $\kappa_2 = \sigma_{\max}/\sigma_{\min}$
Perturbation bound	$\lVert\delta\mathbf{x}\rVert/\lVert\mathbf{x}\rVert \le \kappa\, \lVert\delta\mathbf{b}\rVert/\lVert\mathbf{b}\rVert$; lose $\approx \log_{10}\kappa$ digits
Thomas algorithm	tridiagonal solve in $\approx 8n$ flops
Stationary iteration	converges $\iff \rho(\mathbf{M}) < 1$; diagonal dominance suffices

Chapter 9 — Vector Spaces and Linear Transformations

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 5 (definite integrals), Ch. 8 (matrices, Gaussian elimination, rank) **Learning outcomes:** After this chapter you can
>
> - recognise a vector space — whether its elements are arrows, columns of numbers, polynomials, matrices or signals — and test whether a subset is a subspace;
> - decide linear independence, find a basis and the dimension of a space, and compute coordinates and change-of-basis matrices;
> - represent a linear transformation by a matrix, and compute bases for its null space, column space, row space and left null space using the rank–nullity theorem;
> - work with inner products on $\mathbb{R}^n$, $\mathbb{C}^n$ and on function spaces, and use orthogonality, norms and the Cauchy–Schwarz inequality;
> - project onto lines and subspaces, build orthonormal bases with Gram–Schmidt (including QR and Legendre polynomials);
> - solve overdetermined systems by least squares and fit lines, polynomials and exponentials to measured data.

Chapter 8 treated a matrix as a table of coefficients and a linear system as something to be solved by elimination. This chapter changes the point of view. A matrix is a *machine* that maps one vector space into another; the questions "does $\mathbf{A}\mathbf{x} = \mathbf{b}$ have a solution?" and "is it unique?" become questions about two subspaces attached to that machine. The same language then applies, almost word for word, to objects that do not look like columns of numbers at all: the set of solutions of a linear differential equation, the set of polynomials of degree at most n, the set of finite-energy signals. That is the real pay-off. When you later expand a periodic waveform in a Fourier series (Ch. 15), you will be doing exactly what this chapter does with arrows in $\mathbb{R}^3$: projecting a vector onto an orthogonal basis. When you fit a calibration curve to noisy measurements, you will be projecting a data vector onto the column space of a matrix.

The chapter is organised in two halves. Sections 9.1–9.6 build the *algebraic* structure: spaces, subspaces, independence, bases, linear maps and the four fundamental subspaces. Sections 9.7–9.11 add *geometry* — lengths, angles and orthogonality — and use it for approximation: projection, Gram–Schmidt and least squares.

9.1 Vector spaces

Motivation

An engineer meets many different objects that can be *added* and *scaled*: forces and field vectors, node-voltage vectors of a circuit, sampled signals $x[0], \dots, x[N-1]$, continuous waveforms $x(t)$, polynomials used in filter design, matrices of network parameters. In each case the same handful of algebraic rules hold — addition is commutative, there is a zero, scaling distributes over addition, and so on. Rather than prove every theorem separately for arrows, for sampled signals and for waveforms, we prove it once for any set obeying those rules. That set is a **vector space**.

The most important consequence is **superposition**. If $x_1(t)$ and $x_2(t)$ are responses of a linear circuit, so is $a x_1(t) + b x_2(t)$. The set of all possible responses is therefore closed under linear combinations — it is a vector space — and everything we learn about bases and dimension tells us how many "independent" responses we need to describe them all.

Definition

Vector space

A **vector space** over a field $\mathbb{F}$ (in this book $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$) is a set V of objects called **vectors**, together with two operations

- vector addition $\mathbf{u} + \mathbf{v} \in V$ for all $\mathbf{u}, \mathbf{v} \in V$,
- scalar multiplication $c\,\mathbf{u} \in V$ for all $c \in \mathbb{F}$, $\mathbf{u} \in V$,

such that for all $\mathbf{u}, \mathbf{v}, \mathbf{w} \in V$ and $a, b \in \mathbb{F}$:

1. $\mathbf{u} + \mathbf{v} = \mathbf{v} + \mathbf{u}$ (commutativity)
2. $(\mathbf{u} + \mathbf{v}) + \mathbf{w} = \mathbf{u} + (\mathbf{v} + \mathbf{w})$ (associativity)
3. there is a **zero vector** $\mathbf{0} \in V$ with $\mathbf{u} + \mathbf{0} = \mathbf{u}$
4. each $\mathbf{u}$ has an **additive inverse** $-\mathbf{u}$ with $\mathbf{u} + (-\mathbf{u}) = \mathbf{0}$
5. $a(\mathbf{u} + \mathbf{v}) = a\mathbf{u} + a\mathbf{v}$
6. $(a + b)\mathbf{u} = a\mathbf{u} + b\mathbf{u}$
7. $a(b\mathbf{u}) = (ab)\mathbf{u}$
8. $1\,\mathbf{u} = \mathbf{u}$

When $\mathbb{F} = \mathbb{R}$ we speak of a **real** vector space, when $\mathbb{F} = \mathbb{C}$ of a **complex** vector space.

The two **closure** requirements (sums and scalar multiples stay inside V) are the ones that fail in practice; the eight axioms are almost always inherited from ordinary arithmetic of numbers or functions. A few consequences follow directly from the axioms and are used constantly:

$$0\,\mathbf{u} = \mathbf{0}, \qquad c\,\mathbf{0} = \mathbf{0}, \qquad (-1)\mathbf{u} = -\mathbf{u}, \qquad c\,\mathbf{u} = \mathbf{0} \;\Rightarrow\; c = 0 \text{ or } \mathbf{u} = \mathbf{0}.$$

Proof of the first. By axiom 6, $0\mathbf{u} = (0 + 0)\mathbf{u} = 0\mathbf{u} + 0\mathbf{u}$. Add $-(0\mathbf{u})$ to both sides: $\mathbf{0} = 0\mathbf{u}$. The others are similar.

The standard examples

Space	Vectors	Addition and scaling	Zero vector
$\mathbb{R}^n$	columns $(x_1, \dots, x_n)^{\mathsf{T}}$ of reals	componentwise	$(0, \dots, 0)^{\mathsf{T}}$
$\mathbb{C}^n$	columns of complex numbers (phasor vectors)	componentwise, complex scalars	$(0, \dots, 0)^{\mathsf{T}}$
$\mathbb{R}^{m \times n}$	$m \times n$ real matrices	entrywise	zero matrix
$\mathcal{P}_n$	polynomials $a_0 + a_1 t + \cdots + a_n t^n$ of degree $\le n$	add/scale coefficients	the zero polynomial
$C[a, b]$	continuous real functions on $[a, b]$	$(f+g)(t) = f(t) + g(t)$, $(cf)(t) = cf(t)$	$f(t) \equiv 0$
ℓ^2 / $\mathbb{R}^N$	sampled signals $x[n]$	samplewise	the all-zero sequence
$L^2(a, b)$	functions with $\int_a^b \lvert f(t)\rvert^2\, dt < \infty$ (finite-energy signals)	pointwise	$f \equiv 0$

The table shows how broad the idea is. A polynomial is "a vector" because two polynomials can be added and scaled and the axioms hold; it does not matter that we never draw it as an arrow. The function spaces $C[a, b]$ and $L^2(a, b)$ are the setting for Fourier analysis: a periodic signal will be treated as a single point in an infinite-dimensional space.

Worked Example 9.1 — Checking the axioms for $\mathcal{P}_2$

Show that $\mathcal{P}_2 = \{a_0 + a_1 t + a_2 t^2 : a_k \in \mathbb{R}\}$ is a real vector space.

Closure. If $p(t) = a_0 + a_1 t + a_2 t^2$ and $q(t) = b_0 + b_1 t + b_2 t^2$, then

$$(p + q)(t) = (a_0 + b_0) + (a_1 + b_1)t + (a_2 + b_2)t^2 \in \mathcal{P}_2, \qquad (cp)(t) = ca_0 + ca_1 t + ca_2 t^2 \in \mathcal{P}_2.$$

Axioms. Each axiom reduces to the same axiom for real numbers applied coefficient by coefficient. For instance, commutativity: $(p + q)(t)$ and $(q + p)(t)$ have coefficients $a_k + b_k = b_k + a_k$. The zero vector is $0 + 0t + 0t^2$; the inverse of p is $-a_0 - a_1 t - a_2 t^2$.

Remark. The set of polynomials of degree *exactly* 2 is **not** a vector space: $t^2 + t$ and $-t^2$ both have degree 2 but their sum t does not, and the zero polynomial is missing.

Non-examples

Most failures are failures of closure or of the zero vector:

- **The first quadrant** $\{(x, y) : x \ge 0,\ y \ge 0\}$: closed under addition but not under scaling by -1.
- **A line not through the origin**, e.g. $\{(x, y) : y = 2x + 1\}$: $(0, 1)$ and $(1, 3)$ are in it but their sum $(1, 4)$ is not; and $(0, 0)$ is not in it. Such a set is an **affine** set — a vector space shifted away from the origin.
- **Unit vectors** $\{\mathbf{x} : \|\mathbf{x}\| = 1\}$: the sum of two unit vectors is generally not a unit vector.
- **Positive voltages** $\{v(t) : v(t) > 0\}$: not closed under multiplication by -1, no zero vector.
- **Solutions of a non-homogeneous equation**, e.g. all $y(t)$ with $y'' + 3y' + 2y = 1$ (worked example below).

Worked Example 9.2 — Solution sets of differential equations

(a) Show that the set S_0 of twice-differentiable functions satisfying $y'' + 3y' + 2y = 0$ is a vector space. (b) Show that the set S_1 satisfying $y'' + 3y' + 2y = 1$ is not.

(a) S_0 is a subset of the vector space of all twice-differentiable functions, so the axioms are inherited; we need only closure (this is the subspace test of Section 9.2). Let $y_1, y_2 \in S_0$ and $a, b \in \mathbb{R}$, and put $y = ay_1 + by_2$. Because differentiation is linear,

$$y'' + 3y' + 2y = a\,(y_1'' + 3y_1' + 2y_1) + b\,(y_2'' + 3y_2' + 2y_2) = a \cdot 0 + b \cdot 0 = 0.$$

So $y \in S_0$. The zero function is in S_0. Hence S_0 is a vector space. (In Ch. 12 you will find $S_0 = \{c_1 e^{-t} + c_2 e^{-2t}\}$.)

(b) Take $y_1 = y_2 = \tfrac{1}{2}$ (a constant: $0 + 0 + 2 \cdot \tfrac{1}{2} = 1$, so it is in S_1). Then $y_1 + y_2 = 1$ gives $0 + 0 + 2 = 2 \neq 1$. Closure fails; also $y \equiv 0$ gives $0 \neq 1$, so the zero vector is absent. S_1 is an affine set: $S_1 = \tfrac{1}{2} + S_0$, a particular solution plus the homogeneous space.

This "particular solution plus vector space" structure is the general shape of the solution set of every consistent linear problem $L(\mathbf{x}) = \mathbf{b}$, whether L is a matrix or a differential operator. It reappears in Section 9.6.

Sinusoids of a fixed frequency

The set

$$\mathcal{S}_\omega = \{A\cos(\omega t + \phi) : A \ge 0,\ \phi \in \mathbb{R}\}$$

of all sinusoids at a fixed angular frequency ω is closed under addition — the sum of two sinusoids at the same frequency is another sinusoid at that frequency — and under real scaling (a negative scale factor is a phase shift by π). With the zero signal ($A = 0$) included it is a real vector space. Writing $A\cos(\omega t + \phi) = a\cos\omega t + b\sin\omega t$ with $a = A\cos\phi$, $b = -A\sin\phi$ shows that each sinusoid is fixed by the pair $(a, b) \in \mathbb{R}^2$; equivalently by the **phasor** $\mathbf{X} = Ae^{j\phi} = a - jb \in \mathbb{C}$. Adding sinusoids corresponds to adding phasors. This is the vector-space reason why phasor analysis (Ch. 2) works: the map "sinusoid $\mapsto$ phasor" respects addition and real scaling, so it is a linear bijection between $\mathcal{S}_\omega$ and $\mathbb{C}$ viewed as the real space $\mathbb{R}^2$ (Section 9.5 calls this an *isomorphism*).

Worked Example 9.3 — Adding sinusoids as vectors

Write $x(t) = 3\cos(\omega t) + 4\cos(\omega t - \pi/2)$ as a single sinusoid.

As vectors in the basis $\{\cos\omega t,\ \sin\omega t\}$**.** $\cos(\omega t - \pi/2) = \sin\omega t$, so $x = 3\cos\omega t + 4\sin\omega t$, i.e. coordinates $(a, b) = (3, 4)$.

Convert. $A = \sqrt{a^2 + b^2} = 5$ and, from $a = A\cos\phi$, $b = -A\sin\phi$: $\cos\phi = 0.6$, $\sin\phi = -0.8$, so $\phi = -0.9273$ rad $= -53.13°$.

$$x(t) = 5\cos(\omega t - 53.13°).$$

Phasor check. $3e^{j0} + 4e^{-j\pi/2} = 3 - 4j = 5\angle -53.13°$. Same answer, because the phasor map is linear.

Common Pitfall — "vector" does not mean "arrow"

In this chapter a vector is *any element of a vector space*. The word says nothing about geometry. A polynomial, a 3×3 matrix and a voltage waveform are all vectors in suitable spaces. Conversely, a list of numbers is only a vector if the operations you intend to perform on it are componentwise addition and scaling: a list of (resistance, temperature, date) readings is a data record, not a meaningful element of $\mathbb{R}^3$.

Engineering Note — why EE lives in complex vector spaces

Steady-state AC analysis replaces each node voltage by a phasor, so the unknown vector of nodal analysis lies in $\mathbb{C}^n$ and the admittance matrix has complex entries. Every definition in this chapter works over $\mathbb{C}$; the one change needed is in the inner product (Section 9.8), where complex conjugation is required so that lengths remain real and positive.

9.2 Subspaces

Motivation

Inside a big vector space we constantly meet smaller sets that are vector spaces in their own right: the plane of all current vectors satisfying Kirchhoff's current law, the set of band-limited signals, the polynomials that vanish at a given point, the set of all outputs a system can produce. Recognising these as **subspaces** lets us use all of the vector-space machinery inside them.

Definition and the subspace test

Subspace

A subset W of a vector space V is a **subspace** if W is itself a vector space under the operations of V.

Checking eight axioms again is unnecessary: they are inherited from V. Only closure and the presence of the zero vector can fail.

Subspace test

A subset $W \subseteq V$ is a subspace if and only if

1. $\mathbf{0} \in W$;
2. $\mathbf{u}, \mathbf{v} \in W \Rightarrow \mathbf{u} + \mathbf{v} \in W$ (closed under addition);
3. $\mathbf{u} \in W,\ c \in \mathbb{F} \Rightarrow c\mathbf{u} \in W$ (closed under scaling).

Conditions 2 and 3 can be merged: W is a subspace iff $\mathbf{0} \in W$ and $a\mathbf{u} + b\mathbf{v} \in W$ for all $\mathbf{u}, \mathbf{v} \in W$ and scalars a, b.

Proof sketch. Necessity is clear. For sufficiency, axioms 1, 2 and 5–8 hold in W because they hold in V and the operations are the same. Axiom 3 is condition 1. For axiom 4, if $\mathbf{u} \in W$ then $-\mathbf{u} = (-1)\mathbf{u} \in W$ by condition 3.

Every vector space V has two **trivial subspaces**: $\{\mathbf{0}\}$ and V itself. The subspaces of $\mathbb{R}^3$ are exactly: $\{\mathbf{0}\}$, lines through the origin, planes through the origin, and $\mathbb{R}^3$. The phrase "through the origin" is essential — it is condition 1.

Worked Example 9.4 — Four subspace tests

Decide which are subspaces.

(a) $W_a = \{(x, y, z) \in \mathbb{R}^3 : x + 2y - z = 0\}$. Zero: $0 + 0 - 0 = 0$ ✓. If $\mathbf{u} = (x_1, y_1, z_1)$ and $\mathbf{v} = (x_2, y_2, z_2)$ satisfy the equation, then $a\mathbf{u} + b\mathbf{v}$ gives $a(x_1 + 2y_1 - z_1) + b(x_2 + 2y_2 - z_2) = 0$ ✓. **Subspace** (a plane through the origin).

(b) $W_b = \{(x, y, z) : x + 2y - z = 4\}$. $(0, 0, 0)$ gives $0 \neq 4$. **Not a subspace** (a parallel plane shifted off the origin).

(c) $W_c = \{p \in \mathcal{P}_3 : p(1) = 0\}$. The zero polynomial vanishes at 1 ✓. $(ap + bq)(1) = a\,p(1) + b\,q(1) = 0$ ✓. **Subspace.**

(d) $W_d = \{(x, y) \in \mathbb{R}^2 : xy = 0\}$ (the union of the two axes). $(1, 0)$ and $(0, 1)$ are in W_d but $(1, 1)$ is not. **Not a subspace.** A union of subspaces is usually not a subspace.

A useful pattern emerges: **the solution set of a homogeneous linear condition is always a subspace; an inhomogeneous condition (right-hand side $\neq 0$) or a nonlinear condition usually is not.**

Span

Linear combination and span

A **linear combination** of $\mathbf{v}_1, \dots, \mathbf{v}_k$ is any vector $c_1\mathbf{v}_1 + \cdots + c_k\mathbf{v}_k$. The **span** of the set is the collection of all linear combinations:

$$\operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\} = \{c_1\mathbf{v}_1 + \cdots + c_k\mathbf{v}_k : c_i \in \mathbb{F}\}.$$

If $\operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\} = W$, the vectors **span** (or **generate**) W.

A span is a subspace

$\operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ is a subspace of V, and it is the *smallest* subspace containing all the $\mathbf{v}_i$.

Proof. The zero vector is the combination with all $c_i = 0$. A linear combination of two linear combinations is again a linear combination (collect coefficients). Any subspace containing every $\mathbf{v}_i$ must, by closure, contain every combination of them.

Deciding whether $\mathbf{b} \in \operatorname{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ in $\mathbb{R}^n$ is the same as deciding whether the linear system

$$\begin{bmatrix} \mathbf{v}_1 & \mathbf{v}_2 & \cdots & \mathbf{v}_k \end{bmatrix} \begin{bmatrix} c_1 \\ \vdots \\ c_k \end{bmatrix} = \mathbf{b}$$

is consistent — a Chapter 8 problem solved by Gaussian elimination.

Worked Example 9.5 — Membership in a span

Is $\mathbf{b} = (1, 4, 7)^{\mathsf{T}}$ in $\operatorname{span}\{\mathbf{v}_1, \mathbf{v}_2\}$ with $\mathbf{v}_1 = (1, 2, 3)^{\mathsf{T}}$, $\mathbf{v}_2 = (0, 1, 2)^{\mathsf{T}}$? What about $\mathbf{d} = (1, 4, 8)^{\mathsf{T}}$?

Row-reduce the augmented matrix with both right-hand sides:

$$\left[\begin{array}{cc|cc} 1 & 0 & 1 & 1 \\ 2 & 1 & 4 & 4 \\ 3 & 2 & 7 & 8 \end{array}\right] \xrightarrow{R_2 - 2R_1,\ R_3 - 3R_1} \left[\begin{array}{cc|cc} 1 & 0 & 1 & 1 \\ 0 & 1 & 2 & 2 \\ 0 & 2 & 4 & 5 \end{array}\right] \xrightarrow{R_3 - 2R_2} \left[\begin{array}{cc|cc} 1 & 0 & 1 & 1 \\ 0 & 1 & 2 & 2 \\ 0 & 0 & 0 & 1 \end{array}\right].$$

For $\mathbf{b}$ the last row reads $0 = 0$: consistent, $c_1 = 1$, $c_2 = 2$. Check: $1(1, 2, 3) + 2(0, 1, 2) = (1, 4, 7)$ ✓.

For $\mathbf{d}$ the last row reads $0 = 1$: inconsistent, so $\mathbf{d} \notin$ the span. Geometrically, the span is the plane through the origin with normal $\mathbf{v}_1 \times \mathbf{v}_2 = (1, -2, 1)$; indeed $1 - 8 + 7 = 0$ for $\mathbf{b}$ but $1 - 8 + 8 = 1 \neq 0$ for $\mathbf{d}$.

Sums and intersections of subspaces

If U and W are subspaces of V, then

- $U \cap W$ is a subspace (check the three conditions — each holds in both);
- $U + W = \{\mathbf{u} + \mathbf{w} : \mathbf{u} \in U,\ \mathbf{w} \in W\}$ is a subspace, the smallest containing both;
- $U \cup W$ is a subspace only if one contains the other (Worked Example 9.4(d)).

When $U \cap W = \{\mathbf{0}\}$ the sum is called **direct**, written $U \oplus W$, and every vector in it splits *uniquely* as $\mathbf{u} + \mathbf{w}$. Example: every function on $[-a, a]$ splits uniquely into an even and an odd part,

$$f(t) = \underbrace{\tfrac{1}{2}\big[f(t) + f(-t)\big]}_{\text{even}} + \underbrace{\tfrac{1}{2}\big[f(t) - f(-t)\big]}_{\text{odd}},$$

and the only function that is both even and odd is 0. So the function space is the direct sum of the even subspace and the odd subspace — the fact behind the cosine-only and sine-only Fourier series of Ch. 15.

Worked Example 9.6 — Intersection of two planes

Let $U = \{x + 2y - z = 0\}$ and $W = \{x - y + z = 0\}$ in $\mathbb{R}^3$. Find $U \cap W$.

Solve both equations together. Adding them: $2x + y = 0$, so $y = -2x$; then $z = x + 2y = -3x$. Thus

$$U \cap W = \operatorname{span}\{(1, -2, -3)^{\mathsf{T}}\},$$

a line through the origin. Check: $1 - 4 + 3 = 0$ ✓ and $1 + 2 - 3 = 0$ ✓. Equivalently, the line is along $\mathbf{n}_U \times \mathbf{n}_W = (1, 2, -1) \times (1, -1, 1) = (1, -2, -3)$.

Signal subspaces

Function spaces have many natural subspaces that matter in signal processing:

- **Zero-mean signals** on $[0, T]$: $\{x : \int_0^T x\,dt = 0\}$ — a homogeneous linear condition, so a subspace (the "AC part" of signals).
- **T-periodic signals**: $x(t + T) = x(t)$ is preserved by sums and scalings.
- **Trigonometric polynomials of order N**: $\operatorname{span}\{1, \cos\omega_0 t, \sin\omega_0 t, \dots, \cos N\omega_0 t, \sin N\omega_0 t\}$ — the space in which a truncated Fourier series lives.
- **Band-limited signals**: those whose Fourier transform vanishes for $|\omega| > W$ (Ch. 16); closed under addition because the transform is linear.
- **Causal signals** $x(t) = 0$ for $t < 0$.

Signals with **peak amplitude at most 1 V**, by contrast, do not form a subspace (scaling by 2 breaks the bound).

Common Pitfall — forgetting the origin

Before doing any work, check whether $\mathbf{0}$ belongs to the set. If it does not, the set is not a subspace and you are done. Most "almost-subspaces" met in practice (operating points, biased signals, regions bounded by tolerances) are affine sets or cones, not subspaces.

Engineering Note — KCL defines a subspace

In a circuit with b branches, collect the branch currents in $\mathbf{i} \in \mathbb{R}^b$. Kirchhoff's current law at each node is a homogeneous linear equation, so the set of all KCL-compatible current vectors is a subspace of $\mathbb{R}^b$. Its dimension (Section 9.6) is the number of independent loop currents — the number of unknowns in mesh analysis.

9.3 Linear independence

Motivation

A spanning set may contain redundant vectors. If a third probe signal is just a combination of the first two, measuring it tells us nothing new; if one KVL equation is the sum of two others, writing it down adds no information and makes the system singular. **Linear independence** is the precise notion of "no redundancy". It decides whether a set of node equations has a unique solution, whether two waveforms can be separated by a receiver, and whether a set of functions can serve as a basis for a general solution of a differential equation.

Definition

Linear independence

Vectors $\mathbf{v}_1, \dots, \mathbf{v}_k$ are **linearly independent** if the only solution of

$$c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \cdots + c_k\mathbf{v}_k = \mathbf{0}$$

is the **trivial** one $c_1 = c_2 = \cdots = c_k = 0$. Otherwise they are **linearly dependent**, and a nontrivial solution is called a **dependence relation**.

Equivalent formulations, each useful in a different setting:

- The set is dependent iff **at least one vector is a linear combination of the others**. (If $c_j \neq 0$ in a dependence relation, solve for $\mathbf{v}_j$.)
- The set is independent iff **every vector in its span has a unique representation** $c_1\mathbf{v}_1 + \cdots + c_k\mathbf{v}_k$. (If two representations existed, their difference would be a nontrivial dependence relation.)
- In $\mathbb{F}^n$, with $\mathbf{V} = [\mathbf{v}_1 \ \cdots \ \mathbf{v}_k]$, the set is independent iff $\mathbf{V}\mathbf{c} = \mathbf{0}$ has only $\mathbf{c} = \mathbf{0}$, iff $\operatorname{rank}\mathbf{V} = k$, iff every column of the echelon form of $\mathbf{V}$ has a pivot.
- For $k = n$ (square $\mathbf{V}$): independent iff $\det\mathbf{V} \neq 0$.

Some quick facts:

- Any set containing $\mathbf{0}$ is dependent ($1 \cdot \mathbf{0} = \mathbf{0}$).
- Two vectors are dependent iff one is a scalar multiple of the other.
- **More than n vectors in $\mathbb{F}^n$ are always dependent**: $\mathbf{V}\mathbf{c} = \mathbf{0}$ then has more unknowns than equations, so a free variable exists.
- A subset of an independent set is independent; a superset of a dependent set is dependent.

Worked Example 9.7 — Testing vectors in $\mathbb{R}^3$

(a) Are $\mathbf{v}_1 = (1,2,0)^{\mathsf{T}}$, $\mathbf{v}_2 = (0,1,1)^{\mathsf{T}}$, $\mathbf{v}_3 = (1,0,-2)^{\mathsf{T}}$ independent?

Row-reduce $\mathbf{V} = [\mathbf{v}_1\ \mathbf{v}_2\ \mathbf{v}_3]$:

$$\begin{bmatrix} 1 & 0 & 1 \\ 2 & 1 & 0 \\ 0 & 1 & -2 \end{bmatrix} \xrightarrow{R_2 - 2R_1} \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & -2 \\ 0 & 1 & -2 \end{bmatrix} \xrightarrow{R_3 - R_2} \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & -2 \\ 0 & 0 & 0 \end{bmatrix}.$$

Column 3 has no pivot, so the set is **dependent**. Back-substitute with $c_3 = 1$: $c_2 = 2$, $c_1 = -1$. Dependence relation:

$$-\mathbf{v}_1 + 2\mathbf{v}_2 + \mathbf{v}_3 = \mathbf{0} \quad\Longleftrightarrow\quad \mathbf{v}_3 = \mathbf{v}_1 - 2\mathbf{v}_2.$$

Check: $(1,2,0) - 2(0,1,1) = (1,0,-2)$ ✓. (Also $\det\mathbf{V} = 0$.)

(b) Are $\mathbf{w}_1 = (1,1,0)^{\mathsf{T}}$, $\mathbf{w}_2 = (1,0,1)^{\mathsf{T}}$, $\mathbf{w}_3 = (0,1,1)^{\mathsf{T}}$ independent?

$$\det\begin{bmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{bmatrix} = 1(0-1) - 1(1-0) + 0 = -2 \neq 0.$$

Independent. Three independent vectors in $\mathbb{R}^3$ — they will turn out to be a basis.

Independence of functions

For vectors in a function space, the coefficients c_i are constants and the relation $c_1 f_1(t) + \cdots + c_k f_k(t) = 0$ must hold **for every** t in the interval. Two practical tests:

1. Evaluate at sample points. If the functions are dependent, then for any points $t_1, \dots, t_k$ the matrix $[f_j(t_i)]$ is singular. So finding *one* set of points where $\det[f_j(t_i)] \neq 0$ proves independence.

2. The Wronskian. For k functions with $k-1$ derivatives, define

$$W(f_1, \dots, f_k)(t) = \det \begin{bmatrix} f_1 & f_2 & \cdots & f_k \\ f_1' & f_2' & \cdots & f_k' \\ \vdots & & & \vdots \\ f_1^{(k-1)} & f_2^{(k-1)} & \cdots & f_k^{(k-1)} \end{bmatrix}.$$

Wronskian test

If $W(f_1, \dots, f_k)(t_0) \neq 0$ at some point t_0 of the interval, then $f_1, \dots, f_k$ are linearly independent there.

If $f_1, \dots, f_k$ are solutions of the same kth-order linear homogeneous ODE with continuous coefficients, then the converse also holds: they are independent iff $W \neq 0$, and in that case $W(t) \neq 0$ for **every** t.

Proof of the first part. Differentiate a dependence relation $\sum c_i f_i(t) = 0$ repeatedly ($k-1$ times); at t_0 this gives the square system $\mathbf{W}(t_0)\mathbf{c} = \mathbf{0}$. If $\det \mathbf{W}(t_0) \neq 0$ then $\mathbf{c} = \mathbf{0}$.

Common Pitfall — $W \equiv 0$ does not prove dependence in general

The functions t^2 and $t|t|$ on $[-1, 1]$ have Wronskian identically zero, yet they are independent (on $t > 0$ they agree, on $t < 0$ they are negatives of each other, so no single constant ratio works). The converse of the Wronskian test needs the extra hypothesis that the functions solve a common linear ODE.

Worked Example 9.8 — Exponentials and trigonometric functions

(a) Show e^t, e^{2t}, e^{3t} are independent on $\mathbb{R}$.

$$W = \det \begin{bmatrix} e^t & e^{2t} & e^{3t} \\ e^t & 2e^{2t} & 3e^{3t} \\ e^t & 4e^{2t} & 9e^{3t} \end{bmatrix} = e^{6t} \det \begin{bmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 4 & 9 \end{bmatrix} = 2e^{6t} \neq 0.$$

The 3×3 determinant is a Vandermonde determinant $(2-1)(3-1)(3-2) = 2$. In general $e^{s_1 t}, \dots, e^{s_k t}$ are independent whenever the s_i are distinct — the reason distinct characteristic roots give independent natural-response modes (Ch. 12).

(b) Are $1, \cos^2 t, \sin^2 t$ independent? No: $1 \cdot 1 - 1 \cdot \cos^2 t - 1 \cdot \sin^2 t = 0$ for all t. Likewise $\{1, \cos^2 t, \cos 2t\}$ is dependent because $\cos 2t = 2\cos^2 t - 1$.

(c) Are $\cos \omega t$ and $\sin \omega t$ independent? $W = \cos \omega t \cdot \omega \cos \omega t - \sin \omega t \cdot (-\omega \sin \omega t) = \omega \neq 0$ for $\omega \neq 0$. Yes — which is why every sinusoid at frequency ω needs exactly two numbers (amplitude and phase, or a and b).

Worked Example 9.9 — Independence in $\mathcal{P}_2$

Are $p_1 = 1 + t$, $p_2 = 1 - t$, $p_3 = t^2$ independent in $\mathcal{P}_2$?

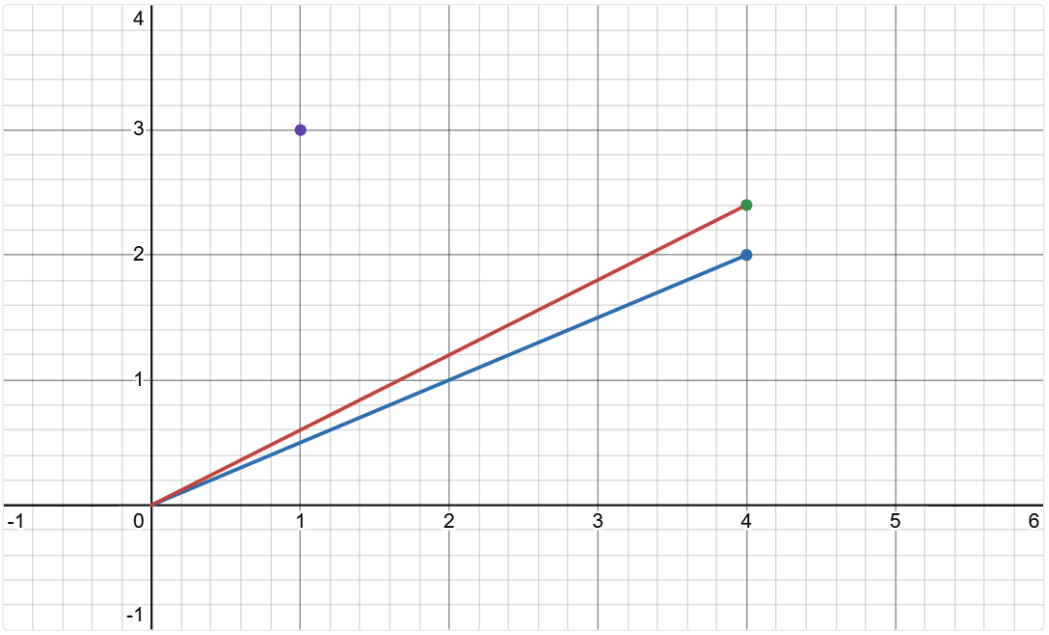
Suppose $c_1(1+t) + c_2(1-t) + c_3 t^2 = 0$ for all t. Collect powers of t:

$$(c_1 + c_2) + (c_1 - c_2)t + c_3 t^2 = 0 \;\Rightarrow\; c_1 + c_2 = 0, \quad c_1 - c_2 = 0, \quad c_3 = 0.$$

Hence $c_1 = c_2 = c_3 = 0$: **independent**. The method — matching coefficients — converts a question about functions into a question about the coefficient vectors $(1, 1, 0)$, $(1, -1, 0)$, $(0, 0, 1)$ in $\mathbb{R}^3$. This translation is made systematic by *coordinates* in Section 9.4.

Geometric picture

In $\mathbb{R}^2$ two vectors are independent iff they are not collinear; in $\mathbb{R}^3$ three vectors are independent iff they are not coplanar. The determinant measures the area or volume of the parallelogram/parallelepiped they span, so "nearly dependent" vectors give a small determinant relative to the product of their lengths. The graph below shows two nearly parallel vectors; any vector in the plane can still be written as a combination of them, but the coefficients become large and very sensitive to noise.



Nearly parallel vectors $\mathbf{v}_1 = (4, 2)$ and $\mathbf{v}_2 = (4, 2.4)$ are independent, but $\mathbf{b} = (1, 3) = -6\,\mathbf{v}_1 + 6.25\,\mathbf{v}_2$ needs large, cancelling coefficients — the hallmark of ill-conditioning.

Engineering Note — near-dependence in measurements

In practice the question is rarely "independent or not?" but "how independent?". Two antenna-array steering vectors at nearly the same angle, two sensor channels that are almost proportional, or regressor columns t and t^2 sampled on $[100, 101]$ are all *technically* independent but numerically almost dependent. The relevant measure is the condition number of the matrix of columns, introduced in Ch. 8 and made precise with singular values in Ch. 10. It reappears in least squares (Section 9.11).

9.4 Basis and dimension

Motivation

A basis is a minimal set of "building blocks" for a space: enough vectors to span it, with no redundancy. Once a basis is chosen, every vector is described by a unique list of numbers — its **coordinates** — and abstract vectors (polynomials, sinusoids, signals) can be handled by matrix computations. The number of vectors in a basis, the **dimension**, is the number of independent degrees of freedom: the number of initial conditions a circuit needs, the number of loop currents, the number of samples needed to pin down a band-limited signal over an interval.

Definition

Basis

A set $\mathcal{B} = \{\mathbf{b}_1, \dots, \mathbf{b}_n\}$ in V is a **basis** of V if

1. $\mathcal{B}$ is linearly independent, and
2. $\mathcal{B}$ spans V.

Unique representation

$\mathcal{B}$ is a basis of V iff every $\mathbf{v} \in V$ can be written in exactly one way as

$$\mathbf{v} = c_1\mathbf{b}_1 + \cdots + c_n\mathbf{b}_n.$$

The numbers $c_1, \dots, c_n$ are the **coordinates** of $\mathbf{v}$ relative to $\mathcal{B}$, written $[\mathbf{v}]_{\mathcal{B}} = (c_1, \dots, c_n)^{\mathsf{T}}$.

Spanning gives existence; independence gives uniqueness. Note that a basis is an *ordered* list: swapping $\mathbf{b}_1$ and $\mathbf{b}_2$ swaps the first two coordinates.

Standard bases.

Space	Standard basis	Dimension
$\mathbb{R}^n$, $\mathbb{C}^n$	$\mathbf{e}_1 = (1, 0, \dots, 0)^{\mathsf{T}}, \dots, \mathbf{e}_n$	n
$\mathcal{P}_n$	$1, t, t^2, \dots, t^n$	$n + 1$
$\mathbb{R}^{m \times n}$	$\mathbf{E}_{ij}$ (1 in position (i, j), zeros elsewhere)	mn
$\mathcal{S}_\omega$ (sinusoids at ω)	$\cos \omega t,\ \sin \omega t$	2
trig. polynomials of order N	$1, \cos k\omega_0 t, \sin k\omega_0 t\ (k = 1, \dots, N)$	$2N + 1$

Space	Standard basis	Dimension
solutions of an nth-order linear homogeneous ODE	any n independent solutions	n

Dimension

The definition of dimension rests on a counting theorem.

Exchange (replacement) lemma

If V is spanned by m vectors, then any linearly independent set in V has at most m vectors.

Proof sketch. Let $\mathbf{w}_1, \dots, \mathbf{w}_m$ span V and let $\mathbf{u}_1, \dots, \mathbf{u}_k$ be independent with $k > m$. Each $\mathbf{u}_j = \sum_i a_{ij}\mathbf{w}_i$, i.e. $[\mathbf{u}_1 \cdots \mathbf{u}_k] = [\mathbf{w}_1 \cdots \mathbf{w}_m]\mathbf{A}$ with $\mathbf{A}$ of size $m \times k$. Since $k > m$, the homogeneous system $\mathbf{A}\mathbf{c} = \mathbf{0}$ has a nonzero solution. Then $\sum_j c_j \mathbf{u}_j = [\mathbf{w}_1 \cdots \mathbf{w}_m]\mathbf{A}\mathbf{c} = \mathbf{0}$ — a nontrivial dependence among the $\mathbf{u}_j$, contradiction.

Invariance of dimension

All bases of a vector space V have the same number of elements. This number is the **dimension** $\dim V$. By convention $\dim\{\mathbf{0}\} = 0$. If no finite set spans V, V is **infinite-dimensional**.

Proof. If $\mathcal{B}_1$ has n_1 elements and $\mathcal{B}_2$ has n_2, apply the lemma both ways: $\mathcal{B}_2$ independent and $\mathcal{B}_1$ spanning gives $n_2 \le n_1$; the reverse gives $n_1 \le n_2$.

The function spaces $C[a,b]$ and $L^2(a,b)$ are infinite-dimensional: for every n the functions $1, t, \dots, t^n$ are independent in them, so no finite set can span. This is why a Fourier series needs infinitely many terms in general, and why "convergence" becomes an issue there (Ch. 15) that never arises in $\mathbb{R}^n$.

Consequences in an n-dimensional space

Let $\dim V = n$.

1. Any $n+1$ or more vectors are dependent; any $n-1$ or fewer cannot span.
2. Any n independent vectors form a basis; any n spanning vectors form a basis. (So for exactly n vectors, check *one* of the two conditions.)
3. Every independent set can be **extended** to a basis; every spanning set can be **pruned** to a basis.
4. If W is a subspace of V then $\dim W \le n$, with equality iff $W = V$.

Property 2 is a great labour-saver: three independent vectors in $\mathbb{R}^3$, such as $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$ of Worked Example 9.7(b), automatically form a basis.

For two subspaces U, W of a finite-dimensional space there is also a counting formula,

$$\dim(U + W) = \dim U + \dim W - \dim(U \cap W),$$

the linear-algebra analogue of $|A \cup B| = |A| + |B| - |A \cap B|$. For the two planes of Worked Example 9.6: $\dim(U+W) = 2 + 2 - 1 = 3$, so together they span $\mathbb{R}^3$.

Worked Example 9.10 — Basis and dimension of a plane

Find a basis and the dimension of $W = \{(x, y, z) : x + 2y - z = 0\}$.

The single equation has one pivot (x) and two free variables (y, z). Write $x = -2y + z$:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = y \begin{bmatrix} -2 \\ 1 \\ 0 \end{bmatrix} + z \begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}.$$

So $W = \operatorname{span}\{(-2,1,0)^{\mathsf T}, (1,0,1)^{\mathsf T}\}$. The two vectors are independent (look at the 2nd and 3rd components: each has a 1 where the other has a 0). Hence they form a basis and $\dim W = 2$.

General rule. The solution space of $\mathbf{A}\mathbf{x} = \mathbf{0}$ has dimension equal to the number of free variables, and the "special solutions" obtained by setting one free variable to 1 and the others to 0 form a basis.

Worked Example 9.11 — Coordinates in a non-standard polynomial basis

Show that $\mathcal{B} = \{1,\ 1+t,\ 1+t+t^2\}$ is a basis of $\mathcal{P}_2$ and find the coordinates of $p(t) = 3 + 2t - t^2$.

Basis. Three vectors in a 3-dimensional space: we only need independence. Their coefficient vectors relative to $\{1, t, t^2\}$ are the columns of an upper-triangular matrix with unit diagonal,

$$\mathbf{P} = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \det \mathbf{P} = 1 \neq 0.$$

Coordinates. Solve $a \cdot 1 + b(1+t) + c(1+t+t^2) = 3 + 2t - t^2$. Matching coefficients:

$$t^2:\ c = -1; \qquad t:\ b + c = 2 \Rightarrow b = 3; \qquad 1:\ a + b + c = 3 \Rightarrow a = 1.$$

So $[p]_{\mathcal{B}} = (1, 3, -1)^{\mathsf T}$. Check: $1 + 3(1+t) - (1+t+t^2) = 3 + 2t - t^2$ ✓.

Change of basis

Let $\mathcal{B} = \{\mathbf{b}_1, \dots, \mathbf{b}_n\}$ be a basis of $\mathbb{F}^n$ and $\mathbf{P}_{\mathcal{B}} = [\mathbf{b}_1 \ \cdots \ \mathbf{b}_n]$. The equation $\mathbf{x} = c_1\mathbf{b}_1 + \cdots + c_n\mathbf{b}_n$ reads

$$\mathbf{x} = \mathbf{P}_{\mathcal{B}}\,[\mathbf{x}]_{\mathcal{B}}, \qquad [\mathbf{x}]_{\mathcal{B}} = \mathbf{P}_{\mathcal{B}}^{-1}\mathbf{x}.$$

$\mathbf{P}_{\mathcal{B}}$ converts $\mathcal{B}$-coordinates to standard coordinates; its inverse goes the other way. Between two non-standard bases $\mathcal{B}$ and $\mathcal{C}$,

$$[\mathbf{x}]_{\mathcal{C}} = \mathbf{P}_{\mathcal{C}\leftarrow\mathcal{B}}[\mathbf{x}]_{\mathcal{B}}, \qquad \mathbf{P}_{\mathcal{C}\leftarrow\mathcal{B}} = \mathbf{P}_{\mathcal{C}}^{-1}\mathbf{P}_{\mathcal{B}},$$

whose jth column is $[\mathbf{b}_j]_{\mathcal{C}}$.

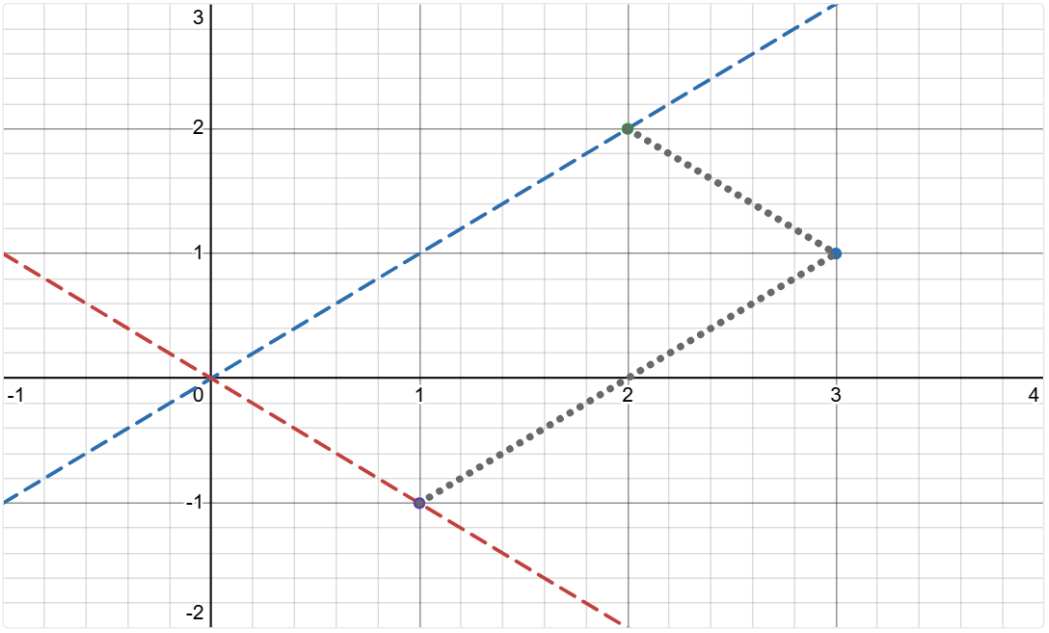
Worked Example 9.12 — Common-mode / differential-mode coordinates

Two-wire signals are often described not by the individual wire voltages (v_1, v_2) but by **common-mode** and **differential-mode** components. Use the basis $\mathbf{b}_1 = (1,1)^{\mathsf{T}}$ (common mode) and $\mathbf{b}_2 = (1,-1)^{\mathsf{T}}$ (differential mode). Find the coordinates of $\mathbf{v} = (3,1)^{\mathsf{T}}$ V.

$$\mathbf{P}_{\mathcal{B}} = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \qquad \mathbf{P}_{\mathcal{B}}^{-1} = \frac{1}{-2}\begin{bmatrix} -1 & -1 \\ -1 & 1 \end{bmatrix} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}.$$

$$[\mathbf{v}]_{\mathcal{B}} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}\begin{bmatrix} 3 \\ 1 \end{bmatrix} = \begin{bmatrix} 2 \\ 1 \end{bmatrix}.$$

So $\mathbf{v} = 2(1,1) + 1(1,-1)$: a common-mode level $v_{cm} = (v_1+v_2)/2 = 2$ V and a differential half-amplitude $(v_1 - v_2)/2 = 1$ V (the full differential voltage is $v_1 - v_2 = 2$ V). A differential amplifier with ideal common-mode rejection responds only to the second coordinate.



The vector $\mathbf{v} = (3,1)$ resolved along the common-mode axis (blue, $y = x$) and the differential-mode axis (red, $y = -x$): $\mathbf{v} = 2\mathbf{b}_1 + 1\mathbf{b}_2$; the dotted lines complete the parallelogram.

Worked Example 9.13 — Dimension of familiar spaces

(a) The 2×2 real symmetric matrices $\begin{bmatrix} a & b \\ b & d \end{bmatrix} = a\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} + b\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} + d\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$ form a space of dimension $\mathbf{3}$.

(b) $W_c = \{p \in \mathcal{P}_3 : p(1) = 0\}$ from Worked Example 9.4. By the factor theorem $p(t) = (t-1)q(t)$ with $q \in \mathcal{P}_2$, so a basis is $\{t-1,\ t(t-1),\ t^2(t-1)\}$ and $\dim W_c = 3 = \dim \mathcal{P}_3 - 1$: one linear constraint removes one dimension.

(c) Solutions of $y'' + 3y' + 2y = 0$: basis $\{e^{-t}, e^{-2t}\}$ (independent by the Wronskian $W = e^{-t}(-2e^{-2t}) - e^{-2t}(-e^{-t}) = -e^{-3t} \neq 0$), dimension $\mathbf{2}$ — matching the two initial conditions $y(0)$, $y'(0)$ a second-order circuit needs.

Common Pitfall — dimension is not the number of components

The plane $x + 2y - z = 0$ consists of vectors with three components, yet its dimension is 2. Dimension counts *degrees of freedom*, not entries. Likewise $\mathcal{P}_2$ has dimension 3 (three coefficients), not 2.

Engineering Note — counting unknowns in circuit analysis

For a connected circuit graph with n nodes and b branches, the space of KCL-compatible branch-current vectors has dimension $b - n + 1$ and the space of branch-voltage vectors that obey KVL has dimension $n - 1$. These are exactly the number of mesh (loop) currents and of node voltages (with one reference node) that mesh and nodal analysis use. Choosing "mesh currents" or "node voltages" is choosing a **basis** for one of these subspaces. Section 9.6 proves the counts with the rank–nullity theorem.

9.5 Linear transformations

Motivation

An amplifier, a filter, a differentiator, a sampler, a coordinate rotation, a Fourier transform — each takes an input from one vector space and produces an output in another, and each obeys **superposition**: the response to a weighted sum of inputs is the same weighted sum of responses. Mappings with this property are **linear transformations** (also called linear maps or linear operators). Superposition is the single most exploited property in electrical engineering: it lets us analyse a circuit one source at a time, decompose a signal into sinusoids and treat each separately, and represent the whole system by a matrix or a transfer function.

Definition

Linear transformation

Let V and W be vector spaces over the same field $\mathbb{F}$. A map $T : V \to W$ is **linear** if for all $\mathbf{u}, \mathbf{v} \in V$ and $c \in \mathbb{F}$

1. $T(\mathbf{u} + \mathbf{v}) = T(\mathbf{u}) + T(\mathbf{v})$ (additivity),
2. $T(c\mathbf{u}) = cT(\mathbf{u})$ (homogeneity).

Equivalently, $T(a\mathbf{u} + b\mathbf{v}) = aT(\mathbf{u}) + bT(\mathbf{v})$ — the **superposition principle**. V is the **domain**, W the **codomain**. A linear map $V \to V$ is often called a linear **operator** on V.

Immediate consequences:

$$T(\mathbf{0}) = \mathbf{0}, \qquad T\Big(\sum_{i} c_i \mathbf{v}_i\Big) = \sum_{i} c_i T(\mathbf{v}_i).$$

The first gives a one-line non-linearity test: **if $T(\mathbf{0}) \neq \mathbf{0}$, T is not linear.** The second says a linear map is completely determined by what it does to a basis: if $\{\mathbf{b}_j\}$ is a basis of V and we know $T(\mathbf{b}_j)$ for each j, we know T everywhere.

Examples and non-examples

Map	Linear?	Reason
$T(\mathbf{x}) = \mathbf{A}\mathbf{x}$, $\mathbf{A} \in \mathbb{F}^{m\times n}$	yes	matrix algebra
rotation of $\mathbb{R}^2$ by angle θ	yes	the rotated parallelogram of $\mathbf{u}, \mathbf{v}$ is the parallelogram of the rotated vectors
$D : \mathcal{P}_n \to \mathcal{P}_{n-1}$, $D(p) = p'$	yes	$(ap + bq)' = ap' + bq'$
$J : C[0,T] \to C[0,T]$, $J(f)(t) = \int_0^t f(\tau)\,d\tau$	yes	linearity of the integral
time shift $(S_\tau x)(t) = x(t - \tau)$	yes	shifts commute with sums
convolution with a fixed h: $x \mapsto h * x$	yes	integral of a linear expression
evaluation $x \mapsto x(t_0)$, sampling $x \mapsto (x(0), x(T_s), \dots)$	yes	pointwise operations
$T(x) = ax + b$ with $b \neq 0$ ("linear" in school algebra)	**no**	$T(0) = b \neq 0$; it is **affine**
squaring $v \mapsto v^2$, rectifier $v \mapsto \lvert v\rvert$, clipper	**no**	$(2v)^2 \neq 2v^2$
$\mathbf{x} \mapsto \lVert\mathbf{x}\rVert$	**no**	$\lVert -\mathbf{x}\rVert \neq -\lVert\mathbf{x}\rVert$
complex conjugation $z \mapsto z^*$ on $\mathbb{C}$ as a *complex* space	**no**	$(jz)^* = -jz^* \neq jz^*$ (but it is linear on $\mathbb{C}$ viewed as the real space $\mathbb{R}^2$)

Worked Example 9.14 — Testing linearity

(a) $T : \mathbb{R}^2 \to \mathbb{R}^2$, $T(x, y) = (x + 2y,\ 3x)$. Write $T(\mathbf{x}) = \begin{bmatrix} 1 & 2 \\ 3 & 0 \end{bmatrix}\mathbf{x}$: linear.

(b) $T(x, y) = (x + 1,\ y)$. $T(0, 0) = (1, 0) \neq \mathbf{0}$: **not linear**.

(c) $T(x, y) = (xy,\ x)$. $T(2(1, 1)) = T(2, 2) = (4, 2)$ but $2T(1, 1) = (2, 2)$: **not linear**.

(d) The RC low-pass filter initially at rest, $RC\,\dot{y} + y = x$, $y(0) = 0$, defines $y = T(x)$ with

$$y(t) = \frac{1}{RC}\int_0^t e^{-(t-\tau)/RC}\,x(\tau)\,d\tau.$$

For inputs x_1, x_2 and scalars a, b, the integral of $ax_1 + bx_2$ splits into a times the first integral plus b times the second: $T(ax_1 + bx_2) = aT(x_1) + bT(x_2)$. **Linear.**

(e) The same filter with a nonzero initial voltage $y(0) = V_0$: now $T(0) = V_0 e^{-t/RC} \neq 0$. **Not linear** in the strict sense — it is affine (zero-input response plus a linear zero-state response). This is why "linear system" in circuit theory always means *zero initial state* when superposition is invoked.

The matrix of a linear map

Every linear map $\mathbb{F}^n \to \mathbb{F}^m$ is a matrix

If $T : \mathbb{F}^n \to \mathbb{F}^m$ is linear, then $T(\mathbf{x}) = \mathbf{A}\mathbf{x}$ for the unique $m \times n$ matrix

$$\mathbf{A} = \begin{bmatrix} T(\mathbf{e}_1) & T(\mathbf{e}_2) & \cdots & T(\mathbf{e}_n) \end{bmatrix},$$

called the **standard matrix** of T.

Proof. $\mathbf{x} = \sum_j x_j \mathbf{e}_j$, so $T(\mathbf{x}) = \sum_j x_j T(\mathbf{e}_j)$, which is the matrix–vector product of $[T(\mathbf{e}_1) \cdots T(\mathbf{e}_n)]$ with $\mathbf{x}$.

Recipe: *the jth column of the matrix is the image of the jth basis vector.*

More generally, for $T : V \to W$ with bases $\mathcal{B} = \{\mathbf{b}_1, \dots, \mathbf{b}_n\}$ of V and $\mathcal{C}$ of W, the **matrix of T relative to $\mathcal{B}$ and $\mathcal{C}$** is

$$[T]_{\mathcal{C} \leftarrow \mathcal{B}} = \begin{bmatrix} [T(\mathbf{b}_1)]_{\mathcal{C}} & \cdots & [T(\mathbf{b}_n)]_{\mathcal{C}} \end{bmatrix}, \qquad [T(\mathbf{v})]_{\mathcal{C}} = [T]_{\mathcal{C} \leftarrow \mathcal{B}} \, [\mathbf{v}]_{\mathcal{B}}.$$

So *any* linear map between finite-dimensional spaces — differentiation of polynomials, a filter acting on a finite set of sinusoids — becomes a matrix once bases are chosen.

Worked Example 9.15 — Rotation and projection in the plane

(a) **Rotation by θ.** $\mathbf{e}_1 = (1, 0)$ rotates to $(\cos\theta, \sin\theta)$ and $\mathbf{e}_2 = (0, 1)$ to $(-\sin\theta, \cos\theta)$, so

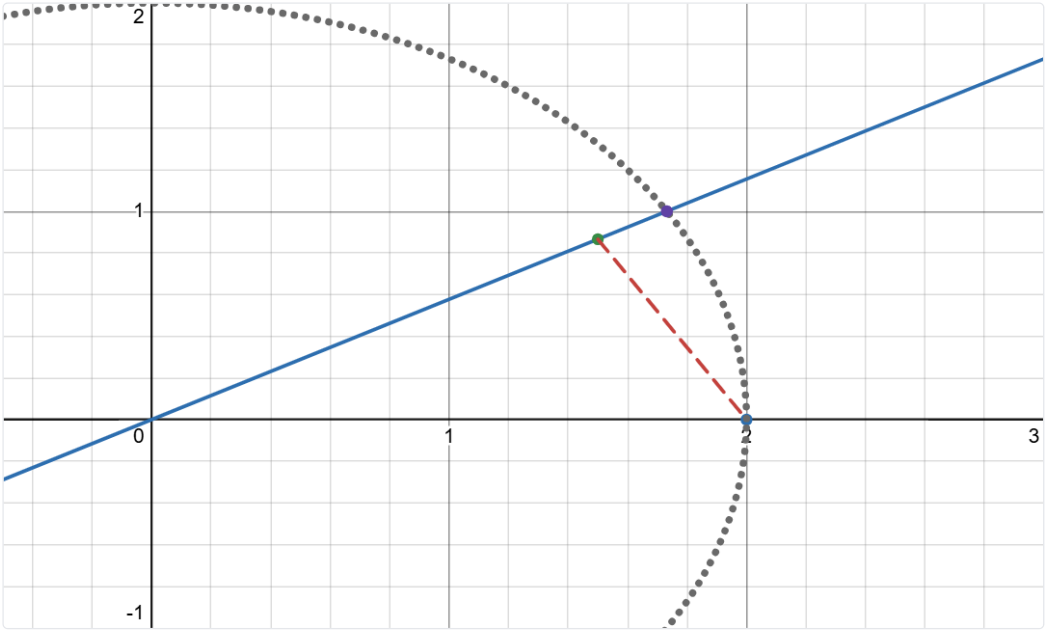
$$\mathbf{R}_\theta = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}.$$

This is the matrix form of multiplying a phasor by $e^{j\theta}$: $(x + jy)e^{j\theta} = (x\cos\theta - y\sin\theta) + j(x\sin\theta + y\cos\theta)$.

(b) **Orthogonal projection onto the line at angle θ** through the origin, with unit direction $\hat{\mathbf{u}} = (\cos\theta, \sin\theta)$. Section 9.9 shows $P(\mathbf{x}) = (\hat{\mathbf{u}} \cdot \mathbf{x})\hat{\mathbf{u}}$. Images of the basis vectors: $P(\mathbf{e}_1) = \cos\theta\,\hat{\mathbf{u}}$, $P(\mathbf{e}_2) = \sin\theta\,\hat{\mathbf{u}}$, so

$$\mathbf{P}_\theta = \begin{bmatrix} \cos^2\theta & \cos\theta\sin\theta \\ \cos\theta\sin\theta & \sin^2\theta \end{bmatrix}.$$

For $\theta = 30^\circ$: $\mathbf{P} = \begin{bmatrix} 3/4 & \sqrt{3}/4 \\ \sqrt{3}/4 & 1/4 \end{bmatrix}$ and $\mathbf{P}(2, 0)^{\mathsf{T}} = (1.5,\ 0.866)^{\mathsf{T}}$. Check: this point lies on $y = x\tan 30^\circ = 0.5774x$ ($1.5 \times 0.5774 = 0.866$ ✓), and the residual $(0.5, -0.866)$ is perpendicular to $\hat{\mathbf{u}}$: $0.5 \cdot 0.866 - 0.866 \cdot 0.5 = 0$ ✓.



The vector $\mathbf{x} = (2, 0)$, its rotation by 30° (on the dotted circle of radius 2) and its orthogonal projection onto the 30° line; the dashed segment is perpendicular to the line.

Worked Example 9.16 — The differentiation matrix

Find the matrix of $D : \mathcal{P}_3 \to \mathcal{P}_2$, $D(p) = p'$, relative to the monomial bases $\{1, t, t^2, t^3\}$ and $\{1, t, t^2\}$, and use it to differentiate $p(t) = 2 - t + 4t^2 + t^3$.

Images of the basis vectors: $D(1) = 0$, $D(t) = 1$, $D(t^2) = 2t$, $D(t^3) = 3t^2$. In coordinates these are $(0,0,0)$, $(1,0,0)$, $(0,2,0)$, $(0,0,3)$, so

$$[D] = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 3 \end{bmatrix}.$$

With $[p] = (2, -1, 4, 1)^{\mathsf{T}}$:

$$[D][p] = \begin{bmatrix} 0\cdot 2 + 1\cdot(-1) \\ 2 \cdot 4 \\ 3 \cdot 1 \end{bmatrix} = \begin{bmatrix} -1 \\ 8 \\ 3 \end{bmatrix} \Rightarrow\ p'(t) = -1 + 8t + 3t^2.$$

Direct check: $\frac{d}{dt}(2 - t + 4t^2 + t^3) = -1 + 8t + 3t^2$ ✓. The matrix has a zero first column: constants are sent to zero, which is the null space of D (Section 9.6).

Composition, inverses and isomorphism

If $S : U \to V$ and $T : V \to W$ are linear, so is the composition $T \circ S$, and in coordinates

$$[T \circ S] = [T]\,[S].$$

Matrix multiplication is *defined* so that this holds — it is the reason the row-times-column rule looks the way it does. A cascade of linear stages (pre-amplifier, filter, ADC) is represented by the product of their matrices, applied **right to left**.

A linear map $T : V \to W$ is

- **one-to-one** (injective) if $T(\mathbf{u}) = T(\mathbf{v}) \Rightarrow \mathbf{u} = \mathbf{v}$;
- **onto** (surjective) if every $\mathbf{w} \in W$ equals $T(\mathbf{v})$ for some $\mathbf{v}$;
- an **isomorphism** if it is both; then T^{-1} exists and is linear.

Coordinates are an isomorphism

If $\dim V = n$ and $\mathcal{B}$ is a basis, the coordinate map $\mathbf{v} \mapsto [\mathbf{v}]_{\mathcal{B}}$ is an isomorphism $V \to \mathbb{F}^n$. Consequently any two vector spaces of the same finite dimension over the same field are isomorphic.

This theorem is what licenses replacing $\mathcal{P}_2$ by $\mathbb{R}^3$, sinusoids at ω by $\mathbb{R}^2$ (or by phasors in $\mathbb{C}$), and so on: every finite-dimensional calculation can be done with columns of numbers.

Change of basis for a linear operator

Let $T : \mathbb{F}^n \to \mathbb{F}^n$ have standard matrix $\mathbf{A}$, and let $\mathcal{B}$ be another basis with $\mathbf{P} = \mathbf{P}_{\mathcal{B}}$. Since $\mathbf{x} = \mathbf{P}[\mathbf{x}]_{\mathcal{B}}$,

$$[T(\mathbf{x})]_{\mathcal{B}} = \mathbf{P}^{-1}\mathbf{A}\mathbf{x} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}\,[\mathbf{x}]_{\mathcal{B}} \quad\Longrightarrow\quad [T]_{\mathcal{B}} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}.$$

Matrices related by $\mathbf{B} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ are **similar**: they represent the *same* operator in different coordinates, so they share every basis-independent property — determinant, trace, rank and (Chapter 10) eigenvalues.

Worked Example 9.17 — A basis that makes an operator simple

Let $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 0 & 2 \end{bmatrix}$ and $\mathcal{B} = \{(1,0)^{\mathsf{T}}, (1,1)^{\mathsf{T}}\}$. Find $[T]_{\mathcal{B}}$.

$$\mathbf{P} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{P}^{-1} = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{A}\mathbf{P} = \begin{bmatrix} 1 & 2 \\ 0 & 2 \end{bmatrix},$$

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 2 \\ 0 & 2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}.$$

In the new basis the operator simply scales the first coordinate by 1 and the second by 2: $\mathbf{A}(1,0) = (1,0)$ and $\mathbf{A}(1,1) = (2,2)$. These special basis vectors are **eigenvectors**; finding them systematically is the subject of Ch. 10. Check invariants: $\det \mathbf{A} = 2 = \det \operatorname{diag}(1,2)$ and $\operatorname{tr}\mathbf{A} = 3 = 1 + 2$ ✓.

Common Pitfall — "linear" versus "affine"

The straight-line function $y = mx + c$ is called linear in school algebra and in device data sheets, but with $c \neq 0$ it is **affine**, not linear: doubling the input does not double the output. A biased transistor stage is affine about its operating point; small-signal analysis subtracts the operating point so that the remaining map *is* linear. Always remove offsets (DC bias, initial conditions) before invoking superposition.

Engineering Note — LTI systems are linear operators on signal spaces

A linear time-invariant (LTI) system is a linear operator T on a signal space that commutes with every time shift: $T \circ S_\tau = S_\tau \circ T$. One can show that every such operator is a convolution $y = h * x$ with its impulse response h. Complex exponentials $e^{j\omega t}$ satisfy $T(e^{j\omega t}) = H(j\omega)e^{j\omega t}$ — they are the "eigenvectors" of every LTI operator, the infinite-dimensional analogue of Worked Example 9.17. Expanding inputs in that basis is exactly Fourier analysis (Ch. 15, Ch. 16).

9.6 Null space and column space

Motivation

For a linear map $T(\mathbf{x}) = \mathbf{A}\mathbf{x}$ two questions dominate:

1. **Existence:** for which outputs $\mathbf{b}$ does $\mathbf{A}\mathbf{x} = \mathbf{b}$ have a solution?
2. **Uniqueness:** if a solution exists, how much freedom is left in it?

The answer to the first is a subspace of the output space, the **column space**; the answer to the second is a subspace of the input space, the **null space**. Their dimensions are tied together by the **rank–nullity theorem**, which in circuit theory counts independent node voltages and loop currents, in control theory counts uncontrollable modes, and in signal processing counts the components of a signal a measurement system cannot see.

Definitions

The four fundamental subspaces

For $\mathbf{A} \in \mathbb{R}^{m\times n}$:

- **Null space (kernel):** $\operatorname{null}(\mathbf{A}) = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{A}\mathbf{x} = \mathbf{0}\} \subseteq \mathbb{R}^n$.
- **Column space (range):** $\operatorname{col}(\mathbf{A}) = \{\mathbf{A}\mathbf{x} : \mathbf{x} \in \mathbb{R}^n\} = \operatorname{span}\{\text{columns of } \mathbf{A}\} \subseteq \mathbb{R}^m$.
- **Row space:** $\operatorname{row}(\mathbf{A}) = \operatorname{col}(\mathbf{A}^{\mathsf{T}}) \subseteq \mathbb{R}^n$.
- **Left null space:** $\operatorname{null}(\mathbf{A}^{\mathsf{T}}) = \{\mathbf{y} \in \mathbb{R}^m : \mathbf{A}^{\mathsf{T}}\mathbf{y} = \mathbf{0}\} \subseteq \mathbb{R}^m$.

For a general linear map $T : V \to W$, $\ker T = \{\mathbf{v} : T(\mathbf{v}) = \mathbf{0}\}$ and $\operatorname{range} T = \{T(\mathbf{v})\}$. The dimension of the column space is the **rank** r; the dimension of the null space is the **nullity**. (Over $\mathbb{C}$ replace T by H.)

Both are subspaces: $\mathbf{A}\mathbf{0} = \mathbf{0}$; if $\mathbf{A}\mathbf{x} = \mathbf{A}\mathbf{y} = \mathbf{0}$ then $\mathbf{A}(a\mathbf{x} + b\mathbf{y}) = \mathbf{0}$; and a span is always a subspace.

The column space viewpoint comes from reading $\mathbf{A}\mathbf{x}$ **column by column**:

$$\mathbf{A}\mathbf{x} = x_1\mathbf{a}_1 + x_2\mathbf{a}_2 + \cdots + x_n\mathbf{a}_n.$$

So $\mathbf{A}\mathbf{x} = \mathbf{b}$ asks: *which combination of the columns produces* $\mathbf{b}$*?*

Existence and structure of solutions

1. $\mathbf{A}\mathbf{x} = \mathbf{b}$ is solvable iff $\mathbf{b} \in \operatorname{col}(\mathbf{A})$.
2. If $\mathbf{x}_p$ is one solution, the complete solution set is
$$\{\mathbf{x}_p + \mathbf{x}_n : \ \mathbf{x}_n \in \operatorname{null}(\mathbf{A})\}.$$
3. The solution is unique iff $\operatorname{null}(\mathbf{A}) = \{\mathbf{0}\}$, i.e. iff the columns of $\mathbf{A}$ are independent. More generally, T is one-to-one iff $\ker T = \{\mathbf{0}\}$.

Proof of 2. If $\mathbf{A}\mathbf{x} = \mathbf{b}$ then $\mathbf{A}(\mathbf{x} - \mathbf{x}_p) = \mathbf{b} - \mathbf{b} = \mathbf{0}$, so $\mathbf{x} - \mathbf{x}_p \in \operatorname{null}(\mathbf{A})$; conversely $\mathbf{A}(\mathbf{x}_p + \mathbf{x}_n) = \mathbf{b} + \mathbf{0}$.

This is the same "particular plus homogeneous" structure as the solution of a linear ODE (Worked Example 9.2): the null space of the operator $L = D^2 + 3D + 2$ is the space of natural responses, and any forced response is one particular solution plus an element of that null space.

Computing bases

All four subspaces are read off from the reduced row echelon form $\mathbf{R} = \operatorname{rref}(\mathbf{A})$ (Ch. 8).

Subspace	Basis	Dimension
$\operatorname{col}(\mathbf{A})$	the **pivot columns of the original** $\mathbf{A}$	r
$\operatorname{row}(\mathbf{A})$	the nonzero rows of $\mathbf{R}$	r
$\operatorname{null}(\mathbf{A})$	special solutions: one per free variable	$n - r$
$\operatorname{null}(\mathbf{A}^{\mathsf{T}})$	null space of $\mathbf{A}^{\mathsf{T}}$ (or last $m - r$ rows of $\mathbf{E}$ where $\mathbf{E}\mathbf{A} = \mathbf{R}$)	$m - r$

Why the pivot columns of $\mathbf{A}$ (not of $\mathbf{R}$)? Row operations change the column space, but they do **not** change linear relations among the columns, because $\mathbf{A}\mathbf{x} = \mathbf{0} \iff \mathbf{R}\mathbf{x} = \mathbf{0}$. In $\mathbf{R}$ the pivot columns are obviously independent and every other column is a combination of them; the same relations hold among the columns of $\mathbf{A}$.

Row operations replace rows by combinations of rows, so the row space *is* unchanged, and the nonzero rows of $\mathbf{R}$ are independent (each has a leading 1 where the others have 0).

Rank–nullity

Rank–nullity theorem

For $\mathbf{A} \in \mathbb{F}^{m \times n}$ (or a linear map $T : V \to W$ with $\dim V = n$),

$$\operatorname{rank}(\mathbf{A}) + \dim \operatorname{null}(\mathbf{A}) = n \quad \text{(number of columns)}.$$

Moreover $\dim \operatorname{row}(\mathbf{A}) = \dim \operatorname{col}(\mathbf{A}) = r$ ("row rank equals column rank"), and $\dim \operatorname{null}(\mathbf{A}^{\mathsf{T}}) = m - r$.

Proof (matrix form). Every column of $\mathbf{R}$ is either a pivot column (r of them) or a free column. The null space has one special solution per free column, and these are independent (each has a 1 in its own free position and 0 in the other free positions), so the nullity is $n - r$. The column space has the r pivot columns as basis. The row space has the r nonzero rows as basis. Applying the result to $\mathbf{A}^{\mathsf{T}}$ (n rows, m columns, rank r) gives $\dim \operatorname{null}(\mathbf{A}^{\mathsf{T}}) = m - r$.

Proof (abstract form). Choose a basis $\mathbf{k}_1, \dots, \mathbf{k}_q$ of $\ker T$ and extend it to a basis $\mathbf{k}_1, \dots, \mathbf{k}_q, \mathbf{v}_1, \dots, \mathbf{v}_s$ of V, so $q + s = n$. Then $T(\mathbf{v}_1), \dots, T(\mathbf{v}_s)$ span the range (the $T(\mathbf{k}_i)$ are zero) and are independent (a relation $\sum c_i T(\mathbf{v}_i) = \mathbf{0}$ puts $\sum c_i \mathbf{v}_i$ in the kernel, which forces all $c_i = 0$ by independence of the full basis). So $\dim \operatorname{range} T = s = n - q$.

In words: **each input dimension either survives to the output or is lost in the null space.** The map cannot create dimensions.

Worked Example 9.18 — All four subspaces of a 3×4 matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 1 & 0 \\ 2 & 4 & 0 & 2 \\ 3 & 6 & 1 & 2 \end{bmatrix}.$$

Row-reduce. $R_2 - 2R_1$, $R_3 - 3R_1$ give rows $(0, 0, -2, 2)$ and $(0, 0, -2, 2)$; then $R_3 - R_2$ kills row 3; scale row 2 by $-\frac{1}{2}$ and clear above:

$$\mathbf{R} = \begin{bmatrix} 1 & 2 & 0 & 1 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

Pivots in columns 1 and 3, so $r = 2$; free variables x_2, x_4.

Column space (pivot columns of $\mathbf{A}$): $\{(1, 2, 3)^{\mathsf{T}}, (1, 0, 1)^{\mathsf{T}}\}$, dimension 2 — a plane in $\mathbb{R}^3$.

Row space: $\{(1, 2, 0, 1), (0, 0, 1, -1)\}$, dimension 2.

Null space. From $\mathbf{R}$: $x_1 = -2x_2 - x_4$, $x_3 = x_4$. Special solutions:

$$x_2 = 1, x_4 = 0 : \ \mathbf{n}_1 = (-2, 1, 0, 0)^{\mathsf{T}}; \qquad x_2 = 0, x_4 = 1 : \ \mathbf{n}_2 = (-1, 0, 1, 1)^{\mathsf{T}}.$$

Dimension $2 = n - r = 4 - 2$ ✓. Check: $\mathbf{A}\mathbf{n}_2 = (-1 + 1, \ -2 + 2, \ -3 + 1 + 2) = \mathbf{0}$ ✓.

Left null space. Solve $\mathbf{A}^{\mathsf{T}}\mathbf{y} = \mathbf{0}$; one finds $\mathbf{y} = (-1, -1, 1)^{\mathsf{T}}$ (row 3 = row 1 + row 2). Dimension $1 = m - r = 3 - 2$ ✓.

Solvability. $\mathbf{A}\mathbf{x} = \mathbf{b}$ is solvable iff $\mathbf{b} \in \operatorname{col}(\mathbf{A})$, which here is equivalent to $\mathbf{y}^{\mathsf{T}}\mathbf{b} = 0$, i.e. $b_3 = b_1 + b_2$. For $\mathbf{b} = (2, 2, 4)^{\mathsf{T}}$: $4 = 2 + 2$ ✓. Reducing $[\mathbf{A} \mid \mathbf{b}]$ gives $x_1 + 2x_2 + x_4 = 1$, $x_3 - x_4 = 1$; with the free variables zero, $\mathbf{x}_p = (1, 0, 1, 0)^{\mathsf{T}}$ (check: $\mathbf{A}\mathbf{x}_p = (2, 2, 4)^{\mathsf{T}}$ ✓). Complete solution:

$$\mathbf{x} = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} + s \begin{bmatrix} -2 \\ 1 \\ 0 \\ 0 \end{bmatrix} + t \begin{bmatrix} -1 \\ 0 \\ 1 \\ 1 \end{bmatrix}, \qquad s, t \in \mathbb{R}.$$

For $\mathbf{b} = (1, 1, 1)^{\mathsf{T}}$: $1 \neq 1 + 1$, no solution — $\mathbf{b}$ lies off the column-space plane. Section 9.11 finds the best approximate solution.

The left null space acts as a set of **consistency checks** on the right-hand side: $\mathbf{A}\mathbf{x} = \mathbf{b}$ is solvable iff $\mathbf{y}^{\mathsf{T}}\mathbf{b} = 0$ for every $\mathbf{y} \in \operatorname{null}(\mathbf{A}^{\mathsf{T}})$. (Proof: $\mathbf{y}^{\mathsf{T}}\mathbf{A}\mathbf{x} = (\mathbf{A}^{\mathsf{T}}\mathbf{y})^{\mathsf{T}}\mathbf{x} = 0$ for every $\mathbf{x}$, so every $\mathbf{b}$ in the column space is orthogonal to the left null space; Section 9.7 shows the converse.)

Worked Example 9.19 — The incidence matrix of a circuit graph

A circuit has 4 nodes and 5 branches: $1\colon\ 1 \to 2$, $2\colon\ 2 \to 3$, $3\colon\ 3 \to 1$, $4\colon\ 3 \to 4$, $5\colon\ 4 \to 1$. The **node–branch incidence matrix** $\mathbf{A}$ (4×5) has $a_{kb} = +1$ if branch b leaves node k, -1 if it enters, 0 otherwise:

$$\mathbf{A} = \begin{bmatrix} 1 & 0 & -1 & 0 & -1 \\ -1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 1 & 0 \\ 0 & 0 & 0 & -1 & 1 \end{bmatrix}.$$

KCL says $\mathbf{A}\mathbf{i} = \mathbf{0}$ for the branch-current vector $\mathbf{i}$: allowed currents form $\operatorname{null}(\mathbf{A})$.

Rank. Every column has one $+1$ and one -1, so the four rows sum to zero: $\mathbf{y} = (1,1,1,1)^{\mathsf{T}}$ is in the left null space and $r \le 3$. Deleting the reference node (row 4) leaves three independent rows, so $r = 3 = n - 1$.

Null space. Dimension $b - r = 5 - 3 = 2$: two independent loop currents. A basis:

$$\boldsymbol{\ell}_1 = (1,1,1,0,0)^{\mathsf{T}} \text{ (loop } 1 \to 2 \to 3 \to 1), \qquad \boldsymbol{\ell}_2 = (1,1,0,1,1)^{\mathsf{T}} \text{ (loop } 1 \to 2 \to 3 \to 4 \to 1).$$

Check $\mathbf{A}\boldsymbol{\ell}_2$: row 1: $1 - 0 - 1 = 0$; row 2: $-1 + 1 = 0$; row 3: $-1 + 1 = 0$; row 4: $-1 + 1 = 0$ ✓.

Interpretation. Every KCL-compatible current distribution is $\mathbf{i} = I_1\boldsymbol{\ell}_1 + I_2\boldsymbol{\ell}_2$ — mesh analysis needs exactly $b - n + 1 = 2$ unknowns. Dually, branch voltages derived from node potentials, $\mathbf{v} = \mathbf{A}^{\mathsf{T}}\mathbf{e}$, fill $\operatorname{row}(\mathbf{A})$ of dimension $n - 1 = 3$, and the node potentials are determined only up to the left-null-space vector $(1,1,1,1)$ — a common offset, removed by grounding one node.

Worked Example 9.20 — Kernel and range of differentiation

For $D : \mathcal{P}_3 \to \mathcal{P}_2$ (Worked Example 9.16): $\ker D = \{\text{constants}\} = \operatorname{span}\{1\}$, nullity 1. Every $q \in \mathcal{P}_2$ is the derivative of some cubic (integrate it), so range $D = \mathcal{P}_2$, rank 3. Rank–nullity: $3 + 1 = 4 = \dim \mathcal{P}_3$ ✓. The matrix $[D]$ of Worked Example 9.16 shows the same thing: three pivots, one free (first) column. The "constant of integration" of calculus is precisely the freedom given by the null space.

The invertible matrix theorem (vector-space form)

For a square $\mathbf{A} \in \mathbb{F}^{n \times n}$ the following are equivalent: $\mathbf{A}$ is invertible; $\operatorname{rank}\mathbf{A} = n$; $\operatorname{null}(\mathbf{A}) = \{\mathbf{0}\}$; $\operatorname{col}(\mathbf{A}) = \mathbb{F}^n$; the columns form a basis of $\mathbb{F}^n$; the rows form a basis; $\det\mathbf{A} \neq 0$; $\mathbf{A}\mathbf{x} = \mathbf{b}$ has exactly one solution for every $\mathbf{b}$; $T(\mathbf{x}) = \mathbf{A}\mathbf{x}$ is one-to-one; T is onto.

For a square matrix, one-to-one and onto are *equivalent* — a direct consequence of rank–nullity ($r = n \iff n - r = 0$). For rectangular matrices they are not: a tall matrix ($m > n$) can be one-to-one but never onto; a wide matrix ($m < n$) can be onto but never one-to-one.

Common Pitfall — reading the column space from the wrong matrix

The pivot columns of $\mathbf{R} = \operatorname{rref}(\mathbf{A})$ are standard unit vectors such as $(1,0,0)^{\mathsf{T}}$ and $(0,1,0)^{\mathsf{T}}$; they span a *different* plane from $\operatorname{col}(\mathbf{A})$ in general. Use the pivot **positions** from $\mathbf{R}$ but take the **columns** from $\mathbf{A}$. (For the row space it is the other way round: the rows of $\mathbf{R}$ are fine.)

Engineering Note — what a measurement cannot see

If a sensor array produces readings $\mathbf{y} = \mathbf{H}\mathbf{x}$ of an unknown source vector $\mathbf{x}$, any component of $\mathbf{x}$ in $\operatorname{null}(\mathbf{H})$ is invisible: adding it changes nothing in $\mathbf{y}$. In tomography, phased arrays and state estimation (observability in control), the first design question is therefore "what is the null space of the measurement matrix?" A wide $\mathbf{H}$ (fewer measurements than unknowns) always has a nontrivial null space, so extra assumptions — minimum norm, sparsity, smoothness — are needed to choose among the infinitely many consistent $\mathbf{x}$.

9.7 Orthogonality

Motivation

So far nothing has been said about lengths or angles; a vector space is pure algebra. Yet the most useful bases in engineering are **orthogonal** ones: the $\hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$ axes of field theory, the in-phase and quadrature carriers $\cos\omega_c t$ and $\sin\omega_c t$ of a modulator, the harmonics of a Fourier series, the subcarriers of OFDM. With an orthogonal basis, coordinates are found by a single dot product each instead of by solving a linear system, energy splits into a sum of independent parts (Pythagoras), and signals sent along orthogonal directions do not interfere. This section develops orthogonality in $\mathbb{R}^n$ with the ordinary dot product; Section 9.8 generalises it to complex vectors and to functions.

Dot product, length and angle

Dot product, norm, distance

For $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$,

$$\mathbf{x} \cdot \mathbf{y} = \mathbf{x}^{\mathsf{T}}\mathbf{y} = \sum_{k=1}^{n} x_k y_k, \qquad \|\mathbf{x}\| = \sqrt{\mathbf{x} \cdot \mathbf{x}}, \qquad d(\mathbf{x},\mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|.$$

A **unit vector** has $\|\mathbf{x}\| = 1$; **normalising** $\mathbf{x} \neq \mathbf{0}$ means forming $\hat{\mathbf{x}} = \mathbf{x}/\|\mathbf{x}\|$.

Cauchy–Schwarz inequality

$$|\mathbf{x}\cdot\mathbf{y}| \le \|\mathbf{x}\|\,\|\mathbf{y}\|,$$

with equality iff $\mathbf{x}$ and $\mathbf{y}$ are parallel (one is a scalar multiple of the other).

Proof. If $\mathbf{y}=\mathbf{0}$ both sides vanish. Otherwise, for every real s,

$$0 \le \|\mathbf{x}-s\mathbf{y}\|^2 = \|\mathbf{x}\|^2 - 2s\,\mathbf{x}\cdot\mathbf{y} + s^2\|\mathbf{y}\|^2.$$

Choose the minimising value $s=\mathbf{x}\cdot\mathbf{y}/\|\mathbf{y}\|^2$: $0 \le \|\mathbf{x}\|^2 - (\mathbf{x}\cdot\mathbf{y})^2/\|\mathbf{y}\|^2$, which rearranges to the inequality. Equality means $\mathbf{x}-s\mathbf{y}=\mathbf{0}$.

The proof is worth remembering, because the same "minimise $\|\mathbf{x}-s\mathbf{y}\|^2$" step is a projection (Section 9.9) and it works verbatim in any inner-product space.

Cauchy–Schwarz guarantees $-1 \le \dfrac{\mathbf{x}\cdot\mathbf{y}}{\|\mathbf{x}\|\|\mathbf{y}\|} \le 1$, so the **angle** between nonzero vectors can be *defined* in any dimension by

$$\cos\theta = \frac{\mathbf{x}\cdot\mathbf{y}}{\|\mathbf{x}\|\,\|\mathbf{y}\|}, \qquad 0 \le \theta \le \pi.$$

It also gives the **triangle inequality** $\|\mathbf{x}+\mathbf{y}\| \le \|\mathbf{x}\| + \|\mathbf{y}\|$: expand $\|\mathbf{x}+\mathbf{y}\|^2 = \|\mathbf{x}\|^2 + 2\mathbf{x}\cdot\mathbf{y} + \|\mathbf{y}\|^2 \le (\|\mathbf{x}\|+\|\mathbf{y}\|)^2$.

Orthogonal vectors and sets

Orthogonality

$\mathbf{x}$ and $\mathbf{y}$ are **orthogonal**, $\mathbf{x}\perp\mathbf{y}$, if $\mathbf{x}\cdot\mathbf{y}=0$. A set $\{\mathbf{u}_1,\dots,\mathbf{u}_k\}$ is **orthogonal** if $\mathbf{u}_i\cdot\mathbf{u}_j=0$ for all $i\neq j$, and **orthonormal** if in addition every $\|\mathbf{u}_i\|=1$, i.e. $\mathbf{u}_i\cdot\mathbf{u}_j=\delta_{ij}$.

Pythagoras

$\mathbf{x}\perp\mathbf{y} \iff \|\mathbf{x}+\mathbf{y}\|^2 = \|\mathbf{x}\|^2+\|\mathbf{y}\|^2$. For an orthogonal set, $\left\|\sum_i \mathbf{u}_i\right\|^2 = \sum_i \|\mathbf{u}_i\|^2$.

Orthogonal sets are independent

An orthogonal set of nonzero vectors is linearly independent.

Proof. Take the dot product of $\sum_i c_i\mathbf{u}_i=\mathbf{0}$ with $\mathbf{u}_j$: all cross terms vanish, leaving $c_j\|\mathbf{u}_j\|^2=0$, so $c_j=0$.

Hence n mutually orthogonal nonzero vectors in $\mathbb{R}^n$ are automatically a basis. Their real advantage is how easy coordinates become:

Coordinates in an orthogonal basis

If $\{\mathbf{u}_1,\dots,\mathbf{u}_n\}$ is an orthogonal basis then

$$\mathbf{x} = \sum_{j=1}^{n} \frac{\mathbf{x}\cdot\mathbf{u}_j}{\mathbf{u}_j\cdot\mathbf{u}_j}\,\mathbf{u}_j,$$

and if it is orthonormal, $\mathbf{x}=\sum_j (\mathbf{x}\cdot\mathbf{u}_j)\,\mathbf{u}_j$ and $\|\mathbf{x}\|^2=\sum_j(\mathbf{x}\cdot\mathbf{u}_j)^2$ (Parseval).

Proof. Write $\mathbf{x}=\sum c_i\mathbf{u}_i$ and dot with $\mathbf{u}_j$: $\mathbf{x}\cdot\mathbf{u}_j = c_j\,\mathbf{u}_j\cdot\mathbf{u}_j$.

Compare: in a general basis we must solve an $n\times n$ system; in an orthogonal basis each coordinate is computed independently. This is *exactly* the structure of the Fourier coefficient formulas of Ch. 15, where the dot product becomes an integral.

Worked Example 9.21 — Lengths and angles

Find the angle between $\mathbf{x}=(1,2,2)^{\mathsf T}$ and $\mathbf{y}=(2,0,1)^{\mathsf T}$ and verify Cauchy–Schwarz.

$\mathbf{x}\cdot\mathbf{y} = 2+0+2 = 4$, $\|\mathbf{x}\| = \sqrt{1+4+4} = 3$, $\|\mathbf{y}\| = \sqrt{5} = 2.236$.

$$\cos\theta = \frac{4}{3\sqrt{5}} = 0.5963, \qquad \theta = 53.4^\circ.$$

Cauchy–Schwarz: $4 \le 3\times 2.236 = 6.708$ ✓. Triangle inequality: $\|\mathbf{x}+\mathbf{y}\| = \|(3,2,3)\| = \sqrt{22} = 4.690 \le 3 + 2.236$ ✓.

Worked Example 9.22 — Expanding in an orthonormal basis

Verify that

$$\mathbf{u}_1 = \tfrac{1}{\sqrt{3}}(1,1,1), \qquad \mathbf{u}_2 = \tfrac{1}{\sqrt{2}}(1,-1,0), \qquad \mathbf{u}_3 = \tfrac{1}{\sqrt{6}}(1,1,-2)$$

is an orthonormal basis of $\mathbb{R}^3$, and expand $\mathbf{x} = (3,1,2)$.

Orthogonality. $(1,1,1)\cdot(1,-1,0) = 0$, $(1,1,1)\cdot(1,1,-2) = 0$, $(1,-1,0)\cdot(1,1,-2) = 0$ ✓. Each vector has been divided by its length ($\sqrt{3}$, $\sqrt{2}$, $\sqrt{6}$), so all are unit vectors.

Coordinates by dot products:

$$\mathbf{x}\cdot\mathbf{u}_1 = \tfrac{6}{\sqrt{3}} = 2\sqrt{3}, \qquad \mathbf{x}\cdot\mathbf{u}_2 = \tfrac{2}{\sqrt{2}} = \sqrt{2}, \qquad \mathbf{x}\cdot\mathbf{u}_3 = \tfrac{3+1-4}{\sqrt{6}} = 0.$$

So $\mathbf{x} = 2\sqrt{3}\,\mathbf{u}_1 + \sqrt{2}\,\mathbf{u}_2 = 2(1,1,1) + (1,-1,0) = (3,1,2)$ ✓.

Parseval. $(2\sqrt{3})^2 + (\sqrt{2})^2 + 0^2 = 12 + 2 = 14 = \|\mathbf{x}\|^2 = 9 + 1 + 4$ ✓.

Interpretation. $\mathbf{u}_1$ is the "average" (DC) direction: $\mathbf{x}\cdot\mathbf{u}_1\,\mathbf{u}_1 = (2,2,2)$ is the mean value of the entries repeated. The rest, $(1,-1,0)$, is the zero-mean (AC) part. Energy splits as 12 (DC) $+$ 2 (AC).

Orthogonal matrices

Orthogonal matrix

A square real matrix $\mathbf{Q}$ is **orthogonal** if its columns are orthonormal, equivalently

$$\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}, \qquad \text{i.e.} \qquad \mathbf{Q}^{-1} = \mathbf{Q}^{\mathsf{T}}.$$

(The complex analogue, $\mathbf{U}^{\mathsf{H}}\mathbf{U} = \mathbf{I}$, is a **unitary** matrix.)

Orthogonal matrices preserve dot products, lengths and angles:

$$(\mathbf{Q}\mathbf{x})\cdot(\mathbf{Q}\mathbf{y}) = \mathbf{x}^{\mathsf{T}}\mathbf{Q}^{\mathsf{T}}\mathbf{Q}\mathbf{y} = \mathbf{x}\cdot\mathbf{y}, \qquad \|\mathbf{Q}\mathbf{x}\| = \|\mathbf{x}\|.$$

They are the rotations and reflections, and $\det\mathbf{Q} = \pm 1$. The rotation $\mathbf{R}_\theta$ of Worked Example 9.15 is orthogonal; so is the matrix $[\mathbf{u}_1\ \mathbf{u}_2\ \mathbf{u}_3]$ of Worked Example 9.22. Numerically they are ideal: $\kappa(\mathbf{Q}) = 1$, so solving $\mathbf{Q}\mathbf{x} = \mathbf{b}$ by $\mathbf{x} = \mathbf{Q}^{\mathsf{T}}\mathbf{b}$ never amplifies errors. This is why orthogonal transforms (the DFT scaled by $1/\sqrt{N}$, the discrete cosine transform, Householder reflections in QR) dominate numerical signal processing.

Orthogonal complements

Orthogonal complement

For a subspace W of $\mathbb{R}^n$, its **orthogonal complement** is

$$W^{\perp} = \{\mathbf{x} \in \mathbb{R}^n : \ \mathbf{x}\cdot\mathbf{w} = 0 \text{ for all } \mathbf{w} \in W\}.$$

$W^{\perp}$ is a subspace, and it suffices to check orthogonality against a *spanning set* of W. Key properties:

$$W \cap W^{\perp} = \{\mathbf{0}\}, \qquad \dim W + \dim W^{\perp} = n, \qquad (W^{\perp})^{\perp} = W, \qquad \mathbb{R}^n = W \oplus W^{\perp}.$$

Fundamental theorem of linear algebra (orthogonality part)

For $\mathbf{A} \in \mathbb{R}^{m\times n}$:

$$\operatorname{null}(\mathbf{A}) = \operatorname{row}(\mathbf{A})^{\perp} \text{ in } \mathbb{R}^n, \qquad \operatorname{null}(\mathbf{A}^{\mathsf{T}}) = \operatorname{col}(\mathbf{A})^{\perp} \text{ in } \mathbb{R}^m.$$

Proof. $\mathbf{A}\mathbf{x} = \mathbf{0}$ says that the dot product of $\mathbf{x}$ with every row of $\mathbf{A}$ is zero, i.e. $\mathbf{x}$ is orthogonal to the row space. Apply this to $\mathbf{A}^{\mathsf{T}}$ for the second statement.

Together with rank–nullity this gives the complete picture: $\mathbb{R}^n$ splits orthogonally into the row space ($\dim r$) and the null space ($\dim n - r$); $\mathbb{R}^m$ splits into the column space ($\dim r$) and the left null space ($\dim m - r$). $\mathbf{A}$ maps the row space one-to-one onto the column space and sends the null space to zero. The second statement also completes the solvability test of Section 9.6: $\mathbf{b} \in \operatorname{col}(\mathbf{A})$ **iff** $\mathbf{b} \perp \operatorname{null}(\mathbf{A}^{\mathsf{T}})$.

Worked Example 9.23 — Complements and the four subspaces

(a) Find $W^\perp$ for $W = \text{span}\{(1,1,1)\}$.

$\mathbf{x} \perp (1,1,1) \iff x+y+z=0$. So $W^\perp$ is the plane $x+y+z=0$, with basis $\{(-1,1,0),(-1,0,1)\}$; $\dim W + \dim W^\perp = 1+2=3$ ✓. In the language of Worked Example 9.22: the orthogonal complement of the DC direction is the subspace of zero-mean vectors.

(b) For $\mathbf{A}$ of Worked Example 9.18, check $\text{null}(\mathbf{A}) \perp \text{row}(\mathbf{A})$:

$$(-2,1,0,0)\cdot(1,2,0,1)=0,\quad (-2,1,0,0)\cdot(0,0,1,-1)=0,\quad (-1,0,1,1)\cdot(1,2,0,1)=0,\quad (-1,0,1,1)\cdot(0,0,1,-1)=0\ \checkmark.$$

And $\text{null}(\mathbf{A}^\mathsf{T}) = \text{span}\{(-1,-1,1)\} \perp \text{col}(\mathbf{A})$: $(-1,-1,1)\cdot(1,2,3)=0$ and $(-1,-1,1)\cdot(1,0,1)=0$ ✓. Dimensions $2+2=4=n$ and $2+1=3=m$ ✓.

Common Pitfall — orthogonal is not the same as independent

Orthogonal nonzero vectors are independent, but independent vectors need not be orthogonal: $(1,0)$ and $(1,1)$ are independent and meet at 45°. Also, "orthogonal matrix" means ortho*normal* columns; a matrix with merely orthogonal columns satisfies $\mathbf{Q}^\mathsf{T}\mathbf{Q}$ = diagonal, not $\mathbf{I}$, and its inverse is *not* its transpose.

Engineering Note — I/Q modulation and orthogonal channels

Over one symbol period T containing an integer number of carrier cycles, $\cos\omega_c t$ and $\sin\omega_c t$ are orthogonal (Section 9.8). A QAM transmitter sends $s(t) = a\cos\omega_c t - b\sin\omega_c t$; the receiver recovers a and b separately by taking inner products with each carrier — exactly the orthonormal-coordinate formula of this section. OFDM extends this to hundreds of mutually orthogonal subcarriers, and CDMA to orthogonal spreading codes (rows of a Hadamard matrix, which satisfies $\mathbf{H}^\mathsf{T}\mathbf{H} = N\mathbf{I}$).

9.8 Inner products

Motivation

The dot product gave $\mathbb{R}^n$ lengths, angles and orthogonality. To do the same for complex phasor vectors, for vectors whose components have different importance (weights), and above all for **signals**, we abstract its essential properties. The result, an **inner product**, turns the function space of finite-energy signals into a geometric space in which a signal has a length (its RMS value or the square root of its energy), two signals have an angle (their correlation), and the harmonics $\cos k\omega_0 t$, $\sin k\omega_0 t$ are mutually perpendicular axes. This is the bridge from linear algebra to Fourier analysis.

Definition

Inner product

An **inner product** on a vector space V over $\mathbb{F}$ assigns to each pair $\mathbf{u},\mathbf{v}$ a scalar $\langle \mathbf{u},\mathbf{v}\rangle \in \mathbb{F}$ such that for all $\mathbf{u},\mathbf{v},\mathbf{w}$ and scalars a,b:

1. **Linearity in the first argument:** $\langle a\mathbf{u}+b\mathbf{w},\mathbf{v}\rangle = a\langle\mathbf{u},\mathbf{v}\rangle + b\langle\mathbf{w},\mathbf{v}\rangle$;
2. **Conjugate symmetry:** $\langle\mathbf{u},\mathbf{v}\rangle = \overline{\langle\mathbf{v},\mathbf{u}\rangle}$ (plain symmetry when $\mathbb{F}=\mathbb{R}$);
3. **Positivity:** $\langle\mathbf{u},\mathbf{u}\rangle > 0$ for $\mathbf{u}\neq\mathbf{0}$ (and $\langle\mathbf{0},\mathbf{0}\rangle = 0$).

A vector space with an inner product is an **inner-product space**. The induced **norm** is $\|\mathbf{u}\| = \sqrt{\langle\mathbf{u},\mathbf{u}\rangle}$, and $\mathbf{u}\perp\mathbf{v}$ means $\langle\mathbf{u},\mathbf{v}\rangle = 0$.

Properties 1 and 2 together give **conjugate linearity in the second argument**: $\langle\mathbf{u},a\mathbf{v}\rangle = \bar{a}\langle\mathbf{u},\mathbf{v}\rangle$. This book follows the engineering and signal-processing convention (linear in the first slot, conjugated in the second); physics texts often use the opposite convention. Both give the same norms and the same notion of orthogonality.

Results that hold in every inner-product space

- **Cauchy–Schwarz:** $|\langle\mathbf{u},\mathbf{v}\rangle| \le \|\mathbf{u}\|\,\|\mathbf{v}\|$, equality iff $\mathbf{u},\mathbf{v}$ are parallel.
- **Triangle inequality:** $\|\mathbf{u}+\mathbf{v}\| \le \|\mathbf{u}\| + \|\mathbf{v}\|$.
- **Pythagoras:** if $\mathbf{u}\perp\mathbf{v}$ then $\|\mathbf{u}+\mathbf{v}\|^2 = \|\mathbf{u}\|^2 + \|\mathbf{v}\|^2$.
- **Parallelogram law:** $\|\mathbf{u}+\mathbf{v}\|^2 + \|\mathbf{u}-\mathbf{v}\|^2 = 2\|\mathbf{u}\|^2 + 2\|\mathbf{v}\|^2$.
- Orthogonal nonzero vectors are independent, and coordinates in an orthogonal basis are $c_j = \langle\mathbf{x},\mathbf{u}_j\rangle / \langle\mathbf{u}_j,\mathbf{u}_j\rangle$.

The proofs of Section 9.7 go through unchanged, with $\mathbf{x}\cdot\mathbf{y}$ replaced by $\langle\mathbf{x},\mathbf{y}\rangle$. (In the complex case of Cauchy–Schwarz, minimise $\|\mathbf{u}-s\mathbf{v}\|^2$ over complex s; the minimiser is $s = \langle\mathbf{u},\mathbf{v}\rangle/\|\mathbf{v}\|^2$.)

Inner products on $\mathbb{R}^n$ and $\mathbb{C}^n$

Standard complex inner product.

$$\langle\mathbf{u},\mathbf{v}\rangle = \sum_{k=1}^{n} u_k\,\overline{v_k} = \mathbf{v}^\mathsf{H}\mathbf{u}, \qquad \|\mathbf{u}\|^2 = \sum_k |u_k|^2.$$

The conjugate is essential. Without it, $(1,j)$ would have "squared length" $1^2 + j^2 = 0$, violating positivity.

Weighted inner product. For a symmetric positive-definite matrix $\mathbf{W}$ (Ch. 10), $\langle \mathbf{u}, \mathbf{v} \rangle_{\mathbf{W}} = \mathbf{v}^{\mathsf{T}} \mathbf{W} \mathbf{u}$. The diagonal case $\mathbf{W} = \operatorname{diag}(w_1, \dots, w_n)$ with $w_k > 0$ weights each component by its reliability — the basis of weighted least squares (Section 9.11).

Worked Example 9.24 — A complex inner product

Let $\mathbf{u} = (1 + j,\ 2)^{\mathsf{T}}$ and $\mathbf{v} = (j,\ 1 - j)^{\mathsf{T}}$ in $\mathbb{C}^2$. Compute $\langle \mathbf{u}, \mathbf{v} \rangle$, both norms, and check Cauchy–Schwarz.

$$\langle \mathbf{u}, \mathbf{v} \rangle = (1 + j)(j)^* + 2(1 - j)^* = (1 + j)(-j) + 2(1 + j) = (-j + 1) + (2 + 2j) = 3 + j.$$

$$\|\mathbf{u}\|^2 = |1 + j|^2 + |2|^2 = 2 + 4 = 6, \qquad \|\mathbf{v}\|^2 = |j|^2 + |1 - j|^2 = 1 + 2 = 3.$$

Cauchy–Schwarz: $|3 + j| = \sqrt{10} = 3.162 \le \sqrt{6}\sqrt{3} = \sqrt{18} = 4.243$ ✓. Conjugate symmetry: $\langle \mathbf{v}, \mathbf{u} \rangle = j(1 - j) + (1 - j) \cdot 2 = (j + 1) + (2 - 2j) = 3 - j = \langle \mathbf{u}, \mathbf{v} \rangle^*$ ✓.

Inner products of functions and signals

For real continuous functions on $[a, b]$, the natural inner product replaces the sum over components by an integral over t:

$$\langle f, g \rangle = \int_a^b f(t)\, g(t)\, dt, \qquad \|f\|^2 = \int_a^b f(t)^2\, dt.$$

For complex-valued signals, $\langle f, g \rangle = \int_a^b f(t)\, g^*(t)\, dt$. Positivity holds because a continuous function with $\int f^2 = 0$ is identically zero. (On L^2, functions that differ only on a set of zero length — say at isolated points — are regarded as the same vector, so that positivity still holds.)

The analogy with $\mathbb{R}^n$ is exact if you think of a function as a vector with a continuum of components indexed by t: sampling f and g at spacing Δt gives vectors whose dot product times Δt is a Riemann sum for $\int f g\, dt$.

Two inner products are standard in signal analysis:

Signal class	Inner product	Squared norm	Physical meaning
energy signals on $\mathbb{R}$	$\langle x, y \rangle = \int_{-\infty}^{\infty} x(t) y^*(t)\, dt$	$E_x = \int \lvert x \rvert^2 dt$	energy delivered to a 1 Ω load
T-periodic (power) signals	$\langle x, y \rangle_T = \frac{1}{T} \int_T x(t) y^*(t)\, dt$	$P_x = \frac{1}{T} \int_T \lvert x \rvert^2 dt$	average power in 1 Ω; $\|x\|_T$ = RMS value

So **the RMS value of a periodic waveform is its norm** in the power inner product, and the energy of a pulse is its squared norm.

Orthogonality of harmonics

Orthogonality of the trigonometric system

Let $\omega_0 = 2\pi / T$. For integers $m, n \ge 0$, over any interval of length T:

$$\int_T \cos m\omega_0 t\, \cos n\omega_0 t\, dt = \begin{cases} 0, & m \ne n \\ T/2, & m = n \ge 1 \\ T, & m = n = 0 \end{cases} \qquad \int_T \sin m\omega_0 t\, \sin n\omega_0 t\, dt = \begin{cases} 0, & m \ne n \\ T/2, & m = n \ge 1 \end{cases}$$

$$\int_T \cos m\omega_0 t\, \sin n\omega_0 t\, dt = 0 \quad \text{for all } m, n.$$

In complex form, with the power inner product,

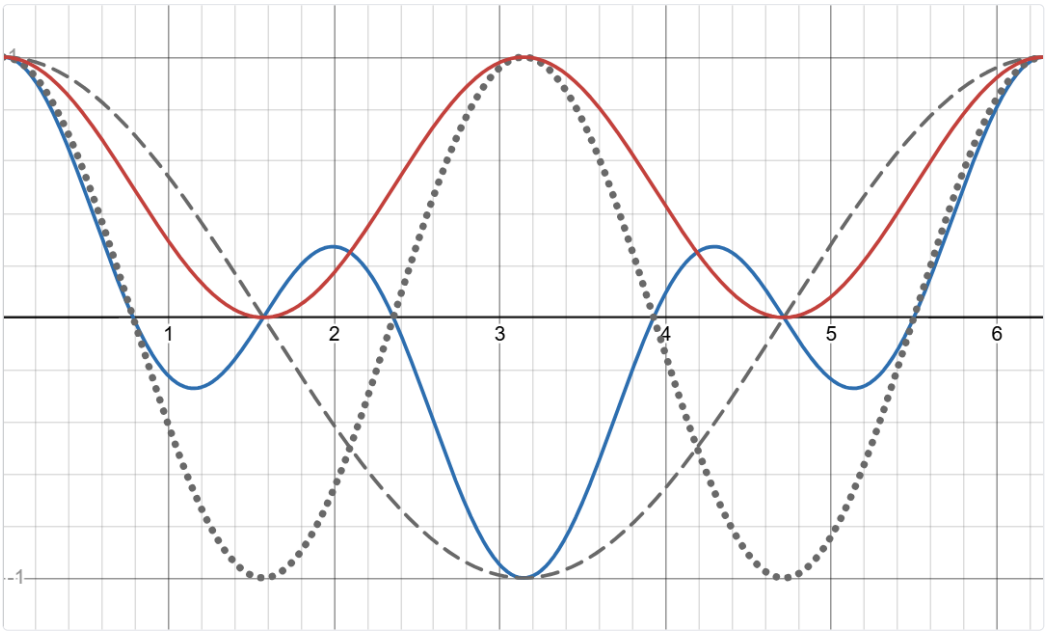
$$\left\langle e^{jm\omega_0 t}, e^{jn\omega_0 t} \right\rangle_T = \frac{1}{T} \int_T e^{j(m-n)\omega_0 t}\, dt = \delta_{mn} \qquad (m, n \in \mathbb{Z}),$$

so $\{ e^{jn\omega_0 t} \}_{n \in \mathbb{Z}}$ is an **orthonormal** set.

Derivation. The complex form is the cleanest: if $m = n$ the integrand is 1 and the integral is T. If $m \ne n$, put $k = m - n \ne 0$:

$$\int_{t_0}^{t_0 + T} e^{jk\omega_0 t}\, dt = \frac{e^{jk\omega_0 t_0} \left(e^{jk\omega_0 T} - 1 \right)}{jk\omega_0} = 0,$$

because $k\omega_0 T = 2\pi k$. The real formulas follow from product-to-sum identities, e.g. $\cos m\omega_0 t \cos n\omega_0 t = \tfrac{1}{2}[\cos(m - n)\omega_0 t + \cos(m + n)\omega_0 t]$: each cosine integrates to zero over a period unless its frequency is zero.



Over one period $[0, 2\pi]$, the product $\cos t \cos 2t$ (blue) has equal positive and negative areas, so the inner product is 0; the product $\cos^2 t$ (red) is never negative and integrates to $\pi = T/2$.

Consequently, if a signal is a finite trigonometric sum $x(t) = \sum_{n=-N}^{N} c_n e^{jn\omega_0 t}$, its coefficients are its coordinates in an orthonormal basis:

$$c_n = \langle x, e^{jn\omega_0 t} \rangle_T = \frac{1}{T}\int_T x(t)\, e^{-jn\omega_0 t}\, dt, \qquad P_x = \sum_n |c_n|^2.$$

These are the **Fourier coefficient formula** and **Parseval's relation** of Ch. 15 — here obtained purely from the orthonormal-coordinate theorem. What Chapter 15 adds is the analysis of what happens when $N \to \infty$.

Worked Example 9.25 — Angles between polynomials

(a) On $[-1, 1]$ with $\langle f, g \rangle = \int_{-1}^{1} fg\, dt$: $\langle 1, t \rangle = \int_{-1}^{1} t\, dt = 0$ and $\langle t, t^2 \rangle = \int_{-1}^{1} t^3\, dt = 0$. Any even function is orthogonal to any odd function on a symmetric interval — the subspaces of even and odd functions are orthogonal complements. Norms: $\|1\|^2 = 2$, $\|t\|^2 = 2/3$, $\|t^2\|^2 = 2/5$. But $\langle 1, t^2 \rangle = 2/3 \neq 0$: the monomials are *not* an orthogonal set (Section 9.10 fixes this).

(b) On $[0, 1]$ the same functions behave very differently:

$$\langle t, t^2 \rangle = \int_0^1 t^3\, dt = \tfrac{1}{4}, \quad \|t\| = \sqrt{\int_0^1 t^2 dt} = \tfrac{1}{\sqrt{3}}, \quad \|t^2\| = \tfrac{1}{\sqrt{5}},$$

$$\cos\theta = \frac{1/4}{(1/\sqrt{3})(1/\sqrt{5})} = \frac{\sqrt{15}}{4} = 0.9682, \qquad \theta = 14.5^\circ.$$

On $[0, 1]$, t and t^2 are nearly parallel. This geometric fact is the root of the ill-conditioning of polynomial fitting with monomials (Section 9.11). The inner product — and hence orthogonality — depends on the interval.

Worked Example 9.26 — Energy, correlation and distance of two pulses

Let $x_1(t) = e^{-t}u(t)$ and $x_2(t) = e^{-2t}u(t)$ (volts, t in seconds, 1 Ω reference).

$$E_1 = \|x_1\|^2 = \int_0^\infty e^{-2t} dt = \tfrac{1}{2}\ \text{J}, \qquad E_2 = \int_0^\infty e^{-4t} dt = \tfrac{1}{4}\ \text{J}, \qquad \langle x_1, x_2 \rangle = \int_0^\infty e^{-3t} dt = \tfrac{1}{3}.$$

Correlation coefficient (cosine of the angle):

$$\rho = \frac{\langle x_1, x_2 \rangle}{\|x_1\|\|x_2\|} = \frac{1/3}{\sqrt{1/8}} = \frac{2\sqrt{2}}{3} = 0.943.$$

Distance (energy of the difference): $\|x_1 - x_2\|^2 = E_1 + E_2 - 2\langle x_1, x_2 \rangle = \tfrac{1}{2} + \tfrac{1}{4} - \tfrac{2}{3} = \tfrac{1}{12}$ J. A receiver deciding between these two pulses in noise has a hard job: the pulses are nearly parallel and close together. In digital communications, error probability is governed by exactly this distance between signal vectors.

Worked Example 9.27 — RMS value by Pythagoras

Find the RMS value of $v(t) = 3 + 4\cos\omega_0 t - 2\sin 3\omega_0 t$ V.

The three terms are mutually orthogonal in the power inner product, so their powers add:

$$P = \|3\|_T^2 + \|4\cos\omega_0 t\|_T^2 + \|2\sin 3\omega_0 t\|_T^2 = 9 + \frac{16}{2} + \frac{4}{2} = 19\ \text{V}^2,$$

using $\frac{1}{T}\int_T \cos^2 = \frac{1}{T}\int_T \sin^2 = \frac{1}{2}$. Hence $V_{\text{rms}} = \sqrt{19} = 4.359$ V. Without orthogonality we would have to expand v^2 and integrate nine cross terms; orthogonality says the six cross terms all vanish.

Cauchy–Schwarz and the matched filter

Cauchy–Schwarz has a celebrated engineering reading. A known pulse $s(t)$ arrives in white noise and is passed through a filter whose output at the sampling instant is an inner product $\langle s, h\rangle$ with some template h. The signal-to-noise ratio turns out to be proportional to

$$\frac{|\langle s, h\rangle|^2}{\|h\|^2} \le \frac{\|s\|^2\|h\|^2}{\|h\|^2} = \|s\|^2 = E_s,$$

with equality iff h is parallel to s. The optimal template is the signal itself (the **matched filter**), and the best achievable SNR depends only on the pulse energy, not its shape. The derivation of the noise side belongs to Ch. 21; the optimisation step is pure Cauchy–Schwarz.

Common Pitfall — forgetting the conjugate, or the interval

With complex vectors or signals, $\sum u_k v_k$ (no conjugate) is *not* an inner product, and "orthogonality" computed with it is meaningless. Similarly, $\cos t$ and $\cos 2t$ are orthogonal over $[0, 2\pi]$ but not over $[0, 1]$: orthogonality of sinusoids requires an interval containing a whole number of periods of each (more precisely, of their difference frequency). Truncating a measurement to a non-integer number of periods destroys orthogonality and causes spectral leakage in the DFT.

Engineering Note — signal space

Digital modulation is analysed in **signal space**: choose an orthonormal basis $\phi_1(t), \dots, \phi_N(t)$ for the set of transmitted waveforms (for QPSK, $\sqrt{2/T}\cos\omega_c t$ and $\sqrt{2/T}\sin\omega_c t$ over one symbol). Each waveform becomes a point in $\mathbb{R}^N$ — the constellation diagram — energies become squared lengths, and the receiver's correlators compute the coordinates $\langle r, \phi_k\rangle$. Every geometric statement of this chapter has a direct meaning on that diagram.

9.9 Projection

Motivation

Most approximation problems in engineering have the same shape: we want to represent a complicated object (a measured data vector, a distorted waveform, a field) by the closest member of a simpler family (a straight line, a few harmonics, a low-order model). When the simpler family is a subspace and "closest" is measured by an inner-product norm — energy, RMS error, sum of squared residuals — the answer is always the **orthogonal projection**, and it is characterised by one geometric fact: *the error is perpendicular to the subspace*. Least squares (Section 9.11), truncated Fourier series (Ch. 15) and Wiener filtering are all instances.

Projection onto a line

Let $\mathbf{a} \neq \mathbf{0}$ span a line through the origin. The point $\mathbf{p} = \hat{c}\,\mathbf{a}$ closest to $\mathbf{b}$ is determined by requiring the error $\mathbf{e} = \mathbf{b} - \hat{c}\mathbf{a}$ to be orthogonal to $\mathbf{a}$:

$$\langle \mathbf{b} - \hat{c}\,\mathbf{a}, \mathbf{a}\rangle = 0 \quad\Longrightarrow\quad \hat{c} = \frac{\langle \mathbf{b}, \mathbf{a}\rangle}{\langle \mathbf{a}, \mathbf{a}\rangle}, \qquad \mathbf{p} = \operatorname{proj}_{\mathbf{a}}\mathbf{b} = \frac{\langle \mathbf{b}, \mathbf{a}\rangle}{\langle \mathbf{a}, \mathbf{a}\rangle}\,\mathbf{a}.$$

In $\mathbb{R}^n$ the projection is a matrix acting on $\mathbf{b}$:

$$\mathbf{p} = \frac{\mathbf{a}\mathbf{a}^{\mathsf{T}}}{\mathbf{a}^{\mathsf{T}}\mathbf{a}}\,\mathbf{b} = \mathbf{P}\mathbf{b}, \qquad \mathbf{P} = \frac{\mathbf{a}\mathbf{a}^{\mathsf{T}}}{\mathbf{a}^{\mathsf{T}}\mathbf{a}} \ \ (\text{rank } 1).$$

The scalar $\langle \mathbf{b}, \mathbf{a}\rangle / \|\mathbf{a}\|$ is the **scalar component** of $\mathbf{b}$ along $\mathbf{a}$, equal to $\|\mathbf{b}\|\cos\theta$.

Worked Example 9.28 — Projecting onto the DC direction

Project $\mathbf{b} = (1, 2, 3)^{\mathsf{T}}$ onto $\mathbf{a} = (1, 1, 1)^{\mathsf{T}}$.

$\hat{c} = \dfrac{\mathbf{b}\cdot\mathbf{a}}{\mathbf{a}\cdot\mathbf{a}} = \dfrac{6}{3} = 2$, so $\mathbf{p} = (2, 2, 2)^{\mathsf{T}}$ and $\mathbf{e} = \mathbf{b} - \mathbf{p} = (-1, 0, 1)^{\mathsf{T}}$.

Check: $\mathbf{e}\cdot\mathbf{a} = -1 + 0 + 1 = 0$ ✓. **Pythagoras:** $\|\mathbf{b}\|^2 = 14 = \|\mathbf{p}\|^2 + \|\mathbf{e}\|^2 = 12 + 2$ ✓.

$\hat{c} = 2$ is the **mean** of the entries of $\mathbf{b}$: projecting onto the all-ones vector extracts the average, and the error is the zero-mean residual. The distance from $\mathbf{b}$ to the line is $\|\mathbf{e}\| = \sqrt{2} - \sqrt{3}$ times the (population) standard deviation of the entries $1, 2, 3$, which is $\sqrt{2/3}$.

Projection onto a subspace

Best approximation (orthogonal projection) theorem

Let W be a finite-dimensional subspace of an inner-product space V and $\mathbf{b} \in V$. There is a unique $\mathbf{p} \in W$ closest to $\mathbf{b}$:

$$\|\mathbf{b} - \mathbf{p}\| < \|\mathbf{b} - \mathbf{w}\| \quad \text{for every } \mathbf{w} \in W,\ \mathbf{w} \neq \mathbf{p}.$$

It is characterised by the **orthogonality principle**: $\mathbf{b} - \mathbf{p} \perp W$. We write $\mathbf{p} = \operatorname{proj}_W \mathbf{b}$.

Proof. Suppose $\mathbf{p} \in W$ with $\mathbf{e} = \mathbf{b} - \mathbf{p} \perp W$. For any $\mathbf{w} \in W$, $\mathbf{p} - \mathbf{w} \in W$, so by Pythagoras

$$\|\mathbf{b} - \mathbf{w}\|^2 = \|(\mathbf{b} - \mathbf{p}) + (\mathbf{p} - \mathbf{w})\|^2 = \|\mathbf{e}\|^2 + \|\mathbf{p} - \mathbf{w}\|^2 \geq \|\mathbf{e}\|^2,$$

with equality only if $\mathbf{w} = \mathbf{p}$. Existence: construct $\mathbf{p}$ with an orthogonal basis (next formula) or by the normal equations.

With an orthogonal basis $\{\mathbf{u}_1, \dots, \mathbf{u}_k\}$ of W the projection is the sum of the projections onto each basis vector:

$$\operatorname{proj}_W \mathbf{b} = \sum_{j=1}^{k} \frac{\langle \mathbf{b}, \mathbf{u}_j \rangle}{\langle \mathbf{u}_j, \mathbf{u}_j \rangle}\, \mathbf{u}_j \qquad \Big(= \sum_j \langle \mathbf{b}, \mathbf{u}_j \rangle \mathbf{u}_j \text{ if orthonormal} \Big).$$

Check of orthogonality: $\langle \mathbf{b} - \mathbf{p}, \mathbf{u}_i \rangle = \langle \mathbf{b}, \mathbf{u}_i \rangle - \frac{\langle \mathbf{b}, \mathbf{u}_i \rangle}{\langle \mathbf{u}_i, \mathbf{u}_i \rangle} \langle \mathbf{u}_i, \mathbf{u}_i \rangle = 0$, the cross terms having vanished by orthogonality.

Common Pitfall — the sum formula needs an orthogonal basis

Adding up the projections onto each basis vector gives the projection onto their span **only** if the basis is orthogonal. For a non-orthogonal basis the individual projections "double count" the overlap. Either orthogonalise first (Gram–Schmidt, Section 9.10) or use the normal-equation formula below.

With an arbitrary basis — the columns of $\mathbf{A} \in \mathbb{R}^{m \times k}$, assumed independent — write $\mathbf{p} = \mathbf{A}\hat{\mathbf{x}}$. Orthogonality of the error to every column means $\mathbf{A}^{\mathsf{T}}(\mathbf{b} - \mathbf{A}\hat{\mathbf{x}}) = \mathbf{0}$:

$$\mathbf{A}^{\mathsf{T}}\mathbf{A}\,\hat{\mathbf{x}} = \mathbf{A}^{\mathsf{T}}\mathbf{b} \qquad \text{(normal equations)},$$

$$\hat{\mathbf{x}} = (\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{b}, \qquad \mathbf{p} = \mathbf{P}\mathbf{b}, \qquad \mathbf{P} = \mathbf{A}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}.$$

$\mathbf{A}^{\mathsf{T}}\mathbf{A}$ is invertible precisely when the columns of $\mathbf{A}$ are independent: if $\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{0}$ then $\mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2 = 0$, so $\mathbf{A}\mathbf{x} = \mathbf{0}$, so $\mathbf{x} = \mathbf{0}$. For complex data replace T by H.

Properties of projection matrices

The orthogonal projection matrix $\mathbf{P}$ onto a subspace W satisfies

1. $\mathbf{P}^2 = \mathbf{P}$ (**idempotent**: projecting twice changes nothing);
2. $\mathbf{P}^{\mathsf{T}} = \mathbf{P}$ (**symmetric**);
3. $\operatorname{col}(\mathbf{P}) = W$, $\operatorname{null}(\mathbf{P}) = W^{\perp}$, $\operatorname{rank}\mathbf{P} = \dim W$;
4. $\mathbf{I} - \mathbf{P}$ is the projection onto $W^{\perp}$, and $\mathbf{b} = \mathbf{P}\mathbf{b} + (\mathbf{I} - \mathbf{P})\mathbf{b}$ is the orthogonal splitting $\mathbb{R}^m = W \oplus W^{\perp}$.

Conversely, any matrix with $\mathbf{P}^2 = \mathbf{P} = \mathbf{P}^{\mathsf{T}}$ is the orthogonal projection onto its column space. If W has an orthonormal basis forming the columns of $\mathbf{Q}$, then simply $\mathbf{P} = \mathbf{Q}\mathbf{Q}^{\mathsf{T}}$.

Proof of 1. $\mathbf{P}^2 = \mathbf{A}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}(\mathbf{A}^{\mathsf{T}}\mathbf{A})(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}} = \mathbf{P}$. Property 2 follows because $(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}$ is symmetric.

A matrix with $\mathbf{P}^2 = \mathbf{P}$ but $\mathbf{P}^{\mathsf{T}} \neq \mathbf{P}$ is an **oblique** projection: it maps onto a subspace along a direction that is not perpendicular to it.

Worked Example 9.29 — Projection onto a plane in $\mathbb{R}^3$

Project $\mathbf{b} = (6, 0, 0)^{\mathsf{T}}$ onto the column space of

$$\mathbf{A} = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \end{bmatrix}.$$

Normal equations.

$$\mathbf{A}^{\mathsf{T}}\mathbf{A} = \begin{bmatrix} 3 & 3 \\ 3 & 5 \end{bmatrix}, \qquad \mathbf{A}^{\mathsf{T}}\mathbf{b} = \begin{bmatrix} 6 \\ 0 \end{bmatrix}, \qquad \begin{bmatrix} 3 & 3 \\ 3 & 5 \end{bmatrix}\begin{bmatrix} \hat{x}_1 \\ \hat{x}_2 \end{bmatrix} = \begin{bmatrix} 6 \\ 0 \end{bmatrix}.$$

Subtracting the first equation from the second: $2\hat{x}_2 = -6$, $\hat{x}_2 = -3$; then $3\hat{x}_1 - 9 = 6$, $\hat{x}_1 = 5$.

Projection and error. $\mathbf{p} = \mathbf{A}\hat{\mathbf{x}} = 5(1,1,1) - 3(0,1,2) = (5, 2, -1)^{\mathsf{T}}$, $\mathbf{e} = \mathbf{b} - \mathbf{p} = (1, -2, 1)^{\mathsf{T}}$.

Checks. $\mathbf{A}^{\mathsf{T}}\mathbf{e} = (1 - 2 + 1,\ 0 - 2 + 2) = (0, 0)$ ✓ — the error is orthogonal to both columns. $\|\mathbf{b}\|^2 = 36 = \|\mathbf{p}\|^2 + \|\mathbf{e}\|^2 = 30 + 6$ ✓.

Projection matrix. $(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1} = \frac{1}{6}\begin{bmatrix} 5 & -3 \\ -3 & 3 \end{bmatrix}$ and

$$\mathbf{P} = \mathbf{A}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}} = \frac{1}{6}\begin{bmatrix} 5 & 2 & -1 \\ 2 & 2 & 2 \\ -1 & 2 & 5 \end{bmatrix}.$$

Its first column is $\mathbf{P}\mathbf{e}_1 = \frac{1}{6}(5, 2, -1)$, consistent with $\mathbf{P}\mathbf{b} = 6\,\mathbf{P}\mathbf{e}_1 = (5, 2, -1)$ ✓. Its trace is $12/6 = 2 = \operatorname{rank}\mathbf{P}$ (the trace of a projection equals the dimension of the subspace). This same matrix reappears in Section 9.11 as fitting a straight line to three data points.

Worked Example 9.30 — Projection with an orthonormal basis

Project $\mathbf{x} = (3, 1, 2)^{\mathsf{T}}$ onto the plane $W:\ x + y + z = 0$.

From Worked Example 9.22, $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1, -1, 0)$ and $\mathbf{u}_3 = \frac{1}{\sqrt{6}}(1, 1, -2)$ form an orthonormal basis of W (both are orthogonal to $(1, 1, 1)$). Then

$$\operatorname{proj}_W \mathbf{x} = (\mathbf{x}\cdot\mathbf{u}_2)\mathbf{u}_2 + (\mathbf{x}\cdot\mathbf{u}_3)\mathbf{u}_3 = \sqrt{2}\cdot\tfrac{1}{\sqrt{2}}(1, -1, 0) + 0 = (1, -1, 0).$$

Alternative via the complement: $W^{\perp} = \operatorname{span}\{(1, 1, 1)\}$, so $\operatorname{proj}_W \mathbf{x} = \mathbf{x} - \operatorname{proj}_{(1,1,1)}\mathbf{x} = (3, 1, 2) - (2, 2, 2) = (1, -1, 0)$ ✓. When the complement is smaller than the subspace, projecting onto the complement and subtracting is quicker.

Projection in function spaces and Bessel's inequality

Everything above works in a function space with the integral inner product. If $\{\phi_1, \dots, \phi_N\}$ is an orthogonal set of functions, the best approximation of f in their span (minimum $\int |f - \hat{f}|^2$) is

$$\hat{f} = \sum_{n=1}^{N} c_n \phi_n, \qquad c_n = \frac{\langle f, \phi_n \rangle}{\langle \phi_n, \phi_n \rangle},$$

and Pythagoras gives the error energy and **Bessel's inequality**:

$$\|f - \hat{f}\|^2 = \|f\|^2 - \sum_{n=1}^{N} |c_n|^2 \|\phi_n\|^2 \ \geq 0 \quad \Longrightarrow \quad \sum_{n=1}^{N} |c_n|^2 \|\phi_n\|^2 \leq \|f\|^2.$$

Two important consequences:

1. **The coefficients do not change when N grows.** Adding ϕ_{N+1} to the basis adds a term but leaves $c_1, \dots, c_N$ alone — a property unique to orthogonal bases, and the reason Fourier coefficients can be computed one at a time.
2. **The error energy decreases monotonically with N.** If it tends to zero for every f, the orthogonal set is **complete** and Bessel's inequality becomes **Parseval's identity** $\sum |c_n|^2 \|\phi_n\|^2 = \|f\|^2$ — the central convergence statement of Ch. 15.

A simple but important special case: the projection of f onto the constant function 1 on $[a, b]$ is $\langle f, 1\rangle / \langle 1, 1\rangle = \frac{1}{b-a}\int_a^b f\,dt$, the **average value**. The DC component of a signal is its projection onto the constants.

Worked Example 9.31 — Best sinusoidal approximation of a square wave

Let $q(t) = \operatorname{sgn}(\sin t)$ on $[-\pi, \pi]$ (a ± 1 square wave, period 2π). Find its best approximation (least error energy) in $\operatorname{span}\{\sin t\}$ and then in $\operatorname{span}\{\sin t, \sin 3t\}$, and the fraction of energy left in the error.

Inner products. $\|q\|^2 = \int_{-\pi}^{\pi} 1\, dt = 2\pi$, $\|\sin nt\|^2 = \pi$, and since $q(t)\sin nt$ is even,

$$\langle q, \sin nt\rangle = 2\int_0^{\pi} \sin nt\, dt = \frac{2(1-\cos n\pi)}{n} = \begin{cases} 4/n, & n \text{ odd} \\ 0, & n \text{ even.} \end{cases}$$

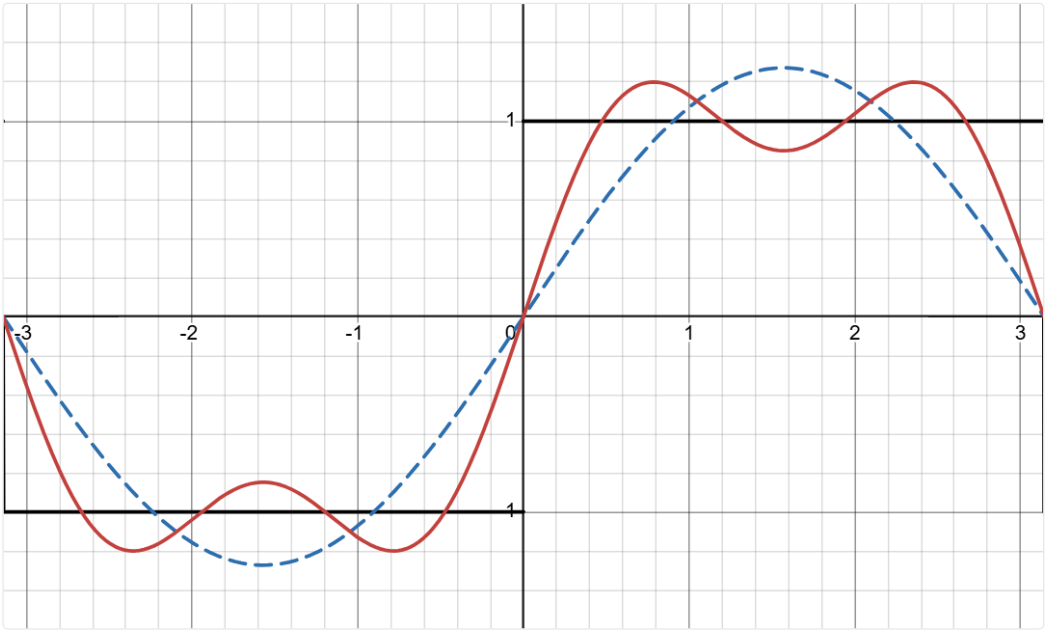
One term. $c_1 = \dfrac{4}{\pi} = 1.2732$, so $\hat{q}_1(t) = \dfrac{4}{\pi}\sin t$. Note that the best amplitude is *larger* than the square wave's amplitude 1.

Error energy: $\|q\|^2 - c_1^2\|\sin t\|^2 = 2\pi - \dfrac{16}{\pi^2}\pi = 2\pi - \dfrac{16}{\pi} = 6.2832 - 5.0930 = 1.1902$. Fraction of energy in the error: $1 - \dfrac{8}{\pi^2} = 0.1894$ (18.9 %).

Two terms. $\sin t \perp \sin 3t$, so c_1 is unchanged and $c_3 = \dfrac{4/3}{\pi} = \dfrac{4}{3\pi} = 0.4244$. Error fraction:

$$1 - \frac{8}{\pi^2}\left(1 + \frac{1}{9}\right) = 0.0994 \quad (9.9\ \%).$$

Adding the third harmonic halves the error energy, and c_1 did not have to be recomputed.



A ± 1 square wave (black), its orthogonal projection onto $\operatorname{span}\{\sin t\}$ (blue dashed, amplitude $4/\pi$) and onto $\operatorname{span}\{\sin t, \sin 3t\}$ (red). Each added orthogonal direction reduces the error energy without altering the earlier coefficients.

Engineering Note — the orthogonality principle in estimation

The condition "error $\perp$ every allowed direction" is the **orthogonality principle** of estimation theory. In a Wiener filter or a linear minimum-mean-square-error estimator, the vector space consists of random variables with inner product $\langle X, Y\rangle = E[XY]$, and the optimal linear estimate makes the estimation error uncorrelated with every observation used. Only the inner product has changed; the geometry is that of this section (Ch. 21).

9.10 Gram–Schmidt orthogonalization

Motivation

Orthogonal bases make coordinates, projections and approximations trivial — but the bases that arise naturally (the columns of a data matrix, the monomials $1, t, t^2, \ldots$, a set of measured waveforms) are rarely orthogonal. The **Gram–Schmidt process** converts any independent set into an orthonormal set with the same span, one vector at a time. In matrix form it is the **QR factorisation** $\mathbf{A} = \mathbf{QR}$, the standard numerical route to least squares; applied to polynomials it produces the **Legendre polynomials**, and applied to other weights it produces the other classical orthogonal polynomials used in filter design and spectral methods.

The algorithm

Given independent $\mathbf{a}_1, \ldots, \mathbf{a}_k$ in an inner-product space, subtract from each new vector its projections onto the orthogonal vectors already built:

$$\begin{aligned}
\mathbf{v}_1 &= \mathbf{a}_1,\\
\mathbf{v}_2 &= \mathbf{a}_2 - \frac{\langle \mathbf{a}_2,\mathbf{v}_1\rangle}{\langle \mathbf{v}_1,\mathbf{v}_1\rangle}\mathbf{v}_1,\\
\mathbf{v}_3 &= \mathbf{a}_3 - \frac{\langle \mathbf{a}_3,\mathbf{v}_1\rangle}{\langle \mathbf{v}_1,\mathbf{v}_1\rangle}\mathbf{v}_1 - \frac{\langle \mathbf{a}_3,\mathbf{v}_2\rangle}{\langle \mathbf{v}_2,\mathbf{v}_2\rangle}\mathbf{v}_2,\\
&\;\;\vdots\\
\mathbf{v}_j &= \mathbf{a}_j - \sum_{i=1}^{j-1}\frac{\langle \mathbf{a}_j,\mathbf{v}_i\rangle}{\langle \mathbf{v}_i,\mathbf{v}_i\rangle}\mathbf{v}_i = \mathbf{a}_j - \operatorname{proj}_{W_{j-1}}\mathbf{a}_j,
\end{aligned}$$

where $W_{j-1}=\operatorname{span}\{\mathbf{a}_1,\dots,\mathbf{a}_{j-1}\}$. Finally normalise: $\mathbf{q}_j=\mathbf{v}_j/\|\mathbf{v}_j\|$.

Gram–Schmidt

If $\mathbf{a}_1,\dots,\mathbf{a}_k$ are linearly independent, the vectors $\mathbf{q}_1,\dots,\mathbf{q}_k$ produced above are orthonormal and, for every j,

$$\operatorname{span}\{\mathbf{q}_1,\dots,\mathbf{q}_j\}=\operatorname{span}\{\mathbf{a}_1,\dots,\mathbf{a}_j\}.$$

Consequently every finite-dimensional inner-product space has an orthonormal basis.

Proof by induction. Suppose $\mathbf{v}_1,\dots,\mathbf{v}_{j-1}$ are orthogonal, nonzero and span W_{j-1}. Then $\mathbf{v}_j=\mathbf{a}_j-\operatorname{proj}_{W_{j-1}}\mathbf{a}_j$ is orthogonal to W_{j-1} by the best-approximation theorem (the error of a projection is perpendicular to the subspace). It is nonzero, because otherwise $\mathbf{a}_j\in W_{j-1}$, contradicting independence. And $\mathbf{v}_j$ is $\mathbf{a}_j$ minus an element of W_{j-1}, so $\operatorname{span}\{\mathbf{v}_1,\dots,\mathbf{v}_j\}=\operatorname{span}\{\mathbf{a}_1,\dots,\mathbf{a}_j\}$.

If the input vectors are dependent, some $\mathbf{v}_j$ comes out as $\mathbf{0}$; dropping it and continuing yields an orthonormal basis of the span. In numerical work a "nearly zero" $\mathbf{v}_j$ is a warning of near-dependence.

Worked Example 9.32 — Gram–Schmidt in $\mathbb{R}^3$

Orthonormalise $\mathbf{a}_1=(1,1,0)$, $\mathbf{a}_2=(1,0,1)$, $\mathbf{a}_3=(0,1,1)$ (independent by Worked Example 9.7(b)).

Step 1. $\mathbf{v}_1=(1,1,0)$, $\|\mathbf{v}_1\|^2=2$.

Step 2. $\langle \mathbf{a}_2,\mathbf{v}_1\rangle=1$:

$$\mathbf{v}_2=(1,0,1)-\tfrac12(1,1,0)=\left(\tfrac12,-\tfrac12,1\right),\qquad \|\mathbf{v}_2\|^2=\tfrac14+\tfrac14+1=\tfrac32.$$

Step 3. $\langle \mathbf{a}_3,\mathbf{v}_1\rangle=1$, $\langle \mathbf{a}_3,\mathbf{v}_2\rangle=-\tfrac12+1=\tfrac12$:

$$\mathbf{v}_3=(0,1,1)-\tfrac12(1,1,0)-\frac{1/2}{3/2}\left(\tfrac12,-\tfrac12,1\right)=\left(-\tfrac12-\tfrac16,\ \tfrac12+\tfrac16,\ 1-\tfrac13\right)=\left(-\tfrac23,\tfrac23,\tfrac23\right),$$

$\|\mathbf{v}_3\|^2=\tfrac43$.

Checks. $\mathbf{v}_1\cdot\mathbf{v}_2=\tfrac12-\tfrac12+0=0$; $\mathbf{v}_1\cdot\mathbf{v}_3=-\tfrac23+\tfrac23=0$; $\mathbf{v}_2\cdot\mathbf{v}_3=-\tfrac13-\tfrac13+\tfrac23=0$ ✓.

Normalise.

$$\mathbf{q}_1=\tfrac{1}{\sqrt2}(1,1,0),\qquad \mathbf{q}_2=\tfrac{1}{\sqrt6}(1,-1,2),\qquad \mathbf{q}_3=\tfrac{1}{\sqrt3}(-1,1,1).$$

(Scaling $\mathbf{v}_2$ by 2 and $\mathbf{v}_3$ by $\tfrac32$ before normalising avoids fractions — any positive rescaling of a $\mathbf{v}_j$ is harmless.)

QR factorisation

Gram–Schmidt can be recorded as a matrix factorisation. Since each $\mathbf{a}_j$ is a combination of $\mathbf{q}_1,\dots,\mathbf{q}_j$ only,

$$\mathbf{a}_j=r_{1j}\mathbf{q}_1+r_{2j}\mathbf{q}_2+\cdots+r_{jj}\mathbf{q}_j,\qquad r_{ij}=\langle \mathbf{a}_j,\mathbf{q}_i\rangle\ (i<j),\quad r_{jj}=\|\mathbf{v}_j\|>0.$$

QR factorisation

Every $\mathbf{A}\in\mathbb{R}^{m\times n}$ with independent columns can be written

$$\mathbf{A}=\mathbf{Q}\mathbf{R},$$

where $\mathbf{Q}\in\mathbb{R}^{m\times n}$ has orthonormal columns ($\mathbf{Q}^{\mathsf T}\mathbf{Q}=\mathbf{I}_n$) spanning $\operatorname{col}(\mathbf{A})$, and $\mathbf{R}\in\mathbb{R}^{n\times n}$ is upper triangular with positive diagonal. With these sign conventions the factorisation is unique.

Since $\mathbf{Q}^{\mathsf T}\mathbf{Q}=\mathbf{I}$, the triangular factor is obtained as $\mathbf{R}=\mathbf{Q}^{\mathsf T}\mathbf{A}$, and the projection onto the column space is $\mathbf{P}=\mathbf{Q}\mathbf{Q}^{\mathsf T}$.

Worked Example 9.33 — QR of a 3×2 matrix

Factor $\mathbf{A} = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \end{bmatrix}$ (the matrix of Worked Example 9.29).

$\mathbf{a}_1 = (1,1,1)$: $r_{11} = \sqrt{3}$, $\mathbf{q}_1 = \frac{1}{\sqrt{3}}(1,1,1)$.

$\mathbf{a}_2 = (0,1,2)$: $r_{12} = \langle \mathbf{a}_2, \mathbf{q}_1 \rangle = \frac{3}{\sqrt{3}} = \sqrt{3}$. Then $\mathbf{v}_2 = \mathbf{a}_2 - r_{12}\mathbf{q}_1 = (0,1,2) - (1,1,1) = (-1,0,1)$, $r_{22} = \sqrt{2}$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(-1,0,1)$.

$$\mathbf{A} = \underbrace{\begin{bmatrix} 1/\sqrt{3} & -1/\sqrt{2} \\ 1/\sqrt{3} & 0 \\ 1/\sqrt{3} & 1/\sqrt{2} \end{bmatrix}}_{\mathbf{Q}} \underbrace{\begin{bmatrix} \sqrt{3} & \sqrt{3} \\ 0 & \sqrt{2} \end{bmatrix}}_{\mathbf{R}}.$$

Check the second column: $\sqrt{3}\,\mathbf{q}_1 + \sqrt{2}\,\mathbf{q}_2 = (1,1,1) + (-1,0,1) = (0,1,2)$ ✓. Notice that $\mathbf{v}_2 = (-1,0,1)$ is the second column "centred" by removing its mean — Gram–Schmidt against the all-ones column is mean removal.

Orthogonal polynomials: Legendre

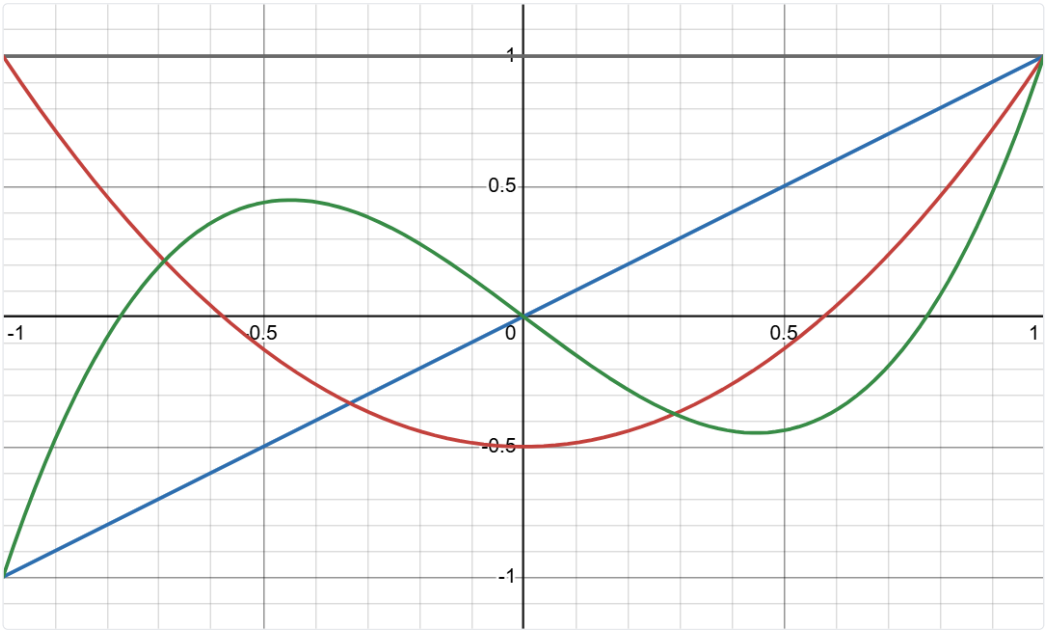
Apply Gram–Schmidt to $1, t, t^2, t^3$ in $C[-1,1]$ with $\langle f, g \rangle = \int_{-1}^{1} f g \, dt$. Useful integrals: $\int_{-1}^{1} t^k \, dt = \frac{2}{k+1}$ for even k, 0 for odd k.

- $v_0 = 1$, $\|v_0\|^2 = 2$.
- $v_1 = t - \frac{\langle t, 1 \rangle}{2} \cdot 1 = t$ (since $\langle t, 1 \rangle = 0$), $\|v_1\|^2 = \frac{2}{3}$.
- $v_2 = t^2 - \frac{\langle t^2, 1 \rangle}{2} \cdot 1 - \frac{\langle t^2, t \rangle}{2/3} t = t^2 - \frac{2/3}{2} = t^2 - \frac{1}{3}$.
- $v_3 = t^3 - \frac{\langle t^3, 1 \rangle}{2} - \frac{\langle t^3, t \rangle}{2/3} t - \frac{\langle t^3, v_2 \rangle}{\|v_2\|^2} v_2 = t^3 - \frac{2/5}{2/3} t = t^3 - \frac{3}{5} t$ (the first and last inner products vanish by odd symmetry).

Rescaled so that $P_n(1) = 1$, these are the **Legendre polynomials**:

$$P_0 = 1, \qquad P_1 = t, \qquad P_2 = \tfrac{1}{2}(3t^2 - 1), \qquad P_3 = \tfrac{1}{2}(5t^3 - 3t), \qquad \int_{-1}^{1} P_m P_n \, dt = \frac{2}{2n+1} \delta_{mn}.$$

They satisfy the three-term recurrence $(n+1)P_{n+1} = (2n+1)tP_n - nP_{n-1}$, which generates them far more cheaply than Gram–Schmidt. Changing the interval or inserting a weight function $w(t)$ in the inner product produces the other classical families: Chebyshev ($w = 1/\sqrt{1-t^2}$ — used in Chebyshev filters and minimax approximation), Laguerre ($w = e^{-t}$ on $[0, \infty)$), Hermite ($w = e^{-t^2}$ on $\mathbb{R}$).



Legendre polynomials P_0 (grey), P_1 (blue), P_2 (red) and P_3 (green) on $[-1,1]$: each has exactly n zeros in the interval and they are mutually orthogonal under $\int_{-1}^{1} f g \, dt$.

Worked Example 9.34 — Checking Legendre orthogonality and norms

Verify $\langle P_0, P_2\rangle = 0$, $\langle P_1, P_3\rangle = 0$ and $\|P_2\|^2 = \tfrac{2}{5}$.

$$\langle P_0, P_2\rangle = \tfrac{1}{2}\int_{-1}^{1} (3t^2 - 1)\,dt = \tfrac{1}{2}(2 - 2) = 0 \checkmark$$

$$\langle P_1, P_3\rangle = \tfrac{1}{2}\int_{-1}^{1} (5t^4 - 3t^2)\,dt = \tfrac{1}{2}\left(5\cdot\tfrac{2}{5} - 3\cdot\tfrac{2}{3}\right) = \tfrac{1}{2}(2 - 2) = 0 \checkmark$$

$$\|P_2\|^2 = \tfrac{1}{4}\int_{-1}^{1} (9t^4 - 6t^2 + 1)\,dt = \tfrac{1}{4}\left(\tfrac{18}{5} - 4 + 2\right) = \tfrac{1}{4}\cdot\tfrac{8}{5} = \tfrac{2}{5} = \tfrac{2}{2\cdot 2+1} \checkmark$$

(Pairs of opposite parity, such as P_0, P_1 or P_2, P_3, are orthogonal automatically by symmetry.)

Numerical behaviour: classical versus modified Gram–Schmidt

In floating-point arithmetic the formula above (**classical** Gram–Schmidt, CGS) computes all the coefficients $\langle \mathbf{a}_j, \mathbf{v}_i\rangle$ from the *original* vector $\mathbf{a}_j$. When the columns are nearly dependent, rounding errors make the computed $\mathbf{q}_j$ lose orthogonality badly. **Modified** Gram–Schmidt (MGS) subtracts the projections one at a time, using the partially updated vector:

$$\mathbf{w} \leftarrow \mathbf{a}_j; \quad \text{for } i = 1, \dots, j-1: \;\; r_{ij} = \langle \mathbf{w}, \mathbf{q}_i\rangle, \;\; \mathbf{w} \leftarrow \mathbf{w} - r_{ij}\mathbf{q}_i; \quad r_{jj} = \|\mathbf{w}\|, \;\; \mathbf{q}_j = \mathbf{w}/r_{jj}.$$

In exact arithmetic CGS and MGS are identical; in floating point MGS loses orthogonality roughly in proportion to $\kappa(\mathbf{A})\,\varepsilon_{\text{mach}}$ rather than $\kappa(\mathbf{A})^2\varepsilon_{\text{mach}}$. Library QR routines use Householder reflections, which are more stable still (Ch. 22).

Common Pitfall — projecting onto the original vectors

A frequent hand-calculation error is to subtract projections onto the *original* $\mathbf{a}_i$ instead of onto the already-orthogonalised $\mathbf{v}_i$. The $\mathbf{a}_i$ are not orthogonal, so the sum-of-projections formula does not apply to them and the result is not orthogonal. Always project onto the $\mathbf{v}_i$ (or $\mathbf{q}_i$), and check each new vector against all previous ones.

Engineering Note — orthogonalising measured signals

Gram–Schmidt is used directly in adaptive signal processing: a **Gram–Schmidt (lattice) canceller** in a radar or antenna array orthogonalises the auxiliary channels one stage at a time, so that interference can be removed from the main channel stage by stage. The same idea appears as "prewhitening" and "decorrelation" in multichannel receivers, and in the QR-based recursive least-squares (QR-RLS) adaptive filter.

9.11 Least-squares approximation

Motivation

Measurements are noisy and models are idealised, so an engineer usually has **more equations than unknowns** and no exact solution. Calibrating a sensor from twenty readings with a two-parameter straight-line model, estimating a resistor's value and an amplifier's offset from many voltage–current pairs, identifying the time constant of an RC network from a sampled decay, fitting a polynomial to a thermistor curve — each is an overdetermined linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ with $\mathbf{b} \notin \operatorname{col}(\mathbf{A})$. The **least-squares** solution chooses $\mathbf{x}$ to make the residual as small as possible in the Euclidean norm. Geometrically it is a projection (Section 9.9); computationally it is solved by the normal equations or, better, by QR (Section 9.10).

The least-squares problem

Least-squares solution

For $\mathbf{A} \in \mathbb{R}^{m\times n}$ and $\mathbf{b} \in \mathbb{R}^m$, a **least-squares solution** of $\mathbf{A}\mathbf{x} = \mathbf{b}$ is any $\hat{\mathbf{x}}$ minimising

$$J(\mathbf{x}) = \|\mathbf{b} - \mathbf{A}\mathbf{x}\|^2 = \sum_{i=1}^{m} \big(b_i - (\mathbf{A}\mathbf{x})_i\big)^2.$$

The vector $\mathbf{r} = \mathbf{b} - \mathbf{A}\hat{\mathbf{x}}$ is the **residual**, and $\|\mathbf{r}\|^2$ is the **sum of squared errors** (SSE).

Normal equations

$\hat{\mathbf{x}}$ is a least-squares solution of $\mathbf{A}\mathbf{x} = \mathbf{b}$ if and only if

$$\mathbf{A}^{\mathsf{T}}\mathbf{A}\,\hat{\mathbf{x}} = \mathbf{A}^{\mathsf{T}}\mathbf{b}.$$

The normal equations are always consistent. The least-squares solution is unique iff the columns of $\mathbf{A}$ are independent ($\operatorname{rank}\mathbf{A} = n$), and then

$$\hat{\mathbf{x}} = (\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}\mathbf{b}, \qquad \mathbf{A}\hat{\mathbf{x}} = \operatorname{proj}_{\operatorname{col}(\mathbf{A})}\mathbf{b}.$$

Geometric derivation. As $\mathbf{x}$ ranges over $\mathbb{R}^n$, $\mathbf{A}\mathbf{x}$ ranges over $\operatorname{col}(\mathbf{A})$. The closest point of that subspace to $\mathbf{b}$ is the orthogonal projection $\mathbf{p}$, characterised by $\mathbf{b} - \mathbf{p} \perp \operatorname{col}(\mathbf{A})$, i.e. $\mathbf{b} - \mathbf{A}\hat{\mathbf{x}} \in \operatorname{col}(\mathbf{A})^{\perp} = \operatorname{null}(\mathbf{A}^{\mathsf{T}})$ (Section 9.7). That is exactly $\mathbf{A}^{\mathsf{T}}(\mathbf{b} - \mathbf{A}\hat{\mathbf{x}}) = \mathbf{0}$. Since $\mathbf{p}$ always exists, the normal equations are always consistent; if $\operatorname{null}(\mathbf{A}) \neq \{\mathbf{0}\}$, any null-space vector can be added to $\hat{\mathbf{x}}$ without changing $\mathbf{A}\hat{\mathbf{x}}$.

Calculus derivation. Expand

$$J(\mathbf{x}) = \mathbf{b}^{\mathsf{T}}\mathbf{b} - 2\mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{b} + \mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x}.$$

Setting the gradient (Ch. 6) to zero gives $\nabla J = -2\mathbf{A}^{\mathsf{T}}\mathbf{b} + 2\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{0}$, the normal equations. The Hessian $2\mathbf{A}^{\mathsf{T}}\mathbf{A}$ is positive semidefinite ($\mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \|\mathbf{A}\mathbf{x}\|^2 \geq 0$), so the stationary point is a minimum — strictly so when the columns are independent. The two derivations agree, as they must: minimising a squared distance *is* projecting.

The minimum value follows from Pythagoras, $\|\mathbf{b}\|^2 = \|\mathbf{A}\hat{\mathbf{x}}\|^2 + \|\mathbf{r}\|^2$, and can be computed as $\|\mathbf{r}\|^2 = \mathbf{b}^{\mathsf{T}}\mathbf{b} - \hat{\mathbf{x}}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{b}$.

Fitting a straight line

Given data (t_i, y_i), $i = 1, \dots, m$, the model $y \approx c_0 + c_1 t$ produces one equation per data point:

$$\underbrace{\begin{bmatrix} 1 & t_1 \\ 1 & t_2 \\ \vdots & \vdots \\ 1 & t_m \end{bmatrix}}_{\mathbf{A}} \begin{bmatrix} c_0 \\ c_1 \end{bmatrix} \approx \underbrace{\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_m \end{bmatrix}}_{\mathbf{b}}, \qquad \mathbf{A}^{\mathsf{T}}\mathbf{A} = \begin{bmatrix} m & \sum t_i \\ \sum t_i & \sum t_i^2 \end{bmatrix}, \quad \mathbf{A}^{\mathsf{T}}\mathbf{b} = \begin{bmatrix} \sum y_i \\ \sum t_i y_i \end{bmatrix}.$$

Solving the 2×2 system gives the familiar regression formulas

$$c_1 = \frac{\sum (t_i - \bar{t})(y_i - \bar{y})}{\sum (t_i - \bar{t})^2}, \qquad c_0 = \bar{y} - c_1 \bar{t},$$

where $\bar{t}, \bar{y}$ are the sample means. (They follow most quickly from the QR remark of Worked Example 9.33: orthogonalising the t column against the ones column replaces t_i by $t_i - \bar{t}$, which decouples the two unknowns.) In particular **the least-squares line passes through the centroid** $(\bar{t}, \bar{y})$, and the residuals sum to zero (the residual is orthogonal to the column of ones).

Worked Example 9.35 — The smallest line-fitting problem

Fit $y = c_0 + c_1 t$ to the points $(0, 6)$, $(1, 0)$, $(2, 0)$.

This is exactly Worked Example 9.29 with $\mathbf{A} = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \end{bmatrix}$ and $\mathbf{b} = (6, 0, 0)^{\mathsf{T}}$. The normal equations gave $c_0 = 5$, $c_1 = -3$:

$$\hat{y} = 5 - 3t, \qquad \text{fitted values } (5, 2, -1), \qquad \text{residuals } (1, -2, 1), \qquad \text{SSE} = 6.$$

Checks. Residuals sum to zero ✓. The line passes through the centroid $(\bar{t}, \bar{y}) = (1, 2)$: $5 - 3 = 2$ ✓. The regression formula: $\bar{t} = 1$, $\sum (t_i - \bar{t})(y_i - \bar{y}) = (-1)(4) + 0 + (1)(-2) = -6$, $\sum (t_i - \bar{t})^2 = 2$, so $c_1 = -3$ ✓.

Via QR (Worked Example 9.33): $\mathbf{Q}^{\mathsf{T}}\mathbf{b} = \left(\frac{6}{\sqrt{3}}, -\frac{6}{\sqrt{2}}\right) = (2\sqrt{3}, -3\sqrt{2})$. Back-substitute in $\mathbf{R}\hat{\mathbf{x}} = \mathbf{Q}^{\mathsf{T}}\mathbf{b}$: $\sqrt{2}\, c_1 = -3\sqrt{2} \Rightarrow c_1 = -3$; $\sqrt{3}\, c_0 + \sqrt{3}(-3) = 2\sqrt{3} \Rightarrow c_0 = 5$ ✓.

Worked Example 9.36 — Resistance and offset from V–I measurements

A resistor is measured with a voltmeter that may have an offset. The data are

I (mA)	0	1	2	3	4
V (V)	0.1	1.9	4.2	5.8	8.1

Fit $V = V_{\text{off}} + RI$.

Sums. $m = 5$, $\sum I = 10$, $\sum I^2 = 30$, $\sum V = 20.1$, $\sum IV = 0 + 1.9 + 8.4 + 17.4 + 32.4 = 60.1$.

Normal equations.

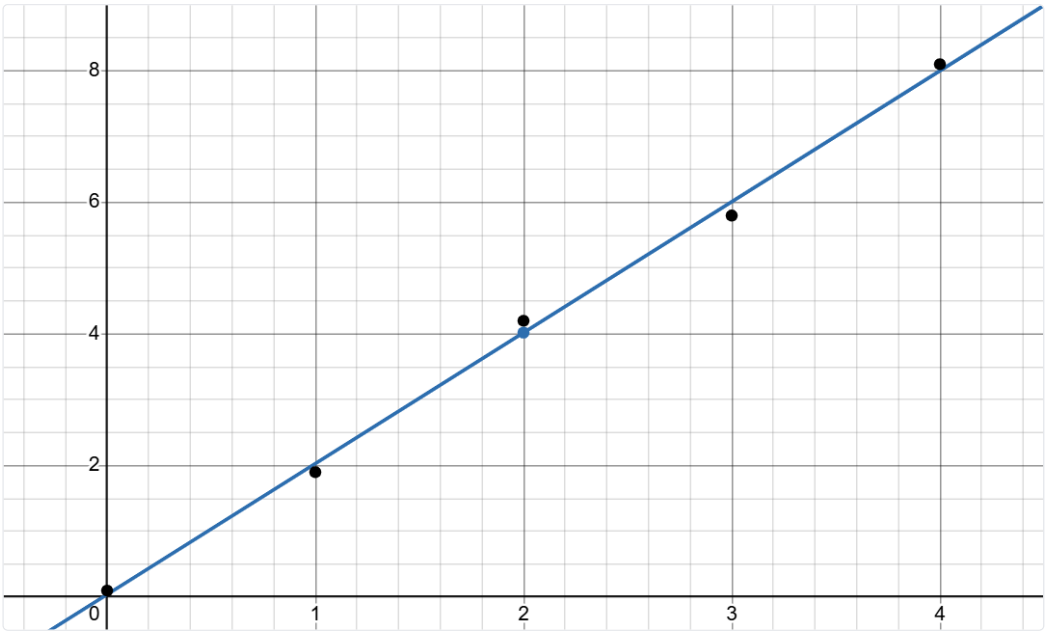
$$\begin{bmatrix} 5 & 10 \\ 10 & 30 \end{bmatrix} \begin{bmatrix} V_{\text{off}} \\ R \end{bmatrix} = \begin{bmatrix} 20.1 \\ 60.1 \end{bmatrix}.$$

Determinant $5 \cdot 30 - 10 \cdot 10 = 50$. By Cramer's rule,

$$V_{\text{off}} = \frac{30(20.1) - 10(60.1)}{50} = \frac{603 - 601}{50} = 0.04 \text{ V}, \qquad R = \frac{5(60.1) - 10(20.1)}{50} = \frac{300.5 - 201}{50} = 1.99 \text{ V/mA} = 1.99 \text{ k}\Omega.$$

Residuals. Fitted values $0.04, 2.03, 4.02, 6.01, 8.00$; residuals $0.06, -0.13, 0.18, -0.21, 0.10$ (sum 0 ✓); SSE $= 0.107$ V^2.

Quality of fit. The total variation about the mean is $\sum (V_i - \bar{V})^2 = \sum V_i^2 - m\bar{V}^2 = 120.51 - 5(4.02)^2 = 39.71$, so the coefficient of determination is $R^2 = 1 - 0.107/39.71 = 0.9973$. **Units check:** V_{off} in volts, R in V/mA — each column of $\mathbf{A}$ carries its own units, and each unknown takes the units that make $\mathbf{A}\mathbf{x}$ volts.



Least-squares line $V = 0.04 + 1.99I$ through the five measured points; it passes through the centroid $(\bar{I}, \bar{V}) = (2, 4.02)$, and the vertical residuals are what is minimised.

Polynomial and general linear-in-the-parameters models

The same machinery fits *any* model that is **linear in its unknown parameters**, however nonlinear it is in t:

$$y(t) \approx c_1\phi_1(t) + c_2\phi_2(t) + \cdots + c_n\phi_n(t), \qquad \mathbf{A} = \big[\phi_j(t_i)\big]_{m\times n}.$$

Examples: polynomials ($\phi_j = t^{j-1}$, giving a **Vandermonde** matrix), sinusoids of known frequency ($\phi = \cos\omega t, \sin\omega t$, which estimates amplitude and phase), exponentials with known rates, splines. The column j of $\mathbf{A}$ is simply the jth basis function sampled at the measurement times.

Worked Example 9.37 — A quadratic fit

Fit $y = c_0 + c_1 t + c_2 t^2$ to

t	-2	-1	0	1	2
y	8.2	2.4	0.9	3.6	10.1

Matrix. Rows $(1, t_i, t_i^2)$. Because the t_i are symmetric about 0, all odd power sums vanish: $\sum t_i = \sum t_i^3 = 0$, $\sum t_i^2 = 10$, $\sum t_i^4 = 34$.

$$\mathbf{A}^{\mathsf T}\mathbf{A} = \begin{bmatrix} 5 & 0 & 10 \\ 0 & 10 & 0 \\ 10 & 0 & 34 \end{bmatrix}, \qquad \mathbf{A}^{\mathsf T}\mathbf{b} = \begin{bmatrix} \sum y_i \\ \sum t_i y_i \\ \sum t_i^2 y_i \end{bmatrix} = \begin{bmatrix} 25.2 \\ 5.0 \\ 79.2 \end{bmatrix}.$$

($\sum t_i y_i = -16.4 - 2.4 + 0 + 3.6 + 20.2 = 5.0$; $\sum t_i^2 y_i = 32.8 + 2.4 + 0 + 3.6 + 40.4 = 79.2$.)

Solve. The middle equation decouples: $10c_1 = 5 \Rightarrow c_1 = 0.5$. From the first, $c_0 = 5.04 - 2c_2$; substitute in the third: $10(5.04 - 2c_2) + 34c_2 = 79.2 \Rightarrow 14c_2 = 28.8 \Rightarrow c_2 = 2.0571$, and $c_0 = 0.9257$.

$$\hat{y} = 0.9257 + 0.5t + 2.0571t^2.$$

Residuals $(0.046, -0.083, -0.026, 0.117, -0.054)$, SSE $= 0.0263$. Symmetric sample points made t orthogonal to both 1 and t^2 — a small taste of the simplification orthogonal bases bring.

Worked Example 9.38 — Time constant of an RC discharge (linearised fit)

A capacitor discharging through a resistor is sampled:

t (ms)	0	1	2	3	4
v (V)	5.00	3.02	1.85	1.10	0.68

Estimate V_0 and τ in $v = V_0 e^{-t/\tau}$.

Linearise. The model is not linear in τ, but $\ln v = \ln V_0 - t/\tau$ is linear in the parameters $a = \ln V_0$ and $b = -1/\tau$. Take logs: $\ln v = (1.6094,\ 1.1053,\ 0.6152,\ 0.0953,\ -0.3857)$.

Normal equations (same $\mathbf{A}^{\mathsf T}\mathbf{A}$ as Worked Example 9.36 since the t_i are again $0,\dots,4$):

$$\begin{bmatrix} 5 & 10 \\ 10 & 30 \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} \sum \ln v_i \\ \sum t_i \ln v_i \end{bmatrix} = \begin{bmatrix} 3.0395 \\ 1.0789 \end{bmatrix}.$$

$$a = \frac{30(3.0395) - 10(1.0789)}{50} = 1.6079, \qquad b = \frac{5(1.0789) - 10(3.0395)}{50} = -0.5000 \ \text{ms}^{-1}.$$

Result. $V_0 = e^{1.6079} = 4.99$ V and $\tau = -1/b = 2.00$ ms. Fitted values $4.99, 3.03, 1.84, 1.11, 0.68$ V agree with the data to within 0.02 V.

Caveat. Minimising squared errors in $\ln v$ is *not* the same as minimising squared errors in v: the log transform gives small voltages (late samples, where relative noise is largest) as much weight as large ones. When that matters, use weighted least squares (below) with weights $w_i \propto v_i^2$, or a genuinely nonlinear least-squares fit (Ch. 23).

Weighted least squares

If some measurements are more reliable than others — say measurement i has noise standard deviation σ_i — minimise the weighted sum

$$J_{\mathbf{W}}(\mathbf{x}) = \sum_{i} w_i \big(b_i - (\mathbf{A}\mathbf{x})_i\big)^2 = (\mathbf{b} - \mathbf{A}\mathbf{x})^{\mathsf T}\mathbf{W}(\mathbf{b} - \mathbf{A}\mathbf{x}), \qquad \mathbf{W} = \operatorname{diag}(w_i),\ w_i = 1/\sigma_i^2.$$

This is ordinary least squares in the weighted inner product $\langle \mathbf{u}, \mathbf{v}\rangle_{\mathbf{W}} = \mathbf{v}^{\mathsf T}\mathbf{W}\mathbf{u}$ of Section 9.8, so the orthogonality principle gives the **weighted normal equations**

$$\mathbf{A}^{\mathsf T}\mathbf{W}\mathbf{A}\,\hat{\mathbf{x}} = \mathbf{A}^{\mathsf T}\mathbf{W}\mathbf{b}.$$

Equivalently, scale row i of $\mathbf{A}$ and $\mathbf{b}$ by $\sqrt{w_i}$ and solve an ordinary problem. The statistical justification (best linear unbiased estimation) and confidence intervals for the fitted parameters belong to Ch. 20.

Worked Example 9.39 — Averaging measurements of unequal quality

A voltage is measured three times: 5.02 V and 4.98 V with a meter of $\sigma = 0.02$ V, and 5.20 V with a meter of $\sigma = 0.10$ V. Find the weighted least-squares estimate.

The model is $v \approx x$ for each reading: $\mathbf{A} = (1,1,1)^{\mathsf T}$, $\mathbf{b} = (5.02, 4.98, 5.20)^{\mathsf T}$, weights $w = (2500, 2500, 100)$ V^{-2}.

$$\hat{x} = \frac{\mathbf{A}^{\mathsf T}\mathbf{W}\mathbf{b}}{\mathbf{A}^{\mathsf T}\mathbf{W}\mathbf{A}} = \frac{2500(5.02) + 2500(4.98) + 100(5.20)}{2500 + 2500 + 100} = \frac{25\,520}{5100} = 5.0039 \ \text{V}.$$

The unweighted mean would be 5.0667 V, pulled up by the poor reading. Weighted least squares with a single constant column is simply the **inverse-variance-weighted mean**.

Numerical aspects: normal equations versus QR

Forming $\mathbf{A}^{\mathsf T}\mathbf{A}$ squares the condition number:

$$\kappa(\mathbf{A}^{\mathsf T}\mathbf{A}) = \kappa(\mathbf{A})^2.$$

If $\kappa(\mathbf{A}) = 10^6$, the normal equations have $\kappa = 10^{12}$ and, in double precision, only about four correct digits can be expected. The QR route avoids the squaring. With $\mathbf{A} = \mathbf{Q}\mathbf{R}$,

$$\mathbf{A}^{\mathsf T}\mathbf{A}\hat{\mathbf{x}} = \mathbf{A}^{\mathsf T}\mathbf{b} \implies \mathbf{R}^{\mathsf T}\mathbf{Q}^{\mathsf T}\mathbf{Q}\mathbf{R}\hat{\mathbf{x}} = \mathbf{R}^{\mathsf T}\mathbf{Q}^{\mathsf T}\mathbf{b} \implies \mathbf{R}\hat{\mathbf{x}} = \mathbf{Q}^{\mathsf T}\mathbf{b},$$

a triangular system solved by back substitution (Worked Example 9.35). This is what `numpy.linalg.lstsq`, MATLAB's backslash and similar routines do (some use the SVD of Ch. 10, which also handles rank deficiency gracefully).

The classic ill-conditioned case is polynomial fitting with the monomial basis. In the continuous version — approximating f on $[0,1]$ by $\sum_{j=0}^{n-1} c_j t^j$ — the normal-equation matrix has entries $\langle t^i, t^j\rangle = \int_0^1 t^{i+j}\,dt = \frac{1}{i+j+1}$: the **Hilbert matrix**. Its condition number explodes:

n	3	6	10
$\kappa(\mathbf{H}_n)$	5.2×10^2	1.5×10^7	1.6×10^{13}

The cause is the near-parallelism of t^i and t^j seen in Worked Example 9.25(b). The cure is to use an orthogonal basis, which makes the normal-equation matrix diagonal.

Continuous least squares and orthogonal polynomials

To approximate a function f on $[a,b]$ by an element of a finite-dimensional subspace W in the sense of least integrated squared error, project in the function-space inner product (Section 9.9). With an orthogonal basis $\{\phi_k\}$ of W there is no system to solve at all:

$$\hat f=\sum_k c_k\phi_k,\qquad c_k=\frac{\langle f,\phi_k\rangle}{\langle \phi_k,\phi_k\rangle},\qquad \|f-\hat f\|^2=\|f\|^2-\sum_k |c_k|^2\|\phi_k\|^2.$$

Worked Example 9.40 — Best quadratic approximation of e^t on $[-1,1]$

Find the quadratic $q(t)$ minimising $\int_{-1}^{1}(e^t-q(t))^2\,dt$ and compare it with the Taylor polynomial $1+t+t^2/2$.

Use Legendre polynomials (Section 9.10), $\|P_k\|^2=\frac{2}{2k+1}$, so $c_k=\frac{2k+1}{2}\int_{-1}^{1}e^tP_k\,dt$. The integrals ($\int te^t dt=(t-1)e^t$, $\int t^2e^t dt=(t^2-2t+2)e^t$):

$$\int_{-1}^{1}e^t\,dt=e-e^{-1},\qquad \int_{-1}^{1}te^t\,dt=\frac{2}{e},\qquad \int_{-1}^{1}t^2e^t\,dt=e-\frac{5}{e}.$$

Hence

$$c_0=\tfrac12(e-e^{-1})=\sinh 1=1.1752,\qquad c_1=\tfrac32\cdot\tfrac{2}{e}=\tfrac{3}{e}=1.1036,$$

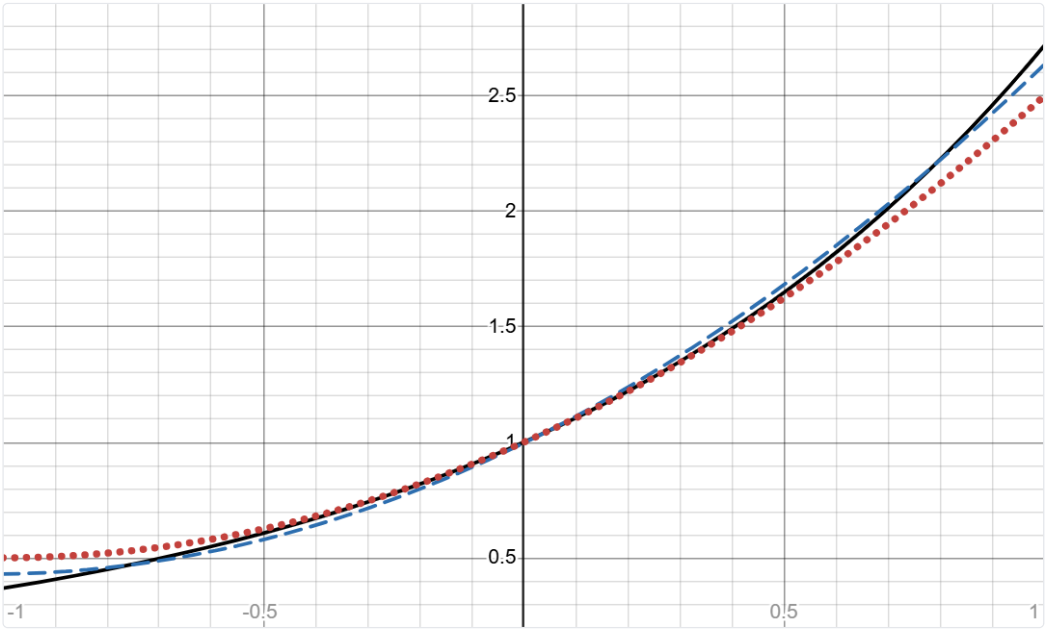
$$c_2=\tfrac52\int_{-1}^{1}\tfrac{3t^2-1}{2}e^t\,dt=\tfrac52\Big[\tfrac32\big(e-\tfrac5e\big)-\tfrac12\big(e-\tfrac1e\big)\Big]=\tfrac52\Big(e-\tfrac{7}{e}\Big)=0.3578.$$

Assemble. $q=c_0+c_1t+c_2\cdot\frac{3t^2-1}{2}$:

$$q(t)=\big(1.1752-0.1789\big)+1.1036\,t+0.5367\,t^2=0.9963+1.1036\,t+0.5367\,t^2.$$

Error. Numerically, $\int_{-1}^{1}(e^t-q)^2dt=1.44\times10^{-3}$ (RMS error 0.027 over the interval), whereas the Taylor polynomial gives 8.99×10^{-3} — more than six times larger. Taylor is perfect at $t=0$ and poor at the ends; least squares spreads the error over the whole interval (errors -0.061, 0.004, 0.082 at $t=-1,0,1$).

Monomial check. Solving the 3×3 normal equations in the basis $1,t,t^2$ (Gram matrix entries $\int_{-1}^{1}t^{i+j}dt$) gives the same q, as it must — the projection does not depend on the basis — but requires solving a coupled system.



e^t (black), its least-squares quadratic on $[-1,1]$ (blue dashed, nearly indistinguishable) and the Taylor quadratic about 0 (red dotted), which drifts away towards $t=\pm1$.

Fourier series as least squares

Take $W=\operatorname{span}\{1,\cos\omega_0t,\sin\omega_0t,\dots,\cos N\omega_0t,\sin N\omega_0t\}$ on one period. This basis is orthogonal (Section 9.8), so the best approximation of a periodic f in W — the trigonometric polynomial of order N with least mean-square error — has coefficients

$$a_0=\frac{1}{T}\int_T f\,dt,\qquad a_k=\frac{2}{T}\int_T f\cos k\omega_0t\,dt,\qquad b_k=\frac{2}{T}\int_T f\sin k\omega_0t\,dt.$$

These are precisely the Fourier coefficients. In other words, **the truncated Fourier series is the least-squares approximation of f by harmonics up to order N**, the error is orthogonal to every retained harmonic, and adding more harmonics never changes the earlier coefficients (Worked Example 9.31). In discrete form, fitting N samples with the DFT basis is a least-squares problem whose matrix has orthogonal columns, which is why the DFT can be inverted by a conjugate transpose. Ch. 15 takes up convergence as $N\to\infty$, Gibbs' phenomenon and power relations; Ch. 16 extends the idea to aperiodic signals.

Common Pitfall — extrapolating and over-fitting

A least-squares polynomial is only as good as the range of the data. A high-degree polynomial fitted to m points can pass close to every one of them while oscillating wildly between and beyond them; with degree $m-1$ it interpolates exactly, the residual is zero, and noise is fitted along with signal. Choose the model order from physics or from residual behaviour on held-out data, not by driving the SSE to zero, and never trust a polynomial fit outside the measured interval.

Engineering Note — where least squares runs in hardware

Least squares is computed continuously inside modern electronics: channel estimation in a Wi-Fi or LTE receiver solves a small least-squares problem against known pilot symbols on every frame; GPS receivers solve linearised least squares for position and clock bias from four or more pseudoranges; battery-management ICs fit equivalent-circuit parameters; adaptive equalisers run recursive least squares (RLS), which updates $\hat{\mathbf{x}}$ as each new row of $\mathbf{A}$ arrives without re-solving from scratch. The mathematics is always this section's: project the measurement vector onto the column space of the model.

Summary

Concept	Key formula / statement
Vector space	closed under $\mathbf{u}+\mathbf{v}$ and $c\mathbf{u}$; eight axioms; contains $\mathbf{0}$
Subspace test	$\mathbf{0}\in W$ and $a\mathbf{u}+b\mathbf{v}\in W$ for all $\mathbf{u},\mathbf{v}\in W$
Span	$\operatorname{span}\{\mathbf{v}_i\}=\{\sum c_i\mathbf{v}_i\}$, the smallest subspace containing the $\mathbf{v}_i$
Linear independence	$\sum c_i\mathbf{v}_i=\mathbf{0}\Rightarrow$ all $c_i=0$; in $\mathbb{F}^m$: $\operatorname{rank}[\mathbf{v}_1\cdots\mathbf{v}_k]=k$
Wronskian	$W(f_1,\dots,f_k)(t_0)\neq 0\Rightarrow$ independent
Basis, coordinates	independent + spanning; $\mathbf{x}=\mathbf{P}_{\mathcal{B}}[\mathbf{x}]_{\mathcal{B}}$
Dimension	number of vectors in any basis; $\dim\mathcal{P}_n=n+1$, $\dim\mathbb{R}^{m\times n}=mn$
Linear map	$T(a\mathbf{u}+b\mathbf{v})=aT(\mathbf{u})+bT(\mathbf{v})$; matrix columns $=T(\mathbf{e}_j)$
Change of basis	$[T]_{\mathcal{B}}=\mathbf{P}^{-1}\mathbf{A}\mathbf{P}$ (similar matrices)
Rank–nullity	$\operatorname{rank}\mathbf{A}+\dim\operatorname{null}\mathbf{A}=n$
Four subspaces	$\dim\operatorname{col}=\dim\operatorname{row}=r$, $\dim\operatorname{null}=n-r$, $\dim\operatorname{null}(\mathbf{A}^{\mathsf{T}})=m-r$
Orthogonal complements	$\operatorname{null}(\mathbf{A})=\operatorname{row}(\mathbf{A})^{\perp}$, $\operatorname{null}(\mathbf{A}^{\mathsf{T}})=\operatorname{col}(\mathbf{A})^{\perp}$
Solution structure	$\mathbf{x}=\mathbf{x}_p+\mathbf{x}_n$, $\mathbf{x}_n\in\operatorname{null}(\mathbf{A})$; solvable iff $\mathbf{b}\in\operatorname{col}(\mathbf{A})$
Cauchy–Schwarz	$\lvert\langle\mathbf{u},\mathbf{v}\rangle\rvert\le\lVert\mathbf{u}\rVert\lVert\mathbf{v}\rVert$; $\cos\theta=\langle\mathbf{u},\mathbf{v}\rangle/(\lVert\mathbf{u}\rVert\lVert\mathbf{v}\rVert)$
Complex inner product	$\langle\mathbf{u},\mathbf{v}\rangle=\mathbf{v}^{\mathsf{H}}\mathbf{u}=\sum u_kv_k^*$
Signal inner products	$\langle x,y\rangle=\int x\,y^*\,dt$ (energy); $\langle x,y\rangle_T=\frac{1}{T}\int_T x\,y^*\,dt$ (power, norm $=$ RMS)
Orthogonal harmonics	$\frac{1}{T}\int_T e^{jm\omega_0 t}e^{-jn\omega_0 t}dt=\delta_{mn}$
Orthogonal coordinates	$c_j=\langle\mathbf{x},\mathbf{u}_j\rangle/\langle\mathbf{u}_j,\mathbf{u}_j\rangle$; Parseval $\lVert\mathbf{x}\rVert^2=\sum\lvert c_j\rvert^2\lVert\mathbf{u}_j\rVert^2$
Orthogonal matrix	$\mathbf{Q}^{\mathsf{T}}\mathbf{Q}=\mathbf{I}$, $\mathbf{Q}^{-1}=\mathbf{Q}^{\mathsf{T}}$, $\lVert\mathbf{Q}\mathbf{x}\rVert=\lVert\mathbf{x}\rVert$
Projection onto a line	$\operatorname{proj}_{\mathbf{a}}\mathbf{b}=\dfrac{\langle\mathbf{b},\mathbf{a}\rangle}{\langle\mathbf{a},\mathbf{a}\rangle}\mathbf{a}$
Projection onto $\operatorname{col}(\mathbf{A})$	$\mathbf{P}=\mathbf{A}(\mathbf{A}^{\mathsf{T}}\mathbf{A})^{-1}\mathbf{A}^{\mathsf{T}}=\mathbf{Q}\mathbf{Q}^{\mathsf{T}}$; $\mathbf{P}^2=\mathbf{P}=\mathbf{P}^{\mathsf{T}}$
Best approximation	$\mathbf{b}-\operatorname{proj}_W\mathbf{b}\perp W$; Bessel $\sum\lvert c_k\rvert^2\lVert\phi_k\rVert^2\le\lVert f\rVert^2$
Gram–Schmidt	$\mathbf{v}_j=\mathbf{a}_j-\sum_{i<j}\frac{\langle\mathbf{a}_j,\mathbf{v}_i\rangle}{\langle\mathbf{v}_i,\mathbf{v}_i\rangle}\mathbf{v}_i$; $\mathbf{A}=\mathbf{Q}\mathbf{R}$
Legendre polynomials	$1,\ t,\ \frac{1}{2}(3t^2-1),\ \frac{1}{2}(5t^3-3t)$; $\int_{-1}^{1}P_mP_n\,dt=\frac{2}{2n+1}\delta_{mn}$
Normal equations	$\mathbf{A}^{\mathsf{T}}\mathbf{A}\hat{\mathbf{x}}=\mathbf{A}^{\mathsf{T}}\mathbf{b}$; via QR: $\mathbf{R}\hat{\mathbf{x}}=\mathbf{Q}^{\mathsf{T}}\mathbf{b}$
Line fit	$c_1=\dfrac{\sum(t_i-\bar{t})(y_i-\bar{y})}{\sum(t_i-\bar{t})^2}$, $c_0=\bar{y}-c_1\bar{t}$
Weighted LS	$\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A}\hat{\mathbf{x}}=\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{b}$, $w_i=1/\sigma_i^2$
Conditioning	$\kappa(\mathbf{A}^{\mathsf{T}}\mathbf{A})=\kappa(\mathbf{A})^2$ — prefer QR or SVD

Chapter 10 — Eigenvalues and Eigenvectors

> **Prerequisites:** Ch. 2 (complex numbers, polar form), Ch. 8 (determinants, inverses, Gaussian elimination, rank), Ch. 9 (bases, change of basis, null space, inner products, orthogonality, Gram–Schmidt) **Learning outcomes:** After this chapter you can
>
> - form and solve the characteristic equation of a square matrix, and use trace, determinant and the Cayley–Hamilton theorem as checks and shortcuts;
> - compute eigenvalues, eigenvectors and eigenspaces (real and complex), and decide whether a matrix is diagonalizable;
> - diagonalize a matrix and use the factorization to compute powers $\mathbf{A}^k$, the matrix exponential $e^{\mathbf{A}t}$ and the long-run behaviour of difference equations;
> - apply the spectral theorem to symmetric and Hermitian matrices, find principal axes of quadratic forms, and test a matrix for positive definiteness;
> - compute and interpret the singular value decomposition, including matrix norm, condition number, rank, low-rank approximation and the pseudoinverse;
> - decouple vibrating and oscillating systems into normal modes, and judge the stability of linear (and linearized) continuous- and discrete-time systems from their eigenvalues.

Chapters 8 and 9 asked what a matrix *does* to a vector: it maps $\mathbf{x}$ to $\mathbf{A}\mathbf{x}$, generally rotating it, stretching it and mixing its components. This chapter asks a sharper question: **are there special directions that the matrix does not rotate at all?** Along such a direction the matrix acts like a plain number, $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$. The number λ is an *eigenvalue* (German *eigen*, "own" or "characteristic") and $\mathbf{v}$ an *eigenvector*.

The idea sounds modest, but it is one of the most productive in applied mathematics. If a matrix has enough eigenvectors to form a basis, then in that basis the matrix is *diagonal*: a coupled problem in n unknowns falls apart into n independent scalar problems. A system of coupled differential equations $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ becomes n separate first-order equations $\dot{y}_i = \lambda_i y_i$, each solved by an exponential $e^{\lambda_i t}$. Coupled masses or coupled resonant circuits separate into *normal modes*, each vibrating at its own frequency. Repeated multiplication $\mathbf{A}^k$ — the heart of every discrete-time recursion, Markov chain and iterative algorithm — becomes repeated multiplication of numbers, λ_i^k. And the question "is this system stable?" reduces to "do all the eigenvalues lie in the left half-plane (or inside the unit circle)?"

For an electrical engineer, eigenvalues are hiding in plain sight. The **natural frequencies** of a circuit, the **poles** of its transfer function, the **resonant modes** of a cavity or a coupled-line filter, the **principal axes** of a polarisation ellipse or of an anisotropic dielectric tensor, the **principal components** of a set of sensor measurements, the **singular values** that measure how close a MIMO channel is to losing a spatial stream — all are eigenvalue problems. Chapters 11–14 use the results of this chapter constantly.

The plan is as follows. Sections 10.1–10.4 develop the general theory: the characteristic equation, eigenvectors, diagonalization and matrix powers (including the matrix exponential). Sections 10.5–10.7 specialise to the symmetric and Hermitian matrices that arise from energy, power and covariance, culminating in the singular value decomposition, which works for *every* matrix. Sections 10.8–10.9 turn the theory onto dynamics: normal-mode analysis and stability.

10.1 Characteristic equations

Motivation

Suppose we want a nonzero vector $\mathbf{v}$ and a scalar λ with $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$. Unlike $\mathbf{A}\mathbf{x} = \mathbf{b}$, this is not a linear system for $\mathbf{v}$ in the usual sense, because λ is unknown too and multiplies $\mathbf{v}$. The trick is to separate the two unknowns. We first ask *for which* λ the equation has a nonzero solution at all; that condition turns out to be a single polynomial equation in λ — the **characteristic equation**. Only after the eigenvalues are known do we go back and find the eigenvectors, which is then an ordinary homogeneous linear system.

The characteristic equation is not new to you. When you solved $a\ddot{y} + b\dot{y} + cy = 0$ by trying $y = e^{st}$ and obtained $as^2 + bs + c = 0$, that quadratic was the characteristic equation of a 2×2 matrix in disguise (Example 10.3 below makes the connection exact). The roots of the denominator of a transfer function — the poles — are likewise eigenvalues of the system's state matrix (Section 10.9).

Derivation

Rewrite $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ as

$$\mathbf{A}\mathbf{v} - \lambda\mathbf{I}\mathbf{v} = \mathbf{0} \quad \Longleftrightarrow \quad (\mathbf{A} - \lambda\mathbf{I})\,\mathbf{v} = \mathbf{0}.$$

The identity $\mathbf{I}$ is needed: $\mathbf{A} - \lambda$ (matrix minus number) is meaningless. For a fixed number λ this *is* a homogeneous linear system. It always has the trivial solution $\mathbf{v} = \mathbf{0}$, and by the invertible matrix theorem of Ch. 8 it has a nonzero solution if and only if the coefficient matrix $\mathbf{A} - \lambda\mathbf{I}$ is singular, i.e. if and only if its determinant vanishes.

> **Characteristic polynomial and characteristic equation**
>
> Let $\mathbf{A}$ be an $n \times n$ matrix (real or complex). Its **characteristic polynomial** is
>
> $$p(\lambda) = \det(\mathbf{A} - \lambda\mathbf{I}),$$
>
> a polynomial of degree exactly n in λ. The equation $p(\lambda) = 0$ is the **characteristic equation**, and its roots are the **eigenvalues** of $\mathbf{A}$. The multiset of eigenvalues is the **spectrum** of $\mathbf{A}$, and $\rho(\mathbf{A}) = \max_i |\lambda_i|$ is the **spectral radius**.

Some texts use $\det(\lambda\mathbf{I} - \mathbf{A})$ instead; the two differ by the factor $(-1)^n$ and have the same roots. The form $\det(\lambda\mathbf{I} - \mathbf{A})$ has leading coefficient $+1$ (it is *monic*), which is convenient for control-system work where it matches the denominator of a transfer function. We shall use whichever is tidier and say which.

Why is the degree exactly n? Expanding the determinant as a sum of signed products, one per permutation (Ch. 8), the only product that contains n factors of λ is the product of the diagonal entries $(a_{11}-\lambda)(a_{22}-\lambda)\cdots(a_{nn}-\lambda)$, which contributes $(-\lambda)^n$. Every other permutation leaves out at least two diagonal entries and therefore has degree at most $n-2$.

Coefficients: trace, determinant and principal minors

The same expansion gives two coefficients immediately. The coefficient of λ^{n-1} also comes only from the diagonal product, and equals $(-1)^{n-1}(a_{11}+\cdots+a_{nn})$. The constant term is $p(0)=\det\mathbf{A}$. On the other hand, by the fundamental theorem of algebra p factors over $\mathbb{C}$ as

$$p(\lambda)=(\lambda_1-\lambda)(\lambda_2-\lambda)\cdots(\lambda_n-\lambda),$$

whose λ^{n-1} coefficient is $(-1)^{n-1}(\lambda_1+\cdots+\lambda_n)$ and whose constant term is $\lambda_1\lambda_2\cdots\lambda_n$. Comparing:

Trace and determinant

If $\lambda_1,\dots,\lambda_n$ are the eigenvalues of $\mathbf{A}$, repeated according to algebraic multiplicity, then

$$\lambda_1+\lambda_2+\cdots+\lambda_n=\operatorname{tr}\mathbf{A}=\sum_{i=1}^{n}a_{ii},\qquad \lambda_1\lambda_2\cdots\lambda_n=\det\mathbf{A}.$$

In particular $\mathbf{A}$ is singular if and only if 0 is an eigenvalue.

More generally, the coefficient of λ^{n-k} in $\det(\lambda\mathbf{I}-\mathbf{A})$ is $(-1)^k E_k$, where E_k is the sum of all $k\times k$ **principal minors** of $\mathbf{A}$ (determinants of submatrices obtained by keeping the same k rows and columns). This gives the very useful closed forms

$$\begin{aligned} n=2:&\quad \det(\lambda\mathbf{I}-\mathbf{A})=\lambda^2-(\operatorname{tr}\mathbf{A})\,\lambda+\det\mathbf{A},\\ n=3:&\quad \det(\lambda\mathbf{I}-\mathbf{A})=\lambda^3-(\operatorname{tr}\mathbf{A})\,\lambda^2+E_2\,\lambda-\det\mathbf{A},\end{aligned}$$

with $E_2=(a_{11}a_{22}-a_{12}a_{21})+(a_{11}a_{33}-a_{13}a_{31})+(a_{22}a_{33}-a_{23}a_{32})$.

For a 2×2 matrix the quadratic formula then gives the eigenvalues in one line:

$$\lambda_{1,2}=\frac{\operatorname{tr}\mathbf{A}}{2}\pm\sqrt{\left(\frac{\operatorname{tr}\mathbf{A}}{2}\right)^2-\det\mathbf{A}}.$$

The sign of the discriminant $(\operatorname{tr}\mathbf{A})^2-4\det\mathbf{A}$ decides whether the eigenvalues are real and distinct, real and repeated, or a complex-conjugate pair — the same three cases (overdamped, critically damped, underdamped) you meet for second-order circuits in Ch. 12. Section 10.9 turns this observation into a complete classification of two-dimensional dynamics.

Algebraic multiplicity and complex roots

Algebraic multiplicity

If $p(\lambda)=(\lambda_0-\lambda)^m q(\lambda)$ with $q(\lambda_0)\neq0$, the eigenvalue λ_0 has **algebraic multiplicity** m. The multiplicities of the distinct eigenvalues add up to n.

Two facts follow from elementary polynomial algebra (Ch. 1, Ch. 2):

- **Every $n\times n$ matrix has exactly n eigenvalues in $\mathbb{C}$**, counted with multiplicity. A real matrix may have *no* real eigenvalues (a rotation of the plane is the standard example), so eigenvalue theory naturally lives over the complex numbers.
- **A real matrix has real characteristic-polynomial coefficients, so its non-real eigenvalues occur in conjugate pairs** λ,λ^*. A real 3×3 matrix therefore always has at least one real eigenvalue.

Special structures

Several structures let you read eigenvalues off without solving anything:

- **Triangular and diagonal matrices.** If $\mathbf{A}$ is upper or lower triangular, so is $\mathbf{A}-\lambda\mathbf{I}$, and its determinant is the product of its diagonal entries. Hence *the eigenvalues of a triangular matrix are its diagonal entries.*
- **Block-triangular matrices.** If $\mathbf{A}=\begin{bmatrix}\mathbf{A}_{11}&\mathbf{A}_{12}\\ \mathbf{0}&\mathbf{A}_{22}\end{bmatrix}$ with square diagonal blocks, then $\det(\mathbf{A}-\lambda\mathbf{I})=\det(\mathbf{A}_{11}-\lambda\mathbf{I})\det(\mathbf{A}_{22}-\lambda\mathbf{I})$: the spectrum is the union of the spectra of the diagonal blocks. This is how a system made of a cascade of subsystems inherits the natural frequencies of each stage.
- **Transpose.** $\det(\mathbf{A}^{\mathsf T}-\lambda\mathbf{I})=\det\left((\mathbf{A}-\lambda\mathbf{I})^{\mathsf T}\right)=\det(\mathbf{A}-\lambda\mathbf{I})$, so $\mathbf{A}$ and $\mathbf{A}^{\mathsf T}$ have the same eigenvalues (but usually different eigenvectors).
- **Similar matrices.** If $\mathbf{B}=\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ for some invertible $\mathbf{S}$, then

$$\det(\mathbf{B}-\lambda\mathbf{I})=\det\left(\mathbf{S}^{-1}(\mathbf{A}-\lambda\mathbf{I})\mathbf{S}\right)=\det(\mathbf{S}^{-1})\det(\mathbf{A}-\lambda\mathbf{I})\det(\mathbf{S})=\det(\mathbf{A}-\lambda\mathbf{I}).$$

Similar matrices have the same characteristic polynomial, hence the same eigenvalues, trace and determinant. Since $\mathbf{S}$ is a change of basis (Ch. 9), this says that **eigenvalues belong to the linear transformation, not to the particular matrix that represents it.** Choosing different state variables for the same circuit changes the state matrix but never its eigenvalues — the natural frequencies are physical.

Companion matrices

Every monic polynomial is the characteristic polynomial of some matrix. For $q(\lambda)=\lambda^n+c_{n-1}\lambda^{n-1}+\cdots+c_1\lambda+c_0$, the **companion matrix**

$$\mathbf{C} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -c_0 & -c_1 & -c_2 & \cdots & -c_{n-1} \end{bmatrix}$$

satisfies $\det(\lambda \mathbf{I} - \mathbf{C}) = q(\lambda)$ (expand along the last row, or verify for $n = 2$ and induct). The companion matrix is exactly what you obtain when you convert the scalar ODE $y^{(n)} + c_{n-1} y^{(n-1)} + \cdots + c_0 y = 0$ to first-order form with the state $\mathbf{x} = (y, \dot{y}, \ldots, y^{(n-1)})$. It is also how numerical software finds polynomial roots: `numpy.roots` builds the companion matrix and calls an eigenvalue routine, because eigenvalue algorithms are more robust than direct root-finding.

The Cayley–Hamilton theorem

Cayley–Hamilton

Every square matrix satisfies its own characteristic equation: if $p(\lambda) = \det(\lambda \mathbf{I} - \mathbf{A}) = \lambda^n + c_{n-1}\lambda^{n-1} + \cdots + c_0$, then

$$p(\mathbf{A}) = \mathbf{A}^n + c_{n-1}\mathbf{A}^{n-1} + \cdots + c_1 \mathbf{A} + c_0 \mathbf{I} = \mathbf{0}.$$

Proof sketch. The adjugate identity of Ch. 8 gives $(\lambda \mathbf{I} - \mathbf{A})\,\operatorname{adj}(\lambda \mathbf{I} - \mathbf{A}) = p(\lambda)\mathbf{I}$. The entries of the adjugate are polynomials of degree at most $n-1$ in λ, so we can write $\operatorname{adj}(\lambda \mathbf{I} - \mathbf{A}) = \mathbf{B}_{n-1}\lambda^{n-1} + \cdots + \mathbf{B}_1 \lambda + \mathbf{B}_0$ with constant matrices $\mathbf{B}_k$. Multiplying out and equating coefficients of each power of λ gives $n+1$ matrix equations: $\mathbf{B}_{n-1} = \mathbf{I}$, $\mathbf{B}_{k-1} - \mathbf{A}\mathbf{B}_k = c_k \mathbf{I}$, and $-\mathbf{A}\mathbf{B}_0 = c_0 \mathbf{I}$. Multiply the equation for λ^k on the left by $\mathbf{A}^k$ and add them all: the left side telescopes to $\mathbf{0}$ and the right side is $p(\mathbf{A})$. (Simply "substituting $\lambda = \mathbf{A}$ into $\det(\lambda \mathbf{I} - \mathbf{A})$" is *not* a valid proof, because the determinant of a matrix with matrix entries is not defined that way.) $\square$

Cayley–Hamilton has three practical uses. First, $\mathbf{A}^n$ — and therefore every higher power — is a linear combination of $\mathbf{I}, \mathbf{A}, \ldots, \mathbf{A}^{n-1}$, so any polynomial or power series in $\mathbf{A}$ (including $e^{\mathbf{A}t}$, Section 10.4) can be reduced to a polynomial of degree at most $n-1$. Second, if $c_0 = \pm \det \mathbf{A} \neq 0$ we can solve for the inverse:

$$\mathbf{A}^{-1} = -\frac{1}{c_0}\left(\mathbf{A}^{n-1} + c_{n-1}\mathbf{A}^{n-2} + \cdots + c_1 \mathbf{I}\right).$$

Third, it underlies the controllability and observability tests of state-space control theory, where powers of $\mathbf{A}$ beyond $n-1$ never add new directions.

Worked examples

Worked Example 10.1 — A 2×2 characteristic equation

Find the eigenvalues of $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$.

Step 1 — form $\mathbf{A} - \lambda \mathbf{I}$. Subtract λ from the diagonal only:

$$\mathbf{A} - \lambda \mathbf{I} = \begin{bmatrix} 4 - \lambda & 1 \\ 2 & 3 - \lambda \end{bmatrix}.$$

Step 2 — take the determinant.

$$p(\lambda) = (4 - \lambda)(3 - \lambda) - (1)(2) = \lambda^2 - 7\lambda + 12 - 2 = \lambda^2 - 7\lambda + 10.$$

Step 3 — check with the shortcut. $\operatorname{tr} \mathbf{A} = 7$ and $\det \mathbf{A} = 12 - 2 = 10$, so $\lambda^2 - 7\lambda + 10$ is confirmed.

Step 4 — solve. $\lambda^2 - 7\lambda + 10 = (\lambda - 5)(\lambda - 2)$, so $\lambda_1 = 5$, $\lambda_2 = 2$.

Check: $\lambda_1 + \lambda_2 = 7 = \operatorname{tr} \mathbf{A}$ and $\lambda_1 \lambda_2 = 10 = \det \mathbf{A}$. ✓

Worked Example 10.2 — A 3×3 tridiagonal matrix

Find the eigenvalues of

$$\mathbf{B} = \begin{bmatrix} 2 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 2 \end{bmatrix}.$$

Step 1 — expand along the first row.

$$\det(\mathbf{B} - \lambda \mathbf{I}) = (2-\lambda)\begin{vmatrix} 2-\lambda & 1 \\ 1 & 2-\lambda \end{vmatrix} - 1 \cdot \begin{vmatrix} 1 & 1 \\ 0 & 2-\lambda \end{vmatrix} = (2-\lambda)\big[(2-\lambda)^2 - 1\big] - (2-\lambda).$$

Step 2 — factor before expanding. The common factor $(2-\lambda)$ is the key labour-saver:

$$\det(\mathbf{B} - \lambda \mathbf{I}) = (2-\lambda)\big[(2-\lambda)^2 - 2\big].$$

Step 3 — solve. Either $\lambda = 2$, or $(2-\lambda)^2 = 2$, i.e. $\lambda = 2 \pm \sqrt{2}$. The eigenvalues are

$$\lambda_1 = 2 + \sqrt{2} \approx 3.4142, \qquad \lambda_2 = 2, \qquad \lambda_3 = 2 - \sqrt{2} \approx 0.5858.$$

Step 4 — check with principal minors. $\operatorname{tr}\mathbf{B} = 6$; $E_2 = (4-1) + (4-0) + (4-1) = 10$; $\det \mathbf{B} = 2(4-1) - 1(2-0) = 4$. So $\det(\lambda\mathbf{I} - \mathbf{B}) = \lambda^3 - 6\lambda^2 + 10\lambda - 4$. Sum of roots $= 6$ ✓; product $= 2\,(4-2) = 4$ ✓; and substituting $\lambda = 2$: $8 - 24 + 20 - 4 = 0$ ✓.

Matrices of this "2 on the diagonal, 1 off it" type (with sign changes) arise whenever identical elements are chained — an LC ladder, a discretised transmission line, a finite-difference Laplacian (Ch. 13). Their eigenvalues are known in closed form: for the $n \times n$ version, $\lambda_k = 2 + 2\cos\frac{k\pi}{n+1}$, $k = 1, \dots, n$, which for $n = 3$ gives $2 + \sqrt{2},\ 2,\ 2 - \sqrt{2}$.

Worked Example 10.3 — The companion matrix of a third-order ODE

The differential equation $\dddot{y} + 6\ddot{y} + 11\dot{y} + 6y = 0$ is put into state form with $x_1 = y$, $x_2 = \dot{y}$, $x_3 = \ddot{y}$:

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -6 & -11 & -6 \end{bmatrix} \mathbf{x} = \mathbf{C}\mathbf{x}.$$

Step 1 — characteristic polynomial. Expand $\det(\lambda\mathbf{I} - \mathbf{C})$ along the first column:

$$\det \begin{bmatrix} \lambda & -1 & 0 \\ 0 & \lambda & -1 \\ 6 & 11 & \lambda + 6 \end{bmatrix} = \lambda\big[\lambda(\lambda+6) + 11\big] + 6\big[(-1)(-1) - 0 \cdot \lambda\big] = \lambda^3 + 6\lambda^2 + 11\lambda + 6.$$

This is precisely the characteristic polynomial you would obtain by substituting $y = e^{\lambda t}$ into the ODE.

Step 2 — roots. Trying $\lambda = -1$: $-1 + 6 - 11 + 6 = 0$. Dividing, $\lambda^3 + 6\lambda^2 + 11\lambda + 6 = (\lambda+1)(\lambda^2 + 5\lambda + 6) = (\lambda+1)(\lambda+2)(\lambda+3)$.

The eigenvalues $-1, -2, -3$ are the natural frequencies (in s^{-1}, if t is in seconds) of the system; all are negative, so every solution decays (Section 10.9). **Check:** $\operatorname{tr}\mathbf{C} = -6 = -1 - 2 - 3$ ✓, $\det\mathbf{C} = -6 = (-1)(-2)(-3)$ ✓.

Worked Example 10.4 — Inverse and powers by Cayley–Hamilton

For $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ of Example 10.1, Cayley–Hamilton gives $\mathbf{A}^2 - 7\mathbf{A} + 10\mathbf{I} = \mathbf{0}$.

Inverse. Rearranging, $\mathbf{A}(7\mathbf{I} - \mathbf{A}) = 10\mathbf{I}$, so

$$\mathbf{A}^{-1} = \frac{1}{10}(7\mathbf{I} - \mathbf{A}) = \frac{1}{10}\begin{bmatrix} 3 & -1 \\ -2 & 4 \end{bmatrix}.$$

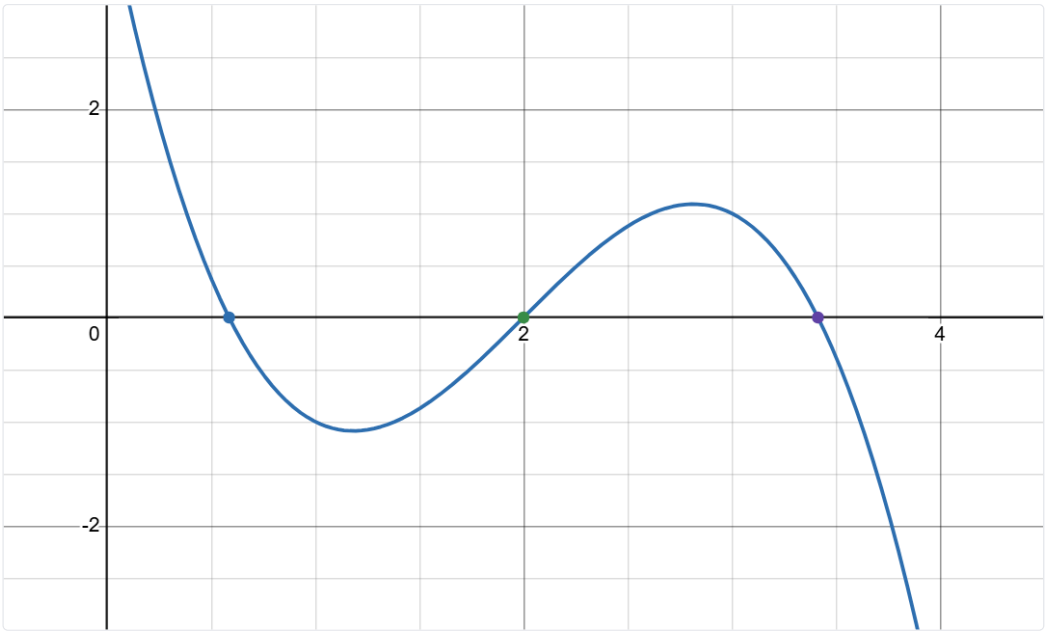
Check: $\mathbf{A}\mathbf{A}^{-1} = \frac{1}{10}\begin{bmatrix} 12-2 & -4+4 \\ 6-6 & -2+12 \end{bmatrix} = \mathbf{I}$ ✓.

Cube. $\mathbf{A}^2 = 7\mathbf{A} - 10\mathbf{I}$, so $\mathbf{A}^3 = 7\mathbf{A}^2 - 10\mathbf{A} = 7(7\mathbf{A} - 10\mathbf{I}) - 10\mathbf{A} = 39\mathbf{A} - 70\mathbf{I}$:

$$\mathbf{A}^3 = \begin{bmatrix} 156 - 70 & 39 \\ 78 & 117 - 70 \end{bmatrix} = \begin{bmatrix} 86 & 39 \\ 78 & 47 \end{bmatrix},$$

which agrees with direct multiplication. Every power $\mathbf{A}^k$ is of the form $\alpha_k\mathbf{A} + \beta_k\mathbf{I}$; Section 10.4 finds α_k, β_k in closed form.

The characteristic polynomial of Example 10.2 is worth seeing as a graph. Its three real roots are where the cubic crosses the axis; for a symmetric matrix (Section 10.5) such crossings are guaranteed to be real.



The characteristic polynomial $p(\lambda) = \det(\mathbf{B} - \lambda\mathbf{I}) = -\lambda^3 + 6\lambda^2 - 10\lambda + 4$ of Example 10.2 (horizontal axis λ); its zeros are the eigenvalues and its intercept is $\det \mathbf{B}$.

Common Pitfall — subtracting λ everywhere, or expanding too early

Two errors account for most wrong characteristic polynomials. (i) λ is subtracted from the **diagonal entries only**; writing $a_{12} - \lambda$ is wrong. (ii) Multiplying everything out and then hunting for roots of a cubic is laborious and error-prone; look for a common factor first (Example 10.2) or row-reduce cleverly. Always finish with the trace and determinant checks — they cost seconds and catch almost every arithmetic slip.

Common Pitfall — row reduction changes eigenvalues

Gaussian elimination preserves the *solution set* of $\mathbf{A}\mathbf{x} = \mathbf{b}$ but not the eigenvalues of $\mathbf{A}$. The echelon form of $\begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ is $\begin{bmatrix} 4 & 1 \\ 0 & 2.5 \end{bmatrix}$, with diagonal $4, 2.5$ — not the eigenvalues $5, 2$. You may row-reduce $\mathbf{A} - \lambda\mathbf{I}$ to find *eigenvectors* once λ is fixed, but never row-reduce $\mathbf{A}$ to read off eigenvalues. Only *similarity* transformations $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ preserve them.

Engineering Note — never compute large characteristic polynomials numerically

For hand work with $n \le 3$ the characteristic polynomial is the right tool. For n in the tens or thousands — a power-system network, a finite-element model, a circuit simulator's Jacobian — the roots of a polynomial are extraordinarily sensitive to rounding of its coefficients (Wilkinson's famous example: perturbing one coefficient of $\prod_{k=1}^{20}(\lambda - k)$ by 2^{-23} makes several roots complex). Production software (LAPACK, MATLAB `eig`, NumPy) never forms $p(\lambda)$; it applies a sequence of orthogonal similarity transformations — the QR algorithm — that drive $\mathbf{A}$ to triangular form, whose diagonal holds the eigenvalues. The method is treated in Ch. 22; this chapter is about what the answers mean.

10.2 Eigenvalues and eigenvectors

Motivation

Once the eigenvalues are known, the eigenvectors tell us *where* the matrix acts as pure scaling. Geometrically: a 2×2 matrix turns the unit circle into an ellipse and generally rotates every direction; an eigenvector is a direction that comes out parallel to itself — stretched by λ, shrunk, or reversed if $\lambda < 0$. Physically: in a vibrating structure an eigenvector is a *mode shape*, the pattern of relative amplitudes with which all parts move together at one frequency; in a Markov chain the eigenvector for $\lambda = 1$ is the long-run probability distribution; in an antenna array or a MIMO channel the dominant eigenvector of the correlation matrix is the best beam-forming direction.

Definitions

Eigenvalue, eigenvector, eigenspace

Let $\mathbf{A}$ be $n \times n$. A scalar $\lambda \in \mathbb{C}$ is an **eigenvalue** of $\mathbf{A}$ if there is a **nonzero** vector $\mathbf{v} \in \mathbb{C}^n$ with

$$\mathbf{A}\mathbf{v} = \lambda\mathbf{v}.$$

Such a $\mathbf{v}$ is an **eigenvector** belonging to λ, and $(\lambda, \mathbf{v})$ is an **eigenpair**. The set

$$E_\lambda = \operatorname{null}(\mathbf{A} - \lambda\mathbf{I}) = \{\mathbf{v} : \mathbf{A}\mathbf{v} = \lambda\mathbf{v}\}$$

is the **eigenspace** of λ; it consists of all eigenvectors for λ together with $\mathbf{0}$. Its dimension $g = \dim E_\lambda = n - \operatorname{rank}(\mathbf{A} - \lambda\mathbf{I})$ is the **geometric multiplicity** of λ.

Three remarks clarify the definition.

1. **The zero vector is excluded as an eigenvector** (otherwise every λ would be an eigenvalue), but $\lambda = 0$ is a perfectly good eigenvalue: it means $\mathbf{A}\mathbf{v} = \mathbf{0}$ for some $\mathbf{v} \neq \mathbf{0}$, i.e. $\mathbf{A}$ is singular and $\mathbf{v}$ lies in its null space.
2. **Eigenvectors are never unique.** If $\mathbf{v}$ is an eigenvector, so is $c\mathbf{v}$ for every $c \neq 0$ (including complex c). An eigenvector really specifies a *direction* (a line through the origin), and when the eigenspace has dimension $g > 1$, any nonzero vector in that g-dimensional subspace qualifies. Different software normalises differently — unit length, largest entry 1, first entry 1 — so do not be alarmed when your hand answer differs from MATLAB's by a scale factor or a sign.
3. **The eigenspace is a subspace** (Ch. 9): it is the null space of a matrix, so it is closed under addition and scaling.

Finding eigenvectors

The procedure is a direct application of null-space computation:

1. Solve $\det(\mathbf{A} - \lambda\mathbf{I}) = 0$ for the eigenvalues.
2. For each distinct eigenvalue λ_i, row-reduce $\mathbf{A} - \lambda_i\mathbf{I}$. Because λ_i makes this matrix singular, at least one row must reduce to zero — **if it doesn't, your eigenvalue is wrong.**
3. Express the basic variables in terms of the free variables; one free variable per dimension of E_{λ_i}. Setting each free variable to 1 in turn (others 0) gives a basis of the eigenspace.
4. Check $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ by direct multiplication.

For a 2×2 matrix step 2 is trivial. If $\mathbf{A} - \lambda\mathbf{I} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ is singular, its rows are proportional, and $\mathbf{v} = \begin{bmatrix} b \\ -a \end{bmatrix}$ (or $\begin{bmatrix} d \\ -c \end{bmatrix}$) is an eigenvector whenever it is nonzero — it is perpendicular to the first row.

Algebraic versus geometric multiplicity

Multiplicity inequality

For every eigenvalue λ_0 of $\mathbf{A}$,

$$1 \le g(\lambda_0) \le m(\lambda_0),$$

where g is the geometric and m the algebraic multiplicity.

Proof sketch. $g \ge 1$ because $\mathbf{A} - \lambda_0\mathbf{I}$ is singular. For the upper bound, take a basis $\mathbf{v}_1, \dots, \mathbf{v}_g$ of E_{λ_0} and extend it to a basis of $\mathbb{C}^n$; put these vectors as the columns of $\mathbf{S}$. In the new basis the first g columns of $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ are $\lambda_0\mathbf{e}_1, \dots, \lambda_0\mathbf{e}_g$, so $\mathbf{S}^{-1}\mathbf{A}\mathbf{S} = \begin{bmatrix} \lambda_0\mathbf{I}_g & * \\ \mathbf{0} & \mathbf{C} \end{bmatrix}$. This block-triangular matrix has characteristic polynomial $(\lambda_0 - \lambda)^g \det(\mathbf{C} - \lambda\mathbf{I})$, and similar matrices share characteristic polynomials, so $(\lambda_0 - \lambda)^g$ divides $p(\lambda)$: $g \le m$. $\square$

An eigenvalue with $g < m$ is called **defective**, and so is a matrix having one. The standard example is the **shear**

$$\mathbf{N} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}: \qquad p(\lambda) = (1-\lambda)^2, \quad m = 2, \qquad \mathbf{N} - \mathbf{I} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad g = 1.$$

The only eigenvector direction is $\mathbf{e}_1 = (1, 0)$: the shear slides every horizontal line along itself, so only horizontal vectors keep their direction. Defective matrices are exactly the ones that cannot be diagonalized (Section 10.3); in dynamics they produce the $te^{\lambda t}$ terms familiar from critically damped circuits.

Independence of eigenvectors

Eigenvectors for distinct eigenvalues are independent

If $\mathbf{v}_1, \dots, \mathbf{v}_k$ are eigenvectors of $\mathbf{A}$ belonging to **distinct** eigenvalues $\lambda_1, \dots, \lambda_k$, then $\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ is linearly independent.

Proof. Suppose not, and let r be the smallest number such that $\mathbf{v}_{r+1}$ is a combination of the independent set $\mathbf{v}_1, \dots, \mathbf{v}_r$: $\mathbf{v}_{r+1} = c_1\mathbf{v}_1 + \cdots + c_r\mathbf{v}_r$. Apply $\mathbf{A}$: $\lambda_{r+1}\mathbf{v}_{r+1} = c_1\lambda_1\mathbf{v}_1 + \cdots + c_r\lambda_r\mathbf{v}_r$. Subtract λ_{r+1} times the first relation:

$$\mathbf{0} = c_1(\lambda_1 - \lambda_{r+1})\mathbf{v}_1 + \cdots + c_r(\lambda_r - \lambda_{r+1})\mathbf{v}_r.$$

Since $\mathbf{v}_1, \dots, \mathbf{v}_r$ are independent and every $\lambda_i - \lambda_{r+1} \neq 0$, all $c_i = 0$, so $\mathbf{v}_{r+1} = \mathbf{0}$ — impossible for an eigenvector. $\square$

The same argument shows that if we take bases of several eigenspaces for distinct eigenvalues and pool them, the pooled set is still independent. This is the engine of the diagonalization theorem in Section 10.3.

Eigenvalues of related matrices

If $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$, then repeated application gives $\mathbf{A}^k\mathbf{v} = \lambda^k\mathbf{v}$, and linear combinations give the following table. The eigenvector $\mathbf{v}$ is the **same** in every row except the last.

Matrix	Eigenvalue	Condition
$\mathbf{A}^k$, $k = 1, 2, \dots$	λ^k	—
$\mathbf{A}^{-1}$	$1/\lambda$	$\mathbf{A}$ invertible ($\lambda \neq 0$)
$\mathbf{A} + c\mathbf{I}$	$\lambda + c$	— (spectral shift)
$c\mathbf{A}$	$c\lambda$	—

Matrix	Eigenvalue	Condition
$q(\mathbf{A}) = \sum_k q_k \mathbf{A}^k$	$q(\lambda)$	any polynomial q
$(\mathbf{A} - \mu\mathbf{I})^{-1}$	$1/(\lambda - \mu)$	μ not an eigenvalue
$e^{\mathbf{A}t}$	$e^{\lambda t}$	(Section 10.4)
$\mathbf{A}^{\mathsf{T}}$	λ	eigenvector generally different

The shifted-inverse row is the basis of the *inverse iteration* algorithm: choosing μ close to a wanted eigenvalue makes $1/(\lambda - \mu)$ huge, so that eigenvalue dominates. The last row has an important companion: vectors with $\mathbf{w}^{\mathsf{T}}\mathbf{A} = \lambda\mathbf{w}^{\mathsf{T}}$, i.e. eigenvectors of $\mathbf{A}^{\mathsf{T}}$, are called **left eigenvectors**. A left eigenvector for λ_i is orthogonal to every right eigenvector for a different eigenvalue λ_j, since $\lambda_i \mathbf{w}_i^{\mathsf{T}}\mathbf{v}_j = \mathbf{w}_i^{\mathsf{T}}\mathbf{A}\mathbf{v}_j = \lambda_j \mathbf{w}_i^{\mathsf{T}}\mathbf{v}_j$ forces $\mathbf{w}_i^{\mathsf{T}}\mathbf{v}_j = 0$. Left eigenvectors reappear in modal analysis (Section 10.8) as the tools that extract modal amplitudes.

Complex eigenvalues of real matrices

When a real matrix has a complex eigenvalue $\lambda = \sigma + j\omega$ ($\omega \neq 0$), its eigenvector is necessarily complex, and conjugating $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ (with $\mathbf{A}$ real) gives $\mathbf{A}\mathbf{v}^* = \lambda^*\mathbf{v}^*$: **the conjugate eigenvalue has the conjugate eigenvector**, so only one of each pair needs to be computed. Geometrically, a complex pair signals *rotation*: no real direction is preserved. The prototype is

$$\mathbf{A} = \begin{bmatrix} \sigma & -\omega \\ \omega & \sigma \end{bmatrix} = r \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}, \qquad r = \sqrt{\sigma^2 + \omega^2},\ \theta = \angle(\sigma + j\omega),$$

with eigenvalues $\sigma \pm j\omega = re^{\pm j\theta}$ and eigenvectors $(1, \mp j)$. This matrix is multiplication by the complex number $re^{j\theta}$ written in real coordinates (Ch. 2): rotate by θ, scale by r. Section 10.3 shows that *every* real 2×2 matrix with complex eigenvalues is similar to this rotation-scaling form.

Worked examples

Worked Example 10.5 — Eigenvectors of a 2×2 matrix

Find the eigenvectors of $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ (eigenvalues 5 and 2, Example 10.1).

$\lambda_1 = 5$. $\mathbf{A} - 5\mathbf{I} = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix}$. The second row is -2 times the first, as it must be. The first row says $-v_1 + v_2 = 0$, so $v_2 = v_1$:

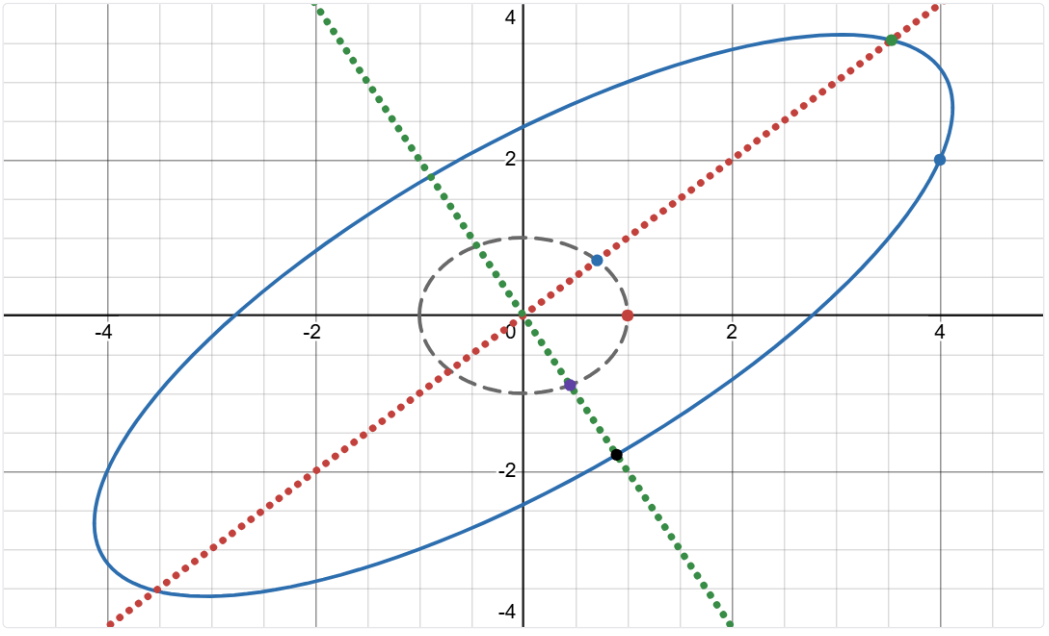
$$\mathbf{v}_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \qquad \mathbf{A}\mathbf{v}_1 = \begin{bmatrix} 5 \\ 5 \end{bmatrix} = 5\mathbf{v}_1 \ \checkmark$$

$\lambda_2 = 2$. $\mathbf{A} - 2\mathbf{I} = \begin{bmatrix} 2 & 1 \\ 2 & 1 \end{bmatrix}$, giving $2v_1 + v_2 = 0$:

$$\mathbf{v}_2 = \begin{bmatrix} 1 \\ -2 \end{bmatrix}, \qquad \mathbf{A}\mathbf{v}_2 = \begin{bmatrix} 2 \\ -4 \end{bmatrix} = 2\mathbf{v}_2 \ \checkmark$$

The eigenvectors are independent (distinct eigenvalues) but **not** orthogonal: $\mathbf{v}_1 \cdot \mathbf{v}_2 = 1 - 2 = -1$. Orthogonality is a privilege of symmetric matrices (Section 10.5).

The graph below shows the geometry. The matrix maps the unit circle onto an ellipse: the image of $\|\mathbf{x}\| = 1$ is the set of $\mathbf{y}$ with $\|\mathbf{A}^{-1}\mathbf{y}\| = 1$, i.e. $\mathbf{y}^{\mathsf{T}}(\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1}\mathbf{y} = 1$, which here is $13x^2 - 22xy + 17y^2 = 100$. Points of the circle on the eigenvector lines land on the same lines, scaled by 5 and 2; the point $(1, 0)$ is rotated off its line to $(4, 2)$.



The unit circle (dashed) and its image under $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ (blue ellipse). Vectors on the eigenvector lines $y = x$ (red, $\lambda = 5$) and $y = -2x$ (green, $\lambda = 2$) are only stretched; every other direction, such as $\mathbf{e}_1 \mapsto (4, 2)$, is also turned. The eigenvector lines are not the ellipse's axes — that happens only for symmetric matrices.

Worked Example 10.6 — A repeated eigenvalue with a two-dimensional eigenspace

Find all eigenvalues and eigenspaces of

$$\mathbf{L} = \begin{bmatrix} 4 & -1 & 6 \\ 2 & 1 & 6 \\ 2 & -1 & 8 \end{bmatrix}.$$

Step 1 — eigenvalues. $\operatorname{tr}\mathbf{L} = 13$, $E_2 = (4+2) + (32-12) + (8+6) = 40$, $\det\mathbf{L} = 4(8+6) + 1(16-12) + 6(-2-2) = 56 + 4 - 24 = 36$. Hence

$$\det(\lambda\mathbf{I} - \mathbf{L}) = \lambda^3 - 13\lambda^2 + 40\lambda - 36.$$

Trying $\lambda = 2$: $8 - 52 + 80 - 36 = 0$. Dividing out, $\lambda^3 - 13\lambda^2 + 40\lambda - 36 = (\lambda - 2)(\lambda^2 - 11\lambda + 18) = (\lambda - 2)^2(\lambda - 9)$. So $\lambda = 2$ with $m = 2$ and $\lambda = 9$ with $m = 1$.

Step 2 — eigenspace for $\lambda = 2$.

$$\mathbf{L} - 2\mathbf{I} = \begin{bmatrix} 2 & -1 & 6 \\ 2 & -1 & 6 \\ 2 & -1 & 6 \end{bmatrix} \longrightarrow \begin{bmatrix} 2 & -1 & 6 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

Rank 1, so $g = 3 - 1 = 2$. The single equation $2v_1 - v_2 + 6v_3 = 0$ gives $v_2 = 2v_1 + 6v_3$ with v_1, v_3 free. Choosing $(v_1, v_3) = (1, 0)$ and $(0, 1)$:

$$E_2 = \operatorname{span}\left\{ \begin{bmatrix} 1 \\ 2 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 6 \\ 1 \end{bmatrix} \right\}.$$

(Equally valid: $(1, 2, 0)$ and $(-3, 0, 1)$ — any two independent solutions of the plane equation.)

Step 3 — eigenspace for $\lambda = 9$.

$$\mathbf{L} - 9\mathbf{I} = \begin{bmatrix} -5 & -1 & 6 \\ 2 & -8 & 6 \\ 2 & -1 & -1 \end{bmatrix}.$$

The third row gives $v_2 = 2v_1 - v_3$; substituting into the first, $-5v_1 - 2v_1 + v_3 + 6v_3 = 0$, so $v_3 = v_1$ and then $v_2 = v_1$. Thus $E_9 = \operatorname{span}\{(1, 1, 1)\}$. Check with the second row: $2 - 8 + 6 = 0$ ✓, and $\mathbf{L}(1,1,1)^{\mathsf{T}} = (9, 9, 9)^{\mathsf{T}}$ ✓.

Conclusion. Here $g(2) = m(2) = 2$, so the repeated eigenvalue is *not* defective, and the three eigenvectors $(1, 2, 0)$, $(0, 6, 1)$, $(1, 1, 1)$ form a basis of $\mathbb{R}^3$. Section 10.3 uses this to diagonalize $\mathbf{L}$. Contrast the shear $\mathbf{N}$ above, where the double eigenvalue had only a one-dimensional eigenspace.

Worked Example 10.7 — Complex eigenvalues and eigenvectors

Find the eigenpairs of $\mathbf{R} = \begin{bmatrix} 1 & -2 \\ 1 & 3 \end{bmatrix}$.

Step 1 — eigenvalues. $\operatorname{tr}\mathbf{R} = 4$, $\det\mathbf{R} = 3 + 2 = 5$, so $\lambda^2 - 4\lambda + 5 = 0$ and

$$\lambda = 2 \pm \sqrt{4 - 5} = 2 \pm j.$$

Step 2 — eigenvector for $\lambda = 2 + j$.

$$\mathbf{R} - (2+j)\mathbf{I} = \begin{bmatrix} -1 - j & -2 \\ 1 & 1 - j \end{bmatrix}.$$

Use the simpler second row: $v_1 + (1 - j)v_2 = 0$. With $v_2 = 1$, $v_1 = -1 + j$, so

$$\mathbf{v} = \begin{bmatrix} -1 + j \\ 1 \end{bmatrix}.$$

Check the first row, which must also vanish: $(-1 - j)(-1 + j) - 2 = (1 + 1) - 2 = 0$ ✓.

Step 3 — the conjugate pair. For $\lambda^* = 2 - j$ the eigenvector is $\mathbf{v}^* = (-1 - j,\ 1)$, with no further work.

Interpretation. $|\lambda| = \sqrt{5}$ and $\angle\lambda = \arctan(1/2) = 26.57°$: in a suitable (non-orthogonal) coordinate system, $\mathbf{R}$ rotates by $26.57°$ and scales by $\sqrt{5} \approx 2.236$. In continuous-time dynamics $\dot{\mathbf{x}} = \mathbf{R}\mathbf{x}$, the pair $2 \pm j$ means oscillation at 1 rad/s inside a growing envelope e^{2t} — an unstable spiral (Section 10.9).

Worked Example 10.8 — Eigenvalues of functions of a matrix

With $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ (eigenvalues $5, 2$), find the eigenvalues of $\mathbf{B} = \mathbf{A}^2 - 3\mathbf{A} + \mathbf{I}$, of $\mathbf{A}^{-1}$ and of $\mathbf{A} - 6\mathbf{I}$, and decide whether $\mathbf{B}$ is invertible — without computing $\mathbf{B}$.

- $q(\lambda) = \lambda^2 - 3\lambda + 1$: $q(5) = 11$, $q(2) = -1$. Eigenvalues of $\mathbf{B}$: $11, -1$. Since neither is zero, $\mathbf{B}$ is invertible, with $\det \mathbf{B} = -11$.
- $\mathbf{A}^{-1}$: $1/5,\ 1/2$ (compare Example 10.4: $\operatorname{tr} \mathbf{A}^{-1} = (3+4)/10 = 0.7 = 0.2 + 0.5$ ✓).
- $\mathbf{A} - 6\mathbf{I}$: $-1,\ -4$. Shifting moves the whole spectrum without changing any eigenvector.

Direct check for B. $\mathbf{A}^2 = \begin{bmatrix} 18 & 7 \\ 14 & 11 \end{bmatrix}$, so $\mathbf{B} = \begin{bmatrix} 18 - 12 + 1 & 7 - 3 \\ 14 - 6 & 11 - 9 + 1 \end{bmatrix} = \begin{bmatrix} 7 & 4 \\ 8 & 3 \end{bmatrix}$; $\operatorname{tr} \mathbf{B} = 10 = 11 + (-1)$ ✓, $\det \mathbf{B} = 21 - 32 = -11$ ✓. And $\mathbf{B}(1,1)^{\mathsf{T}} = (11, 11)^{\mathsf{T}}$: same eigenvector as for $\mathbf{A}$ ✓.

Common Pitfall — eigenvalues of sums and products

The table above concerns functions of a **single** matrix. In general the eigenvalues of $\mathbf{A} + \mathbf{B}$ are **not** sums of eigenvalues of $\mathbf{A}$ and $\mathbf{B}$, and those of $\mathbf{AB}$ are not products — unless $\mathbf{A}$ and $\mathbf{B}$ share a full set of eigenvectors (which happens, for diagonalizable matrices, exactly when $\mathbf{AB} = \mathbf{BA}$). Example: $\begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$ and $\begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}$ both have only the eigenvalue 0, but their sum $\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$ has eigenvalues ± 1. What *is* true: $\operatorname{tr}(\mathbf{A} + \mathbf{B}) = \operatorname{tr} \mathbf{A} + \operatorname{tr} \mathbf{B}$, and $\mathbf{AB}$ and $\mathbf{BA}$ have the same eigenvalues.

Engineering Note — what eigenvalues mean physically

When $\mathbf{A}$ maps a physical state to its rate of change ($\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$), the eigenvalues have units of s^{-1}: a real eigenvalue $-1/\tau$ is a decay rate with time constant τ, and a complex pair $-\alpha \pm j\omega_d$ is a damped oscillation at ω_d rad/s. When $\mathbf{A}$ maps a state at one sample to the next ($\mathbf{x}[k+1] = \mathbf{A}\mathbf{x}[k]$), the eigenvalues are dimensionless multipliers per step. When $\mathbf{A}$ is a covariance matrix of voltages, its eigenvalues are in V^2 — the variance (power) carried along each eigenvector direction. Always ask what $\mathbf{A}$ maps from and to; the units of the eigenvalues follow.

10.3 Diagonalization

Motivation

A diagonal matrix is the simplest matrix there is: it scales the i-th coordinate by d_i and leaves the coordinates uncoupled. Its powers, inverse, exponential and every other function are computed entry by entry. A general matrix couples the coordinates — the rate of change of the capacitor voltage depends on the inductor current and vice versa — and that coupling is what makes systems hard to analyse. **Diagonalization** removes the coupling by changing to a basis of eigenvectors. In that basis the matrix is diagonal with the eigenvalues on the diagonal, and every computation becomes n scalar computations. Afterwards we change back.

This is the matrix version of a strategy used all through this book: transform a hard problem into a domain where it is easy (phasors, Laplace, Fourier), solve it there, and transform back. Here the "transform" is multiplication by $\mathbf{P}^{-1}$, the "easy domain" is modal coordinates, and the "inverse transform" is multiplication by $\mathbf{P}$.

The factorization

Suppose $\mathbf{A}$ has n linearly independent eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ with eigenvalues $\lambda_1, \dots, \lambda_n$ (not necessarily distinct). Place the eigenvectors as columns of $\mathbf{P}$ and the eigenvalues, **in the same order**, on the diagonal of $\mathbf{D}$. Then, column by column,

$$\mathbf{A}\mathbf{P} = \mathbf{A}\begin{bmatrix} \mathbf{v}_1 & \cdots & \mathbf{v}_n \end{bmatrix} = \begin{bmatrix} \lambda_1\mathbf{v}_1 & \cdots & \lambda_n\mathbf{v}_n \end{bmatrix} = \begin{bmatrix} \mathbf{v}_1 & \cdots & \mathbf{v}_n \end{bmatrix} \begin{bmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_n \end{bmatrix} = \mathbf{P}\mathbf{D}.$$

Since the columns of $\mathbf{P}$ are independent, $\mathbf{P}$ is invertible, and

$$\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}, \qquad \mathbf{D} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}.$$

Conversely, if $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ with $\mathbf{D}$ diagonal, then $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{D}$ says exactly that each column of $\mathbf{P}$ is an eigenvector with eigenvalue the corresponding diagonal entry of $\mathbf{D}$.

Diagonalizable matrix

A square matrix $\mathbf{A}$ is **diagonalizable** if it is similar to a diagonal matrix: there exist an invertible $\mathbf{P}$ and a diagonal $\mathbf{D}$ with $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$. The columns of $\mathbf{P}$ form an **eigenbasis**.

Diagonalization theorem

For an $n \times n$ matrix $\mathbf{A}$ the following are equivalent:

1. $\mathbf{A}$ is diagonalizable;
2. $\mathbf{A}$ has n linearly independent eigenvectors;
3. for every eigenvalue, the geometric multiplicity equals the algebraic multiplicity, $g(\lambda_i) = m(\lambda_i)$;
4. the dimensions of the eigenspaces add up to n.

In particular, **an $n \times n$ matrix with n distinct eigenvalues is diagonalizable.**

Proof sketch. (1)⇔(2) is the computation above. For (2)⇔(3)⇔(4): the sum of algebraic multiplicities is always n and $g_i \le m_i$, so $\sum g_i = n$ if and only if $g_i = m_i$ for all i. Pooling bases of the eigenspaces gives an independent set (Section 10.2) with $\sum g_i$ vectors, and no independent set of eigenvectors can be larger. The final statement follows because each distinct eigenvalue has $g = m = 1$. □

The "distinct eigenvalues" criterion is sufficient but not necessary: the identity matrix has a single eigenvalue repeated n times yet is already diagonal, and $\mathbf{L}$ of Example 10.6 has a double eigenvalue but is diagonalizable.

Interpretation as a change of basis

Read $\mathbf{A}\mathbf{x} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}\mathbf{x}$ from right to left:

1. $\mathbf{y} = \mathbf{P}^{-1}\mathbf{x}$ — find the coordinates of $\mathbf{x}$ in the eigenbasis, i.e. write $\mathbf{x} = y_1\mathbf{v}_1 + \cdots + y_n\mathbf{v}_n$ (Ch. 9);
2. $\mathbf{D}\mathbf{y}$ — scale each coordinate by its eigenvalue: $y_i \mapsto \lambda_i y_i$;
3. $\mathbf{P}(\mathbf{D}\mathbf{y})$ — reassemble: $\mathbf{A}\mathbf{x} = \lambda_1 y_1 \mathbf{v}_1 + \cdots + \lambda_n y_n \mathbf{v}_n$.

The same reading applied to the linear system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ is the whole of modal analysis. Substituting $\mathbf{x} = \mathbf{P}\mathbf{y}$ gives $\mathbf{P}\dot{\mathbf{y}} = \mathbf{A}\mathbf{P}\mathbf{y}$, i.e.

$$\dot{\mathbf{y}} = \mathbf{P}^{-1}\mathbf{A}\mathbf{P}\,\mathbf{y} = \mathbf{D}\mathbf{y} \quad \Longleftrightarrow \quad \dot{y}_i = \lambda_i y_i, \quad i = 1, \dots, n,$$

n uncoupled first-order equations with solutions $y_i(t) = y_i(0)e^{\lambda_i t}$. The coordinates y_i are the **modal coordinates** (Section 10.8).

Diagonalizing with complex eigenvalues; the real block form

A real matrix with complex eigenvalues is diagonalizable over $\mathbb{C}$ (if its eigenvalues are distinct), with complex $\mathbf{P}$ and $\mathbf{D}$. Often we prefer to stay real. For a 2×2 real matrix with eigenvalues $\sigma \pm j\omega$ ($\omega \neq 0$) and eigenvector $\mathbf{v} = \mathbf{a} + j\mathbf{b}$ for $\sigma + j\omega$ (with $\mathbf{a}, \mathbf{b}$ real), separate $\mathbf{A}(\mathbf{a} + j\mathbf{b}) = (\sigma + j\omega)(\mathbf{a} + j\mathbf{b})$ into real and imaginary parts:

$$\mathbf{A}\mathbf{a} = \sigma\mathbf{a} - \omega\mathbf{b}, \qquad \mathbf{A}\mathbf{b} = \omega\mathbf{a} + \sigma\mathbf{b}.$$

With $\mathbf{P} = \begin{bmatrix}\mathbf{a} & \mathbf{b}\end{bmatrix}$ (real and invertible, since $\mathbf{a}, \mathbf{b}$ are independent when $\omega \neq 0$), these two lines say

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{bmatrix} \sigma & \omega \\ -\omega & \sigma \end{bmatrix}.$$

This **real block form** is a rotation-scaling matrix. For an $n \times n$ real matrix, each complex pair contributes such a 2×2 block and each real eigenvalue a 1×1 block; the result is block-diagonal and entirely real. In state-space terms the two real coordinates of a block are the in-phase and quadrature components of an oscillating mode.

When diagonalization fails: the Jordan form

A defective matrix has too few eigenvectors to form a basis. The best that similarity can achieve is the **Jordan canonical form**: $\mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}$ with $\mathbf{J}$ block-diagonal, each block of the form

$$\mathbf{J}_k(\lambda) = \begin{bmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{bmatrix} \quad (k \times k).$$

The columns of $\mathbf{P}$ for a 2×2 Jordan block are an eigenvector $\mathbf{v}$ and a **generalized eigenvector** $\mathbf{w}$ satisfying

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{v} = \mathbf{0}, \qquad (\mathbf{A} - \lambda\mathbf{I})\mathbf{w} = \mathbf{v}.$$

Then $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ and $\mathbf{A}\mathbf{w} = \mathbf{v} + \lambda\mathbf{w}$, which is the column statement of $\mathbf{A}\mathbf{P} = \mathbf{P}\mathbf{J}_2(\lambda)$. Jordan forms are numerically fragile — an arbitrarily small perturbation makes a defective matrix diagonalizable with nearly parallel eigenvectors — so they are a theoretical tool rather than a computational one. Their practical message is the appearance of polynomial-times-exponential terms, $te^{\lambda t}$ and $k\lambda^{k-1}$ (Section 10.4).

Simultaneous diagonalization

Two diagonalizable matrices $\mathbf{A}$ and $\mathbf{B}$ can be diagonalized by the **same** $\mathbf{P}$ if and only if they commute, $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$. One direction is immediate: diagonal matrices commute, so $\mathbf{P}\mathbf{D}_1\mathbf{P}^{-1}\mathbf{P}\mathbf{D}_2\mathbf{P}^{-1} = \mathbf{P}\mathbf{D}_2\mathbf{D}_1\mathbf{P}^{-1}$. This is why, for instance, all circulant matrices (which commute with the cyclic shift) are diagonalized by the same matrix — the DFT matrix — a fact that underlies fast convolution (Ch. 16, Ch. 24).

Worked examples

Worked Example 10.9 — Diagonalizing a 2×2 matrix

Diagonalize $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$.

Step 1 — eigenpairs (Examples 10.1, 10.5): $(5, (1,1))$ and $(2, (1,-2))$.

Step 2 — assemble.

$$\mathbf{P} = \begin{bmatrix} 1 & 1 \\ 1 & -2 \end{bmatrix}, \qquad \mathbf{D} = \begin{bmatrix} 5 & 0 \\ 0 & 2 \end{bmatrix}.$$

Step 3 — invert $\mathbf{P}$. $\det \mathbf{P} = -2 - 1 = -3$, so

$$\mathbf{P}^{-1} = \frac{1}{-3}\begin{bmatrix} -2 & -1 \\ -1 & 1 \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 2 & 1 \\ 1 & -1 \end{bmatrix}.$$

Step 4 — verify.

$$\mathbf{P}\mathbf{D}\mathbf{P}^{-1} = \begin{bmatrix} 5 & 2 \\ 5 & -4 \end{bmatrix} \cdot \frac{1}{3}\begin{bmatrix} 2 & 1 \\ 1 & -1 \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 12 & 3 \\ 6 & 9 \end{bmatrix} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix} \checkmark$$

Remarks. Reordering the columns of $\mathbf{P}$ (and correspondingly the diagonal of $\mathbf{D}$) or rescaling any column of $\mathbf{P}$ gives an equally valid factorization; software might return $\mathbf{P} = \begin{bmatrix} -1 & 1 \\ 2 & 1 \end{bmatrix}$, $\mathbf{D} = \operatorname{diag}(2, 5)$. The rows of $\mathbf{P}^{-1}$, $(2,1)/3$ and $(1,-1)/3$, are left eigenvectors of $\mathbf{A}$: indeed $(2,1)\mathbf{A} = (10, 5) = 5(2,1)$.

Worked Example 10.10 — A 3×3 matrix with a repeated eigenvalue

Diagonalize $\mathbf{L} = \begin{bmatrix} 4 & -1 & 6 \\ 2 & 1 & 6 \\ 2 & -1 & 8 \end{bmatrix}$ from Example 10.6.

Step 1 — check diagonalizability. $m(2) = 2 = g(2)$ and $m(9) = 1 = g(9)$, so the eigenspace dimensions sum to 3: diagonalizable.

Step 2 — assemble (eigenvectors in the order $2, 2, 9$):

$$\mathbf{P} = \begin{bmatrix} 1 & 0 & 1 \\ 2 & 6 & 1 \\ 0 & 1 & 1 \end{bmatrix}, \qquad \mathbf{D} = \begin{bmatrix} 2 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 9 \end{bmatrix}.$$

Step 3 — invert. $\det \mathbf{P} = 1(6-1) - 0 + 1(2-0) = 7$, and the adjugate gives

$$\mathbf{P}^{-1} = \frac{1}{7}\begin{bmatrix} 5 & 1 & -6 \\ -2 & 1 & 1 \\ 2 & -1 & 6 \end{bmatrix}.$$

Step 4 — verify without inverting (cheaper and just as conclusive): check $\mathbf{L}\mathbf{P} = \mathbf{P}\mathbf{D}$.

$$\mathbf{L}\mathbf{P} = \begin{bmatrix} 4-2 & 0-6+6 & 4-1+6 \\ 2+2 & 0+6+6 & 2+1+6 \\ 2-2 & 0-6+8 & 2-1+8 \end{bmatrix} = \begin{bmatrix} 2 & 0 & 9 \\ 4 & 12 & 9 \\ 0 & 2 & 9 \end{bmatrix} = \mathbf{P}\mathbf{D} \checkmark$$

(The columns of $\mathbf{P}\mathbf{D}$ are $2\times$, $2\times$ and $9\times$ the columns of $\mathbf{P}$.)

Worked Example 10.11 — A defective matrix and its Jordan form

Show that $\mathbf{A} = \begin{bmatrix} 3 & 1 \\ -1 & 1 \end{bmatrix}$ is not diagonalizable and find its Jordan form.

Step 1 — eigenvalues. $\operatorname{tr} \mathbf{A} = 4$, $\det \mathbf{A} = 3 + 1 = 4$: $\lambda^2 - 4\lambda + 4 = (\lambda - 2)^2$. Double eigenvalue $\lambda = 2$, $m = 2$.

Step 2 — eigenspace. $\mathbf{A} - 2\mathbf{I} = \begin{bmatrix} 1 & 1 \\ -1 & -1 \end{bmatrix}$ has rank 1, so $g = 1 < m$. Defective: not diagonalizable. Eigenvector $\mathbf{v} = (1, -1)$.

Step 3 — generalized eigenvector. Solve $(\mathbf{A} - 2\mathbf{I})\mathbf{w} = \mathbf{v}$: $w_1 + w_2 = 1$. Take $\mathbf{w} = (1, 0)$.

Step 4 — Jordan form.

$$\mathbf{P} = \begin{bmatrix} 1 & 1 \\ -1 & 0 \end{bmatrix}, \qquad \mathbf{J} = \begin{bmatrix} 2 & 1 \\ 0 & 2 \end{bmatrix}, \qquad \mathbf{A} = \mathbf{P}\mathbf{J}\mathbf{P}^{-1}.$$

Check $\mathbf{A}\mathbf{P} = \begin{bmatrix} 2 & 3 \\ -2 & -1 \end{bmatrix}$ and $\mathbf{P}\mathbf{J} = \begin{bmatrix} 2 & 1+2 \\ -2 & -1+0 \end{bmatrix} = \begin{bmatrix} 2 & 3 \\ -2 & -1 \end{bmatrix}$ ✓.

Consequence. The system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ has solutions containing te^{2t}; indeed (Section 10.4) $e^{\mathbf{A}t} = e^{2t}\begin{bmatrix} 1+t & t \\ -t & 1-t \end{bmatrix}$. In circuit language: a critically damped response.

Worked Example 10.12 — Real block form of a rotation-scaling matrix

Bring $\mathbf{R} = \begin{bmatrix} 1 & -2 \\ 1 & 3 \end{bmatrix}$ (Example 10.7, eigenvalues $2 \pm j$) to real block form.

Step 1 — split the eigenvector. For $\lambda = 2 + j$, $\mathbf{v} = (-1 + j,\ 1) = \underbrace{(-1, 1)}_{\mathbf{a}} + j\,\underbrace{(1, 0)}_{\mathbf{b}}$.

Step 2 — form $\mathbf{P} = [\mathbf{a}\ \mathbf{b}]$. $\mathbf{P} = \begin{bmatrix} -1 & 1 \\ 1 & 0 \end{bmatrix}$, $\det \mathbf{P} = -1$, $\mathbf{P}^{-1} = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix}$.

Step 3 — compute.

$$\mathbf{RP} = \begin{bmatrix} -3 & 1 \\ 2 & 1 \end{bmatrix}, \qquad \mathbf{P}^{-1}\mathbf{RP} = \begin{bmatrix} 0 & 1 \\ 1 & 1 \end{bmatrix}\begin{bmatrix} -3 & 1 \\ 2 & 1 \end{bmatrix} = \begin{bmatrix} 2 & 1 \\ -1 & 2 \end{bmatrix} = \begin{bmatrix} \sigma & \omega \\ -\omega & \sigma \end{bmatrix}$$

with $\sigma = 2$, $\omega = 1$, as predicted. In the coordinates defined by $\mathbf{a}$ and $\mathbf{b}$, $\mathbf{R}$ is exactly "scale by $\sqrt{5}$, rotate by $26.57°$" (clockwise, given this sign arrangement).

Common Pitfall — mismatched order, and "distinct" misread

The i-th column of $\mathbf{P}$ must be the eigenvector for the i-th diagonal entry of $\mathbf{D}$; swapping one without the other produces a matrix that is not $\mathbf{A}$. Also, "distinct eigenvalues $\Rightarrow$ diagonalizable" is one-way: a repeated eigenvalue does **not** imply non-diagonalizable. Always compute $\operatorname{rank}(\mathbf{A} - \lambda\mathbf{I})$ for each repeated eigenvalue before deciding.

Engineering Note — nearly defective means sensitive

Matrices that are close to defective have eigenvector matrices $\mathbf{P}$ that are close to singular (nearly parallel eigenvectors). The condition number $\kappa(\mathbf{P})$ then bounds how much eigenvalues can move under a perturbation of $\mathbf{A}$ (the Bauer–Fike theorem: each eigenvalue of $\mathbf{A} + \mathbf{E}$ lies within $\kappa(\mathbf{P})\|\mathbf{E}\|$ of an eigenvalue of $\mathbf{A}$). In control design, closed-loop poles placed with a nearly defective $\mathbf{A}$ are very sensitive to component tolerances, and large $\kappa(\mathbf{P})$ also predicts large transient overshoot before an eventually stable response decays (Section 10.9). Symmetric matrices, whose $\mathbf{P}$ can be orthogonal with $\kappa = 1$, are the opposite extreme.

10.4 Matrix powers

Motivation

Many engineering processes advance in steps: a digital filter updates its internal state once per sample, an iterative solver refines its estimate once per sweep, a Markov model of a communication channel moves between "good" and "bad" states once per packet, a power-flow solver repeats a Newton step. If each step is linear, $\mathbf{x}[k+1] = \mathbf{A}\mathbf{x}[k]$, then after k steps

$$\mathbf{x}[k] = \mathbf{A}^k \mathbf{x}[0].$$

Everything about the long-run behaviour — growth, decay, oscillation, convergence to a steady state — is encoded in $\mathbf{A}^k$. Multiplying out $\mathbf{A}^k$ directly costs $k-1$ matrix products and reveals nothing about the trend. Diagonalization turns it into n scalar powers and makes the trend obvious. The same machinery then gives the **matrix exponential** $e^{\mathbf{A}t}$, which plays for continuous-time systems $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ exactly the role that $\mathbf{A}^k$ plays for discrete-time ones.

Powers by diagonalization

If $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$, the inner factors cancel in pairs:

$$\mathbf{A}^k = (\mathbf{P}\mathbf{D}\mathbf{P}^{-1})(\mathbf{P}\mathbf{D}\mathbf{P}^{-1})\cdots(\mathbf{P}\mathbf{D}\mathbf{P}^{-1}) = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}, \qquad \mathbf{D}^k = \begin{bmatrix} \lambda_1^k & & \\ & \ddots & \\ & & \lambda_n^k \end{bmatrix}.$$

The formula also holds for negative k when $\mathbf{A}$ is invertible, and suggests a definition of $\mathbf{A}^{1/2}$ when all $\lambda_i \geq 0$ (Section 10.6).

An equivalent and often more illuminating form expands the initial state in the eigenbasis. If $\mathbf{x}[0] = c_1\mathbf{v}_1 + \cdots + c_n\mathbf{v}_n$, i.e. $\mathbf{c} = \mathbf{P}^{-1}\mathbf{x}[0]$, then

$$\mathbf{x}[k] = \mathbf{A}^k\mathbf{x}[0] = c_1\lambda_1^k\mathbf{v}_1 + c_2\lambda_2^k\mathbf{v}_2 + \cdots + c_n\lambda_n^k\mathbf{v}_n.$$

Each eigen-direction evolves independently, multiplied by λ_i at every step. This **modal expansion** answers the qualitative questions at a glance:

- terms with $|\lambda_i| < 1$ die out geometrically, those with $|\lambda_i| > 1$ grow, those with $|\lambda_i| = 1$ persist;
- a negative real λ_i makes its term alternate in sign every step; a complex pair $re^{\pm j\theta}$ makes the pair rotate by θ per step while scaling by r;
- for large k, the term with the largest $|\lambda_i|$ (if unique, and if $c_i \neq 0$) **dominates**: $\mathbf{x}[k] \approx c_1\lambda_1^k\mathbf{v}_1$, so the state lines up with the dominant eigenvector and grows or decays like $\rho(\mathbf{A})^k$.

The last observation is the **power method** for computing a dominant eigenpair: start from any vector, multiply repeatedly by $\mathbf{A}$ and normalise. It converges at the rate $|\lambda_2/\lambda_1|^k$ and is the basis of Google's PageRank and of many large-scale eigen-solvers (Ch. 22).

Powers of a Jordan block and the spectral-radius theorem

For a defective matrix we use the Jordan form instead. Write $\mathbf{J}_2(\lambda) = \lambda\mathbf{I} + \mathbf{N}$ with $\mathbf{N} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, $\mathbf{N}^2 = \mathbf{0}$. Because $\lambda\mathbf{I}$ commutes with $\mathbf{N}$, the binomial theorem applies and stops after two terms:

$$\mathbf{J}_2(\lambda)^k = \lambda^k \mathbf{I} + k\lambda^{k-1}\mathbf{N} = \begin{bmatrix} \lambda^k & k\lambda^{k-1} \\ 0 & \lambda^k \end{bmatrix}.$$

For an $m \times m$ block, entries $\binom{k}{i}\lambda^{k-i}$ appear for $i < m$. Polynomial factors like k are eventually overwhelmed by $|\lambda|^k$ when $|\lambda| < 1$, but they can make $\mathbf{A}^k$ grow substantially before it decays. Combining the diagonalizable and Jordan cases:

Convergence of matrix powers

For any square matrix $\mathbf{A}$:

1. $\mathbf{A}^k \to \mathbf{0}$ as $k \to \infty$ **if and only if** $\rho(\mathbf{A}) < 1$ (all eigenvalues strictly inside the unit circle).
2. If $\rho(\mathbf{A}) > 1$, $\|\mathbf{A}^k \mathbf{x}\| \to \infty$ for almost every starting vector $\mathbf{x}$.
3. If $\rho(\mathbf{A}) = 1$, the powers stay bounded if and only if every eigenvalue with $|\lambda| = 1$ is non-defective.
4. (Gelfand) For any matrix norm, $\|\mathbf{A}^k\|^{1/k} \to \rho(\mathbf{A})$.

Part 1 is the stability condition for discrete-time linear systems (Section 10.9) and the convergence condition for stationary iterative solvers such as Jacobi and Gauss–Seidel, whose error obeys $\mathbf{e}[k+1] = \mathbf{G}\mathbf{e}[k]$ for an iteration matrix $\mathbf{G}$.

The matrix exponential

For a scalar, $\dot{x} = ax$ has solution $x(t) = e^{at}x(0)$. For the system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ we want a matrix that does the same job. Define, by analogy with the Taylor series of Ch. 4,

$$e^{\mathbf{A}t} = \mathbf{I} + \mathbf{A}t + \frac{(\mathbf{A}t)^2}{2!} + \frac{(\mathbf{A}t)^3}{3!} + \cdots = \sum_{k=0}^{\infty} \frac{\mathbf{A}^k t^k}{k!}.$$

The series converges for every square $\mathbf{A}$ and every t (each entry is bounded by the scalar series for $e^{\|\mathbf{A}\|t}$). Differentiating term by term,

$$\frac{d}{dt}e^{\mathbf{A}t} = \mathbf{A} + \mathbf{A}^2 t + \frac{\mathbf{A}^3 t^2}{2!} + \cdots = \mathbf{A}e^{\mathbf{A}t} = e^{\mathbf{A}t}\mathbf{A},$$

so $\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}(0)$ satisfies $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ with the right initial value; by uniqueness (Ch. 11) it is *the* solution. In control texts $e^{\mathbf{A}t}$ is called the **state-transition matrix** $\mathbf{\Phi}(t)$.

Properties of the matrix exponential

For square $\mathbf{A}, \mathbf{B}$ and scalars t, s:

1. $e^{\mathbf{0}} = \mathbf{I}$ and $e^{\mathbf{A}(t+s)} = e^{\mathbf{A}t}e^{\mathbf{A}s}$;
2. $e^{\mathbf{A}t}$ is always invertible, with $(e^{\mathbf{A}t})^{-1} = e^{-\mathbf{A}t}$;
3. if $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ then $e^{\mathbf{A}t} = \mathbf{P}e^{\mathbf{D}t}\mathbf{P}^{-1}$ with $e^{\mathbf{D}t} = \operatorname{diag}(e^{\lambda_1 t}, \dots, e^{\lambda_n t})$;
4. the eigenvalues of $e^{\mathbf{A}t}$ are $e^{\lambda_i t}$, so $\det e^{\mathbf{A}t} = e^{(\operatorname{tr}\mathbf{A})t}$;
5. $e^{(\mathbf{A}+\mathbf{B})t} = e^{\mathbf{A}t}e^{\mathbf{B}t}$ **if** $\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{A}$ — but not in general.

Property 3 follows from $\mathbf{A}^k = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}$ applied term by term. With the modal expansion $\mathbf{x}(0) = \sum c_i \mathbf{v}_i$ it gives the continuous-time analogue of the discrete result:

$$\mathbf{x}(t) = c_1 e^{\lambda_1 t}\mathbf{v}_1 + c_2 e^{\lambda_2 t}\mathbf{v}_2 + \cdots + c_n e^{\lambda_n t}\mathbf{v}_n.$$

Now the dividing line is $\operatorname{Re}\lambda_i = 0$ instead of $|\lambda_i| = 1$: $e^{\lambda t}$ decays if $\operatorname{Re}\lambda < 0$. The two pictures are linked by sampling: if $\mathbf{x}(t)$ is sampled every T seconds, $\mathbf{x}[k+1] = e^{\mathbf{A}T}\mathbf{x}[k]$, and the eigenvalue λ maps to $z = e^{\lambda T}$ — the left half of the s-plane maps to the inside of the unit circle of the z-plane, exactly the $s \to z$ correspondence of Ch. 17.

For a Jordan block, $e^{\mathbf{J}_2(\lambda)t} = e^{\lambda t}e^{\mathbf{N}t} = e^{\lambda t}(\mathbf{I} + \mathbf{N}t) = e^{\lambda t}\begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix}$ — the origin of the $te^{\lambda t}$ terms. A rotation generator gives the familiar oscillation:

$$\exp\left(\begin{bmatrix} 0 & -\omega \\ \omega & 0 \end{bmatrix} t\right) = \begin{bmatrix} \cos\omega t & -\sin\omega t \\ \sin\omega t & \cos\omega t \end{bmatrix},$$

the real-matrix form of $e^{j\omega t}$ — a rotating phasor.

Functions of a matrix via Cayley–Hamilton (Sylvester interpolation)

By Cayley–Hamilton, every power $\mathbf{A}^k$ with $k \geq n$ reduces to a combination of $\mathbf{I}, \mathbf{A}, \dots, \mathbf{A}^{n-1}$, and so does any convergent power series. Hence for an analytic function f (such as λ^k or $e^{\lambda t}$),

$$f(\mathbf{A}) = \alpha_0\mathbf{I} + \alpha_1\mathbf{A} + \cdots + \alpha_{n-1}\mathbf{A}^{n-1}$$

for some scalars α_i. Applying both sides to an eigenvector shows that the polynomial $r(\lambda) = \alpha_0 + \alpha_1\lambda + \cdots + \alpha_{n-1}\lambda^{n-1}$ must agree with f at each eigenvalue:

$$f(\lambda_i) = r(\lambda_i), \qquad i = 1, \dots, n.$$

With distinct eigenvalues this is n linear equations for the n unknowns α_i. For an eigenvalue of multiplicity m, also match the first $m-1$ derivatives, $f^{(q)}(\lambda_i) = r^{(q)}(\lambda_i)$. This method avoids eigenvectors altogether and is convenient for 2×2 and 3×3 hand calculations.

Worked examples

Worked Example 10.13 — A tenth power

Compute $\mathbf{A}^{10}$ for $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$.

Step 1 — use Example 10.9. $\mathbf{P} = \begin{bmatrix} 1 & 1 \\ 1 & -2 \end{bmatrix}$, $\mathbf{D} = \operatorname{diag}(5, 2)$, $\mathbf{P}^{-1} = \frac{1}{3}\begin{bmatrix} 2 & 1 \\ 1 & -1 \end{bmatrix}$.

Step 2 — multiply.

$$\mathbf{A}^{10} = \begin{bmatrix} 1 & 1 \\ 1 & -2 \end{bmatrix} \begin{bmatrix} 5^{10} & 0 \\ 0 & 2^{10} \end{bmatrix} \frac{1}{3} \begin{bmatrix} 2 & 1 \\ 1 & -1 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 2 \cdot 5^{10} + 2^{10} & 5^{10} - 2^{10} \\ 2 \cdot 5^{10} - 2 \cdot 2^{10} & 5^{10} + 2 \cdot 2^{10} \end{bmatrix}.$$

Step 3 — numbers. $5^{10} = 9\,765\,625$, $2^{10} = 1024$:

$$\mathbf{A}^{10} = \begin{bmatrix} 6\,510\,758 & 3\,254\,867 \\ 6\,509\,734 & 3\,255\,891 \end{bmatrix}.$$

Checks. $\operatorname{tr} \mathbf{A}^{10} = 9\,766\,649 = 5^{10} + 2^{10}$ ✓. The general formula at $k = 1$ returns $\frac{1}{3}\begin{bmatrix} 12 & 3 \\ 6 & 9 \end{bmatrix} = \mathbf{A}$ ✓. Notice how the 5^{10} term dominates: the columns of $\mathbf{A}^{10}$ are both nearly parallel to $\mathbf{v}_1 = (1, 1)$ — the power method at work.

Sylvester alternative. Write $\mathbf{A}^{10} = \alpha_0 \mathbf{I} + \alpha_1 \mathbf{A}$ with $5^{10} = \alpha_0 + 5\alpha_1$, $2^{10} = \alpha_0 + 2\alpha_1$. Then $\alpha_1 = (5^{10} - 2^{10})/3 = 3\,254\,867$ and $\alpha_0 = 2^{10} - 2\alpha_1 = -6\,508\,710$. The $(1, 1)$ entry is $\alpha_0 + 4\alpha_1 = 6\,510\,758$ ✓.

Worked Example 10.14 — Fibonacci numbers in closed form

The recursion $F_{k+1} = F_k + F_{k-1}$, $F_0 = 0$, $F_1 = 1$, is the prototype of a second-order linear difference equation (the same structure as an IIR filter with no input). With $\mathbf{x}[k] = (F_{k+1}, F_k)$,

$$\mathbf{x}[k+1] = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} \mathbf{x}[k] = \mathbf{F}\mathbf{x}[k], \qquad \mathbf{x}[0] = \begin{bmatrix} 1 \\ 0 \end{bmatrix}.$$

Step 1 — eigenvalues. $\lambda^2 - \lambda - 1 = 0$: $\varphi = \frac{1+\sqrt{5}}{2} \approx 1.618$ and $\psi = \frac{1-\sqrt{5}}{2} \approx -0.618$.

Step 2 — eigenvectors. $\mathbf{F} - \lambda \mathbf{I} = \begin{bmatrix} 1-\lambda & 1 \\ 1 & -\lambda \end{bmatrix}$; the second row gives $\mathbf{v} = (\lambda, 1)$. So $\mathbf{v}_\varphi = (\varphi, 1)$, $\mathbf{v}_\psi = (\psi, 1)$.

Step 3 — expand the initial state. $(1, 0) = c_1(\varphi, 1) + c_2(\psi, 1)$ gives $c_2 = -c_1$ and $c_1(\varphi - \psi) = 1$, so $c_1 = 1/\sqrt{5}$.

Step 4 — read off the second component.

$$F_k = c_1 \varphi^k + c_2 \psi^k = \frac{\varphi^k - \psi^k}{\sqrt{5}} \qquad \text{(Binet's formula)}.$$

Check. $F_{10} = (1.618034^{10} - (-0.618034)^{10})/\sqrt{5} = (122.9919 - 0.0081)/2.23607 = 55.000$ ✓, and directly $\mathbf{F}^{10} = \begin{bmatrix} 89 & 55 \\ 55 & 34 \end{bmatrix}$. Because $|\psi| < 1$, F_k is the integer nearest to $\varphi^k/\sqrt{5}$, and $F_{k+1}/F_k \to \varphi$: the dominant eigenvalue sets the growth rate.

Worked Example 10.15 — A two-state Markov channel and its steady state

A burst-error channel (Gilbert–Elliott model) is either Good (G) or Bad (B) during each packet. From G it stays G with probability 0.9; from B it returns to G with probability 0.4. With $\mathbf{x}[k] = (P(\mathrm{G}), P(\mathrm{B}))$ at packet k,

$$\mathbf{x}[k+1] = \mathbf{M}\mathbf{x}[k], \qquad \mathbf{M} = \begin{bmatrix} 0.9 & 0.4 \\ 0.1 & 0.6 \end{bmatrix}$$

(each column sums to 1). Find $\mathbf{x}[k]$ if the channel starts Bad, and the long-run fraction of Good packets.

Step 1 — eigenvalues. $\operatorname{tr} \mathbf{M} = 1.5$, $\det \mathbf{M} = 0.54 - 0.04 = 0.5$; $\lambda^2 - 1.5\lambda + 0.5 = (\lambda - 1)(\lambda - 0.5)$. A column-stochastic matrix always has $\lambda = 1$, because $(1, 1)\mathbf{M} = (1, 1)$: the all-ones row is a left eigenvector.

Step 2 — eigenvectors. $\lambda = 1$: $\mathbf{M} - \mathbf{I} = \begin{bmatrix} -0.1 & 0.4 \\ 0.1 & -0.4 \end{bmatrix}$ gives $\mathbf{v}_1 \propto (4, 1)$, normalised as a probability vector $\boldsymbol{\pi} = (0.8, 0.2)$. $\lambda = 0.5$: $\mathbf{M} - 0.5\mathbf{I} = \begin{bmatrix} 0.4 & 0.4 \\ 0.1 & 0.1 \end{bmatrix}$ gives $\mathbf{v}_2 = (1, -1)$ (entries sum to zero, as they must for a mode that does not change total probability).

Step 3 — expand $\mathbf{x}[0] = (0, 1)$. $(0, 1) = \boldsymbol{\pi} + c_2(1, -1)$ forces $c_2 = -0.8$.

Step 4 — solution.

$$\mathbf{x}[k] = \begin{bmatrix} 0.8 \\ 0.2 \end{bmatrix} - 0.8\,(0.5)^k \begin{bmatrix} 1 \\ -1 \end{bmatrix}, \qquad P_k(\mathrm{G}) = 0.8\big(1 - 0.5^k\big).$$

Check. $k = 1$: $P(\mathrm{G}) = 0.4$, matching one step from B ✓. $k = 10$: $0.8(1 - 1/1024) = 0.79922$ (numerical $\mathbf{M}^{10}(0, 1)^{\mathsf{T}}$ agrees). Long run: **80 % of packets are Good**, whatever the initial state. The second eigenvalue 0.5 sets the **mixing rate**: the memory of the initial state halves every packet. A channel with λ_2 close to 1 has long error bursts — which is why interleaver depth is chosen from the second eigenvalue.

Worked Example 10.16 — The state-transition matrix $e^{\mathbf{A}t}$

Compute $e^{\mathbf{A}t}$ for $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}$ (the companion matrix of $\ddot{y} + 3\dot{y} + 2y = 0$) and find $\mathbf{x}(t)$ for $\mathbf{x}(0) = (1, 0)$.

Method 1 — diagonalization. $\lambda^2 + 3\lambda + 2 = (\lambda + 1)(\lambda + 2)$. Eigenvectors of a companion matrix are $(1, \lambda)$: $\mathbf{v}_1 = (1, -1)$, $\mathbf{v}_2 = (1, -2)$. With $\mathbf{P} = \begin{bmatrix} 1 & 1 \\ -1 & -2 \end{bmatrix}$, $\det \mathbf{P} = -1$, $\mathbf{P}^{-1} = \begin{bmatrix} 2 & 1 \\ -1 & -1 \end{bmatrix}$:

$$e^{\mathbf{A}t} = \mathbf{P} \begin{bmatrix} e^{-t} & 0 \\ 0 & e^{-2t} \end{bmatrix} \mathbf{P}^{-1} = \begin{bmatrix} 2e^{-t} - e^{-2t} & e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix}.$$

Method 2 — Sylvester. $e^{\mathbf{A}t} = \alpha_0 \mathbf{I} + \alpha_1 \mathbf{A}$ with $e^{-t} = \alpha_0 - \alpha_1$ and $e^{-2t} = \alpha_0 - 2\alpha_1$, so $\alpha_1 = e^{-t} - e^{-2t}$, $\alpha_0 = 2e^{-t} - e^{-2t}$. Then $e^{\mathbf{A}t} = \begin{bmatrix} \alpha_0 & \alpha_1 \\ -2\alpha_1 & \alpha_0 - 3\alpha_1 \end{bmatrix}$, identical to Method 1 (e.g. $\alpha_0 - 3\alpha_1 = -e^{-t} + 2e^{-2t}$ ✓).

Response. $\mathbf{x}(t) = e^{\mathbf{A}t}(1, 0)^{\mathsf{T}}$ is the first column: $y(t) = 2e^{-t} - e^{-2t}$, $\dot{y}(t) = -2e^{-t} + 2e^{-2t}$.

Checks. $t = 0$ gives $\mathbf{I}$ ✓. $\det e^{\mathbf{A}t} = e^{-3t} = e^{(\operatorname{tr}\mathbf{A})t}$ (expand: $(2e^{-t} - e^{-2t})(-e^{-t} + 2e^{-2t}) + (e^{-t} - e^{-2t})(2e^{-t} - 2e^{-2t}) = e^{-3t}$) ✓. At $t = 1$: $2e^{-1} - e^{-2} = 0.6004$ and $e^{-1} - e^{-2} = 0.2325$, matching a numerical `expm` ✓.

Worked Example 10.17 — Exponential of a defective matrix

For the defective $\mathbf{A} = \begin{bmatrix} 3 & 1 \\ -1 & 1 \end{bmatrix}$ of Example 10.11 (double eigenvalue 2), Sylvester's method needs the derivative condition. Write $e^{\mathbf{A}t} = \alpha_0 \mathbf{I} + \alpha_1 \mathbf{A}$ and match $f(\lambda) = e^{\lambda t}$ and $f'(\lambda) = te^{\lambda t}$ (derivative with respect to λ) at $\lambda = 2$:

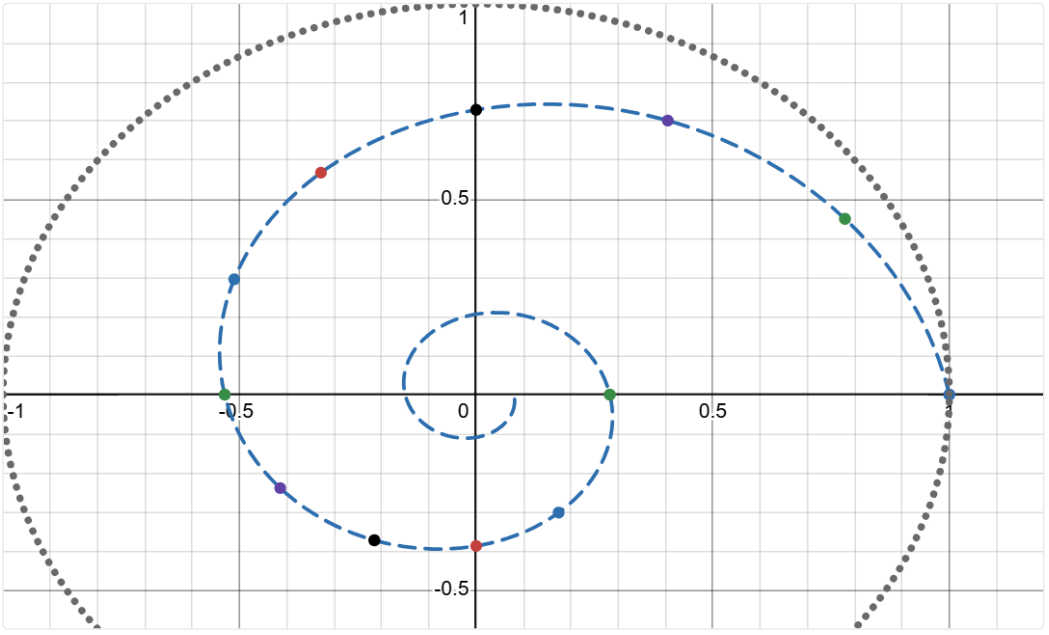
$$e^{2t} = \alpha_0 + 2\alpha_1, \qquad te^{2t} = \alpha_1.$$

So $\alpha_1 = te^{2t}$, $\alpha_0 = (1 - 2t)e^{2t}$, and

$$e^{\mathbf{A}t} = (1 - 2t)e^{2t}\mathbf{I} + te^{2t} \begin{bmatrix} 3 & 1 \\ -1 & 1 \end{bmatrix} = e^{2t} \begin{bmatrix} 1 + t & t \\ -t & 1 - t \end{bmatrix}.$$

Check via Jordan form: $\mathbf{P}e^{\mathbf{J}t}\mathbf{P}^{-1}$ with $e^{\mathbf{J}t} = e^{2t}\begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix}$ gives the same matrix, and $\frac{d}{dt}$ at $t = 0$ returns $\begin{bmatrix} 2 + 1 & 1 \\ -1 & 2 - 1 \end{bmatrix} = \mathbf{A}$ ✓.

The graph shows the discrete-time counterpart of a complex eigenvalue pair. For $\mathbf{A} = 0.9 \begin{bmatrix} \cos 30^\circ & -\sin 30^\circ \\ \sin 30^\circ & \cos 30^\circ \end{bmatrix}$ (eigenvalues $0.9e^{\pm j\pi/6}$), the iterates $\mathbf{x}[k] = \mathbf{A}^k(1, 0)$ rotate 30° per step and shrink by 10%; they lie on the logarithmic spiral $r = 0.9^{6\theta/\pi} = e^{-0.2012\theta}$.



Iterates of a discrete-time system with eigenvalues $0.9e^{\pm j\pi/6}$: each step rotates by $\angle\lambda = 30^\circ$ and scales by $|\lambda| = 0.9$, so the state spirals into the origin along $r = e^{-0.2012\theta}$; the dotted unit circle is the stability boundary $|\lambda| = 1$.

Common Pitfall — exponentiating entry by entry

$e^{\mathbf{A}t}$ is **not** the matrix of $e^{a_{ij}t}$ (except for diagonal $\mathbf{A}$), and $\mathbf{A}^k$ is not the matrix of a_{ij}^k. Equally, $e^{(\mathbf{A}+\mathbf{B})t} \neq e^{\mathbf{A}t}e^{\mathbf{B}t}$ unless $\mathbf{A}$ and $\mathbf{B}$ commute — which matters when a state matrix is split into "nominal" and "perturbation" parts, or when switching between circuit topologies in a switched-mode converter.

Engineering Note — computing $e^{\mathbf{A}T}$ in practice

Discretising a continuous-time model for a digital controller or a circuit simulator needs $\mathbf{\Phi} = e^{\mathbf{A}T}$ for the sample period T. Diagonalization is fine for small, well-conditioned problems, but robust software (MATLAB `expm`, SciPy `scipy.linalg.expm`) uses **scaling and squaring** with a Padé approximant: compute $e^{\mathbf{A}T/2^s}$ for an s that makes the argument small, then square s times. This avoids both the ill-conditioning of nearly defective $\mathbf{P}$ and the catastrophic cancellation of the raw Taylor series for large $\|\mathbf{A}T\|$ (Moler and Van Loan's classic survey lists nineteen methods and why most of them are dubious).

10.5 Symmetric matrices

Motivation

A remarkable fraction of the matrices an engineer meets are symmetric, $\mathbf{A}^{\mathsf{T}} = \mathbf{A}$, or their complex cousins, Hermitian, $\mathbf{A}^{\mathsf{H}} = \mathbf{A}$. The nodal conductance matrix of a resistive network is symmetric (reciprocity: the current at node j due to a voltage at node i equals the current at i due to the same voltage at j). Inductance and capacitance matrices of coupled conductors are symmetric because they come from stored energy. Covariance and correlation matrices of noise are symmetric (real signals) or Hermitian (complex baseband). Hessian matrices of second derivatives are symmetric (Ch. 6). The impedance matrix of a lossless reciprocal network at a given frequency is j times a real symmetric matrix.

For all of these, eigen-theory is as good as it can possibly be: the eigenvalues are real, the eigenvectors are orthogonal, and diagonalization never fails. This section proves these facts and draws out their geometry.

Real eigenvalues and orthogonal eigenvectors

Symmetric and Hermitian matrices: real eigenvalues

If $\mathbf{A}$ is Hermitian ($\mathbf{A}^{\mathsf{H}} = \mathbf{A}$; in particular if $\mathbf{A}$ is real symmetric), every eigenvalue of $\mathbf{A}$ is real.

Proof. Let $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$, possibly complex. Multiply on the left by $\mathbf{v}^{\mathsf{H}}$: $\mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v} = \lambda\,\mathbf{v}^{\mathsf{H}}\mathbf{v} = \lambda\|\mathbf{v}\|^2$. The scalar $\mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v}$ is real, because it equals its own conjugate: $(\mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v})^* = (\mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v})^{\mathsf{H}} = \mathbf{v}^{\mathsf{H}}\mathbf{A}^{\mathsf{H}}\mathbf{v} = \mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v}$. Since $\|\mathbf{v}\|^2 > 0$ is real too, $\lambda = \mathbf{v}^{\mathsf{H}}\mathbf{A}\mathbf{v}/\|\mathbf{v}\|^2$ is real. $\square$

For a real symmetric matrix, real λ means $\mathbf{A} - \lambda\mathbf{I}$ is real, so the eigenvectors can be chosen real.

Orthogonality of eigenvectors

Eigenvectors of a Hermitian matrix belonging to distinct eigenvalues are orthogonal.

Proof. Let $\mathbf{A}\mathbf{v}_1 = \lambda_1\mathbf{v}_1$, $\mathbf{A}\mathbf{v}_2 = \lambda_2\mathbf{v}_2$, $\lambda_1 \neq \lambda_2$ (both real). Then

$$\lambda_1\,\mathbf{v}_2^{\mathsf{H}}\mathbf{v}_1 = \mathbf{v}_2^{\mathsf{H}}\mathbf{A}\mathbf{v}_1 = (\mathbf{A}^{\mathsf{H}}\mathbf{v}_2)^{\mathsf{H}}\mathbf{v}_1 = (\mathbf{A}\mathbf{v}_2)^{\mathsf{H}}\mathbf{v}_1 = \lambda_2\,\mathbf{v}_2^{\mathsf{H}}\mathbf{v}_1,$$

so $(\lambda_1 - \lambda_2)\langle\mathbf{v}_1, \mathbf{v}_2\rangle = 0$ and $\langle\mathbf{v}_1, \mathbf{v}_2\rangle = 0$. $\square$

Within a repeated eigenvalue's eigenspace the eigenvectors are not automatically orthogonal, but the eigenspace is a subspace, so Gram–Schmidt (Ch. 9) produces an orthonormal basis of it — and the orthogonalised vectors are still eigenvectors.

The spectral theorem

Spectral theorem

A real $n \times n$ matrix $\mathbf{A}$ is symmetric **if and only if** it can be factored as

$$\mathbf{A} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}},$$

where $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1, \dots, \lambda_n)$ is real and $\mathbf{Q}$ is **orthogonal** ($\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}$, so $\mathbf{Q}^{-1} = \mathbf{Q}^{\mathsf{T}}$) with orthonormal eigenvectors $\mathbf{q}_1, \dots, \mathbf{q}_n$ as columns. Likewise a complex matrix is Hermitian if and only if $\mathbf{A} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^{\mathsf{H}}$ with $\mathbf{U}$ unitary ($\mathbf{U}^{\mathsf{H}}\mathbf{U} = \mathbf{I}$) and $\mathbf{\Lambda}$ real.

Proof sketch. "If": $(\mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}})^{\mathsf{T}} = \mathbf{Q}\mathbf{\Lambda}^{\mathsf{T}}\mathbf{Q}^{\mathsf{T}} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}$. "Only if", by induction on n: $\mathbf{A}$ has a real eigenvalue λ_1 with a unit eigenvector $\mathbf{q}_1$. Extend $\mathbf{q}_1$ to an orthonormal basis and let $\mathbf{Q}_1$ have these as columns. The first column of $\mathbf{Q}_1^{\mathsf{T}}\mathbf{A}\mathbf{Q}_1$ is $\lambda_1\mathbf{e}_1$; because $\mathbf{Q}_1^{\mathsf{T}}\mathbf{A}\mathbf{Q}_1$ is again symmetric, its first row is $\lambda_1\mathbf{e}_1^{\mathsf{T}}$ too:

$$\mathbf{Q}_1^{\mathsf{T}}\mathbf{A}\mathbf{Q}_1 = \begin{bmatrix} \lambda_1 & \mathbf{0}^{\mathsf{T}} \\ \mathbf{0} & \mathbf{A}_1 \end{bmatrix},$$

with $\mathbf{A}_1$ symmetric of size $n-1$. Apply the induction hypothesis to $\mathbf{A}_1$ and assemble. Note what symmetry bought: the zero block in the *top right*, which is what prevents Jordan blocks. $\square$

So a symmetric matrix is never defective, and its eigenvector matrix is as well-conditioned as a matrix can be: $\kappa(\mathbf{Q}) = 1$.

Spectral decomposition

Multiplying out $\mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}$ column-by-row gives the **spectral decomposition**

$$\mathbf{A} = \lambda_1\mathbf{q}_1\mathbf{q}_1^{\mathsf{T}} + \lambda_2\mathbf{q}_2\mathbf{q}_2^{\mathsf{T}} + \cdots + \lambda_n\mathbf{q}_n\mathbf{q}_n^{\mathsf{T}}.$$

Each $\mathbf{P}_i = \mathbf{q}_i\mathbf{q}_i^{\mathsf{T}}$ is the orthogonal projector onto the line through $\mathbf{q}_i$ (Ch. 9); these projectors satisfy $\mathbf{P}_i^2 = \mathbf{P}_i$, $\mathbf{P}_i\mathbf{P}_k = \mathbf{0}$ for $i \neq k$ and $\sum_i \mathbf{P}_i = \mathbf{I}$. A symmetric matrix is therefore a weighted sum of mutually perpendicular projections: to apply $\mathbf{A}$, resolve $\mathbf{x}$ into its components along the eigenvectors, scale each by its eigenvalue, and add. Functions of $\mathbf{A}$ follow at once: $f(\mathbf{A}) = \sum_i f(\lambda_i)\mathbf{q}_i\mathbf{q}_i^{\mathsf{T}}$, e.g. $\mathbf{A}^{-1} = \sum \lambda_i^{-1}\mathbf{q}_i\mathbf{q}_i^{\mathsf{T}}$.

Quadratic forms and principal axes

A **quadratic form** is a function $Q(\mathbf{x}) = \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \sum_{i,k} a_{ik}x_i x_k$. Only the symmetric part of $\mathbf{A}$ contributes (since $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{x}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{x}$), so we always take $\mathbf{A}$ symmetric: for $Q = ax^2 + 2bxy + cy^2$, $\mathbf{A} = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$ — note the **half** of the cross coefficient off the diagonal. Energy expressions are quadratic forms: $\tfrac{1}{2}\mathbf{i}^{\mathsf{T}}\mathbf{L}\mathbf{i}$ for coupled inductors, $\tfrac{1}{2}\mathbf{v}^{\mathsf{T}}\mathbf{C}\mathbf{v}$ for a capacitance matrix, $\mathbf{v}^{\mathsf{T}}\mathbf{G}\mathbf{v}$ for power dissipated in a conductance network.

Substituting $\mathbf{x} = \mathbf{Q}\mathbf{y}$ (a rotation, possibly with a reflection) and using $\mathbf{Q}^{\mathsf{T}}\mathbf{A}\mathbf{Q} = \mathbf{\Lambda}$:

$$\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{y}^{\mathsf{T}}\mathbf{\Lambda}\mathbf{y} = \lambda_1 y_1^2 + \lambda_2 y_2^2 + \cdots + \lambda_n y_n^2.$$

Principal axes theorem

Every real quadratic form can be reduced by an orthogonal change of variables $\mathbf{x} = \mathbf{Q}\mathbf{y}$ to a sum of squares $\sum \lambda_i y_i^2$ with no cross terms. The new axes — the eigenvectors $\mathbf{q}_i$ — are the **principal axes** of the form. For $n = 2$, the level curve $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = 1$ is an ellipse with semi-axes $1/\sqrt{\lambda_1}$, $1/\sqrt{\lambda_2}$ along $\mathbf{q}_1, \mathbf{q}_2$ when both eigenvalues are positive, and a hyperbola when they have opposite signs.

The Rayleigh quotient and extremal eigenvalues

Rayleigh quotient

For symmetric $\mathbf{A}$ and $\mathbf{x} \neq \mathbf{0}$, the **Rayleigh quotient** is

$$R(\mathbf{x}) = \frac{\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}}{\mathbf{x}^{\mathsf{T}}\mathbf{x}}.$$

Expand $\mathbf{x} = \sum y_i \mathbf{q}_i$ with eigenvalues ordered $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$:

$$R(\mathbf{x}) = \frac{\lambda_1 y_1^2 + \cdots + \lambda_n y_n^2}{y_1^2 + \cdots + y_n^2},$$

a weighted average of the eigenvalues with weights $y_i^2 \geq 0$. Hence:

Rayleigh's principle

$$\lambda_{\min} = \lambda_n \leq R(\mathbf{x}) \leq \lambda_1 = \lambda_{\max} \quad \text{for all } \mathbf{x} \neq \mathbf{0},$$

with $\max R = \lambda_1$ attained at $\mathbf{x} = \mathbf{q}_1$ and $\min R = \lambda_n$ at $\mathbf{x} = \mathbf{q}_n$. More generally (Courant–Fischer), λ_k is the maximum of R over vectors orthogonal to $\mathbf{q}_1, \ldots, \mathbf{q}_{k-1}$.

Two consequences are used constantly. First, R **is stationary at every eigenvector**, so an approximate eigenvector with error ε gives an eigenvalue estimate with error of order ε^2 — the reason Rayleigh's method gives excellent natural-frequency estimates from rough guesses of mode shape. Second, maximising a quadratic form on the unit sphere is an eigenvalue problem: the direction of maximum output power of a beamformer, the direction of largest variance in data (principal component analysis), the polarisation that maximises received power — each is the top eigenvector of a suitable symmetric or Hermitian matrix.

Worked examples

Worked Example 10.18 — Orthogonal diagonalization of a 2×2 symmetric matrix

Diagonalize $\mathbf{S} = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix}$ orthogonally and write its spectral decomposition.

Step 1 — eigenvalues. $\lambda^2 - 6\lambda + 8 = 0$: $\lambda_1 = 4$, $\lambda_2 = 2$.

Step 2 — unit eigenvectors. $\lambda = 4$: $\mathbf{S} - 4\mathbf{I} = \begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix}$, $\mathbf{q}_1 = \frac{1}{\sqrt{2}}(1, 1)$. $\lambda = 2$: $\mathbf{S} - 2\mathbf{I} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$, $\mathbf{q}_2 = \frac{1}{\sqrt{2}}(1, -1)$. They are orthogonal, as guaranteed.

Step 3 — factor.

$$\mathbf{Q} = \frac{1}{\sqrt{2}}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad \mathbf{\Lambda} = \begin{bmatrix} 4 & 0 \\ 0 & 2 \end{bmatrix}, \quad \mathbf{S} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}.$$

No matrix inversion was needed: $\mathbf{Q}^{-1} = \mathbf{Q}^{\mathsf{T}}$.

Step 4 — spectral decomposition.

$$\mathbf{S} = 4 \cdot \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} + 2 \cdot \frac{1}{2}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} = \begin{bmatrix} 2 & 2 \\ 2 & 2 \end{bmatrix} + \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix} \checkmark$$

Interpretation. This is the matrix of a symmetric two-port or a pair of identical coupled lines. The eigenvectors are the **common mode** $(1, 1)$ and **differential mode** $(1, -1)$ of Ch. 9; any symmetric structure with two identical halves has them as eigenvectors, which is why even/odd-mode analysis works.

Worked Example 10.19 — A repeated eigenvalue and Gram–Schmidt

Orthogonally diagonalize $\mathbf{A} = \begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix}$.

Step 1 — eigenvalues. Write $\mathbf{A} = \mathbf{I} + \mathbf{J}$ with $\mathbf{J}$ the all-ones matrix. $\mathbf{J}$ has rank 1, so eigenvalue 0 twice, and $\operatorname{tr}\mathbf{J} = 3$ is its third eigenvalue (eigenvector $(1,1,1)$). Adding 1: the eigenvalues of $\mathbf{A}$ are $4, 1, 1$. (Check: $\operatorname{tr}\mathbf{A} = 6$ ✓; $\det\mathbf{A} = 2(3) - 1(1) + 1(-1) = 4$ ✓.)

Step 2 — $\lambda = 4$. $\mathbf{q}_1 = \frac{1}{\sqrt{3}}(1,1,1)$.

Step 3 — $\lambda = 1$. $\mathbf{A} - \mathbf{I} = \mathbf{J}$, so the eigenspace is the plane $x_1 + x_2 + x_3 = 0$. A natural basis is $\mathbf{w}_1 = (1,-1,0)$, $\mathbf{w}_2 = (1,0,-1)$ — valid eigenvectors but **not orthogonal** ($\mathbf{w}_1 \cdot \mathbf{w}_2 = 1$). Apply Gram–Schmidt inside the eigenspace:

$$\mathbf{q}_2 = \frac{\mathbf{w}_1}{\|\mathbf{w}_1\|} = \frac{1}{\sqrt{2}}(1,-1,0), \qquad \mathbf{w}_2 - (\mathbf{w}_2 \cdot \mathbf{q}_2)\mathbf{q}_2 = (1,0,-1) - \tfrac{1}{2}(1,-1,0) = \left(\tfrac{1}{2}, \tfrac{1}{2}, -1\right),$$

normalised: $\mathbf{q}_3 = \frac{1}{\sqrt{6}}(1,1,-2)$. It still satisfies $x_1 + x_2 + x_3 = 0$, so it is still an eigenvector.

Step 4 — result.

$$\mathbf{Q} = \begin{bmatrix} 1/\sqrt{3} & 1/\sqrt{2} & 1/\sqrt{6} \\ 1/\sqrt{3} & -1/\sqrt{2} & 1/\sqrt{6} \\ 1/\sqrt{3} & 0 & -2/\sqrt{6} \end{bmatrix}, \qquad \mathbf{\Lambda} = \operatorname{diag}(4,1,1).$$

Check via projectors. $\mathbf{q}_1\mathbf{q}_1^{\mathsf{T}} = \frac{1}{3}\mathbf{J}$ and, since the three projectors sum to $\mathbf{I}$, $\mathbf{q}_2\mathbf{q}_2^{\mathsf{T}} + \mathbf{q}_3\mathbf{q}_3^{\mathsf{T}} = \mathbf{I} - \frac{1}{3}\mathbf{J}$. So $\mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}} = 4 \cdot \frac{1}{3}\mathbf{J} + 1 \cdot (\mathbf{I} - \frac{1}{3}\mathbf{J}) = \mathbf{I} + \mathbf{J} = \mathbf{A}$ ✓. In a balanced three-phase system this same matrix structure gives the **zero-sequence** vector $(1,1,1)$ and a two-dimensional space of positive/negative-sequence vectors — the symmetrical-components decomposition is a spectral decomposition.

Rayleigh check. $\mathbf{x} = (1,1,0)$: $\mathbf{A}\mathbf{x} = (3,3,2)$, $R = 6/2 = 3$, which lies in $[\lambda_{\min}, \lambda_{\max}] = [1,4]$ ✓.

Worked Example 10.20 — Principal axes of a conic

Identify and sketch the curve $5x^2 + 4xy + 2y^2 = 6$.

Step 1 — matrix. $Q = \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}$ with $\mathbf{A} = \begin{bmatrix} 5 & 2 \\ 2 & 2 \end{bmatrix}$ (half of 4 off the diagonal).

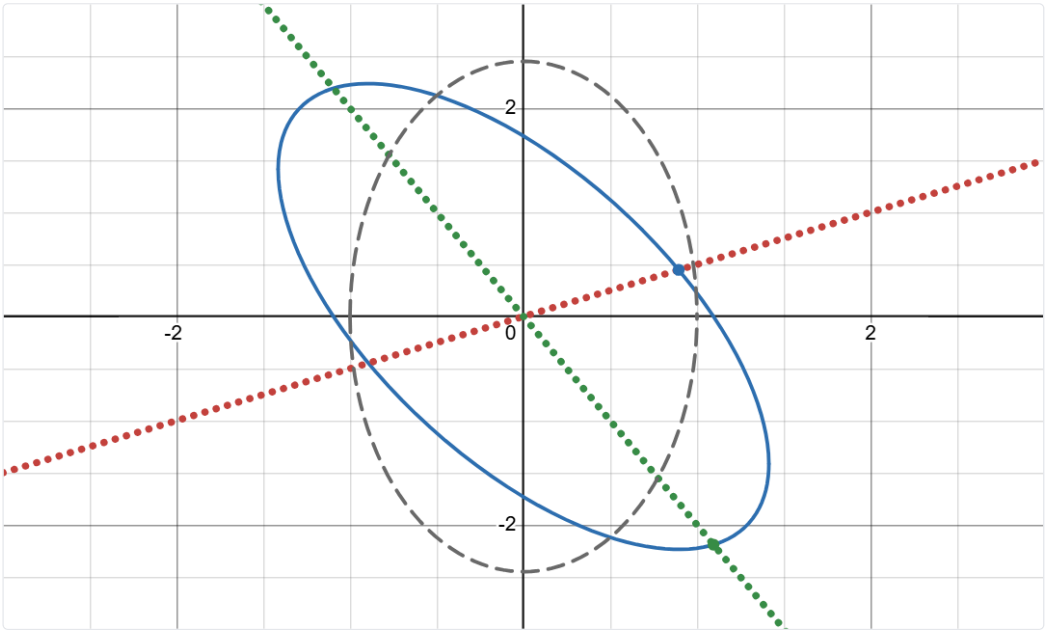
Step 2 — eigen-decomposition. $\lambda^2 - 7\lambda + 6 = 0$: $\lambda_1 = 6$, $\lambda_2 = 1$. $\lambda = 6$: $\mathbf{A} - 6\mathbf{I} = \begin{bmatrix} -1 & 2 \\ 2 & -4 \end{bmatrix}$, $\mathbf{q}_1 = \frac{1}{\sqrt{5}}(2,1)$. $\lambda = 1$: $\mathbf{q}_2 = \frac{1}{\sqrt{5}}(1,-2)$.

Step 3 — rotate. With $\mathbf{x} = u\mathbf{q}_1 + v\mathbf{q}_2$, the equation becomes $6u^2 + v^2 = 6$, i.e.

$$\frac{u^2}{1} + \frac{v^2}{6} = 1 :$$

an ellipse with semi-major axis $\sqrt{6} \approx 2.449$ along $\mathbf{q}_2$ (the direction of the **smaller** eigenvalue) and semi-minor axis 1 along $\mathbf{q}_1$.

Step 4 — check a vertex. $\sqrt{6}\,\mathbf{q}_2 = (1.0954, -2.1909)$: $5(1.2) + 4(1.0954)(-2.1909) + 2(4.8) = 6 - 9.6 + 9.6 = 6$ ✓. The tilt of the major axis is $\arctan(-2) = -63.43°$.



The conic $5x^2 + 4xy + 2y^2 = 6$ (blue) and its principal axes along the eigenvectors $\mathbf{q}_1 \propto (2,1)$ ($\lambda = 6$, red) and $\mathbf{q}_2 \propto (1,-2)$ ($\lambda = 1$, green). The dashed ellipse $6u^2 + v^2 = 6$ is the same curve drawn in principal-axis coordinates before rotation: the eigenvector change of variables simply rotates it into place.

Worked Example 10.21 — A Hermitian matrix

Find the eigenvalues and orthonormal eigenvectors of $\mathbf{H} = \begin{bmatrix} 2 & 1+j \\ 1-j & 3 \end{bmatrix}$.

Step 1 — eigenvalues. $\operatorname{tr}\mathbf{H} = 5$, $\det\mathbf{H} = 6 - (1+j)(1-j) = 6 - 2 = 4$. So $\lambda^2 - 5\lambda + 4 = 0$: $\lambda = 4, 1$ — real, as promised, even though $\mathbf{H}$ is complex.

Step 2 — eigenvectors. $\lambda = 4$: $\mathbf{H} - 4\mathbf{I} = \begin{bmatrix} -2 & 1+j \\ 1-j & -1 \end{bmatrix}$. From the first row, $\mathbf{v}_1 = (1+j,\ 2)$; check the second row: $(1-j)(1+j) - 2 = 0$ ✓. $\lambda = 1$: first row $v_1 + (1+j)v_2 = 0$, so $\mathbf{v}_2 = (1+j,\ -1)$.

Step 3 — orthogonality with the Hermitian inner product. $\mathbf{v}_1^{\mathsf{H}}\mathbf{v}_2 = (1-j)(1+j) + 2(-1) = 2 - 2 = 0$ ✓. Norms: $\|\mathbf{v}_1\|^2 = 2 + 4 = 6$, $\|\mathbf{v}_2\|^2 = 2 + 1 = 3$.

$$\mathbf{U} = \begin{bmatrix} (1+j)/\sqrt{6} & (1+j)/\sqrt{3} \\ 2/\sqrt{6} & -1/\sqrt{3} \end{bmatrix}, \qquad \mathbf{H} = \mathbf{U}\begin{bmatrix} 4 & 0 \\ 0 & 1 \end{bmatrix}\mathbf{U}^{\mathsf{H}}.$$

Check. $\mathbf{H}\mathbf{v}_1 = \big(2(1+j) + 2(1+j),\ (1-j)(1+j) + 6\big) = (4+4j,\ 8) = 4\mathbf{v}_1$ ✓. Hermitian matrices of this kind are the spatial covariance matrices of two-antenna receivers; the eigenvalue 4 is the power captured by the best beamformer $\mathbf{u}_1$, and 1 the power in the orthogonal direction.

Worked Example 10.22 — Rayleigh's quotient as an eigenvalue estimator

Estimate the largest eigenvalue of the tridiagonal $\mathbf{B}$ of Example 10.2 ($\lambda_{\max} = 2 + \sqrt{2} = 3.414214$) from trial vectors.

- $\mathbf{x} = (1, 1, 1)$: $\mathbf{B}\mathbf{x} = (3, 4, 3)$, $R = 10/3 = 3.3333$ — error 0.081.
- $\mathbf{x} = (1, 1.4, 1)$ (a better mode-shape guess, centre bulging): $\mathbf{B}\mathbf{x} = (3.4, 4.8, 3.4)$, $\mathbf{x}^{\mathsf{T}}\mathbf{B}\mathbf{x} = 3.4 + 6.72 + 3.4 = 13.52$, $\mathbf{x}^{\mathsf{T}}\mathbf{x} = 3.96$, $R = 3.414141$ — error 7×10^{-5}.

The exact eigenvector is $(1, \sqrt{2}, 1)$; the second trial vector has its middle entry about 1% too small, yet the eigenvalue is accurate to five significant figures. Both estimates are **below** $\lambda_{\max}$, as Rayleigh's principle guarantees. This quadratic accuracy is why a rough guess of a mode shape gives a good resonant frequency.

Common Pitfall — "symmetric" complex matrices

A complex matrix with $\mathbf{A}^{\mathsf{T}} = \mathbf{A}$ (without conjugation) is **complex symmetric**, not Hermitian, and none of the theorems of this section apply: $\begin{bmatrix} 1 & j \\ j & -1 \end{bmatrix}$ is complex symmetric with the double eigenvalue 0 and only one eigenvector — it is defective. Impedance and admittance matrices of *lossy* reciprocal networks are complex symmetric. Their eigenvalues are generally complex and the eigenvectors are orthogonal only in the unconjugated sense $\mathbf{v}_i^{\mathsf{T}}\mathbf{v}_k = 0$. Check which transpose the theorem needs before using it.

Engineering Note — principal component analysis of sensor data

Given N zero-mean measurement vectors $\mathbf{x}_k \in \mathbb{R}^n$ (for example, the outputs of n microphones), the sample covariance $\mathbf{C} = \frac{1}{N}\sum_k \mathbf{x}_k\mathbf{x}_k^{\mathsf{T}}$ is symmetric with non-negative eigenvalues. Its spectral decomposition sorts the signal space into orthogonal directions by power: λ_i is the average power along $\mathbf{q}_i$. Projecting onto the top few eigenvectors keeps most of the energy and discards mostly noise — principal component analysis, also known as the Karhunen–Loève transform. The statistics side is in Ch. 20 and Ch. 21; the mathematics is the spectral theorem.

10.6 Positive-definite matrices

Motivation

Energy is never negative. The energy stored in a set of coupled inductors, $W = \frac{1}{2}\mathbf{i}^{\mathsf{T}}\mathbf{L}\mathbf{i}$, is positive for every nonzero current vector; so is the electrostatic energy $\frac{1}{2}\mathbf{v}^{\mathsf{T}}\mathbf{C}\mathbf{v}$ of a system of conductors, and the power $\mathbf{v}^{\mathsf{T}}\mathbf{G}\mathbf{v}$ dissipated in a passive resistive network. The variance of any linear combination $\mathbf{w}^{\mathsf{T}}\mathbf{x}$ of random voltages is $\mathbf{w}^{\mathsf{T}}\mathbf{C}_{xx}\mathbf{w} \geq 0$. A smooth function has a strict local minimum where its gradient vanishes and its Hessian quadratic form is positive for every displacement (Ch. 6, Ch. 23). In all these cases a symmetric matrix $\mathbf{A}$ has the property $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$ — it is **positive definite**. Such matrices are the "positive numbers" of matrix algebra: they have square roots, they can be factored as $\mathbf{R}^{\mathsf{T}}\mathbf{R}$, linear systems with them can be solved stably without pivoting, and they define inner products and distances.

Definitions

Definiteness

A real symmetric (or complex Hermitian) $n \times n$ matrix $\mathbf{A}$ is

- **positive definite** (PD, $\mathbf{A} \succ 0$) if $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0$ for every $\mathbf{x} \neq \mathbf{0}$;
- **positive semidefinite** (PSD, $\mathbf{A} \succeq 0$) if $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} \geq 0$ for every $\mathbf{x}$;
- **negative definite / semidefinite** if $-\mathbf{A}$ is positive definite / semidefinite;
- **indefinite** if $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}$ takes both signs.

For complex Hermitian matrices replace $\mathbf{x}^{\mathsf{T}}$ by $\mathbf{x}^{\mathsf{H}}$; the form $\mathbf{x}^{\mathsf{H}}\mathbf{A}\mathbf{x}$ is then real.

Definiteness is normally defined only for symmetric matrices, because the quadratic form only sees the symmetric part $\frac{1}{2}(\mathbf{A} + \mathbf{A}^{\mathsf{T}})$.

Equivalent tests

Tests for positive definiteness

For a real symmetric $\mathbf{A}$, the following are equivalent:

1. $\mathbf{x}^\mathsf{T}\mathbf{A}\mathbf{x} > 0$ for all $\mathbf{x} \neq \mathbf{0}$;
2. **all eigenvalues of A are positive**;
3. **all leading principal minors are positive** (Sylvester's criterion): $\Delta_1 = a_{11} > 0$, $\Delta_2 = \det \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} > 0$, ..., $\Delta_n = \det \mathbf{A} > 0$;
4. **all pivots** of Gaussian elimination without row exchanges are positive;
5. $\mathbf{A} = \mathbf{R}^\mathsf{T}\mathbf{R}$ for some matrix $\mathbf{R}$ with independent columns — in particular, the **Cholesky factorization** $\mathbf{A} = \mathbf{L}\mathbf{L}^\mathsf{T}$ exists with $\mathbf{L}$ lower triangular with positive diagonal.

Proof sketch. (1)⇔(2): with $\mathbf{x} = \mathbf{Q}\mathbf{y}$, $\mathbf{x}^\mathsf{T}\mathbf{A}\mathbf{x} = \sum \lambda_i y_i^2$; this is positive for all $\mathbf{y} \neq \mathbf{0}$ exactly when every $\lambda_i > 0$ (take $\mathbf{y} = \mathbf{e}_i$ for necessity). (2)⇒(3): the upper-left $k \times k$ block $\mathbf{A}_k$ is itself PD (restrict (1) to vectors whose last $n-k$ entries are zero), so its eigenvalues are positive and $\Delta_k = \det \mathbf{A}_k$ — their product — is positive. (3)⇔(4): elimination without row exchanges gives pivots $d_k = \Delta_k / \Delta_{k-1}$ (with $\Delta_0 = 1$), because the determinant of each leading block is the product of its pivots. (4)⇒(5): elimination gives $\mathbf{A} = \mathbf{L}_1\mathbf{D}\mathbf{L}_1^\mathsf{T}$ with unit lower-triangular $\mathbf{L}_1$ and $\mathbf{D} = \operatorname{diag}(d_k)$; set $\mathbf{L} = \mathbf{L}_1\mathbf{D}^{1/2}$. (5)⇒(1): $\mathbf{x}^\mathsf{T}\mathbf{R}^\mathsf{T}\mathbf{R}\mathbf{x} = \|\mathbf{R}\mathbf{x}\|^2 \geq 0$, with equality only if $\mathbf{R}\mathbf{x} = \mathbf{0}$, i.e. $\mathbf{x} = \mathbf{0}$ because $\mathbf{R}$ has independent columns. □

For semidefiniteness the tests weaken to: all eigenvalues ≥ 0; $\mathbf{A} = \mathbf{R}^\mathsf{T}\mathbf{R}$ for *some* $\mathbf{R}$; or **all** principal minors (not just the leading ones) ≥ 0.

In practice: for a 2×2 matrix, check $a_{11} > 0$ and $\det \mathbf{A} > 0$. For 3×3 by hand, use leading minors or pivots. For large matrices, attempt a Cholesky factorization — it succeeds if and only if the matrix is PD, and it costs about half as much as an LU factorization.

Gram matrices and the energy form

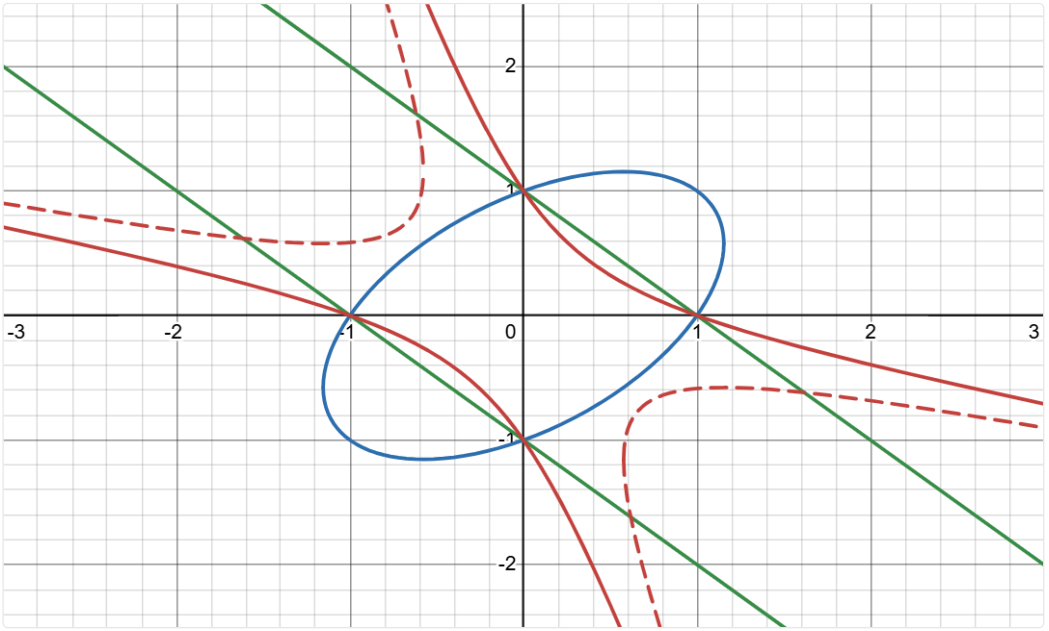
The test (5) has a very useful reading. For **any** $m \times n$ matrix $\mathbf{R}$, the **Gram matrix** $\mathbf{R}^\mathsf{T}\mathbf{R}$ is symmetric positive semidefinite, and it is positive definite iff the columns of $\mathbf{R}$ are linearly independent. The normal-equation matrix $\mathbf{A}^\mathsf{T}\mathbf{A}$ of least squares (Ch. 9), sample covariance matrices and the matrices $\mathbf{A}^\mathsf{T}\mathbf{A}$, $\mathbf{A}\mathbf{A}^\mathsf{T}$ of the SVD (Section 10.7) are all Gram matrices.

Physical matrices often arrive in exactly this form. The conductance matrix of a resistor network is $\mathbf{G} = \mathbf{B}^\mathsf{T} \operatorname{diag}(g_e)\mathbf{B}$, where $\mathbf{B}$ is the branch–node incidence matrix (each branch voltage is a difference of node voltages) and $g_e > 0$ are the branch conductances; the dissipated power $\mathbf{v}^\mathsf{T}\mathbf{G}\mathbf{v} = \sum_e g_e (\text{branch voltage})^2$ is a sum of squares. Grounding at least one node makes $\mathbf{B}$'s columns independent and $\mathbf{G}$ positive definite.

Geometry: level curves

The level sets $\mathbf{x}^\mathsf{T}\mathbf{A}\mathbf{x} = c$ show definiteness at a glance. In principal-axis coordinates they read $\sum \lambda_i y_i^2 = c$:

- **PD**: ellipses (ellipsoids) centred at the origin; Q is a bowl with a unique minimum.
- **PSD but singular**: a zero eigenvalue makes the ellipse degenerate into a pair of parallel lines (a cylinder in 3-D); Q is a trough, flat along the null-space direction.
- **Indefinite**: hyperbolas; Q is a saddle.



Level curves of three quadratic forms: positive definite $x^2 - xy + y^2 = 1$ (blue ellipse, eigenvalues 1.5 and 0.5); positive semidefinite $(x+y)^2 = 1$ (green parallel lines, eigenvalues 2 and 0); indefinite $x^2 + 4xy + y^2 = \pm 1$ (red hyperbolas, eigenvalues 3 and -1).

Square roots and the energy norm

A PSD matrix has a unique PSD **square root** $\mathbf{A}^{1/2} = \mathbf{Q}\mathbf{\Lambda}^{1/2}\mathbf{Q}^{\mathsf{T}}$, with $\mathbf{\Lambda}^{1/2} = \operatorname{diag}(\sqrt{\lambda_i})$; indeed $\mathbf{A}^{1/2}\mathbf{A}^{1/2} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}} = \mathbf{A}$. Both $\mathbf{A}^{1/2}$ and the Cholesky factor $\mathbf{L}^{\mathsf{T}}$ are "square roots" in the sense $\mathbf{A} = \mathbf{R}^{\mathsf{T}}\mathbf{R}$; they differ by an orthogonal factor. A PD matrix also defines an inner product $\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{A}} = \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y}$ and an **energy norm** $\|\mathbf{x}\|_{\mathbf{A}} = \sqrt{\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}}$; the Mahalanobis distance of statistics is the energy norm of the inverse covariance, and "whitening" noise means multiplying by $\mathbf{C}^{-1/2}$ or $\mathbf{L}^{-1}$ so that the noise covariance becomes $\mathbf{I}$.

Worked examples

Worked Example 10.23 — Three tests on one matrix

Show that $\mathbf{K} = \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{bmatrix}$ is positive definite, in three ways.

Leading minors. $\Delta_1 = 2$, $\Delta_2 = 4 - 1 = 3$, $\Delta_3 = 2(4-1) - (-1)(-2-0) = 6 - 2 = 4$. All positive $\Rightarrow$ PD.

Pivots. $d_k = \Delta_k / \Delta_{k-1}$: $2,\ 3/2,\ 4/3$ — all positive. (Elimination directly: $R_2 + \frac{1}{2}R_1$ gives pivot $2 - \frac{1}{2} = \frac{3}{2}$; $R_3 + \frac{2}{3}R_2$ gives $2 - \frac{2}{3} = \frac{4}{3}$ ✓.)

Eigenvalues. $\mathbf{K} = \mathbf{S}\mathbf{B}\mathbf{S}$ with $\mathbf{S} = \operatorname{diag}(1,-1,1) = \mathbf{S}^{-1}$ and $\mathbf{B}$ the matrix of Example 10.2, so $\mathbf{K}$ is similar to $\mathbf{B}$ and has eigenvalues $2 - \sqrt{2},\ 2,\ 2 + \sqrt{2}$, all positive. (Check: product $= 4 = \Delta_3$ ✓.)

Energy. Better than any test is to *see* the sum of squares:

$$\mathbf{x}^{\mathsf{T}}\mathbf{K}\mathbf{x} = 2x_1^2 + 2x_2^2 + 2x_3^2 - 2x_1x_2 - 2x_2x_3 = x_1^2 + (x_1 - x_2)^2 + (x_2 - x_3)^2 + x_3^2,$$

which vanishes only if $x_1 = 0$, $x_1 = x_2$, $x_2 = x_3$, $x_3 = 0$. This is the stiffness (or conductance) matrix of a chain of four identical springs (resistors) between two fixed walls (grounded ends): the four squares are the four element energies.

Worked Example 10.24 — Cholesky factorization

Factor $\mathbf{A} = \begin{bmatrix} 4 & 2 & -2 \\ 2 & 10 & 2 \\ -2 & 2 & 6 \end{bmatrix}$ as $\mathbf{L}\mathbf{L}^{\mathsf{T}}$.

Write $\mathbf{L} = \begin{bmatrix} l_{11} & 0 & 0 \\ l_{21} & l_{22} & 0 \\ l_{31} & l_{32} & l_{33} \end{bmatrix}$ and match entries of $\mathbf{L}\mathbf{L}^{\mathsf{T}}$ column by column:

- $l_{11}^2 = 4 \Rightarrow l_{11} = 2$; $l_{21}l_{11} = 2 \Rightarrow l_{21} = 1$; $l_{31}l_{11} = -2 \Rightarrow l_{31} = -1$.
- $l_{21}^2 + l_{22}^2 = 10 \Rightarrow l_{22} = \sqrt{9} = 3$; $l_{31}l_{21} + l_{32}l_{22} = 2 \Rightarrow l_{32} = (2+1)/3 = 1$.
- $l_{31}^2 + l_{32}^2 + l_{33}^2 = 6 \Rightarrow l_{33} = \sqrt{6 - 1 - 1} = 2$.

$$\mathbf{L} = \begin{bmatrix} 2 & 0 & 0 \\ 1 & 3 & 0 \\ -1 & 1 & 2 \end{bmatrix}.$$

Every square root had a positive argument, which certifies that $\mathbf{A}$ is PD. **By-products:** $\det \mathbf{A} = (2 \cdot 3 \cdot 2)^2 = 144$, and the pivots are $l_{kk}^2 = 4, 9, 4$. To solve $\mathbf{A}\mathbf{x} = \mathbf{b}$, solve $\mathbf{L}\mathbf{y} = \mathbf{b}$ forward and $\mathbf{L}^{\mathsf{T}}\mathbf{x} = \mathbf{y}$ backward. **Check:** row 3 of $\mathbf{L}$ dotted with itself, $1 + 1 + 4 = 6 = a_{33}$ ✓; with row 2, $-1 + 3 + 0 = 2 = a_{32}$ ✓.

Worked Example 10.25 — For which parameter values is a matrix PD?

For which real k is $\mathbf{A}(k) = \begin{bmatrix} 1 & k & 0 \\ k & 1 & k \\ 0 & k & 1 \end{bmatrix}$ positive definite?

Leading minors. $\Delta_1 = 1 > 0$; $\Delta_2 = 1 - k^2 > 0 \iff |k| < 1$; $\Delta_3 = 1(1-k^2) - k(k-0) = 1 - 2k^2 > 0 \iff |k| < 1/\sqrt{2}$. The binding condition is the last:

$$\mathbf{A}(k) \succ 0 \iff |k| < \tfrac{1}{\sqrt{2}} \approx 0.7071.$$

Eigenvalue check. Expanding $\det(\mathbf{A} - \lambda\mathbf{I}) = (1-\lambda)[(1-\lambda)^2 - 2k^2]$ gives $\lambda = 1,\ 1 \pm \sqrt{2}\,k$. The smallest, $1 - \sqrt{2}|k|$, is positive exactly when $|k| < 1/\sqrt{2}$ ✓. At $k = 1/\sqrt{2}$ the matrix is PSD and singular, with null vector $(1, -\sqrt{2}, 1)$.

Moral. Positivity of all entries, or diagonal entries larger than off-diagonal ones (here $1 > k$ for $k = 0.8$), does **not** imply definiteness; at $k = 0.8$, $\Delta_3 = -0.28 < 0$.

Worked Example 10.26 — Coupled inductors: the energy condition $k < 1$

Two coupled coils have inductance matrix $\mathbf{L} = \begin{bmatrix} L_1 & M \\ M & L_2 \end{bmatrix}$ and stored energy $W = \tfrac{1}{2}\mathbf{i}^{\mathsf{T}}\mathbf{L}\mathbf{i} = \tfrac{1}{2}(L_1 i_1^2 + 2M i_1 i_2 + L_2 i_2^2)$.

Condition. Passivity requires $W > 0$ for all nonzero currents: $\mathbf{L} \succ 0 \iff L_1 > 0$ and $L_1 L_2 - M^2 > 0$, i.e. the **coupling coefficient** $k = |M|/\sqrt{L_1 L_2} < 1$.

Numbers. $L_1 = 4$ mH, $L_2 = 9$ mH, $M = 5$ mH: $k = 5/6 = 0.833$, $\det \mathbf{L} = 36 - 25 = 11$ mH$^2 > 0$. Eigenvalues: $\lambda = \tfrac{1}{2}\left(13 \pm \sqrt{169 - 44}\right) = 12.09$ mH and 0.910 mH. For opposing currents $\mathbf{i} = (1, -1)$ A, $W = \tfrac{1}{2}(4 - 10 + 9) = 1.5$ mJ > 0, and indeed no current vector gives less than $\tfrac{1}{2}(0.910\text{ mH})\|\mathbf{i}\|^2$.

The limit $k = 1$. With $M = 6$ mH, $\det \mathbf{L} = 0$: PSD, not PD. The null vector $\mathbf{i} = (3, -2)$ A gives $W = \tfrac{1}{2}(4 \cdot 9 - 2 \cdot 6 \cdot 6 + 9 \cdot 4) = 0$: the two coils' fluxes cancel exactly. An ideal transformer is this singular limit; a value $k > 1$ in a simulator netlist describes a device that could deliver energy from nothing, and the simulation will typically blow up.

Common Pitfall — leading minors and semidefiniteness

Sylvester's criterion with $\geq$ instead of $>$ does **not** test semidefiniteness. $\begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}$ has leading minors 0 and 0, both ≥ 0, yet it is negative semidefinite. For PSD you must check *all* principal minors (here the 1×1 minor -1 fails) or the eigenvalues. Also, for **negative** definiteness the leading minors must *alternate* in sign, $\Delta_1 < 0,\ \Delta_2 > 0,\ \Delta_3 < 0, \ldots$ — not all be negative.

Engineering Note — positive definiteness as a modelling check

Numerically extracted parasitic matrices (field-solver $\mathbf{L}$, $\mathbf{C}$ and $\mathbf{G}$ for packages and interconnect), measured covariance matrices with missing samples, and estimated Hessians in optimisation all lose positive definiteness through rounding or estimation error. A non-PD inductance or capacitance matrix makes a passive model non-passive, and transient simulators then produce growing oscillations. Standard practice is to test with a Cholesky attempt and, if it fails, repair the matrix by clipping negative eigenvalues to a small positive floor: $\mathbf{A} \leftarrow \mathbf{Q}\max(\mathbf{\Lambda}, \epsilon\mathbf{I})\mathbf{Q}^{\mathsf{T}}$, the nearest PD matrix in the Frobenius norm.

10.7 Singular value decomposition

Motivation

Eigen-decomposition has three limitations: it applies only to square matrices; it may fail (defective matrices); and, for non-symmetric matrices, the eigenvectors are not orthogonal, so $\mathbf{P}$ can be badly conditioned. Many engineering matrices are not square — a 4×2 MIMO channel matrix from 2 transmit to 4 receive antennas, a 1000×3 regression matrix of measurements against model parameters, an $m \times n$ image. The **singular value decomposition** (SVD) repairs all three defects at once. Every matrix, of any shape, factors as

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}}$$

with **orthogonal** $\mathbf{U}$ and $\mathbf{V}$ and a non-negative diagonal $\mathbf{\Sigma}$. The price is that we use two different orthonormal bases — one for the input space and one for the output space — instead of one eigenbasis. The SVD is arguably the most useful single factorization in applied linear algebra: it gives the rank, the norm and the condition number of a matrix, the best low-rank approximation, the pseudoinverse and the least-squares solution, and the capacity-achieving decomposition of a MIMO channel into parallel independent sub-channels.

Statement

Singular value decomposition

Every real $m \times n$ matrix $\mathbf{A}$ of rank r can be factored as

$$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}},$$

where $\mathbf{U}$ ($m \times m$) and $\mathbf{V}$ ($n \times n$) are orthogonal and $\mathbf{\Sigma}$ ($m \times n$) is zero except for its leading diagonal entries

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0 = \sigma_{r+1} = \ldots .$$

The σ_i are the **singular values**, the columns $\mathbf{u}_i$ of $\mathbf{U}$ the **left singular vectors** and the columns $\mathbf{v}_i$ of $\mathbf{V}$ the **right singular vectors**. They satisfy

$$\mathbf{A}\mathbf{v}_i = \sigma_i \mathbf{u}_i, \qquad \mathbf{A}^{\mathsf{T}}\mathbf{u}_i = \sigma_i \mathbf{v}_i,$$

and σ_i^2 are the nonzero eigenvalues of both $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ and $\mathbf{A}\mathbf{A}^{\mathsf{T}}$. For complex $\mathbf{A}$, replace transposes by conjugate transposes and "orthogonal" by "unitary"; the σ_i are still real and non-negative.

The singular values are unique; the singular vectors are unique up to sign (or a phase factor, in the complex case) when the σ_i are distinct.

Derivation

The construction uses only the spectral theorem. The $n \times n$ matrix $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ is symmetric and positive semidefinite (a Gram matrix, Section 10.6), so it has orthonormal eigenvectors $\mathbf{v}_1, \ldots, \mathbf{v}_n$ with eigenvalues $\mu_1 \geq \cdots \geq \mu_n \geq 0$. Exactly $r = \operatorname{rank}\mathbf{A}$ of them are positive, because $\operatorname{null}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \operatorname{null}(\mathbf{A})$. Define

$$\sigma_i = \sqrt{\mu_i}, \qquad \mathbf{u}_i = \frac{\mathbf{A}\mathbf{v}_i}{\sigma_i} \quad (i = 1, \ldots, r).$$

These $\mathbf{u}_i$ are orthonormal:

$$\mathbf{u}_i^{\mathsf{T}}\mathbf{u}_k = \frac{\mathbf{v}_i^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{v}_k}{\sigma_i\sigma_k} = \frac{\mu_k\,\mathbf{v}_i^{\mathsf{T}}\mathbf{v}_k}{\sigma_i\sigma_k} = \begin{cases} 1 & i = k \\ 0 & i \neq k. \end{cases}$$

Extend $\mathbf{u}_1, \dots, \mathbf{u}_r$ to an orthonormal basis of $\mathbb{R}^m$ (Gram–Schmidt). Then $\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i$ for $i \le r$ and $\mathbf{A}\mathbf{v}_i = \mathbf{0}$ for $i > r$; in matrix form $\mathbf{A}\mathbf{V} = \mathbf{U}\boldsymbol{\Sigma}$, and multiplying on the right by $\mathbf{V}^{\mathsf{T}} = \mathbf{V}^{-1}$ gives the SVD. □

The derivation is also a hand-computation recipe: eigen-decompose the smaller of $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ and $\mathbf{A}\mathbf{A}^{\mathsf{T}}$, then get the other set of singular vectors from $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$ (or $\mathbf{v}_i = \mathbf{A}^{\mathsf{T}}\mathbf{u}_i/\sigma_i$). Do **not** compute $\mathbf{U}$ and $\mathbf{V}$ independently from the two Gram matrices: each eigenvector is only determined up to sign, and independently chosen signs may not match.

Geometry

Reading $\mathbf{A}\mathbf{x} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\mathsf{T}}\mathbf{x}$ right to left, **every linear map is a rotation (or reflection), followed by axis-aligned stretching, followed by another rotation**. In particular, $\mathbf{A}$ maps the unit sphere in $\mathbb{R}^n$ onto an ellipsoid (possibly flattened) in $\mathbb{R}^m$ whose semi-axes are $\sigma_i\mathbf{u}_i$; the right singular vectors $\mathbf{v}_i$ are the orthogonal input directions that map onto those axes. Compare the graph in Section 10.2: eigenvectors are directions that are not rotated; singular vectors are orthogonal directions that *stay* orthogonal.

The SVD and the four fundamental subspaces

The SVD supplies orthonormal bases for all four fundamental subspaces of Ch. 9 at once:

Subspace	Orthonormal basis	Dimension
column space $\mathcal{C}(\mathbf{A})$	$\mathbf{u}_1, \dots, \mathbf{u}_r$	r
left null space $\mathcal{N}(\mathbf{A}^{\mathsf{T}})$	$\mathbf{u}_{r+1}, \dots, \mathbf{u}_m$	$m - r$
row space $\mathcal{C}(\mathbf{A}^{\mathsf{T}})$	$\mathbf{v}_1, \dots, \mathbf{v}_r$	r
null space $\mathcal{N}(\mathbf{A})$	$\mathbf{v}_{r+1}, \dots, \mathbf{v}_n$	$n - r$

Keeping only the first r columns gives the **compact** (or "thin") SVD and the **outer-product expansion**

$$\mathbf{A} = \mathbf{U}_r\boldsymbol{\Sigma}_r\mathbf{V}_r^{\mathsf{T}} = \sigma_1\mathbf{u}_1\mathbf{v}_1^{\mathsf{T}} + \sigma_2\mathbf{u}_2\mathbf{v}_2^{\mathsf{T}} + \cdots + \sigma_r\mathbf{u}_r\mathbf{v}_r^{\mathsf{T}},$$

a sum of r rank-one matrices in decreasing order of importance.

Norms, condition number and rank

The SVD measures matrices. Because orthogonal matrices preserve lengths,

$$\|\mathbf{A}\|_2 = \max_{\mathbf{x}\neq\mathbf{0}} \frac{\|\mathbf{A}\mathbf{x}\|}{\|\mathbf{x}\|} = \sigma_1, \qquad \|\mathbf{A}\|_F = \sqrt{\sum_{i,k} a_{ik}^2} = \sqrt{\sigma_1^2 + \cdots + \sigma_r^2},$$

the spectral norm (maximum gain) and the Frobenius norm. For a square invertible matrix, $|\det\mathbf{A}| = \sigma_1\sigma_2\cdots\sigma_n$, $\|\mathbf{A}^{-1}\|_2 = 1/\sigma_n$, and the **condition number** introduced in Ch. 8 is

$$\kappa_2(\mathbf{A}) = \|\mathbf{A}\|_2\|\mathbf{A}^{-1}\|_2 = \frac{\sigma_{\max}}{\sigma_{\min}}.$$

It bounds error amplification in solving $\mathbf{A}\mathbf{x} = \mathbf{b}$: a relative perturbation ϵ in $\mathbf{b}$ can cause a relative change of up to $\kappa\epsilon$ in $\mathbf{x}$. Rule of thumb: you lose about $\log_{10}\kappa$ significant digits.

The **numerical rank** is the number of singular values above a tolerance (typically $\max(m,n)\,\sigma_1\,\epsilon_{\text{mach}}$). Unlike the exact rank, which jumps discontinuously under perturbation, the singular values move continuously: $|\sigma_i(\mathbf{A}+\mathbf{E}) - \sigma_i(\mathbf{A})| \le \|\mathbf{E}\|_2$. The smallest singular value is the **distance to the nearest singular matrix**: $\min\{\|\mathbf{E}\|_2 : \mathbf{A}+\mathbf{E} \text{ singular}\} = \sigma_n$.

Eckart–Young (best low-rank approximation)

For $k < r$, the truncated sum $\mathbf{A}_k = \sum_{i=1}^{k}\sigma_i\mathbf{u}_i\mathbf{v}_i^{\mathsf{T}}$ is the closest matrix of rank at most k to $\mathbf{A}$, in both the spectral and Frobenius norms:

$$\min_{\operatorname{rank}\mathbf{B}\le k}\|\mathbf{A}-\mathbf{B}\|_2 = \sigma_{k+1}, \qquad \min_{\operatorname{rank}\mathbf{B}\le k}\|\mathbf{A}-\mathbf{B}\|_F = \sqrt{\sigma_{k+1}^2 + \cdots + \sigma_r^2}.$$

This underlies image and data compression, noise reduction by truncating small singular values, and model-order reduction of large circuits (balanced truncation discards states associated with small *Hankel* singular values).

The pseudoinverse and least squares

Moore–Penrose pseudoinverse

If $\mathbf{A} = \mathbf{U}_r\boldsymbol{\Sigma}_r\mathbf{V}_r^{\mathsf{T}}$ (compact SVD), its **pseudoinverse** is

$$\mathbf{A}^{+} = \mathbf{V}_r\boldsymbol{\Sigma}_r^{-1}\mathbf{U}_r^{\mathsf{T}} = \sum_{i=1}^{r}\frac{1}{\sigma_i}\mathbf{v}_i\mathbf{u}_i^{\mathsf{T}}.$$

For any $\mathbf{b}$, $\mathbf{x}^+ = \mathbf{A}^+\mathbf{b}$ is the **minimum-norm least-squares solution**: among all $\mathbf{x}$ that minimise $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$, it is the one with smallest $\|\mathbf{x}\|$. *Why:* in the rotated coordinates $\mathbf{y} = \mathbf{V}^\mathsf{T}\mathbf{x}$, $\mathbf{c} = \mathbf{U}^\mathsf{T}\mathbf{b}$, the residual is $\|\boldsymbol{\Sigma}\mathbf{y} - \mathbf{c}\|^2 = \sum_{i \le r}(\sigma_i y_i - c_i)^2 + \sum_{i>r} c_i^2$. The first sum is zeroed by $y_i = c_i/\sigma_i$; the second cannot be changed; the remaining y_i ($i > r$) do not affect the residual and are set to zero to minimise the norm. Special cases: if $\mathbf{A}$ has independent columns, $\mathbf{A}^+ = (\mathbf{A}^\mathsf{T}\mathbf{A})^{-1}\mathbf{A}^\mathsf{T}$ (the normal-equation solution of Ch. 9); if it has independent rows, $\mathbf{A}^+ = \mathbf{A}^\mathsf{T}(\mathbf{A}\mathbf{A}^\mathsf{T})^{-1}$; if it is square and invertible, $\mathbf{A}^+ = \mathbf{A}^{-1}$.

The formula also exposes the danger of tiny singular values: noise in c_i is amplified by $1/\sigma_i$. **Truncated SVD** (drop terms with σ_i below a threshold) and **Tikhonov regularisation** (replace $1/\sigma_i$ by $\sigma_i/(\sigma_i^2 + \alpha^2)$) tame this amplification, at the cost of a small bias.

Singular values versus eigenvalues

For a symmetric matrix the SVD and the spectral decomposition coincide up to signs: $\sigma_i = |\lambda_i|$, and a negative λ_i is absorbed by flipping $\mathbf{u}_i = -\mathbf{q}_i$. For a symmetric PSD matrix they are identical. For non-symmetric matrices the two sets of numbers can be very different. For $\mathbf{A} = \begin{bmatrix} 4 & 1 \\ 2 & 3 \end{bmatrix}$ the eigenvalues are $5, 2$ but the singular values are $5.117, 1.954$ (square roots of the eigenvalues $15 \pm \sqrt{125}$ of $\mathbf{A}\mathbf{A}^\mathsf{T}$); their products agree ($|\det \mathbf{A}| = 10$) but nothing else need. Always $\sigma_{\min} \le |\lambda_i| \le \sigma_{\max}$. Eigenvalues govern what happens under *repeated* application of $\mathbf{A}$ (powers, dynamics); singular values govern what happens under a *single* application (gain, sensitivity, rank).

Worked examples

Worked Example 10.27 — SVD of a 2×2 matrix

Find the SVD of $\mathbf{A} = \begin{bmatrix} 3 & 0 \\ 4 & 5 \end{bmatrix}$.

Step 1 — $\mathbf{A}^\mathsf{T}\mathbf{A}$.

$$\mathbf{A}^\mathsf{T}\mathbf{A} = \begin{bmatrix} 3 & 4 \\ 0 & 5 \end{bmatrix}\begin{bmatrix} 3 & 0 \\ 4 & 5 \end{bmatrix} = \begin{bmatrix} 25 & 20 \\ 20 & 25 \end{bmatrix}.$$

Step 2 — its eigen-decomposition. Eigenvalues 25 ± 20: $\mu_1 = 45$, $\mu_2 = 5$, with $\mathbf{v}_1 = \frac{1}{\sqrt{2}}(1,1)$, $\mathbf{v}_2 = \frac{1}{\sqrt{2}}(-1,1)$. Singular values: $\sigma_1 = \sqrt{45} = 3\sqrt{5} \approx 6.708$, $\sigma_2 = \sqrt{5} \approx 2.236$.

Step 3 — left singular vectors from $\mathbf{u}_i = \mathbf{A}\mathbf{v}_i/\sigma_i$.

$$\mathbf{u}_1 = \frac{1}{3\sqrt{5}} \cdot \frac{1}{\sqrt{2}}\begin{bmatrix} 3 \\ 9 \end{bmatrix} = \frac{1}{\sqrt{10}}\begin{bmatrix} 1 \\ 3 \end{bmatrix}, \qquad \mathbf{u}_2 = \frac{1}{\sqrt{5}} \cdot \frac{1}{\sqrt{2}}\begin{bmatrix} -3 \\ 1 \end{bmatrix} = \frac{1}{\sqrt{10}}\begin{bmatrix} -3 \\ 1 \end{bmatrix}.$$

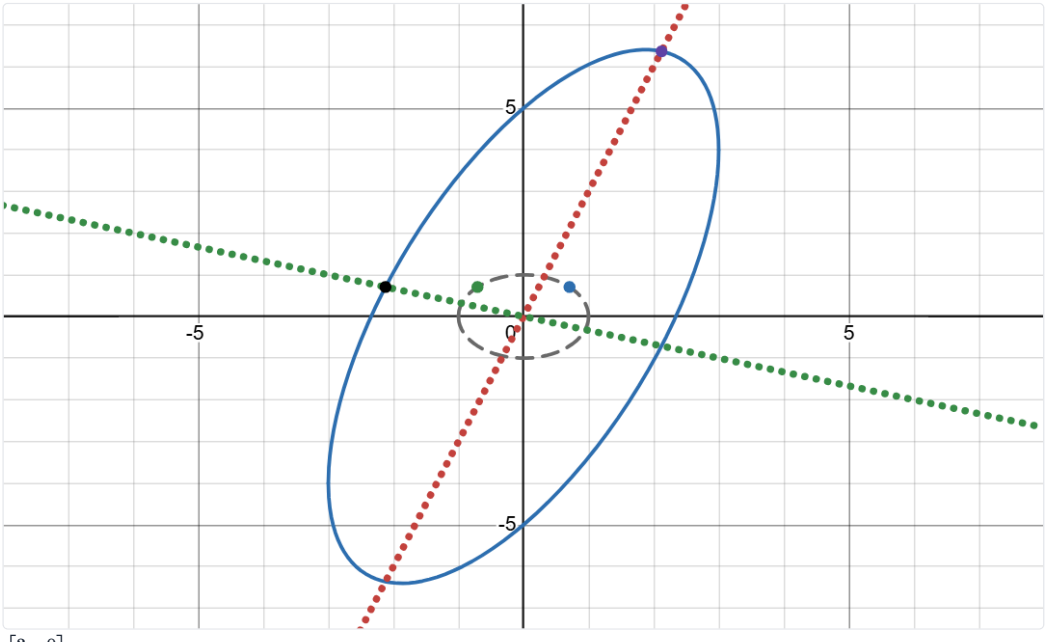
They are orthonormal: $\mathbf{u}_1 \cdot \mathbf{u}_2 = (-3+3)/10 = 0$ ✓.

Step 4 — assemble and verify by outer products.

$$\sigma_1\mathbf{u}_1\mathbf{v}_1^\mathsf{T} + \sigma_2\mathbf{u}_2\mathbf{v}_2^\mathsf{T} = \frac{3\sqrt{5}}{\sqrt{20}}\begin{bmatrix} 1 & 1 \\ 3 & 3 \end{bmatrix} + \frac{\sqrt{5}}{\sqrt{20}}\begin{bmatrix} 3 & -3 \\ -1 & 1 \end{bmatrix} = \begin{bmatrix} 1.5 & 1.5 \\ 4.5 & 4.5 \end{bmatrix} + \begin{bmatrix} 1.5 & -1.5 \\ -0.5 & 0.5 \end{bmatrix} = \begin{bmatrix} 3 & 0 \\ 4 & 5 \end{bmatrix} \checkmark$$

Derived quantities. $\|\mathbf{A}\|_2 = 6.708$; $\|\mathbf{A}\|_F = \sqrt{45 + 5} = \sqrt{50}$ (directly: $\sqrt{9 + 16 + 25}$ ✓); $|\det \mathbf{A}| = 15 = \sigma_1\sigma_2$ ✓; $\kappa_2 = 3$. Note that the eigenvalues of $\mathbf{A}$ are 3 and 5 (triangular), different from the singular values.

Best rank-1 approximation. $\mathbf{A}_1 = \begin{bmatrix} 1.5 & 1.5 \\ 4.5 & 4.5 \end{bmatrix}$, with $\|\mathbf{A} - \mathbf{A}_1\|_2 = \sigma_2 = \sqrt{5}$: no rank-1 matrix is closer.



The matrix $\mathbf{A} = \begin{bmatrix} 3 & 0 \\ 4 & 5 \end{bmatrix}$ maps the unit circle (dashed) onto the blue ellipse $41x^2 - 24xy + 9y^2 = 225$. The orthogonal input directions $\mathbf{v}_1, \mathbf{v}_2$ land on the ellipse's semi-axes $\sigma_1\mathbf{u}_1$ (length 6.708, red line) and $\sigma_2\mathbf{u}_2$ (length 2.236, green line), which are again orthogonal.

Worked Example 10.28 — SVD of a rectangular matrix

Find the SVD of $\mathbf{A} = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix}$ (2×3).

Step 1 — use the smaller Gram matrix. $\mathbf{A}\mathbf{A}^{\mathsf{T}} = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$, eigenvalues 3 and 1, eigenvectors $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1,1)$, $\mathbf{u}_2 = \frac{1}{\sqrt{2}}(1,-1)$. So $\sigma_1 = \sqrt{3}$, $\sigma_2 = 1$, rank 2.

Step 2 — right singular vectors from $\mathbf{v}_i = \mathbf{A}^{\mathsf{T}}\mathbf{u}_i/\sigma_i$.

$$\mathbf{v}_1 = \frac{1}{\sqrt{3}} \cdot \frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ 2 \\ 1 \end{bmatrix} = \frac{1}{\sqrt{6}} \begin{bmatrix} 1 \\ 2 \\ 1 \end{bmatrix}, \qquad \mathbf{v}_2 = \frac{1}{1} \cdot \frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix}.$$

Step 3 — complete $\mathbf{V}$. The third right singular vector spans $\mathcal{N}(\mathbf{A})$: $x_1 + x_2 = 0$, $x_2 + x_3 = 0$ gives $\mathbf{v}_3 = \frac{1}{\sqrt{3}}(1,-1,1)$. Check orthogonality: $\mathbf{v}_1 \cdot \mathbf{v}_3 \propto 1 - 2 + 1 = 0$, $\mathbf{v}_2 \cdot \mathbf{v}_3 \propto 1 - 1 = 0$ ✓.

Step 4 — assemble.

$$\mathbf{A} = \underbrace{\frac{1}{\sqrt{2}}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}}_{\mathbf{U}} \underbrace{\begin{bmatrix} \sqrt{3} & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}}_{\mathbf{\Sigma}} \underbrace{\begin{bmatrix} 1/\sqrt{6} & 2/\sqrt{6} & 1/\sqrt{6} \\ 1/\sqrt{2} & 0 & -1/\sqrt{2} \\ 1/\sqrt{3} & -1/\sqrt{3} & 1/\sqrt{3} \end{bmatrix}}_{\mathbf{V}^{\mathsf{T}}}.$$

Check an entry: $(\mathbf{A})_{12} = \sigma_1 u_{11} v_{21} + \sigma_2 u_{12} v_{22} = \sqrt{3} \cdot \frac{1}{\sqrt{2}} \cdot \frac{2}{\sqrt{6}} + 1 \cdot \frac{1}{\sqrt{2}} \cdot 0 = \frac{2\sqrt{3}}{\sqrt{12}} = 1$ ✓.

Minimum-norm solution of $\mathbf{A}\mathbf{x} = (1,2)$. Independent rows, so $\mathbf{A}^{+} = \mathbf{A}^{\mathsf{T}}(\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1}$ with $(\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1} = \frac{1}{3}\begin{bmatrix} 2 & -1 \\ -1 & 2 \end{bmatrix}$:

$$(\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1}\begin{bmatrix} 1 \\ 2 \end{bmatrix} = \frac{1}{3}\begin{bmatrix} 0 \\ 3 \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \qquad \mathbf{x}^{+} = \mathbf{A}^{\mathsf{T}}\begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix}.$$

$\mathbf{A}\mathbf{x}^{+} = (1,2)$ ✓. Every other solution is $\mathbf{x}^{+} + t\mathbf{v}_3$ with $\|\mathbf{x}\|^2 = 2 + t^2 \cdot 1$ (since $\mathbf{x}^{+} \perp \mathbf{v}_3$), so $\mathbf{x}^{+}$ with norm $\sqrt{2}$ is the shortest. In an under-determined estimation problem (more unknowns than measurements), this is the "least-energy" estimate.

Worked Example 10.29 — Condition number and sensitivity

Solve $\mathbf{A}\mathbf{x} = \mathbf{b}$ with $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.0001 \end{bmatrix}$ for $\mathbf{b} = (2,\ 2.0001)$ and for the slightly perturbed $\mathbf{b}' = (2,\ 2.0002)$.

Solutions. Subtracting the equations: $0.0001 x_2 = b_2 - b_1$. For $\mathbf{b}$: $x_2 = 1$, $x_1 = 1$. For $\mathbf{b}'$: $x_2 = 2$, $x_1 = 0$.

Sizes. $\|\delta\mathbf{b}\|/\|\mathbf{b}\| = 10^{-4}/2.83 = 3.5 \times 10^{-5}$, while $\|\delta\mathbf{x}\|/\|\mathbf{x}\| = \sqrt{2}/\sqrt{2} = 1$: an amplification of about 28 000.

Explanation by SVD. $\mathbf{A}$ is symmetric with eigenvalues $\lambda = \frac{1}{2}\big(2.0001 \pm \sqrt{2.0001^2 - 4 \times 0.0001}\big)$, i.e. $\sigma_1 = 2.00005$, $\sigma_2 = 0.00005$, so $\kappa_2 = 40\,002$. The observed amplification (28 000) is below the bound κ, as it must be. The perturbation $\delta\mathbf{b} = (0, 10^{-4})$ has a large component along the weak direction $\mathbf{u}_2 \approx \frac{1}{\sqrt{2}}(1,-1)$, which $\mathbf{A}^{-1}$ amplifies by $1/\sigma_2 = 20\,000$. Two sensors measuring almost the same combination of two unknowns produce exactly this situation (compare the near-dependence note in Ch. 9).

Worked Example 10.30 — MIMO channel as parallel sub-channels

A 2×2 narrowband MIMO link has $\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n}$, and suppose $\mathbf{H} = \begin{bmatrix} 3 & 0 \\ 4 & 5 \end{bmatrix}$ (in a real channel the entries are complex gains; the same steps apply with H in place of T). With $\mathbf{H} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}}$ from Example 10.27, let the transmitter send $\mathbf{s} = \mathbf{V}\tilde{\mathbf{s}}$ (precoding) and the receiver compute $\tilde{\mathbf{y}} = \mathbf{U}^{\mathsf{T}}\mathbf{y}$:

$$\tilde{\mathbf{y}} = \mathbf{U}^{\mathsf{T}}\mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}}\mathbf{V}\tilde{\mathbf{s}} + \mathbf{U}^{\mathsf{T}}\mathbf{n} = \mathbf{\Sigma}\tilde{\mathbf{s}} + \tilde{\mathbf{n}}, \qquad \text{i.e.} \qquad \tilde{y}_1 = 6.708\,\tilde{s}_1 + \tilde{n}_1, \quad \tilde{y}_2 = 2.236\,\tilde{s}_2 + \tilde{n}_2.$$

Because $\mathbf{U}$ is orthogonal, $\tilde{\mathbf{n}}$ has the same white statistics as $\mathbf{n}$. The coupled 2×2 channel has become **two independent scalar channels** with power gains $\sigma_1^2 = 45$ and $\sigma_2^2 = 5$ (16.5 dB and 7.0 dB). Allocating transmit power across them ("water-filling") is then a one-variable problem per sub-channel. The number of nonzero singular values is the number of spatial streams the channel can carry; a rank-deficient (keyhole) channel has only one.

Common Pitfall — confusing singular values with eigenvalues, and sign mismatches

Singular values are always real and non-negative; eigenvalues need not be either. "The matrix is nearly singular because an eigenvalue is small" is correct, but "the matrix is well conditioned because its eigenvalues are similar in size" is **not** — $\begin{bmatrix} 1 & 1000 \\ 0 & 1 \end{bmatrix}$ has both eigenvalues equal to 1 but $\kappa_2 \approx 10^6$. And when computing an SVD by hand, find one set of singular vectors from a Gram matrix and derive the other from $\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i$; computing both sets independently risks inconsistent signs and a factorization that does not reproduce $\mathbf{A}$.

Engineering Note — the SVD in practice

SVD algorithms (Golub–Kahan bidiagonalization followed by an implicit QR iteration) never form $\mathbf{A}^{\mathsf{T}}\mathbf{A}$, which would square the condition number and lose half the significant digits. Typical engineering uses: computing rank and null spaces robustly (e.g. finding the number of independent loops or the controllable subspace of a large model); least-squares fitting when the normal equations are ill-conditioned; direction-of-arrival estimation (MUSIC and ESPRIT split the SVD of the array data matrix into signal and noise subspaces); principal component analysis; and reduced-order modelling of interconnect and power-delivery networks.

10.8 Modal analysis

Motivation

Couple two identical pendulums with a weak spring, start one swinging and leave the other at rest: the motion slowly transfers to the second pendulum and back again. Couple two identical LC resonators and the single resonance peak splits into two. Excite one conductor of a multi-conductor transmission line and signals appear on its neighbours with two different propagation speeds. Each of these puzzling behaviours becomes simple once the system is viewed in its **normal modes** — the eigenvectors of the system matrices. In a normal mode every part of the system moves at the same frequency with fixed relative amplitudes, as if the system were a single oscillator. Any motion is a superposition of modes, each evolving independently. **Modal analysis** is the systematic use of this fact: find the modes (an eigenvalue problem), project the initial conditions and forcing onto them, solve n scalar problems, and superpose.

Undamped second-order systems: the generalized eigenproblem

Lossless mechanical structures and lossless LC networks obey equations of the form

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0},$$

where $\mathbf{M}$ is symmetric positive definite (mass, or a capacitance matrix) and $\mathbf{K}$ is symmetric positive semidefinite (stiffness, or a reciprocal-inductance matrix $\mathbf{\Gamma} = \mathbf{L}^{-1}$). Both symmetries come from energy: kinetic energy $\tfrac{1}{2}\dot{\mathbf{x}}^{\mathsf{T}}\mathbf{M}\dot{\mathbf{x}}$ and potential energy $\tfrac{1}{2}\mathbf{x}^{\mathsf{T}}\mathbf{K}\mathbf{x}$.

Seek synchronous solutions $\mathbf{x}(t) = \boldsymbol{\phi}\cos(\omega t + \theta)$, in which all coordinates oscillate in phase with a fixed shape $\boldsymbol{\phi}$. Substituting, $(-\omega^2\mathbf{M}\boldsymbol{\phi} + \mathbf{K}\boldsymbol{\phi})\cos(\omega t + \theta) = \mathbf{0}$ for all t, so

$$\mathbf{K}\boldsymbol{\phi} = \omega^2\mathbf{M}\boldsymbol{\phi}, \qquad \text{with} \qquad \det(\mathbf{K} - \omega^2\mathbf{M}) = 0.$$

This is a **generalized eigenvalue problem** with eigenvalue ω^2; the determinant condition is the **frequency equation**. Multiplying by $\mathbf{M}^{-1}$ turns it into the standard problem $\mathbf{M}^{-1}\mathbf{K}\boldsymbol{\phi} = \omega^2\boldsymbol{\phi}$, but $\mathbf{M}^{-1}\mathbf{K}$ is generally not symmetric, so it is better to keep the symmetric pair.

Normal modes of a conservative system

Let $\mathbf{M} \succ 0$ and $\mathbf{K} = \mathbf{K}^{\mathsf{T}} \succeq 0$ be $n \times n$. Then the generalized problem $\mathbf{K}\boldsymbol{\phi} = \omega^2\mathbf{M}\boldsymbol{\phi}$ has n real non-negative eigenvalues $\omega_1^2 \le \cdots \le \omega_n^2$ and real eigenvectors (mode shapes) that can be chosen **$\mathbf{M}$-orthonormal**:

$$\boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{M}\boldsymbol{\phi}_k = \delta_{ik}, \qquad \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{K}\boldsymbol{\phi}_k = \omega_i^2\,\delta_{ik}.$$

With the modal matrix $\mathbf{\Phi} = [\boldsymbol{\phi}_1 \ \cdots \ \boldsymbol{\phi}_n]$: $\mathbf{\Phi}^{\mathsf{T}}\mathbf{M}\mathbf{\Phi} = \mathbf{I}$ and $\mathbf{\Phi}^{\mathsf{T}}\mathbf{K}\mathbf{\Phi} = \mathbf{\Omega}^2 = \operatorname{diag}(\omega_i^2)$.

Proof sketch. Factor $\mathbf{M} = \mathbf{L}\mathbf{L}^{\mathsf{T}}$ (Cholesky) and put $\boldsymbol{\psi} = \mathbf{L}^{\mathsf{T}}\boldsymbol{\phi}$. Then $\mathbf{K}\boldsymbol{\phi} = \omega^2\mathbf{M}\boldsymbol{\phi}$ becomes $\tilde{\mathbf{K}}\boldsymbol{\psi} = \omega^2\boldsymbol{\psi}$ with $\tilde{\mathbf{K}} = \mathbf{L}^{-1}\mathbf{K}\mathbf{L}^{-\mathsf{T}}$, which is symmetric PSD. The spectral theorem (Section 10.5) gives real $\omega_i^2 \ge 0$ and orthonormal $\boldsymbol{\psi}_i$; transforming back, $\boldsymbol{\psi}_i^{\mathsf{T}}\boldsymbol{\psi}_k = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{L}\mathbf{L}^{\mathsf{T}}\boldsymbol{\phi}_k = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{M}\boldsymbol{\phi}_k$. $\square$

$\mathbf{M}$-orthogonality is orthogonality in the kinetic-energy inner product (Section 10.6): modes do not share energy. A zero eigenvalue $\omega^2 = 0$ is a **rigid-body mode** (or, in a circuit, a DC loop current or floating node voltage that the network does not restore).

Modal coordinates and the general solution

Substitute $\mathbf{x} = \mathbf{\Phi}\mathbf{q}$ into $\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}(t)$ (now with a forcing term) and multiply on the left by $\mathbf{\Phi}^{\mathsf{T}}$:

$$\underbrace{\mathbf{\Phi}^{\mathsf{T}}\mathbf{M}\mathbf{\Phi}}_{\mathbf{I}}\ddot{\mathbf{q}} + \underbrace{\mathbf{\Phi}^{\mathsf{T}}\mathbf{K}\mathbf{\Phi}}_{\mathbf{\Omega}^2}\mathbf{q} = \mathbf{\Phi}^{\mathsf{T}}\mathbf{f}(t) \quad \Longleftrightarrow \quad \ddot{q}_i + \omega_i^2 q_i = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{f}(t), \quad i = 1, \dots, n.$$

The **modal coordinates** q_i obey uncoupled single-degree-of-freedom equations. For free vibration,

$$\mathbf{x}(t) = \sum_{i=1}^{n} \boldsymbol{\phi}_i\big(a_i\cos\omega_i t + b_i\sin\omega_i t\big), \qquad a_i = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{M}\mathbf{x}(0), \quad b_i = \frac{\boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{M}\dot{\mathbf{x}}(0)}{\omega_i},$$

where the formulas for a_i, b_i use $\mathbf{M}$-orthonormality to invert $\mathbf{x}(0) = \mathbf{\Phi}\mathbf{a}$ without solving a linear system: $\mathbf{a} = \mathbf{\Phi}^{-1}\mathbf{x}(0) = \mathbf{\Phi}^{\mathsf{T}}\mathbf{M}\mathbf{x}(0)$.

The forced equations reveal two key facts. **Resonance**: a sinusoidal force at frequency ω drives mode i with amplitude proportional to $\boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{f}/(\omega_i^2 - \omega^2)$, which blows up (in the undamped model) as $\omega \to \omega_i$. **Selective excitation**: if $\boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{f} = 0$ — for instance a symmetric force on a symmetric structure and an antisymmetric mode — that mode is not excited at all, regardless of frequency. Likewise a sensor placed at a node of a mode shape (where $\phi_{ik} = 0$) cannot see that mode.

Damping

With a damping matrix, $\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}$, the transformation $\mathbf{\Phi}^{\mathsf{T}}\mathbf{C}\mathbf{\Phi}$ is in general not diagonal and the modes couple. Two cases are standard:

- **Proportional (Rayleigh) damping**, $\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K}$: then $\mathbf{\Phi}^{\mathsf{T}}\mathbf{C}\mathbf{\Phi} = \alpha\mathbf{I} + \beta\mathbf{\Omega}^2$ is diagonal, and each mode obeys $\ddot{q}_i + 2\zeta_i\omega_i\dot{q}_i + \omega_i^2 q_i = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{f}$ with modal damping ratio $\zeta_i = \frac{\alpha}{2\omega_i} + \frac{\beta\omega_i}{2}$. The same mode shapes survive; each decays at its own rate.

- **General damping**: convert to first-order state form with $\mathbf{z} = (\mathbf{x}, \dot{\mathbf{x}})$, $\dot{\mathbf{z}} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \mathbf{z}$, and apply the first-order modal analysis below. The eigenvalues come in pairs $-\zeta_i\omega_i \pm j\omega_i\sqrt{1-\zeta_i^2}$, and the mode shapes become complex (different parts of the structure have different phases).

First-order systems: modal decomposition with left and right eigenvectors

For $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ with diagonalizable $\mathbf{A} = \mathbf{P}\mathbf{\Lambda}\mathbf{P}^{-1}$, let $\mathbf{v}_i$ be the columns of $\mathbf{P}$ (right eigenvectors) and $\mathbf{w}_i^{\mathsf{T}}$ the rows of $\mathbf{W} = \mathbf{P}^{-1}$ (left eigenvectors, normalised so that $\mathbf{w}_i^{\mathsf{T}}\mathbf{v}_k = \delta_{ik}$). Then the zero-input response is

$$\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}(0) = \sum_{i=1}^{n} \mathbf{v}_i \left(\mathbf{w}_i^{\mathsf{T}}\mathbf{x}(0)\right) e^{\lambda_i t}.$$

Each term has a clear reading: $\mathbf{w}_i^{\mathsf{T}}\mathbf{x}(0)$ is **how much the initial state excites** mode i, $e^{\lambda_i t}$ is **how the mode evolves**, and $\mathbf{v}_i$ is **how the mode appears** in the state variables. With input and output $\mathbf{y} = \mathbf{C}\mathbf{x}$, mode i contributes $\dfrac{(\mathbf{C}\mathbf{v}_i)(\mathbf{w}_i^{\mathsf{T}}\mathbf{B})}{s - \lambda_i}$ to the transfer matrix — the partial-fraction expansion of $\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$ (Ch. 14), with residues formed from eigenvectors. If $\mathbf{w}_i^{\mathsf{T}}\mathbf{B} = \mathbf{0}$ the mode is **uncontrollable** from the input; if $\mathbf{C}\mathbf{v}_i = \mathbf{0}$ it is **unobservable** at the output; either way it cancels from the transfer function. In power-system small-signal stability, the products $p_{ki} = v_{ki}w_{ik}$ are the **participation factors** that tell which generator state participates in which electromechanical oscillation mode.

Worked examples

Worked Example 10.31 — Two masses, three springs

Two equal masses $m = 1$ kg are connected wall–spring–mass–spring–mass–spring–wall, all springs $k = 100$ N/m. Find the natural frequencies and mode shapes.

Step 1 — equations. Mass 1 feels $-kx_1$ from the left spring and $-k(x_1 - x_2)$ from the middle one; similarly for mass 2:

$$m\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0}, \qquad \mathbf{K} = k\begin{bmatrix} 2 & -1 \\ -1 & 2 \end{bmatrix}.$$

Step 2 — frequency equation. With $\mathbf{M} = m\mathbf{I}$, $\det(\mathbf{K} - \omega^2 m\mathbf{I}) = 0$ gives $(2k - m\omega^2)^2 = k^2$, so $2k - m\omega^2 = \pm k$:

$$\omega_1^2 = \frac{k}{m}, \qquad \omega_2^2 = \frac{3k}{m}.$$

Numerically $\omega_1 = 10$ rad/s (1.59 Hz) and $\omega_2 = 17.32$ rad/s (2.76 Hz).

Step 3 — mode shapes. ω_1: $(\mathbf{K} - k\mathbf{I})\boldsymbol{\phi} = k\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}\boldsymbol{\phi} = \mathbf{0}$, $\boldsymbol{\phi}_1 \propto (1, 1)$: **in phase** — the middle spring is never stretched, so each mass sees only one spring, $\omega^2 = k/m$. ω_2: $\boldsymbol{\phi}_2 \propto (1, -1)$: **antiphase** — the middle spring's midpoint is stationary, so each mass sees k plus a half-length spring of stiffness $2k$, $\omega^2 = 3k/m$.

Step 4 — M-normalise. $\boldsymbol{\phi}_i^{\mathsf{T}} m \boldsymbol{\phi}_i = 1$ gives $\boldsymbol{\phi}_1 = \frac{1}{\sqrt{2m}}(1, 1)$, $\boldsymbol{\phi}_2 = \frac{1}{\sqrt{2m}}(1, -1)$. **Check:** $\boldsymbol{\phi}_2^{\mathsf{T}}\mathbf{K}\boldsymbol{\phi}_2 = \frac{k}{2m}(2 + 2 + 2) = 3k/m = \omega_2^2$ ✓. The physical reasoning in Step 3 — recognising which springs carry force in each mode — is a valuable check on any computed mode.

Worked Example 10.32 — Two capacitively coupled LC resonators

Two identical parallel tanks ($L = 10$ μH, $C = 1$ nF) have their top nodes joined by a coupling capacitor $C_c = 0.1$ nF. Find the resonant frequencies and the mode shapes.

Step 1 — node equations. KCL at node 1: $C\dot{v}_1 + C_c(\dot{v}_1 - \dot{v}_2) + i_{L1} = 0$ with $\dot{i}_{L1} = v_1/L$. Differentiating once to eliminate i_{L1}, and similarly at node 2:

$$\mathbf{C}_n\ddot{\mathbf{v}} + \frac{1}{L}\mathbf{v} = \mathbf{0}, \qquad \mathbf{C}_n = \begin{bmatrix} C + C_c & -C_c \\ -C_c & C + C_c \end{bmatrix}.$$

This is $\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0}$ with the **capacitance matrix as mass** and the **reciprocal inductance as stiffness**.

Step 2 — modes by symmetry. Both matrices commute with the swap of nodes 1 and 2, so the even and odd vectors are eigenvectors of both (Section 10.3):

- **Even mode** $(1, 1)$: $\mathbf{C}_n(1, 1) = C(1, 1)$; no current in C_c. $\omega_e^2 = \dfrac{1}{LC}$.
- **Odd mode** $(1, -1)$: $\mathbf{C}_n(1, -1) = (C + 2C_c)(1, -1)$; the midpoint of C_c is a virtual ground, so each tank sees an extra $2C_c$. $\omega_o^2 = \dfrac{1}{L(C + 2C_c)}$.

Step 3 — numbers. $f_e = \dfrac{1}{2\pi\sqrt{10^{-5} \cdot 10^{-9}}} = 1.5915$ MHz; $f_o = \dfrac{1}{2\pi\sqrt{10^{-5} \cdot 1.2 \times 10^{-9}}} = 1.4529$ MHz. The single resonance of an isolated tank (1.5915 MHz) has **split** into two, separated by 139 kHz.

Step 4 — coupling coefficient. The standard filter-design measure is $k = \dfrac{f_e^2 - f_o^2}{f_e^2 + f_o^2} = \dfrac{1 - 1/1.2}{1 + 1/1.2} = 0.0909 = \dfrac{C_c}{C + C_c}$ ✓. Coupled-resonator bandpass filters are designed by choosing these mode splittings; the even/odd decomposition is exactly the eigen-decomposition of the symmetric pair $(\mathbf{K}, \mathbf{M})$.

Worked Example 10.33 — Beating and energy exchange between weakly coupled oscillators

Two unit masses on springs $k = 1$ N/m, coupled by a weak spring $k_c = 0.105$ N/m, have $\mathbf{K} = \begin{bmatrix} 1+k_c & -k_c \\ -k_c & 1+k_c \end{bmatrix}$. Mass 1 is displaced by 1 m and released; mass 2 starts at rest. Find $\mathbf{x}(t)$.

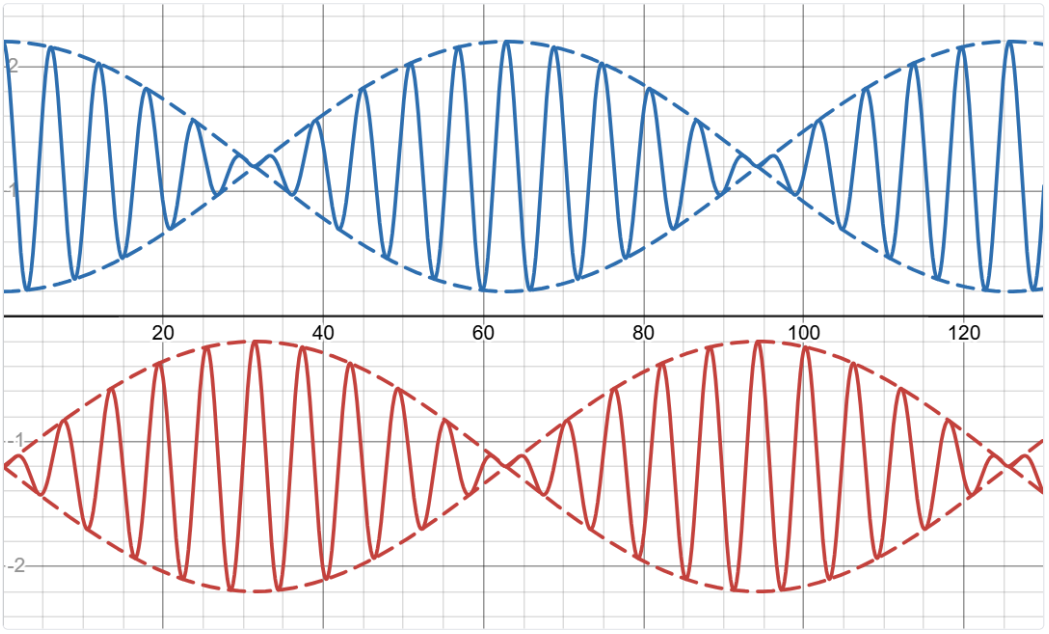
Step 1 — modes. As in Example 10.31: in-phase $(1,1)$ with $\omega_1^2 = 1$, so $\omega_1 = 1$ rad/s; antiphase $(1,-1)$ with $\omega_2^2 = 1 + 2k_c = 1.21$, so $\omega_2 = 1.1$ rad/s.

Step 2 — modal amplitudes. $\mathbf{x}(0) = (1,0) = \tfrac{1}{2}(1,1) + \tfrac{1}{2}(1,-1)$ and $\dot{\mathbf{x}}(0) = \mathbf{0}$, so only cosine terms appear, each with amplitude $\tfrac{1}{2}$.

Step 3 — superpose and simplify with sum-to-product identities (Ch. 3):

$$x_1(t) = \tfrac{1}{2}(\cos t + \cos 1.1t) = \cos(0.05t)\cos(1.05t),$$
$$x_2(t) = \tfrac{1}{2}(\cos t - \cos 1.1t) = \sin(0.05t)\sin(1.05t).$$

Interpretation. Both masses oscillate at the mean frequency 1.05 rad/s under slowly varying envelopes $|\cos 0.05t|$ and $|\sin 0.05t|$. At $t = \pi/0.1 = 31.4$ s mass 1 is momentarily still and mass 2 carries all the motion; at 62.8 s it has all come back. The exchange time $\pi/(\omega_2 - \omega_1)$ is set by the **mode splitting**: the weaker the coupling, the slower the exchange. The same mathematics describes energy transfer in a directional coupler and between coupled optical waveguides, with distance in place of time.



Free motion of two weakly coupled oscillators (Example 10.33), plotted against t in seconds: $x_1(t)$ (blue, offset $+1.2$) and $x_2(t)$ (red, offset -1.2). The dashed envelopes $\pm\cos 0.05t$ and $\pm\sin 0.05t$ show energy passing completely from one oscillator to the other every 31.4 s — the beat between the normal-mode frequencies 1 and 1.1 rad/s.

Worked Example 10.34 — Modes of an RC ladder (first-order modal analysis)

A two-section RC ladder ($R = 1$ kΩ, $C = 1$ μF per section, so $RC = 1$ ms) has its input shorted and both capacitors initially at 1 V. Find $v_1(t)$ and $v_2(t)$.

Step 1 — state equations. KCL at node 1: $C\dot{v}_1 = -v_1/R - (v_1 - v_2)/R$; at node 2: $C\dot{v}_2 = (v_1 - v_2)/R$. With t in ms,

$$\dot{\mathbf{v}} = \mathbf{A}\mathbf{v}, \qquad \mathbf{A} = \begin{bmatrix} -2 & 1 \\ 1 & -1 \end{bmatrix}.$$

Step 2 — eigenvalues. $\lambda^2 + 3\lambda + 1 = 0$: $\lambda = \dfrac{-3 \pm \sqrt{5}}{2}$, i.e. $\lambda_s = -0.382$ and $\lambda_f = -2.618$ ms^{-1}. Time constants: $\tau_s = 2.618$ ms (slow) and $\tau_f = 0.382$ ms (fast).

Step 3 — eigenvectors. $\mathbf{A}$ is symmetric, so they are orthogonal. From the second row, $v_1 = (1 + \lambda)v_2$: $\mathbf{v}_s \propto (0.618, 1) \propto (1, 1.618)$ (both capacitors discharging together, the far one higher) and $\mathbf{v}_f \propto (1, -0.618)$ (charge sloshing between the capacitors). Normalised: $\mathbf{q}_s = (0.5257, 0.8507)$, $\mathbf{q}_f = (0.8507, -0.5257)$.

Step 4 — project the initial state. Orthonormal eigenvectors make the left eigenvectors equal to the right ones: $c_s = \mathbf{q}_s \cdot (1, 1) = 1.3764$, $c_f = \mathbf{q}_f \cdot (1, 1) = 0.3249$.

Step 5 — response.

$$\begin{aligned} v_1(t) &= 0.7236\, e^{-t/2.618} + 0.2764\, e^{-t/0.382}, \\ v_2(t) &= 1.1708\, e^{-t/2.618} - 0.1708\, e^{-t/0.382} \qquad (t \text{ in ms, } v \text{ in V}). \end{aligned}$$

Checks. $t = 0$: $v_1 = 1.0000$, $v_2 = 1.0000$ ✓. At $t = 1$ ms: $v_1 = 0.7236(0.6825) + 0.2764(0.0729) = 0.5140$ V and $v_2 = 0.7866$ V, matching a numerical $e^{\mathbf{A}t}\mathbf{v}(0)$ ✓. After about 1 ms the fast mode has essentially vanished and the circuit behaves as a single-time-constant system with $\tau = 2.618$ ms — the basis of **dominant-pole approximation**. Note that neither time constant equals RC: the sections interact, which is why "n cascaded RC sections" is not n identical poles.

Common Pitfall — normalising modes and projecting initial conditions

When the mass (or capacitance) matrix is not a multiple of $\mathbf{I}$, mode shapes are orthogonal **with respect to** $\mathbf{M}$, not in the ordinary dot product. The modal amplitude is $a_i = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{M}\mathbf{x}(0)$ for $\mathbf{M}$-normalised modes; using $\boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{x}(0)$ gives wrong answers. For non-symmetric first-order systems, use the **left** eigenvectors (rows of $\mathbf{P}^{-1}$) to project; the right eigenvectors are not orthogonal.

Engineering Note — modal analysis at scale

Finite-element models of PCBs, packages, enclosures and antennas have 10^4–10^7 degrees of freedom, but only the few modes in the frequency band of interest matter. Solvers (Lanczos and Arnoldi methods, shift-invert about a target frequency) extract just those eigenpairs from the sparse pair $(\mathbf{K}, \mathbf{M})$. Cavity resonances of a metal enclosure, which can turn a shielded box into an efficient radiator at specific frequencies, are found this way; so are the even and odd propagation modes of coupled microstrip lines (eigenvectors of the product of per-unit-length $\mathbf{L}$ and $\mathbf{C}$ matrices), whose different velocities cause far-end crosstalk.

10.9 Applications to system dynamics and stability

Motivation

Every circuit, control loop and oscillator must answer one question before any other: **if it is disturbed, does it return to rest, settle into a steady oscillation, or run away?** An amplifier that oscillates, a phase-locked loop that loses lock, a switched-mode converter whose output voltage rings ever larger, a power grid whose generators swing apart — all are stability failures, and for linear (or linearized) models all are diagnosed by eigenvalues. This section collects the results: stability criteria for continuous- and discrete-time systems, the complete geometric classification of two-dimensional systems, linearization of nonlinear systems about an equilibrium, and Lyapunov's energy-like test, which brings positive-definite matrices back into the story. Chapters 11 and 12 develop the differential-equation side; here we concentrate on what the matrix tells us.

Stability of linear systems

Consider $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$, whose equilibrium is $\mathbf{x} = \mathbf{0}$. From Section 10.4 every solution is a combination of terms $t^k e^{\lambda_i t}\mathbf{v}$, with polynomial factors t^k only for defective eigenvalues. Since $|e^{\lambda t}| = e^{(\operatorname{Re}\lambda)t}$, the real parts decide everything.

Stability of an equilibrium

The equilibrium $\mathbf{x} = \mathbf{0}$ of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ is

- **asymptotically stable** if every solution tends to $\mathbf{0}$ as $t \to \infty$;
- **marginally stable** (stable but not asymptotically) if every solution stays bounded but some do not tend to $\mathbf{0}$;
- **unstable** if some solution grows without bound.

Eigenvalue criteria for stability

Continuous time, $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$:

- asymptotically stable $\iff$ $\operatorname{Re}\lambda_i < 0$ for every eigenvalue (all eigenvalues in the open left half-plane; $\mathbf{A}$ is then called **Hurwitz**);
- marginally stable $\iff$ $\operatorname{Re}\lambda_i \le 0$ for all i, and every eigenvalue on the imaginary axis is non-defective;
- unstable otherwise.

Discrete time, $\mathbf{x}[k+1] = \mathbf{A}\mathbf{x}[k]$: the same statements with "$\operatorname{Re}\lambda < 0$" replaced by "$|\lambda| < 1$" and "the imaginary axis" by "the unit circle" ($\mathbf{A}$ is then called **Schur**).

For a linear time-invariant system with input and output, the eigenvalues of $\mathbf{A}$ are the **poles** of the transfer function $\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}$ — except for any modes that are uncontrollable or unobservable and therefore cancel (Section 10.8). This is why "all poles in the left half-plane" is the same condition as "all eigenvalues in the left half-plane" for a minimal realisation, and why a hidden unstable mode is dangerous: it does not appear in the transfer function, yet the internal state still grows.

Classifying two-dimensional systems: the trace–determinant plane

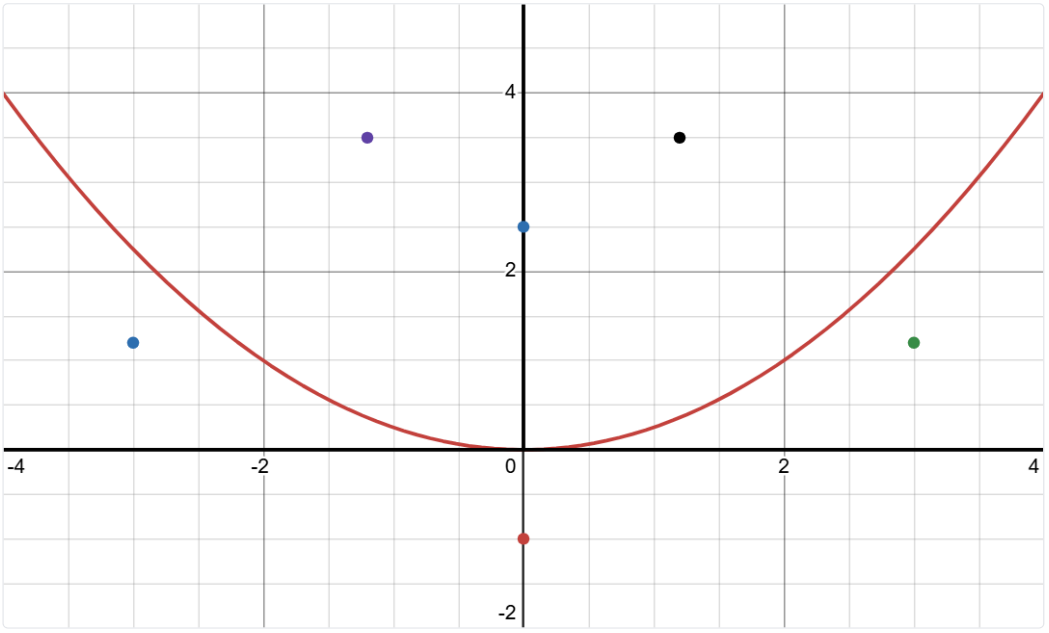
For a real 2×2 matrix, write $\tau = \operatorname{tr}\mathbf{A}$ and $\Delta = \det\mathbf{A}$. The eigenvalues are

$$\lambda_{1,2} = \frac{\tau \pm \sqrt{\tau^2 - 4\Delta}}{2}, \qquad \lambda_1 + \lambda_2 = \tau, \quad \lambda_1\lambda_2 = \Delta,$$

so the two numbers (τ, Δ) determine the qualitative behaviour completely:

Region of the (τ, Δ) plane	Eigenvalues	Equilibrium type
$\Delta < 0$	real, opposite signs	**saddle** (unstable)
$\Delta > 0, \tau^2 > 4\Delta, \tau < 0$	real, both negative	**stable node**
$\Delta > 0, \tau^2 > 4\Delta, \tau > 0$	real, both positive	**unstable node**
$\Delta > 0, \tau^2 < 4\Delta, \tau < 0$	complex, $\operatorname{Re} < 0$	**stable spiral** (focus)
$\Delta > 0, \tau^2 < 4\Delta, \tau > 0$	complex, $\operatorname{Re} > 0$	**unstable spiral**
$\Delta > 0, \tau = 0$	$\pm j\sqrt{\Delta}$	**centre** (marginally stable)
$\tau^2 = 4\Delta$	real, repeated	degenerate (star) node — boundary case
$\Delta = 0$	one zero eigenvalue	line of equilibria — boundary case

The compact stability statement for $n = 2$ is: **asymptotically stable** $\iff$ $\tau < 0$ **and** $\Delta > 0$. For a second-order circuit with characteristic polynomial $\lambda^2 + 2\zeta\omega_0\lambda + \omega_0^2$, $\tau = -2\zeta\omega_0$ and $\Delta = \omega_0^2$, and the parabola $\tau^2 = 4\Delta$ is the critical damping $\zeta = 1$: overdamped circuits are stable nodes, underdamped ones stable spirals, and a lossless LC tank is a centre.



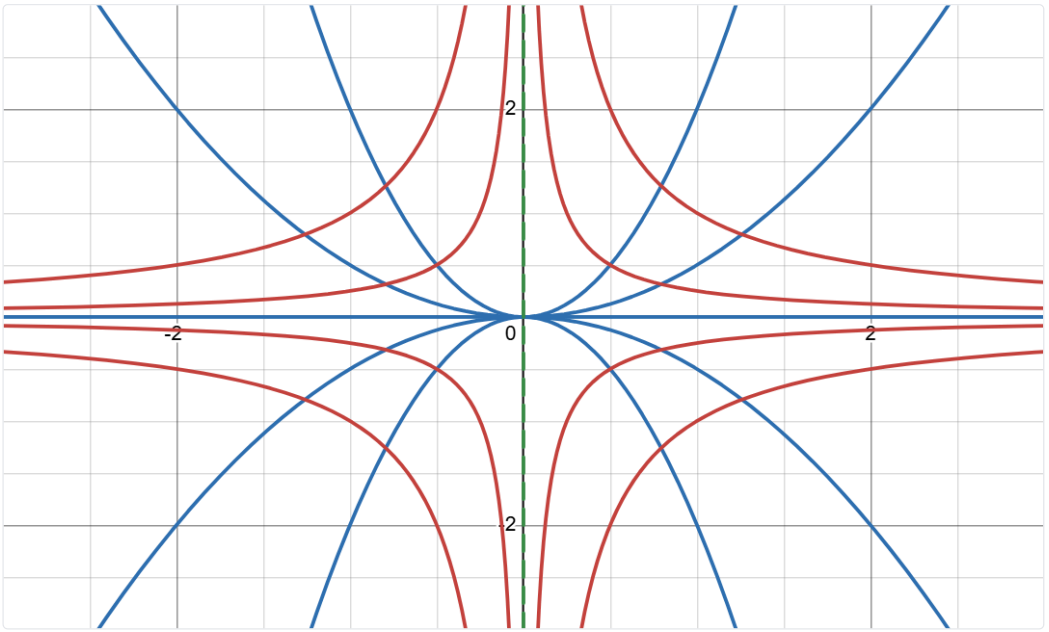
The trace–determinant plane (horizontal axis $\tau = \operatorname{tr}\mathbf{A}$, vertical axis $\Delta = \det\mathbf{A}$). Below the τ-axis lie saddles; above it, the parabola $\Delta = \tau^2/4$ (red, critical damping) separates nodes (outside) from spirals (inside); the positive Δ-axis carries centres. The stable region is the open upper-left quadrant $\tau < 0,\ \Delta > 0$.

Phase portraits from eigenvectors

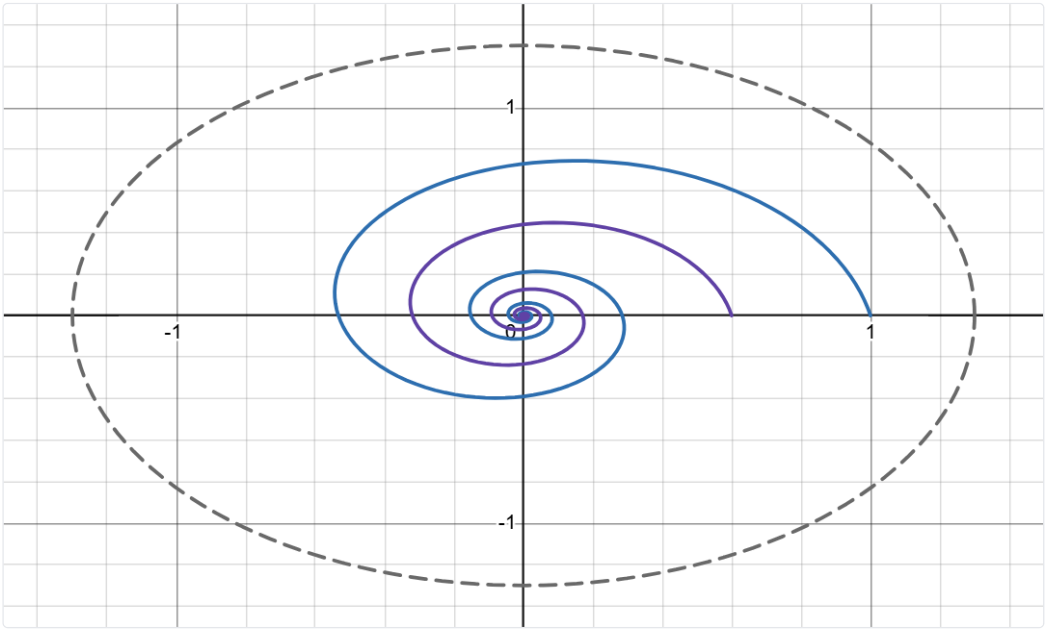
The **phase portrait** draws solution trajectories in the (x_1, x_2) plane. Eigenvectors organise it: a trajectory that starts on a real eigenvector line stays on it (it is the solution $c\,e^{\lambda t}\mathbf{v}$), moving inward if $\lambda < 0$ and outward if $\lambda > 0$. In eigenvector coordinates (y_1, y_2) a system with real eigenvalues is $\dot{y}_1 = \lambda_1 y_1$, $\dot{y}_2 = \lambda_2 y_2$, so $y_i = c_i e^{\lambda_i t}$, and eliminating t gives the **explicit trajectory curves**

$$y_2 = C\,|y_1|^{\lambda_2/\lambda_1}.$$

For a stable node with $\lambda_1 = -1$, $\lambda_2 = -2$: $y_2 = C y_1^2$, a family of parabolas all tangent at the origin to the **slow** eigenvector (y_1-axis). For a saddle with $\lambda_1 = 1$, $\lambda_2 = -1$: $y_1 y_2 = C$, hyperbolas whose asymptotes are the eigenvector lines. For a complex pair $\sigma \pm j\omega$, the real block form $\begin{bmatrix} \sigma & -\omega \\ \omega & \sigma \end{bmatrix}$ in polar coordinates gives $\dot r = \sigma r$, $\dot\theta = \omega$, hence $r = r_0 e^{(\sigma/\omega)(\theta-\theta_0)}$: **logarithmic spirals**, shrinking if $\sigma < 0$. In the original coordinates these pictures are mapped through $\mathbf{P}$, which skews them but preserves their type.



Explicit trajectory families in eigenvector coordinates. Blue: stable node with $\lambda_1 = -1$, $\lambda_2 = -2$, trajectories $y_2 = C y_1^2$, all entering the origin tangent to the slow eigen-direction (the y_1-axis); the fast direction is the y_2-axis (green dashed). Red: saddle with $\lambda_1 = 1$, $\lambda_2 = -1$, trajectories $y_1 y_2 = C$, whose asymptotes are the two eigenvector axes.



Trajectories of a stable spiral with eigenvalues $-0.2 \pm j$ (real block form): $r = r_0 e^{-0.2\theta}$, two starting radii shown. Each turn shrinks the radius by $e^{-0.2\cdot 2\pi} = 0.285$; with $\operatorname{Re}\lambda = 0$ the curves would be circles (a centre, dashed reference), and with $\operatorname{Re}\lambda > 0$ they would spiral outward.

Routh–Hurwitz: stability without eigenvalues

Often only the characteristic polynomial $\det(s\mathbf{I} - \mathbf{A}) = s^n + a_{n-1}s^{n-1} + \cdots + a_0$ is needed, and only the *signs* of the real parts of its roots. The Routh–Hurwitz criterion decides this from the coefficients. Its lowest-order cases are worth memorising:

- $n = 1, 2$: all roots in the left half-plane $\iff$ all coefficients positive.
- $n = 3$: $s^3 + a_2 s^2 + a_1 s + a_0$ is Hurwitz $\iff$ $a_2, a_1, a_0 > 0$ **and** $a_2 a_1 > a_0$.

Positivity of all coefficients is **necessary** for every n (a product of factors $(s+p)$ and $(s^2 + bs + c)$ with $p, b, c > 0$ has only positive coefficients) but not sufficient for $n \geq 3$: $s^3 + s^2 + s + 6$ has positive coefficients but $a_2 a_1 = 1 < 6$, and it has the unstable roots $0.5 \pm j1.66$. The full Routh array for higher orders is part of control theory and is treated with the Laplace transform in Ch. 14.

Linearization of nonlinear systems

Most real systems are nonlinear: $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$. An **equilibrium** $\mathbf{x}^*$ satisfies $\mathbf{f}(\mathbf{x}^*) = \mathbf{0}$ — the DC operating point of a circuit. For small deviations $\boldsymbol{\xi} = \mathbf{x} - \mathbf{x}^*$, the multivariable Taylor expansion of Ch. 6 gives

$$\dot{\boldsymbol{\xi}} = \mathbf{f}(\mathbf{x}^* + \boldsymbol{\xi}) \approx \mathbf{J}\boldsymbol{\xi}, \qquad \mathbf{J} = \left.\frac{\partial \mathbf{f}}{\partial \mathbf{x}}\right|_{\mathbf{x}^*} = \left[\frac{\partial f_i}{\partial x_k}\right]_{\mathbf{x}^*},$$

the **Jacobian matrix**. This is exactly the small-signal model of circuit analysis: transistors and diodes are replaced by their incremental conductances at the operating point.

Linearized stability (Lyapunov's indirect method; Hartman–Grobman)

Let $\mathbf{J}$ be the Jacobian at an equilibrium $\mathbf{x}^*$ of $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$, with $\mathbf{f}$ continuously differentiable.

- If every eigenvalue of $\mathbf{J}$ has $\operatorname{Re}\lambda < 0$, $\mathbf{x}^*$ is locally asymptotically stable.
- If some eigenvalue has $\operatorname{Re}\lambda > 0$, $\mathbf{x}^*$ is unstable.
- If no eigenvalue has zero real part (a *hyperbolic* equilibrium), the nonlinear phase portrait near $\mathbf{x}^*$ has the same type (node, saddle, spiral) as the linearization.

If some eigenvalue has $\operatorname{Re}\lambda = 0$ and none is positive, the linearization is **inconclusive**: the neglected nonlinear terms decide.

Lyapunov's equation: stability through energy

A physical way to prove stability is to exhibit an "energy" that always decreases. For a linear system try a quadratic form $V(\mathbf{x}) = \mathbf{x}^{\mathsf{T}}\mathbf{P}\mathbf{x}$ with $\mathbf{P} \succ 0$. Along solutions,

$$\dot{V} = \dot{\mathbf{x}}^{\mathsf{T}}\mathbf{P}\mathbf{x} + \mathbf{x}^{\mathsf{T}}\mathbf{P}\dot{\mathbf{x}} = \mathbf{x}^{\mathsf{T}}(\mathbf{A}^{\mathsf{T}}\mathbf{P} + \mathbf{P}\mathbf{A})\mathbf{x}.$$

Lyapunov stability theorem (linear case)

$\mathbf{A}$ is Hurwitz (all $\operatorname{Re}\lambda < 0$) **if and only if** for some (equivalently, every) symmetric $\mathbf{Q} \succ 0$ the **Lyapunov equation**

$$\mathbf{A}^{\mathsf{T}}\mathbf{P} + \mathbf{P}\mathbf{A} = -\mathbf{Q}$$

has a symmetric positive-definite solution $\mathbf{P}$. The solution is then unique and equals $\mathbf{P} = \int_0^\infty e^{\mathbf{A}^{\mathsf{T}}t}\mathbf{Q}e^{\mathbf{A}t}\,dt$.

Why it works: with such a $\mathbf{P}$, $V > 0$ away from the origin while $\dot{V} = -\mathbf{x}^{\mathsf{T}}\mathbf{Q}\mathbf{x} < 0$, so V — and with it $\mathbf{x}$ — decays to zero; the level curves of V are nested ellipses that trajectories cross only inwards. The discrete-time counterpart is $\mathbf{A}^{\mathsf{T}}\mathbf{P}\mathbf{A} - \mathbf{P} = -\mathbf{Q}$. The Lyapunov approach matters because it extends to nonlinear and time-varying systems, where eigenvalues alone say little, and because $\mathbf{P}$ itself has meanings: for a stable system driven by white noise, the solution of a closely related Lyapunov equation is the steady-state **covariance** of the state (Ch. 21).

Worked examples

Worked Example 10.35 — Natural frequencies of a series RLC circuit

A series RLC circuit with $R = 100\ \Omega$, $L = 10$ mH, $C = 1\ \mu$F is left to discharge. With state $\mathbf{x} = (i, v_C)$, find the eigenvalues and characterise the response.

Step 1 — state equations. KVL: $L\,di/dt = -Ri - v_C$; capacitor: $C\,dv_C/dt = i$.

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}, \qquad \mathbf{A} = \begin{bmatrix} -R/L & -1/L \\ 1/C & 0 \end{bmatrix} = \begin{bmatrix} -10^4 & -100 \\ 10^6 & 0 \end{bmatrix}.$$

(Units: R/L in s^{-1}; $1/L$ in A/(V·s); $1/C$ in V/(A·s). The off-diagonal units differ, but their product $1/(LC)$ is in s^{-2}, as an entry of $\det \mathbf{A}$ must be.)

Step 2 — trace and determinant. $\tau = -R/L = -10^4\ \text{s}^{-1}$, $\Delta = 1/(LC) = 10^8\ \text{s}^{-2}$. Since $\tau < 0$ and $\Delta > 0$: **asymptotically stable**. Since $\tau^2 = 10^8 < 4\Delta = 4 \times 10^8$: **spiral** (underdamped).

Step 3 — eigenvalues.

$$\lambda = -5000 \pm j\sqrt{10^8 - 2.5 \times 10^7} = -5000 \pm j\,8660\ \text{s}^{-1}.$$

Interpretation. $\omega_0 = \sqrt{\Delta} = 10^4$ rad/s, $\zeta = -\tau/(2\omega_0) = 0.5$; the current rings at $\omega_d = 8660$ rad/s (1.378 kHz) inside an envelope $e^{-t/0.2\,\text{ms}}$. Doubling R to $200\ \Omega$ gives $\tau^2 = 4\Delta$: critical damping, a defective double eigenvalue at $-10^4\ \text{s}^{-1}$, and $te^{-10^4 t}$ terms (compare Example 10.11).

Worked Example 10.36 — Reading the type off trace and determinant

Classify the equilibrium of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ for each matrix.

$\mathbf{A}$	τ	Δ	$\tau^2 - 4\Delta$	Eigenvalues	Type
$\begin{bmatrix} -3 & 1 \\ 1 & -3 \end{bmatrix}$	-6	8	4	$-2,\ -4$	stable node
$\begin{bmatrix} 1 & 2 \\ 3 & -4 \end{bmatrix}$	-3	-10	49	$2,\ -5$	saddle (unstable)
$\begin{bmatrix} -1 & -4 \\ 1 & -1 \end{bmatrix}$	-2	5	-16	$-1 \pm 2j$	stable spiral
$\begin{bmatrix} 0 & 1 \\ -4 & 0 \end{bmatrix}$	0	4	-16	$\pm 2j$	centre
$\begin{bmatrix} 1 & -2 \\ 1 & 3 \end{bmatrix}$	4	5	-4	$2 \pm j$	unstable spiral

Notes. The saddle has negative trace yet is unstable: a negative trace alone proves nothing. Its eigenvector for $\lambda = 2$ is $(2, 1)$ (from $\mathbf{A} - 2\mathbf{I} = \begin{bmatrix} -1 & 2 \\ 3 & -6 \end{bmatrix}$) — the single direction along which almost every trajectory eventually escapes. For the spiral, the sense of rotation follows from any one velocity: at $\mathbf{x} = (1, 0)$, $\dot{\mathbf{x}} = (-1, 1)$ has positive $\dot{x}_2$, so the rotation is counter-clockwise.

Worked Example 10.37 — Linearizing the damped pendulum

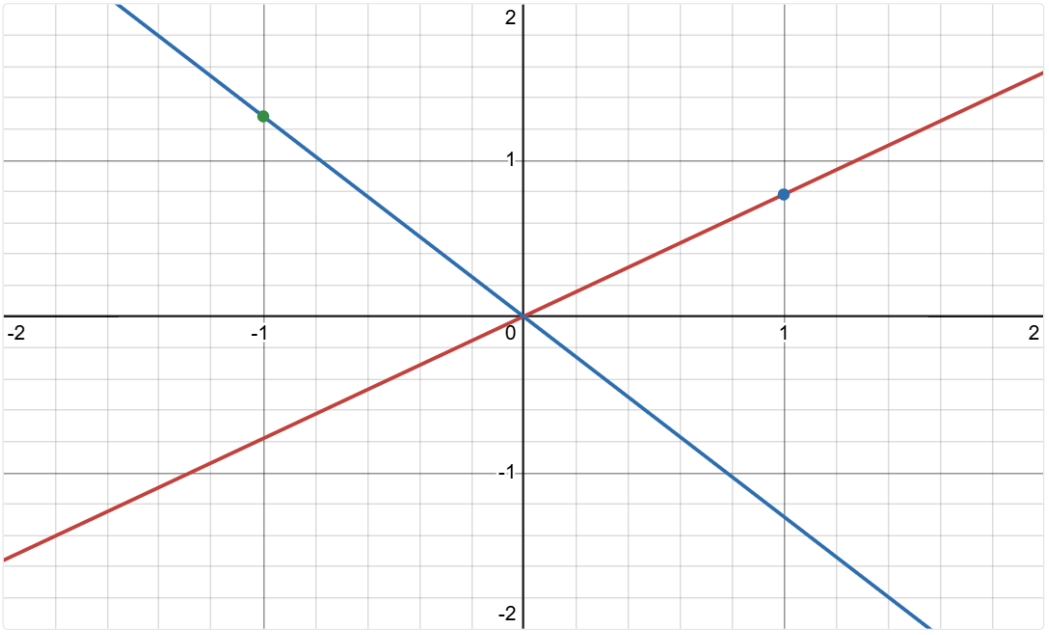
A pendulum (or, equivalently, the swing equation of a synchronous generator against an infinite bus) obeys, in normalised units, $\ddot{\theta} + 0.5\dot{\theta} + \sin\theta = 0$. With $\mathbf{x} = (\theta, \omega)$, $\omega = \dot{\theta}$:

$$\mathbf{f}(\mathbf{x}) = \begin{bmatrix} \omega \\ -\sin\theta - 0.5\,\omega \end{bmatrix}, \qquad \mathbf{J}(\theta, \omega) = \begin{bmatrix} 0 & 1 \\ -\cos\theta & -0.5 \end{bmatrix}.$$

Equilibria. $\omega = 0$, $\sin\theta = 0$: $\theta = 0$ (hanging down) and $\theta = \pi$ (inverted).

At $(0, 0)$. $\mathbf{J} = \begin{bmatrix} 0 & 1 \\ -1 & -0.5 \end{bmatrix}$, $\tau = -0.5$, $\Delta = 1$, $\tau^2 - 4\Delta = -3.75 < 0$. Eigenvalues $-0.25 \pm j\,0.968$: a **stable spiral** (decaying swings). Hyperbolic, so the nonlinear pendulum behaves the same way near the bottom.

At $(\pi, 0)$. $\mathbf{J} = \begin{bmatrix} 0 & 1 \\ 1 & -0.5 \end{bmatrix}$, $\Delta = -1 < 0$: a **saddle**. Eigenvalues from $\lambda^2 + 0.5\lambda - 1 = 0$: $\lambda = \frac{-0.5 \pm \sqrt{4.25}}{2} = 0.781,\ -1.281$. Eigenvectors of this companion-type matrix are $(1, \lambda)$: the unstable direction is $(1, 0.781)$, the stable direction $(1, -1.281)$. The stable eigen-line is the linear approximation of the **separatrix** — the knife-edge set of initial conditions that just reach the inverted position. In power systems the analogous saddle (the unstable equilibrium of the swing equation) defines the boundary of the region from which a generator can recover after a fault.



Eigenvector lines of the linearized pendulum at the inverted equilibrium, plotted in deviation coordinates $(\theta - \pi,\ \omega)$: trajectories approach along the blue stable line and leave along the red unstable line, the local skeleton of the saddle.

Worked Example 10.38 — Start-up condition of a negative-resistance oscillator

A parallel LC tank loaded by a nonlinear negative-resistance device (tunnel diode, cross-coupled transistor pair) obeys the van der Pol equation $\ddot{v} - \varepsilon(1 - v^2)\dot{v} + \omega_0^2 v = 0$, with $\varepsilon > 0$ set by how much negative conductance exceeds the tank losses. Will the oscillation start from noise?

Linearize at $v = \dot{v} = 0$. With $\mathbf{x} = (v, \dot{v})$, the term $\varepsilon v^2 \dot{v}$ is cubic and drops out:

$$\mathbf{J} = \begin{bmatrix} 0 & 1 \\ -\omega_0^2 & \varepsilon \end{bmatrix}, \qquad \tau = \varepsilon > 0,\ \Delta = \omega_0^2 > 0.$$

Classify. $\tau > 0$, $\Delta > 0$: unstable. For $\varepsilon < 2\omega_0$ the eigenvalues $\frac{\varepsilon}{2} \pm j\sqrt{\omega_0^2 - \varepsilon^2/4}$ are complex: an **unstable spiral**. Any tiny noise voltage grows as $e^{\varepsilon t/2}$ while oscillating at nearly ω_0 — the oscillator starts.

What eigenvalues cannot tell. The growth does not continue for ever: as v grows, the nonlinear term reduces the effective negative conductance and the trajectory settles onto a **limit cycle** of amplitude about 2. The linearization predicts *start-up* (Barkhausen's loop-gain condition is the same statement) but not the final amplitude, which is a nonlinear question (Ch. 11).

Worked Example 10.39 — Stability of a digital resonator

The recursion $y[n] = 1.8\,y[n-1] - 0.9\,y[n-2]$ is the homogeneous part of a second-order IIR filter. Is it stable, and at what frequency does it ring?

Step 1 — state form. With $\mathbf{x}[n] = (y[n], y[n-1])$:

$$\mathbf{x}[n+1] = \begin{bmatrix} 1.8 & -0.9 \\ 1 & 0 \end{bmatrix} \mathbf{x}[n], \qquad \det(\lambda\mathbf{I} - \mathbf{A}) = \lambda^2 - 1.8\lambda + 0.9.$$

Step 2 — eigenvalues. $\lambda = 0.9 \pm j\sqrt{0.9 - 0.81} = 0.9 \pm j\,0.3$, so $|\lambda| = \sqrt{0.9} = 0.9487$ and $\angle\lambda = \arctan(0.3/0.9) = 0.3218$ rad $= 18.43^\circ$.

Step 3 — conclusions. $|\lambda| < 1$: **stable**; the ringing decays by a factor 0.9487 per sample (to 1% in $\ln 0.01 / \ln 0.9487 \approx 87$ samples) and oscillates at 0.3218 rad/sample, i.e. $0.3218/(2\pi) = 0.0512$ cycles/sample — 2.46 kHz at a 48 kHz sample rate. Note $|\lambda|^2 = \det \mathbf{A} = 0.9$: for any second-order section $y[n] = a_1 y[n-1] - a_2 y[n-2]$ with complex poles, the pole radius is $\sqrt{a_2}$, so $a_2 < 1$ is required.

Step 4 — the boundary. Changing 0.9 to 1.0 gives $\lambda = e^{\pm j\,0.451}$ on the unit circle: a marginally stable digital oscillator. In fixed-point arithmetic, rounding of the coefficient can push the poles slightly outside the unit circle — a practical reason for using structures (such as coupled-form or lattice filters) whose eigenvalues are less sensitive to coefficient quantisation.

Worked Example 10.40 — Solving a Lyapunov equation

For $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}$ (eigenvalues $-1, -2$) solve $\mathbf{A}^{\mathsf{T}}\mathbf{P} + \mathbf{P}\mathbf{A} = -\mathbf{I}$ and confirm that $\mathbf{P} \succ 0$.

Step 1 — unknowns. $\mathbf{P} = \begin{bmatrix} p_1 & p_2 \\ p_2 & p_3 \end{bmatrix}$. Compute $\mathbf{A}^{\mathsf{T}}\mathbf{P} = \begin{bmatrix} -2p_2 & -2p_3 \\ p_1 - 3p_2 & p_2 - 3p_3 \end{bmatrix}$; $\mathbf{P}\mathbf{A}$ is its transpose.

Step 2 — equate entries of the symmetric sum to $-\mathbf{I}$.

$$(1,1):\ -4p_2 = -1, \qquad (2,2):\ 2p_2 - 6p_3 = -1, \qquad (1,2):\ p_1 - 3p_2 - 2p_3 = 0.$$

So $p_2 = 0.25$, $p_3 = (1 + 0.5)/6 = 0.25$, $p_1 = 3(0.25) + 2(0.25) = 1.25$:

$$\mathbf{P} = \begin{bmatrix} 1.25 & 0.25 \\ 0.25 & 0.25 \end{bmatrix}.$$

Step 3 — definiteness. $p_1 = 1.25 > 0$, $\det \mathbf{P} = 0.3125 - 0.0625 = 0.25 > 0$: $\mathbf{P} \succ 0$, confirming that $\mathbf{A}$ is Hurwitz without computing an eigenvalue. (A numerical `solve_continuous_lyapunov` returns the same $\mathbf{P}$.)

Step 4 — interpretation. $V(\mathbf{x}) = 1.25x_1^2 + 0.5x_1x_2 + 0.25x_2^2$ is an energy-like function with $\dot{V} = -(x_1^2 + x_2^2)$ along every trajectory. Its level sets are ellipses that every trajectory crosses inward.

Common Pitfall — stable eigenvalues, large transients

Eigenvalues describe the behaviour as $t \to \infty$, not the size of the response on the way. For the stable but strongly **non-normal** matrix $\mathbf{A} = \begin{bmatrix} -1 & 50 \\ 0 & -2 \end{bmatrix}$ (eigenvalues $-1, -2$),

$$e^{\mathbf{A}t} = \begin{bmatrix} e^{-t} & 50(e^{-t} - e^{-2t}) \\ 0 & e^{-2t} \end{bmatrix},$$

and the $(1,2)$ entry reaches $50(0.5 - 0.25) = 12.5$ at $t = \ln 2$: a unit initial condition on x_2 produces a twelve-fold excursion in x_1 before decaying. If the model came from linearization, such an excursion can drive the real system out of the region where the linear model is valid — or saturate an amplifier. The eigenvector matrix of such an $\mathbf{A}$ is ill-conditioned (Section 10.3); singular values of $e^{\mathbf{A}t}$, or a Lyapunov function, quantify the transient.

Engineering Note — stability margins and eigenvalue location

Asymptotic stability is a yes/no property, but designs need margins. Requiring all eigenvalues to satisfy $\operatorname{Re}\lambda \le -\alpha$ guarantees decay at least as fast as $e^{-\alpha t}$ (settling time about $4/\alpha$); requiring them inside a sector $|\angle(-\lambda)| \le \arccos\zeta_{\min}$ guarantees a minimum damping ratio and hence bounded overshoot. In power electronics and power systems, the eigenvalue plot of the linearized model versus a parameter (load, gain, line impedance) — a **root locus** — shows how close each mode is to crossing the imaginary axis; the crossing point, where a complex pair reaches $\operatorname{Re}\lambda = 0$, is a **Hopf bifurcation**, the birth of a sustained oscillation as in Example 10.38.

Summary

Concept	Key formula or statement
Eigenpair	$\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$, $\mathbf{v} \neq \mathbf{0}$; eigenspace $E_\lambda = \operatorname{null}(\mathbf{A} - \lambda\mathbf{I})$
Characteristic equation	$\det(\mathbf{A} - \lambda\mathbf{I}) = 0$, degree n, n roots in $\mathbb{C}$
2×2 shortcut	$\lambda^2 - (\operatorname{tr}\mathbf{A})\lambda + \det\mathbf{A} = 0$
3×3 shortcut	$\lambda^3 - (\operatorname{tr}\mathbf{A})\lambda^2 + E_2\lambda - \det\mathbf{A} = 0$, E_2 = sum of 2×2 principal minors
Trace and determinant	$\sum\lambda_i = \operatorname{tr}\mathbf{A}$, $\prod\lambda_i = \det\mathbf{A}$
Cayley–Hamilton	$p(\mathbf{A}) = \mathbf{0}$; e.g. $\mathbf{A}^2 - (\operatorname{tr}\mathbf{A})\mathbf{A} + (\det\mathbf{A})\mathbf{I} = \mathbf{0}$
Multiplicities	$1 \le g(\lambda) \le m(\lambda)$; defective if $g < m$
Functions of $\mathbf{A}$	eigenvalues of $q(\mathbf{A})$, $\mathbf{A}^{-1}$, $e^{\mathbf{A}t}$ are $q(\lambda)$, $1/\lambda$, $e^{\lambda t}$ (same eigenvectors)
Diagonalization	$\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ iff n independent eigenvectors; distinct eigenvalues suffice
Real block form	$\lambda = \sigma \pm j\omega$, $\mathbf{v} = \mathbf{a} + j\mathbf{b}$: $[\mathbf{a}\ \mathbf{b}]^{-1}\mathbf{A}[\mathbf{a}\ \mathbf{b}] = \begin{bmatrix}\sigma & \omega\\ -\omega & \sigma\end{bmatrix}$
Jordan block powers	$\mathbf{J}_2(\lambda)^k = \begin{bmatrix}\lambda^k & k\lambda^{k-1}\\ 0 & \lambda^k\end{bmatrix}$, $e^{\mathbf{J}_2 t} = e^{\lambda t}\begin{bmatrix}1 & t\\ 0 & 1\end{bmatrix}$
Matrix powers	$\mathbf{A}^k = \mathbf{P}\mathbf{D}^k\mathbf{P}^{-1}$; $\mathbf{x}[k] = \sum c_i\lambda_i^k\mathbf{v}_i$; $\mathbf{A}^k \to \mathbf{0} \iff \rho(\mathbf{A}) < 1$
Matrix exponential	$e^{\mathbf{A}t} = \sum\mathbf{A}^k t^k/k! = \mathbf{P}e^{\mathbf{D}t}\mathbf{P}^{-1}$; $\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}(0) = \sum c_i e^{\lambda_i t}\mathbf{v}_i$
Sylvester interpolation	$f(\mathbf{A}) = \sum_{k<n}\alpha_k\mathbf{A}^k$ with $f(\lambda_i) = \sum\alpha_k\lambda_i^k$ (plus derivatives for repeated λ_i)
Spectral theorem	$\mathbf{A} = \mathbf{A}^{\mathsf{T}} \iff \mathbf{A} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}} = \sum\lambda_i\mathbf{q}_i\mathbf{q}_i^{\mathsf{T}}$, λ_i real, $\mathbf{Q}^{\mathsf{T}}\mathbf{Q} = \mathbf{I}$
Rayleigh quotient	$\lambda_{\min} \le \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}/\mathbf{x}^{\mathsf{T}}\mathbf{x} \le \lambda_{\max}$
Principal axes	$\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \sum\lambda_i y_i^2$ with $\mathbf{y} = \mathbf{Q}^{\mathsf{T}}\mathbf{x}$; ellipse semi-axes $1/\sqrt{\lambda_i}$ for $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = 1$
Positive definite	$\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} > 0 \iff$ all $\lambda_i > 0 \iff$ all leading minors $> 0 \iff$ all pivots $> 0 \iff \mathbf{A} = \mathbf{L}\mathbf{L}^{\mathsf{T}}$
2×2 PD test	$a_{11} > 0$ and $a_{11}a_{22} - a_{12}^2 > 0$ (coupled inductors: $M^2 < L_1L_2$)
SVD	$\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}} = \sum\sigma_i\mathbf{u}_i\mathbf{v}_i^{\mathsf{T}}$, $\sigma_i^2 = \lambda_i(\mathbf{A}^{\mathsf{T}}\mathbf{A})$, $\mathbf{A}\mathbf{v}_i = \sigma_i\mathbf{u}_i$
Norms and conditioning	$\|\mathbf{A}\|_2 = \sigma_1$, $\|\mathbf{A}\|_F^2 = \sum\sigma_i^2$, $\kappa_2 = \sigma_{\max}/\sigma_{\min}$
Eckart–Young	$\min_{\operatorname{rank}\mathbf{B}\le k}\|\mathbf{A} - \mathbf{B}\|_2 = \sigma_{k+1}$, attained by truncated SVD
Pseudoinverse	$\mathbf{A}^{+} = \sum_{i\le r}\sigma_i^{-1}\mathbf{v}_i\mathbf{u}_i^{\mathsf{T}}$; $\mathbf{A}^{+}\mathbf{b}$ = minimum-norm least-squares solution
Normal modes	$\mathbf{K}\boldsymbol{\phi} = \omega^2\mathbf{M}\boldsymbol{\phi}$; $\mathbf{\Phi}^{\mathsf{T}}\mathbf{M}\mathbf{\Phi} = \mathbf{I}$, $\mathbf{\Phi}^{\mathsf{T}}\mathbf{K}\mathbf{\Phi} = \mathbf{\Omega}^2$; $\ddot{q}_i + \omega_i^2 q_i = \boldsymbol{\phi}_i^{\mathsf{T}}\mathbf{f}$
Modal response (1st order)	$\mathbf{x}(t) = \sum\mathbf{v}_i(\mathbf{w}_i^{\mathsf{T}}\mathbf{x}(0))e^{\lambda_i t}$, $\mathbf{w}_i^{\mathsf{T}}$ = rows of $\mathbf{P}^{-1}$
Continuous-time stability	asymptotically stable $\iff \operatorname{Re}\lambda_i < 0$ for all i
Discrete-time stability	asymptotically stable $\iff |\lambda_i| < 1$ for all i
2×2 classification	stable $\iff \tau < 0,\ \Delta > 0$; saddle if $\Delta < 0$; spiral if $\tau^2 < 4\Delta$; node if $\tau^2 > 4\Delta$
Third-order Routh–Hurwitz	$s^3 + a_2s^2 + a_1s + a_0$ stable $\iff a_i > 0$ and $a_2a_1 > a_0$
Linearization	$\dot{\boldsymbol{\xi}} = \mathbf{J}\boldsymbol{\xi}$, $\mathbf{J} = \partial\mathbf{f}/\partial\mathbf{x}$ at equilibrium; conclusive if no $\operatorname{Re}\lambda = 0$
Lyapunov equation	$\mathbf{A}$ Hurwitz $\iff \mathbf{A}^{\mathsf{T}}\mathbf{P} + \mathbf{P}\mathbf{A} = -\mathbf{Q}$ has $\mathbf{P} \succ 0$ for $\mathbf{Q} \succ 0$

Part IV — Differential Equations

Chapter 11 — Ordinary Differential Equations

> **Prerequisites:** Ch. 4 (Differential Calculus), Ch. 5 (Integral Calculus), Ch. 6 (Multivariable Calculus), Ch. 8–10 (Matrices, Vector Spaces, Eigenvalues)
>
> **Learning outcomes:** After this chapter you can
>
> - classify an ODE by order, linearity, autonomy and homogeneity, and predict the kind of solution to expect before computing anything;
> - solve first-order equations that are separable, linear, exact (possibly after an integrating factor), Bernoulli or Riccati, and read their qualitative behaviour from a direction field or phase line;
> - use the structure theory of linear nth-order equations — fundamental sets, the Wronskian and Abel's formula, reduction of order, Cauchy–Euler equations, $y = y_h + y_p$ and variation of parameters;
> - state and apply the existence–uniqueness theorems for initial-value problems, and recognise blow-up and non-uniqueness when the hypotheses fail;
> - decide whether a boundary-value problem has one, none or infinitely many solutions, and solve simple Sturm–Liouville eigenvalue problems;
> - write any nth-order equation or lumped network as a first-order system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}$, solve the constant-coefficient case by eigenvectors, and classify equilibria in the phase plane.

A differential equation relates an unknown function to its own derivatives. It is the natural language of anything that *stores* something — charge on a capacitor, flux in an inductor, heat in a package, carriers in a semiconductor, momentum in a motor shaft — because a storage law says how fast the stored quantity changes, not what its value is. Kirchhoff's laws plus the element laws $i_C = C\,dv/dt$ and $v_L = L\,di/dt$ turn every lumped circuit into a set of ODEs.

This chapter gives the **general theory** of ordinary differential equations (ODEs): how they are classified, which solution methods apply to which class, and when a solution exists, is unique and lasts for all time. The emphasis is on methods that work for *variable* coefficients and *nonlinear* equations, because those are what the special-purpose tools cannot handle. The special case that dominates circuit analysis — linear equations with **constant coefficients**, their characteristic equations, natural and forced responses and state-variable form — is developed fully in Chapter 12; the transform route to the same equations is Chapter 14; numerical integration is Chapter 22. Where those chapters take over, this one gives a pointer rather than a duplicate.

11.1 First-order ODEs

Why start with first order

A first-order equation is one storage element, one rate law: an RC or RL network, a thermal mass, a single-pole amplifier, a charging battery, a population. Every higher-order equation can be rewritten as a *system* of first-order equations (§11.5, §11.9), so the ideas met here — direction fields, equilibria, existence and uniqueness — are the ideas of the whole subject in their simplest setting.

Definitions and classification

Ordinary differential equation

An **ordinary differential equation** of order n is a relation

$$F\big(t, y, y', y'', \dots, y^{(n)}\big) = 0$$

between one independent variable t (time) or x (position), an unknown function y and its derivatives up to order n. The **order** is the highest derivative present. "Ordinary" means a single independent variable; with several, the equation is a *partial* differential equation (Ch. 13).

A **first-order** ODE is $F(t, y, y') = 0$. Whenever it can be solved for y' we use the **normal form**

$$y' = f(t, y).$$

The vocabulary below is used throughout the book.

- **Solution on an interval.** A function $y(t)$ is a solution on an open interval I if it is differentiable on I and $y'(t) = f(t, y(t))$ for every $t \in I$. The interval is part of the answer: a formula may satisfy the equation only on a piece of the real line.
- **General solution.** A family $y = \varphi(t, C)$ containing one arbitrary constant, such that (almost) every solution is obtained for some value of C. Its graphs form a one-parameter family of **integral curves**.
- **Particular solution.** One member of the family, usually picked out by an **initial condition** $y(t_0) = y_0$.
- **Singular solution.** A solution not obtainable from the general solution for any finite C. For $y' = y^2$ the general solution is $y = 1/(C - t)$ and $y \equiv 0$ is singular.
- **Explicit vs implicit.** An explicit solution gives y as a function of t; an implicit one is a relation $G(t, y) = 0$ that defines $y(t)$ only implicitly (by the implicit-function theorem of Ch. 6, wherever $G_y \neq 0$).
- **Linear vs nonlinear.** The equation is **linear** if it can be written $a_1(t)\,y' + a_0(t)\,y = r(t)$ — the unknown and its derivative appear to the first power, are not multiplied together, and are not inside other functions. Otherwise it is **nonlinear**.
- **Autonomous.** The equation is autonomous if f does not depend explicitly on t: $y' = f(y)$. Time-invariant circuits with constant sources are autonomous.

Equation	Order	Linear?	Autonomous?
$RC\,\dot v + v = V_s$	1	yes	yes
$\dot y + t\,y = \sin t$	1	yes	no
$C\,\dot v = -I_S\big(e^{v/V_T} - 1\big)$	1	no	yes

Equation	Order	Linear?	Autonomous?
$y' = y^2 + t$	1	no	no
$LC\,\ddot{v} + RC\,\dot{v} + v = v_s(t)$	2	yes	if v_s constant

Worked Example 11.1 — Checking a solution and its interval

Show that $y = 1/(C - t)$ solves $y' = y^2$, and find the largest interval on which the solution through $y(0) = 2$ exists.

Step 1 (verify). $y' = \dfrac{d}{dt}(C - t)^{-1} = (C - t)^{-2} = y^2$. ✓

Step 2 (fit the condition). $y(0) = 1/C = 2$ gives $C = 1/2$, so $y = 1/(\tfrac{1}{2} - t)$.

Step 3 (interval). The formula is undefined at $t = 1/2$. A solution must be differentiable on an *interval* containing $t_0 = 0$, so the solution is defined on $(-\infty, \tfrac{1}{2})$. The branch for $t > \tfrac{1}{2}$ is a *different* solution (it is negative and passes through no point with $t = 0$).

Check. At $t = 0.4$: $y = 1/0.1 = 10$, and the numerical slope $[y(0.401) - y(0.399)]/0.002 = (10.101 - 9.901)/0.002 \approx 100 = y^2$. ✓

Notice that $f(t, y) = y^2$ is perfectly smooth everywhere; the blow-up at $t = 1/2$ is invisible in the equation. §11.7 explains why this can happen only in nonlinear equations.

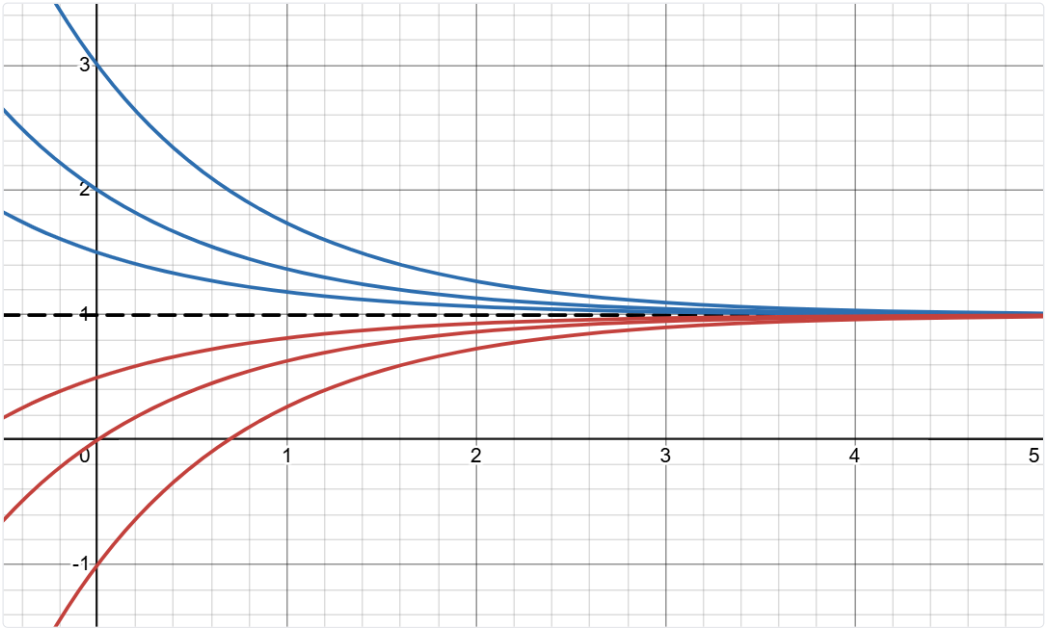
Direction fields

The equation $y' = f(t, y)$ assigns a slope to every point of the (t, y) plane. Drawing a short segment of slope $f(t, y)$ at each point of a grid gives the **direction field** (slope field). Every solution curve is tangent to the field at every point, so the field is a picture of all solutions at once — available before any formula is found, and even when no formula exists.

Two auxiliary ideas make sketching fast:

- **Isoclines** are the curves $f(t, y) = k$ along which all segments have the same slope k. The isocline $k = 0$ (the **nullcline**) is where solutions have horizontal tangents — maxima and minima of $y(t)$.
- **Equilibrium (constant) solutions** are values y^* with $f(t, y^*) = 0$ for all t. Their graphs are horizontal lines that other solutions can approach or leave but — when uniqueness holds — never cross.

For example $y' = 1 - y$ has the single equilibrium $y^* = 1$. Above it $y' < 0$ and below it $y' > 0$, so all solutions move towards $y = 1$. The general solution (derived in §11.3) is $y = 1 + Ce^{-t}$:



Integral curves of $y' = 1 - y$ for $C = \pm 0.5, \pm 1, \pm 2$: every curve approaches the stable equilibrium $y = 1$ (dashed). An RC circuit charging or discharging towards its source voltage behaves the same way.

Autonomous equations and the phase line

For an autonomous equation $y' = f(y)$ the slope depends only on height, so the direction field is the same on every vertical line. All the information fits on a single y-axis — the **phase line** — marked with the equilibria and arrows showing the sign of f between them.

Stability of an equilibrium of $y' = f(y)$

Let f be continuously differentiable and $f(y^*) = 0$.

- If $f'(y^*) < 0$, the equilibrium is **asymptotically stable**: solutions starting close enough to y^* tend to y^* as $t \to \infty$.
- If $f'(y^*) > 0$, it is **unstable**: nearby solutions move away.
- If $f'(y^*) = 0$, the test is inconclusive; look at the sign of f on each side.

Proof sketch (linearisation). Put $y = y^* + \eta$ with η small. Taylor's theorem (Ch. 4) gives $\eta' = f(y^* + \eta) = f'(y^*)\,\eta + O(\eta^2)$. Dropping the quadratic term, $\eta \approx \eta_0\, e^{f'(y^*)\,t}$, which decays if $f'(y^*) < 0$ and grows if $f'(y^*) > 0$. The quantity $-1/f'(y^*)$ is the *local time constant* of the equilibrium. Making the argument rigorous uses the fact that solutions cannot cross the equilibrium line (uniqueness, §11.7). □

Worked Example 11.2 — Phase line of a cubic

Analyse $y' = y - y^3$ without solving it.

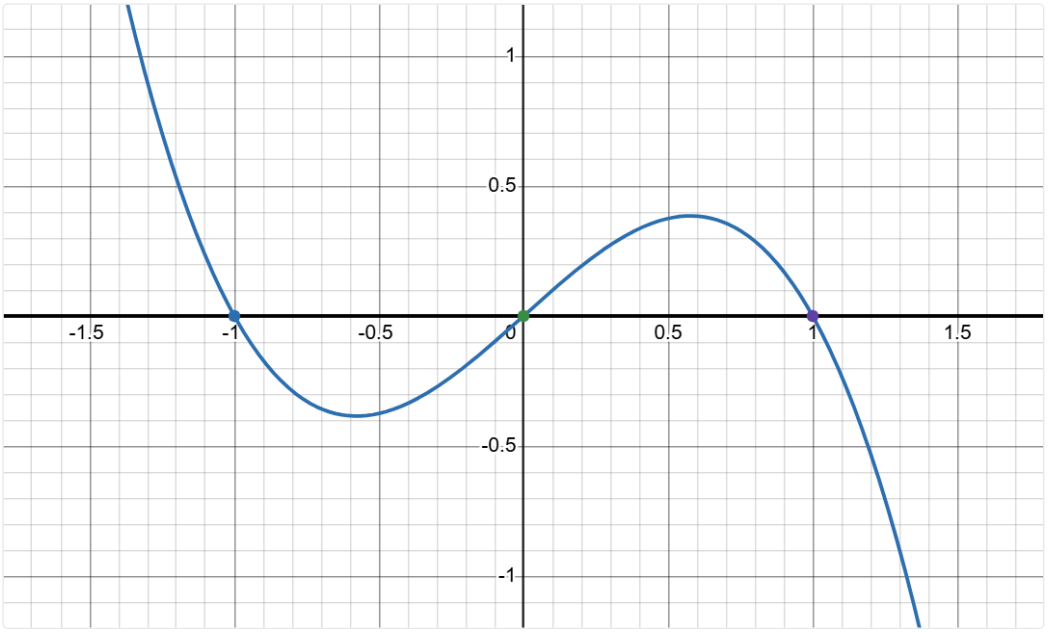
Step 1 (equilibria). $f(y) = y(1-y)(1+y) = 0$ gives $y^* = -1, 0, 1$.

Step 2 (linearise). $f'(y) = 1 - 3y^2$, so $f'(\pm 1) = -2 < 0$ (stable) and $f'(0) = 1 > 0$ (unstable).

Step 3 (signs). $f > 0$ on $(-\infty, -1)$ and $(0, 1)$; $f < 0$ on $(-1, 0)$ and $(1, \infty)$. So every solution with $y(0) > 0$ tends to $+1$, every solution with $y(0) < 0$ tends to -1, and only $y \equiv 0$ stays at zero.

Step 4 (time constant). Near $y^* = 1$, perturbations decay like e^{-2t}, so the local time constant is 0.5. Near 0 they grow like e^{t}.

This is the behaviour of a **bistable latch**: the cross-coupled inverter pair in an SRAM cell has two stable states and an unstable metastable point between them. A latch caught near the middle leaves it at a rate set by $f'(0)$ — the origin of the metastability time constant in synchroniser design.



The function $f(y) = y - y^3$ plotted against y (horizontal axis). Where the curve is above the axis solutions move right (increase); where it is below they move left. Zeros with negative slope attract, the zero with positive slope repels.

Exact equations

Write a first-order equation in **differential form**

$$M(t, y)\, dt + N(t, y)\, dy = 0,$$

which is equivalent to $y' = -M/N$. Suppose there is a function $\Phi(t, y)$ with $\Phi_t = M$ and $\Phi_y = N$. Then along any solution $y(t)$ the chain rule gives

$$\frac{d}{dt}\Phi\big(t, y(t)\big) = \Phi_t + \Phi_y\, y' = M + N y' = 0,$$

so Φ is constant along solutions and the solutions are the **level curves** $\Phi(t, y) = C$.

Test for exactness

Let M, N, M_y, N_t be continuous on a rectangle (or any simply connected region). Then $M\,dt + N\,dy$ is the differential of some Φ — the equation is **exact** — if and only if

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial t}.$$

Necessity is just equality of mixed partials, $\Phi_{ty} = \Phi_{yt}$. Sufficiency is the construction below. This is exactly the test for a conservative two-dimensional vector field (M, N) in Ch. 7, and Φ is its potential.

Construction. Integrate M in t holding y fixed: $\Phi = \int M\,dt + g(y)$. Differentiate in y, set equal to N, and solve for $g'(y)$; exactness guarantees that g' comes out independent of t.

Worked Example 11.3 — An exact equation

Solve $(2ty + 1)\,dt + (t^2 + 3y^2)\,dy = 0$ with $y(1) = 1$.

Step 1 (test). $M_y = 2t$ and $N_t = 2t$. Exact. ✓

Step 2 (integrate M). $\Phi = \int (2ty + 1)\,dt = t^2y + t + g(y)$.

Step 3 (match N). $\Phi_y = t^2 + g'(y) = t^2 + 3y^2$, so $g' = 3y^2$ and $g = y^3$.

Step 4 (solution). $t^2y + t + y^3 = C$. The condition gives $1 + 1 + 1 = 3$, so the solution is the implicit curve $t^2y + t + y^3 = 3$.

Check. $d(t^2y + t + y^3) = (2ty + 1)\,dt + (t^2 + 3y^2)\,dy$. ✓ Numerically, at $t = 2$ the curve gives $y^3 + 4y - 1 = 0$, whose real root is $y \approx 0.2463$; implicit differentiation predicts slope $-M/N = -(2 \cdot 2 \cdot 0.2463 + 1)/(4 + 3 \cdot 0.0607) \approx -0.474$, which matches a finite-difference slope of the root as t varies.

Integrating factors for non-exact equations

If $M_y \neq N_t$, multiplying by a suitable nonzero function $\mu(t, y)$ may make $\mu M\,dt + \mu N\,dy = 0$ exact. The exactness condition for $\mu M, \mu N$ is a PDE for μ, usually harder than the original problem, but two special cases are routine.

Integrating factors depending on one variable

- If $\dfrac{M_y - N_t}{N}$ depends on t only, call it $R(t)$; then $\mu(t) = e^{\int R(t)\,dt}$.
- If $\dfrac{N_t - M_y}{M}$ depends on y only, call it $S(y)$; then $\mu(y) = e^{\int S(y)\,dy}$.

Derivation of the first case. With $\mu = \mu(t)$, exactness of $\mu M\,dt + \mu N\,dy$ requires $(\mu M)_y = (\mu N)_t$, i.e. $\mu M_y = \mu' N + \mu N_t$, i.e. $\mu'/\mu = (M_y - N_t)/N$. This is consistent only if the right side is a function of t alone, and then $\ln \mu = \int R\,dt$. The second case is symmetric. □

Worked Example 11.4 — Making an equation exact

Solve $(3ty + y^2)\,dt + (t^2 + ty)\,dy = 0$ for $t > 0$.

Step 1 (test). $M_y = 3t + 2y$, $N_t = 2t + y$. Not exact.

Step 2 (look for $\mu(t)$). $\dfrac{M_y - N_t}{N} = \dfrac{t + y}{t(t + y)} = \dfrac{1}{t}$, a function of t only. So $\mu = e^{\int dt/t} = t$.

Step 3 (exact form). $(3t^2y + ty^2)\,dt + (t^3 + t^2y)\,dy = 0$. Now $M_y = 3t^2 + 2ty = N_t$. ✓

Step 4 (potential). $\Phi = \int (3t^2y + ty^2)\,dt = t^3y + \tfrac{1}{2}t^2y^2 + g(y)$, and $\Phi_y = t^3 + t^2y + g'(y)$ forces $g' = 0$. The solution is

$$t^3y + \tfrac{1}{2}t^2y^2 = C.$$

Step 5 (explicit form). This is quadratic in y: $y = -t \pm \sqrt{t^2 + 2C/t^2}$.

Check. Take $C = 1/2$ and the $+$ root: at $t = 1$, $y = -1 + \sqrt{2} = 0.4142$. The ODE slope is $-M/N = -(3(0.4142) + 0.1716)/(1 + 0.4142) = -1.0000$; differentiating the explicit formula, $y' = -1 + (t - 2C/t^3)/\sqrt{t^2 + 2C/t^2} = -1 + 0/\sqrt{2} = -1$. ✓

Common pitfall — multiplying can add or remove solutions

An integrating factor that vanishes or blows up somewhere (here $\mu = t$ at $t = 0$) can introduce spurious solutions or hide genuine ones along that curve. State the region ($t > 0$ above) and check the curves where $\mu = 0$ or $\mu = \infty$ separately against the original equation.

Engineering note — conserved quantities

An exact equation says that some function $\Phi(t, y)$ is conserved along trajectories. In circuits and mechanics this is usually an **energy**: for a lossless LC tank $\tfrac{1}{2}Li^2 + \tfrac{1}{2}Cv^2$ is constant, and writing dv/di from the two element laws gives an exact equation whose level curves are the energy ellipses. Spotting a conserved quantity is often the fastest route to the qualitative behaviour of a nonlinear system.

11.2 Separable equations

Motivation

Separable equations are the first-order equations whose solution reduces to *two ordinary integrals*. They cover every autonomous first-order equation $y' = f(y)$ — a capacitor discharging into any nonlinear load, a saturating population, a cooling body — and many time-varying ones. They are also the template for the substitution methods that follow: a clever change of variable often turns an awkward equation into a separable one.

Separable equation

A first-order ODE is **separable** if it can be written

$$\frac{dy}{dt} = g(t)\,h(y),$$

the product of a function of t alone and a function of y alone.

The method and why it works

Solution of a separable equation

Let g be continuous on an interval I and h continuous with $h \neq 0$ on an interval J. Let H be an antiderivative of $1/h$ on J and G an antiderivative of g on I. Then $y(t)$ with values in J solves $y' = g(t)h(y)$ if and only if

$$H\big(y(t)\big) = G(t) + C$$

for some constant C. Informally, $\displaystyle\int \frac{dy}{h(y)} = \int g(t)\,dt + C$.

Proof. If y solves the equation, the chain rule gives $\dfrac{d}{dt}H(y(t)) = H'(y)\,y' = \dfrac{y'}{h(y)} = g(t) = G'(t)$, so $H(y) - G$ is constant. Conversely, differentiating $H(y) = G + C$ reproduces the equation. Because $H' = 1/h$ has one sign on J, H is strictly monotone and can in principle be inverted to give $y = H^{-1}(G(t) + C)$ explicitly. □

The informal manipulation "multiply by dt, divide by $h(y)$" is therefore legitimate — it is shorthand for the chain-rule argument.

Procedure.

1. Find all constant solutions: every root y^* of $h(y^*) = 0$ gives $y \equiv y^*$.
2. On each interval where $h \neq 0$, separate and integrate both sides.
3. Apply the initial condition, solve for y if possible, and state the interval of validity.

Common pitfall — lost solutions

Dividing by $h(y)$ discards every constant solution $y = y^*$ with $h(y^*) = 0$. They are often the equilibria — the most important solutions physically. Sometimes they are recovered by letting the constant take a special value (often $C = 0$); sometimes they are singular solutions that no value of C reproduces. Always list them in step 1.

Worked Example 11.5 — A Gaussian solution

Solve $y' = -2ty$ with $y(0) = 3$.

Step 1. $h(y) = y$ vanishes at $y = 0$, so $y \equiv 0$ is a solution.

Step 2. For $y \neq 0$: $\dfrac{dy}{y} = -2t\,dt$, so $\ln|y| = -t^2 + C_1$, i.e. $|y| = e^{C_1}e^{-t^2}$. Removing the absolute value, $y = Ce^{-t^2}$ with $C = \pm e^{C_1} \neq 0$; allowing $C = 0$ restores the lost solution.

Step 3. $y(0) = C = 3$, so $y = 3e^{-t^2}$, valid for all t.

Check. $y' = -6te^{-t^2} = -2t\,(3e^{-t^2})$. ✓ At $t = 1$, $y = 3e^{-1} = 1.1036$.

Worked Example 11.6 — Capacitor discharging through a square-law device

A capacitor C charged to V_0 discharges through a device whose current is $i = kv^2$ (a crude model of a space-charge-limited or square-law load). KCL at the capacitor node gives $C\,\dot v = -kv^2$, $v(0) = V_0 > 0$. Find $v(t)$ and compare with a resistor of the same initial current.

Step 1. $v \equiv 0$ is a solution; since $V_0 > 0$ and solutions cannot cross it, $v > 0$ for all t.

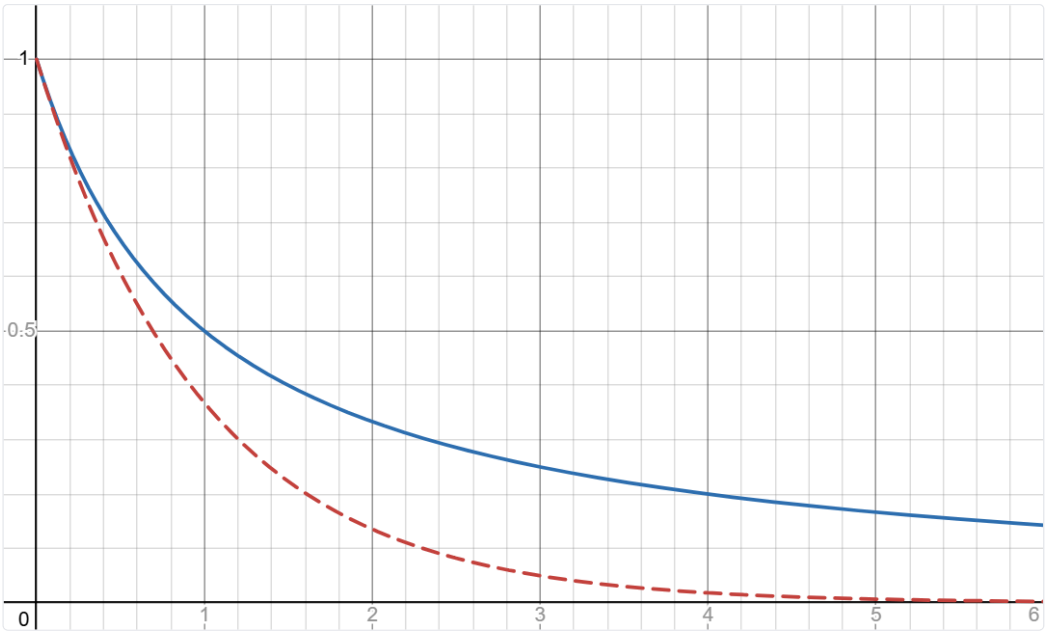
Step 2. $\dfrac{dv}{v^2} = -\dfrac{k}{C}\,dt$, so $-\dfrac{1}{v} = -\dfrac{k}{C}t + C_1$, and $v(0) = V_0$ gives $C_1 = -1/V_0$.

Step 3. Solving for v:

$$v(t) = \frac{V_0}{1 + t/T}, \qquad T = \frac{C}{kV_0}.$$

Units. k is in $\mathrm{A/V^2}$ and C in $\mathrm{A\,s/V}$, so $T = C/(kV_0)$ has units $(\mathrm{A\,s/V})/(\mathrm{A/V^2 \cdot V}) = \mathrm{s}$. ✓

Comparison. A resistor drawing the same initial current kV_0^2 has $R = 1/(kV_0)$ and gives $v = V_0e^{-t/RC} = V_0e^{-t/T}$, the same initial slope. At $t = 5T$ the resistor has left $V_0e^{-5} = 0.0067\,V_0$ while the square-law device has left $V_0/6 = 0.167\,V_0$. The nonlinear element changes the *form* of the transient — an algebraic $1/t$ tail instead of an exponential — not just its speed.



Normalised discharge v/V_0 against t/T: square-law load (blue, $1/(1+t/T)$) and a resistor with the same initial current (red dashed, $e^{-t/T}$). Same initial slope, very different tails.

Worked Example 11.7 — Capacitor discharging through a diode

A capacitor $C = 1$ nF charged to $V_0 = 0.7$ V discharges through an ideal-exponential diode, $i = I_S\left(e^{v/V_T} - 1\right)$ with $I_S = 10^{-14}$ A and $V_T = 25$ mV. Find $v(t)$ and the times at which v reaches 0.6, 0.5, 0.4 and 0.3 V.

Step 1 (set up). KCL: $C\,\dot v = -I_S\left(e^{v/V_T} - 1\right)$. Autonomous, hence separable; $v \equiv 0$ is the only equilibrium.

Step 2 (integrate). Multiply numerator and denominator by e^{-v/V_T}:

$$\int \frac{dv}{e^{v/V_T} - 1} = \int \frac{e^{-v/V_T}\,dv}{1 - e^{-v/V_T}} = V_T \ln\left(1 - e^{-v/V_T}\right).$$

So $V_T \ln\left(1 - e^{-v/V_T}\right) = -\dfrac{I_S}{C}t + C_1$.

Step 3 (solve). With $\tau = CV_T/I_S$ and the initial condition,

$$1 - e^{-v/V_T} = \left(1 - e^{-V_0/V_T}\right)e^{-t/\tau}, \qquad v(t) = -V_T \ln\left[1 - \left(1 - e^{-V_0/V_T}\right)e^{-t/\tau}\right].$$

Step 4 (numbers). $\tau = 10^{-9} \cdot 0.025/10^{-14} = 2500$ s. Inverting, $t = -\tau \ln\left[(1 - e^{-v/V_T})/(1 - e^{-V_0/V_T})\right]$:

v (V)	0.6	0.5	0.4	0.3
t	92.6 ns	5.15 µs	0.281 ms	15.4 ms

Interpretation. Each 0.1 V drop takes about $e^{0.1/V_T} = e^4 \approx 55$ times longer than the previous one. While $v \gg V_T$ the solution is approximately $v \approx -V_T \ln\left(e^{-V_0/V_T} + t/\tau\right)$ — a *logarithmic* decay. The huge τ governs only the final approach once $v \lesssim V_T$.

Check. A stiff numerical integration (Radau, relative tolerance 10^{-10}) of the original ODE from 0.7 V for 15.36 ms ends at 0.30000 V. ✓

Equations reducible to separable form

Two substitutions cover most textbook cases.

(a) $y' = F(y/t)$ — "homogeneous of degree zero". The right side is unchanged when t and y are scaled together. Put $v = y/t$, so $y = vt$ and $y' = v + tv'$. The equation becomes

$$t\,\frac{dv}{dt} = F(v) - v,$$

which is separable in v and t.

(b) $y' = G(at + by + c)$. Put $u = at + by + c$. Then $u' = a + b\,G(u)$, which is autonomous and therefore separable. For example $y' = (t + y)^2$ becomes $u' = 1 + u^2$ with $u = t + y$, so $u = \tan(t + C)$ and $y = \tan(t + C) - t$.

Worked Example 11.8 — A scale-invariant equation

Solve $y' = \dfrac{t^2 + y^2}{ty}$ with $y(1) = 2$, for $t > 0$.

Step 1 (recognise). Dividing top and bottom by t^2, $y' = \dfrac{1 + (y/t)^2}{y/t} = F(y/t)$ with $F(v) = (1 + v^2)/v$.

Step 2 (substitute). $tv' = \dfrac{1 + v^2}{v} - v = \dfrac{1}{v}$, so $v\,dv = \dfrac{dt}{t}$.

Step 3 (integrate). $\tfrac{1}{2}v^2 = \ln t + C$, i.e. $y^2 = t^2(2\ln t + 2C)$.

Step 4 (initial condition). $y(1) = 2$ gives $4 = 2C$, so $y = t\sqrt{2\ln t + 4}$ (positive root, since $y(1) > 0$).

Step 5 (interval). The square root needs $2\ln t + 4 > 0$, i.e. $t > e^{-2} \approx 0.135$. At $t = e^{-2}$ the solution reaches $y = 0$, where the equation itself is singular. The solution lives on (e^{-2}, ∞).

Check. At $t = e$: $y = e\sqrt{6} = 6.658$. The ODE gives $y' = (e^2 + 6e^2)/(e \cdot e\sqrt{6}) = 7/\sqrt{6} = 2.858$; differentiating the formula, $y' = \sqrt{2\ln t + 4} + 1/\sqrt{2\ln t + 4} = \sqrt{6} + 1/\sqrt{6} = 2.858$. ✓

The logistic equation

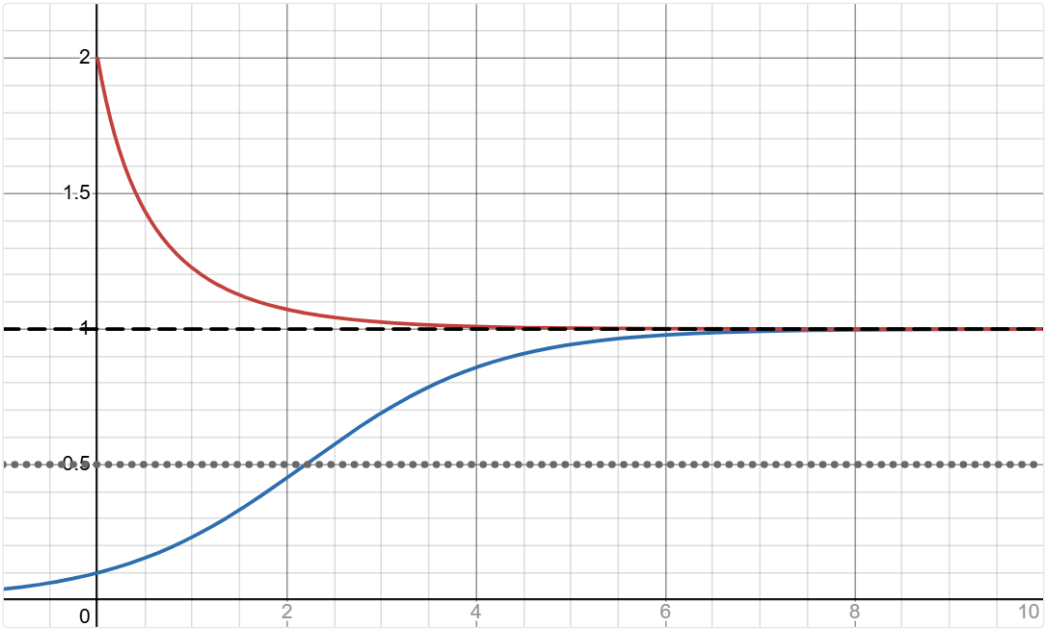
The logistic equation $y' = ry(1 - y/K)$, with growth rate $r > 0$ and capacity $K > 0$, is the standard model of growth that saturates. Its equilibria are $y = 0$ (unstable, $f'(0) = r$) and $y = K$ (stable, $f'(K) = -r$). For $0 < y < K$, partial fractions (Ch. 5) give

$$\int \frac{K\,dy}{y(K - y)} = \int \left(\frac{1}{y} + \frac{1}{K - y}\right) dy = \ln\frac{y}{K - y} = rt + C,$$

and solving with $y(0) = y_0$,

$$y(t) = \frac{K}{1 + \left(\dfrac{K}{y_0} - 1\right)e^{-rt}}.$$

The curve is an S-shape with its steepest point (inflection) at $y = K/2$, where $y'' = f'(y)\,y' = 0$ because $f'(y) = r(1 - 2y/K)$ vanishes there. Logistic behaviour appears in soft-limiting amplifiers, in the build-up of oscillation amplitude in a self-starting oscillator, and in technology-adoption curves (Ch. 25).



Logistic solutions with $r = 1$, $K = 1$: from $y_0 = 0.1$ (blue, S-shaped, steepest at $y = K/2$) and from $y_0 = 2$ (red, decaying to K). Both approach the stable equilibrium $y = K$.

Engineering note — when separation is the right tool

Any single-state circuit with constant sources is autonomous: $C\,\dot{v} = I - g(v)$. It is always separable, so the time to reach a voltage, $t(v) = \int_{V_0}^{v} C\,dv/\big(I - g(v)\big)$, can be written down even when the integral has no closed form — evaluate it numerically. This is how the delay of a nonlinear RC timing stage, or the droop time of a hold capacitor through a leakage diode, is computed in practice.

11.3 Linear first-order equations

Motivation

Linear first-order equations are the one large class of first-order equations that can *always* be solved in closed form (up to evaluating integrals). They describe every single-storage linear circuit — including those with time-varying parameters such as a switched-capacitor stage, a varactor, a thermistor-dependent resistance or a modulated source — and their solution formula already displays the structure of all linear systems: response = (decaying effect of the initial state) + (weighted memory of the input).

Linear first-order ODE

The standard form is

$$y' + p(t)\,y = r(t),$$

with p and r continuous on an interval I. It is **homogeneous** if $r \equiv 0$ and **nonhomogeneous** otherwise. An equation $a_1(t)y' + a_0(t)y = b(t)$ is put in standard form by dividing by a_1, which is allowed only where $a_1 \neq 0$; points where $a_1 = 0$ are **singular points** of the equation.

The homogeneous equation

$y' + p(t)y = 0$ is separable: $dy/y = -p\,dt$, so

$$y_h(t) = C\,e^{-P(t)}, \qquad P(t) = \int p(t)\,dt.$$

Because e^{-P} is never zero, the homogeneous solution never changes sign: a solution that starts positive stays positive. For constant $p = 1/\tau$ this is the familiar $Ce^{-t/\tau}$.

Integrating factor

Solution of the linear first-order equation

Let p, r be continuous on I and $\mu(t) = e^{P(t)}$ with $P' = p$. Then every solution of $y' + py = r$ on I is

$$y(t) = \frac{1}{\mu(t)}\left[\int \mu(t)\,r(t)\,dt + C\right].$$

With the initial condition $y(t_0) = y_0$ and $P(t) = \int_{t_0}^{t} p(s)\,ds$, the unique solution is

$$y(t) = y_0\,e^{-P(t)} + \int_{t_0}^{t} e^{-[P(t)-P(s)]}\,r(s)\,ds,$$

and it exists on the **whole** interval I.

Derivation. The integrating factor is chosen so that the left side becomes an exact derivative. By the product rule, $(\mu y)' = \mu y' + \mu' y$. If $\mu' = p\mu$ — that is, $\mu = e^{P}$ — then $(\mu y)' = \mu(y' + py) = \mu r$. Integrating, $\mu y = \int \mu r\,dt + C$. For the definite form integrate from t_0 to t with $\mu(t_0) = 1$: $\mu(t)y(t) - y_0 = \int_{t_0}^{t} \mu(s)r(s)\,ds$, then divide by $\mu(t) = e^{P(t)}$. Every step is reversible, so there are no other solutions, and the integrals exist wherever p and r are continuous. □

(It is also the special case of §11.1's integrating factor: in differential form $(py - r)\,dt + dy = 0$, the test quantity $(M_y - N_t)/N = p(t)$ depends on t alone.)

The definite form deserves a careful reading:

- $y_0 e^{-P(t)}$ is the **zero-input response**: what the initial state does with no input.
- The integral is the **zero-state response**: each input value $r(s)$ at an earlier time s contributes $r(s)\,ds$, weighted by the factor $e^{-[P(t)-P(s)]}$ by which the system has "forgotten" it by time t.
- For constant $p = 1/\tau$ the weight is $e^{-(t-s)/\tau}$, which depends only on the elapsed time $t - s$, and the integral is a **convolution** of r with $e^{-t/\tau}$. This is the first appearance of the impulse response; Ch. 12 and Ch. 14 develop it.

Whatever the form, the general solution is $y = Ce^{-P} + y_p$: a homogeneous solution plus *one* particular solution. This is the first instance of the structure theorem of §11.6.

Worked Example 11.9 — Exponential forcing

Solve $y' + 2y = e^{-t}$, $y(0) = 0$.

Step 1. $p = 2$, so $\mu = e^{2t}$.

Step 2. $(e^{2t}y)' = e^{2t}e^{-t} = e^{t}$, hence $e^{2t}y = e^{t} + C$ and $y = e^{-t} + Ce^{-2t}$.

Step 3. $y(0) = 1 + C = 0$, so $C = -1$:

$$y(t) = e^{-t} - e^{-2t}.$$

Check. $y' = -e^{-t} + 2e^{-2t}$ and $y' + 2y = -e^{-t} + 2e^{-2t} + 2e^{-t} - 2e^{-2t} = e^{-t}$. ✓

Shape. The response rises from zero, peaks where $y' = 0$, i.e. $e^{-t} = 2e^{-2t}$, so $t = \ln 2 \approx 0.693$ with $y = \tfrac{1}{2} - \tfrac{1}{4} = \tfrac{1}{4}$, then decays like the slower exponential e^{-t}.

The solution $y = e^{-t} - e^{-2t}$ of Example 11.9: a two-time-constant pulse, typical of a first-order stage driven by the decaying output of another stage.

Worked Example 11.10 — Variable coefficient and a singular point

Solve $t\,y' + 2y = 4t^2$ with $y(1) = 2$.

Step 1 (standard form). Dividing by t (allowed for $t \neq 0$): $y' + \dfrac{2}{t}y = 4t$. The coefficient $p = 2/t$ is continuous on $(0, \infty)$, which contains $t_0 = 1$, so the solution exists and is unique on $(0, \infty)$.

Step 2. $\mu = e^{\int 2/t\,dt} = e^{2\ln t} = t^2$.

Step 3. $(t^2 y)' = 4t^3$, so $t^2 y = t^4 + C$ and $y = t^2 + C/t^2$.

Step 4. $y(1) = 1 + C = 2$ gives $C = 1$: $y = t^2 + t^{-2}$.

Check. $t\,y' + 2y = t(2t - 2t^{-3}) + 2t^2 + 2t^{-2} = 4t^2$. ✓

Remark. Every solution except the one with $C = 0$ blows up at the singular point $t = 0$. The theorem promises existence only on $(0, \infty)$; the coefficient's singularity, not the solution formula, sets the interval.

Worked Example 11.11 — Tracking a ramp

An RC low-pass stage with time constant τ is driven by a ramp: $\tau\dot{v} + v = kt$, $v(0) = 0$. Find $v(t)$ and the steady tracking error.

Step 1. Standard form $\dot{v} + v/\tau = kt/\tau$, $\mu = e^{t/\tau}$.

Step 2. $\left(e^{t/\tau}v\right)' = \dfrac{k}{\tau}te^{t/\tau}$. Integrating by parts, $\int te^{t/\tau}\,dt = \tau te^{t/\tau} - \tau^2 e^{t/\tau}$, so $e^{t/\tau}v = k(t-\tau)e^{t/\tau} + C$.

Step 3. $v(0) = -k\tau + C = 0$ gives $C = k\tau$:

$$v(t) = k(t - \tau) + k\tau\, e^{-t/\tau}.$$

Check. $\tau\dot{v} + v = \tau(k - ke^{-t/\tau}) + kt - k\tau + k\tau e^{-t/\tau} = kt$. ✓

Interpretation. After a few time constants the output is a ramp of the same slope, delayed by exactly τ: the tracking error $kt - v \to k\tau$. With $k = 1$ V/ms and $\tau = 0.2$ ms the error settles at 0.2 V; at $t = 1$ ms it is $0.2(1 - e^{-5}) = 0.1987$ V. This lag is why a first-order sample-and-hold or tracking loop always trails a ramp.

Worked Example 11.12 — A time-varying capacitor

A varactor whose capacitance grows linearly, $C(t) = C_0(1 + t/T)$, is charged from 0 V through a resistor R by a constant source V_s. Take $RC_0 = T$. Find $v(t)$.

Step 1 (model). For a time-varying capacitor the charge is $q = C(t)v$, and the current is $i = \dot{q} = C\dot{v} + \dot{C}v$, not just $C\dot{v}$. KVL gives $Ri + v = V_s$:

$$RC_0\Big(1 + \frac{t}{T}\Big)\dot{v} + \Big(\frac{RC_0}{T} + 1\Big)v = V_s.$$

Step 2 (dimensionless time). With $s = t/T$ and $RC_0 = T$, this becomes $(1 + s)\,v' + 2v = V_s$, where $' = d/ds$.

Step 3 (integrating factor). Standard form $v' + \dfrac{2}{1+s}v = \dfrac{V_s}{1+s}$, so $\mu = (1+s)^2$ and $\big((1+s)^2 v\big)' = (1+s)V_s$.

Step 4. $(1+s)^2 v = \frac{1}{2}V_s(1+s)^2 + K$; $v(0) = 0$ gives $K = -V_s/2$:

$$v(t) = \frac{V_s}{2}\left[1 - \frac{1}{(1 + t/T)^2}\right].$$

Interpretation. The voltage approaches $V_s/2$, not V_s, and algebraically rather than exponentially. Physically, holding v constant on a growing capacitor still needs a current $\dot{C}v = C_0 v/T$; at $v = V_s/2$ the resistor drop $RC_0 v/T = v$ supplies exactly that. Time-varying elements break the intuition "a capacitor eventually charges to the source" — which is the principle behind parametric amplifiers and charge pumps.

Check. $(1+s)v' + 2v = (1+s)\cdot V_s(1+s)^{-3} + V_s - V_s(1+s)^{-2} = V_s$. ✓

Bernoulli equations

Bernoulli equation

$$y' + p(t)\,y = q(t)\,y^n, \qquad n \neq 0, 1.$$

(For $n = 0$ or 1 it is already linear.)

Divide by y^n and put $v = y^{1-n}$, so $v' = (1-n)y^{-n}y'$:

$$y^{-n}y' + p\,y^{1-n} = q \quad\Longrightarrow\quad v' + (1-n)\,p(t)\,v = (1-n)\,q(t),$$

which is linear in v. If $n > 0$, $y \equiv 0$ is an extra solution lost by the division.

Worked Example 11.13 — Amplitude of a self-starting oscillator

Near its operating point the slowly varying amplitude $a(t)$ of many oscillators (van der Pol type) obeys $\dot{a} = \alpha a - \beta a^3$: linear growth from the negative-resistance element, cubic limiting from gain compression. Take $\alpha = \beta = 1$ and $a(0) = 1/2$.

Step 1 (recognise). $\dot{a} - a = -a^3$ is Bernoulli with $n = 3$. Put $v = a^{-2}$: $\dot{v} + (1-3)(-1)v = (1-3)(-1)$, i.e. $\dot{v} + 2v = 2$.

Step 2 (solve linear). $v = 1 + Ce^{-2t}$; $v(0) = a(0)^{-2} = 4$ gives $C = 3$.

Step 3 (back-substitute).

$$a(t) = \frac{1}{\sqrt{1 + 3e^{-2t}}}.$$

Check. As $t \to \infty$, $a \to 1 = \sqrt{\alpha/\beta}$, the stable equilibrium of $\dot{a} = a - a^3$ (Example 11.2). At $t = 1$: $a = 1/\sqrt{1 + 3e^{-2}} = 0.8433$. Direct differentiation confirms $\dot{a} = a - a^3$ symbolically. ✓

The amplitude grows like $e^{\alpha t}$ while small and saturates at $\sqrt{\alpha/\beta}$: the oscillator's steady amplitude is set by the ratio of small-signal gain to compression.

Riccati equations

Riccati equation

$$y' = q_0(t) + q_1(t)\,y + q_2(t)\,y^2.$$

Riccati equations generally have no elementary solution, but **if one particular solution y_1 is known**, the substitution $y = y_1 + 1/v$ turns the equation into a linear one for v:

$$v' = -\big(q_1 + 2q_2 y_1\big)v - q_2.$$

(Substitute, use the fact that y_1 satisfies the equation, and multiply by $-v^2$.) Matrix Riccati equations are central in optimal control (the LQR gain) and Kalman filtering, and the scalar case is their prototype.

Worked Example 11.14 — Riccati with a known solution

Solve $y' = 1 + t^2 - 2ty + y^2$, given that $y_1 = t$ is a solution.

Step 1 (verify y_1). $y_1' = 1$ and $1 + t^2 - 2t^2 + t^2 = 1$. ✓

Step 2 (substitute). Here $q_2 = 1$, $q_1 = -2t$, so $q_1 + 2q_2 y_1 = 0$ and the linear equation is $v' = -1$: $v = C - t$.

Step 3. $y = t + \dfrac{1}{C - t}$, plus the solution $y = t$ itself (the limit $C \to \infty$).

Check. $y' = 1 + (C-t)^{-2}$, and $1 + t^2 - 2ty + y^2 = 1 + (y-t)^2 = 1 + (C-t)^{-2}$. ✓ Each solution other than y_1 blows up at $t = C$ — another nonlinear finite escape.

Engineering note — the time constant

Any first-order linear time-invariant system — an RC or RL network, a thermal mass, a single-pole amplifier, a first-order sensor — reduces to $\tau \dot{y} + y = K\,u(t)$. The homogeneous part $e^{-t/\tau}$ falls to 36.8% in one time constant, 13.5% in two, 1.8% in four and under 1% in five. The rule "settled after 5τ" comes from this table. For time-varying coefficients the role of t/τ is played by $P(t) = \int p\,dt$, so the system "forgets" its initial state when P has grown by about 5.

Common pitfall — forgetting the standard form

The integrating factor is $e^{\int p\,dt}$ where p is the coefficient of y **after** the coefficient of y' has been made 1. For $t\,y' + 2y = 4t^2$ the factor is t^2, not e^{2t}. The same mistake in variation of parameters (§11.6) is the commonest error in second-order work.

11.4 Second-order ODEs

Motivation

Two independent energy stores — an inductor and a capacitor, a mass and a spring, an electric and a magnetic field — produce a second-order equation. Second order is the lowest order at which **oscillation** is possible, which is why the series RLC circuit, the tuned amplifier and the mechanical resonator are all second-order systems. It is also the order of the field equations of physics in one dimension (Poisson's equation, the transmission-line equations, Schrödinger's equation), which is where boundary-value problems (§11.8) come from.

Forms of a second-order equation

A second-order ODE is $F(t, y, y', y'') = 0$, or in normal form $y'' = f(t, y, y')$. A solution is fixed by **two** conditions — typically $y(t_0)$ and $y'(t_0)$ — because two integrations are needed. The most important class is the **linear** equation

$$a_2(t)\,y'' + a_1(t)\,y' + a_0(t)\,y = b(t),$$

which on any interval where $a_2 \neq 0$ can be divided through to give the **standard form**

$$y'' + p(t)\,y' + q(t)\,y = r(t).$$

It is convenient to name the left side as an operator: $L[y] = y'' + py' + qy$. The operator is **linear**: $L[c_1 y_1 + c_2 y_2] = c_1 L[y_1] + c_2 L[y_2]$, because differentiation and multiplication by a function are linear.

Existence and uniqueness for linear second-order IVPs

If p, q, r are continuous on an open interval I and $t_0 \in I$, then for any numbers y_0, y_1 there is exactly one solution of $y'' + py' + qy = r$ with $y(t_0) = y_0$, $y'(t_0) = y_1$, and it exists on all of I.

This is proved in §11.7 (by rewriting the equation as a first-order system). Everything in the structure theory below rests on it.

Superposition and the dimension of the solution space

Superposition and dimension

If y_1 and y_2 solve the homogeneous equation $L[y] = 0$ on I, so does every linear combination $c_1 y_1 + c_2 y_2$. The set of all solutions is a vector space (Ch. 9) of dimension exactly 2.

Proof. Closure under combinations is linearity of L. For the dimension, consider the map that sends a solution y to its initial data $\big(y(t_0), y'(t_0)\big) \in \mathbb{R}^2$. It is linear; it is onto by the existence theorem (every pair of initial data is achieved); and it is one-to-one by uniqueness (only $y \equiv 0$ has zero initial data). A linear bijection onto $\mathbb{R}^2$ means the solution space is isomorphic to $\mathbb{R}^2$. $\square$

So the general solution of $L[y] = 0$ is $y = c_1 y_1 + c_2 y_2$ for **any** two linearly independent solutions — a **fundamental set**, i.e. a basis.

Linear independence and the Wronskian

Two functions are linearly dependent on I if one is a constant multiple of the other there. For solutions this is tested with the **Wronskian**

$$W(y_1, y_2)(t) = \det \begin{pmatrix} y_1 & y_2 \\ y_1' & y_2' \end{pmatrix} = y_1 y_2' - y_1' y_2.$$

The determinant is exactly the one that appears when we try to fit initial conditions: solving $c_1 y_1(t_0) + c_2 y_2(t_0) = y_0$, $c_1 y_1'(t_0) + c_2 y_2'(t_0) = y_1$ for c_1, c_2 is possible for *every* right side precisely when this determinant is nonzero (Ch. 8).

Abel's formula and the Wronskian test

Let y_1, y_2 solve $y'' + p(t)y' + q(t)y = 0$ on I, with p, q continuous. Then

$$W(t) = W(t_0)\, \exp\!\left(- \int_{t_0}^{t} p(s)\, ds \right).$$

Consequently W is either **never zero** on I (and y_1, y_2 form a fundamental set) or **identically zero** (and they are dependent).

Proof. Differentiate: $W' = y_1 y_2'' - y_1'' y_2$ (the $y_1' y_2'$ terms cancel). Substituting $y_k'' = -p y_k' - q y_k$,

$$W' = y_1(-p y_2' - q y_2) - (-p y_1' - q y_1) y_2 = -p\,(y_1 y_2' - y_1' y_2) = -p\, W.$$

This is a first-order linear equation for W whose solution is Abel's formula (§11.3). The exponential is never zero, so $W(t)$ vanishes everywhere or nowhere. If $W \equiv 0$, pick t_0; the system for (c_1, c_2) with zero right side has a nontrivial solution, and $c_1 y_1 + c_2 y_2$ is then a solution with zero initial data, hence identically zero by uniqueness — the functions are dependent. $\square$

Abel's formula is useful even without knowing the solutions: it gives W directly from the coefficient p, which is the key ingredient in reduction of order and variation of parameters.

Common pitfall — the Wronskian test needs solutions

For arbitrary functions, $W \equiv 0$ does **not** imply dependence. On $(-1, 1)$, $f = t^2$ and $g = t|t|$ are independent (neither is a constant multiple of the other on the whole interval), yet $W(f, g) = 0$ for every t. The "never or always zero" dichotomy is a property of *solutions of one linear equation with continuous coefficients*; it tells you that t^2 and $t|t|$ cannot both solve such an equation on an interval containing 0.

Reduction of order

If one nonzero solution y_1 of $y'' + py' + qy = 0$ is known, a second one can always be found.

Reduction of order

$$y_2(t) = y_1(t) \int \frac{e^{-\int p\, dt}}{y_1(t)^2}\, dt$$

is a second solution, independent of y_1, on any interval where $y_1 \neq 0$.

Derivation. Seek $y_2 = v(t)\, y_1(t)$. Then $y_2' = v' y_1 + v y_1'$ and $y_2'' = v'' y_1 + 2v' y_1' + v y_1''$. Substituting,

$$L[v y_1] = v'' y_1 + v'(2y_1' + p y_1) + v \underbrace{(y_1'' + p y_1' + q y_1)}_{=0} = 0.$$

The terms in v itself cancel — this is why the method works — leaving a *first-order* linear equation for $w = v'$: $w' + (2y_1'/y_1 + p)w = 0$. Its integrating factor is $y_1^2 e^{\int p\, dt}$, so $w = e^{-\int p\, dt}/y_1^2$, and $v = \int w\, dt$. Since v is not constant, y_2/y_1 is not constant and the solutions are independent. (Alternatively: Abel's formula gives $W = y_1 y_2' - y_1' y_2 = y_1^2 (y_2/y_1)' = e^{-\int p}$, which is the same equation.) $\square$

Worked Example 11.15 — Reduction of order for a Legendre equation

$y_1 = t$ solves $(1-t^2)y'' - 2ty' + 2y = 0$ on $-1 < t < 1$ (Legendre's equation with $n = 1$). Find a second solution.

Step 1 (verify y_1). $y_1'' = 0$, and $-2t \cdot 1 + 2t = 0$. ✓

Step 2 (standard form). $p = -\dfrac{2t}{1-t^2}$, so $-\int p\,dt = \int \dfrac{2t}{1-t^2}\,dt = -\ln(1-t^2)$ and $e^{-\int p\,dt} = \dfrac{1}{1-t^2}$.

Step 3 (integrate). By partial fractions,

$$\frac{1}{t^2(1-t^2)} = \frac{1}{t^2} + \frac{1}{1-t^2}, \qquad \int \left(\frac{1}{t^2} + \frac{1}{1-t^2}\right) dt = -\frac{1}{t} + \frac{1}{2}\ln\frac{1+t}{1-t}.$$

Step 4.

$$y_2 = t\left(-\frac{1}{t} + \frac{1}{2}\ln\frac{1+t}{1-t}\right) = \frac{t}{2}\ln\frac{1+t}{1-t} - 1.$$

Although the integration was done on intervals avoiding $t = 0$, the result is smooth across 0 and solves the equation on all of $(-1, 1)$; it is the Legendre function of the second kind Q_1.

Check. Symbolic substitution gives $(1-t^2)y_2'' - 2ty_2' + 2y_2 = 0$. Numerically at $t = 0.5$: $y_2 = 0.25\ln 3 - 1 = -0.72535$. Abel predicts $W = C/(1-t^2)$, and indeed $W(t, y_2) = ty_2' - y_2 = 1/(1-t^2)$, which at $t = 0.5$ is 1.3333. ✓

y_2 blows up logarithmically at $t = \pm 1$, the singular points where $a_2 = 1 - t^2$ vanishes. This is why only the polynomial solution $P_1 = t$ is admissible in physical problems on a sphere, where $t = \cos\theta$ reaches ± 1 at the poles (Ch. 13).

Cauchy–Euler (equidimensional) equations

The most important variable-coefficient equation with elementary solutions is

$$t^2 y'' + a\,t\,y' + b\,y = 0, \qquad t > 0,$$

with constants a, b. Each term scales the same way under $t \to \lambda t$ (each derivative brings a factor $1/t$ that the power of t cancels), so a power $y = t^m$ should work. Substituting, $t^2 m(m-1)t^{m-2} + a\,t\,mt^{m-1} + bt^m = t^m[m(m-1) + am + b]$, giving the **indicial equation**

$$m^2 + (a-1)m + b = 0.$$

Why it works — the substitution $t = e^x$. Put $x = \ln t$. Then $\dfrac{dy}{dt} = \dfrac{1}{t}\dfrac{dy}{dx}$ and $\dfrac{d^2y}{dt^2} = \dfrac{1}{t^2}\left(\dfrac{d^2y}{dx^2} - \dfrac{dy}{dx}\right)$, so $ty' = \dot y$ and $t^2y'' = \ddot y - \dot y$ (dots meaning d/dx). The equation becomes the constant-coefficient equation

$$\ddot y + (a-1)\dot y + by = 0,$$

whose characteristic equation is exactly the indicial equation, and $e^{mx} = t^m$. The three cases of a constant-coefficient equation (Ch. 12) translate directly:

Roots of $m^2 + (a-1)m + b = 0$	**Fundamental set on $t > 0$**
real, distinct $m_1 \neq m_2$	$t^{m_1},\ t^{m_2}$
repeated m	$t^m,\ t^m \ln t$
complex $\alpha \pm j\beta$	$t^\alpha \cos(\beta \ln t),\ t^\alpha \sin(\beta \ln t)$

For $t < 0$ replace t by $|t|$. The point $t = 0$ is a singular point, and solutions typically blow up or lose smoothness there.

Worked Example 11.16 — Real roots, cross-checked by reduction of order

Solve $t^2y'' - 2ty' + 2y = 0$ for $t > 0$, and check with Abel's formula.

Step 1. $a = -2$, $b = 2$: $m^2 - 3m + 2 = (m-1)(m-2) = 0$, so $y = c_1 t + c_2 t^2$.

Step 2 (reduction from $y_1 = t$). Standard form has $p = -2/t$, so $e^{-\int p\,dt} = t^2$ and $y_2 = t\int t^2/t^2\,dt = t^2$. ✓

Step 3 (Wronskian). $W = t \cdot 2t - 1 \cdot t^2 = t^2 \neq 0$. Abel: $W \propto e^{\int 2/t\,dt} = t^2$. ✓

Worked Example 11.17 — Complex indicial roots

Solve $t^2y'' + ty' + 4y = 0$ with $y(1) = 1, y'(1) = 0$.

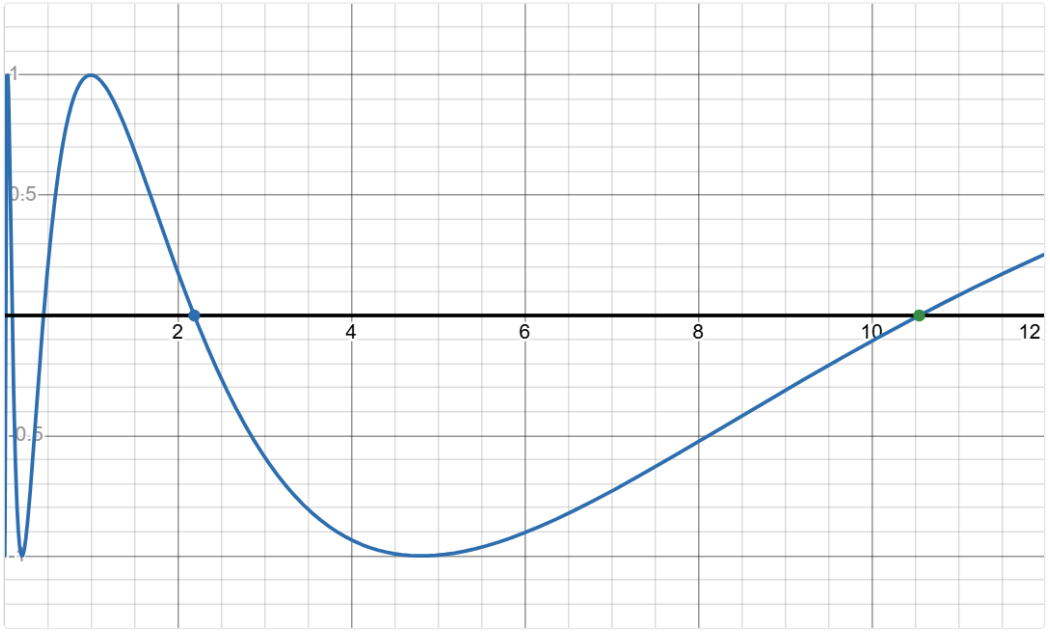
Step 1. $a = 1, b = 4$: $m^2 + 4 = 0$, so $m = \pm 2j$ ($\alpha = 0, \beta = 2$).

Step 2. $y = c_1\cos(2\ln t) + c_2\sin(2\ln t)$, and $y' = \dfrac{2}{t}\big[-c_1\sin(2\ln t) + c_2\cos(2\ln t)\big]$.

Step 3. At $t = 1$ ($\ln t = 0$): $c_1 = 1$ and $2c_2 = 0$. So $y = \cos(2\ln t)$.

Check. $y' = -\dfrac{2}{t}\sin(2\ln t)$, $y'' = \dfrac{2}{t^2}\sin(2\ln t) - \dfrac{4}{t^2}\cos(2\ln t)$. Then $t^2y'' + ty' + 4y = 2\sin - 4\cos - 2\sin + 4\cos = 0$. ✓

Shape. The solution oscillates in $\ln t$, not in t: its zeros are at $t = e^{\pi/4} = 2.193$, $e^{3\pi/4} = 10.55$, $e^{5\pi/4} = 50.75$, ... — equally spaced on a logarithmic axis. Equations of this type arise for fields in regions bounded by coaxial cylinders or wedges, where there is no natural length scale.



$y = \cos(2\ln t)$ from Example 11.17: oscillation whose period grows in proportion to t, the signature of a scale-invariant (Cauchy–Euler) equation.

Worked Example 11.18 — A repeated indicial root

Solve $t^2y'' - ty' + y = 0, t > 0$.

Step 1. $a = -1, b = 1$: $m^2 - 2m + 1 = (m-1)^2$, so $m = 1$ is a double root.

Step 2. $y = (c_1 + c_2\ln t)\,t$.

Check by reduction of order. $p = -1/t$, $e^{-\int p} = t$, so $y_2 = t\int t/t^2\,dt = t\ln t$. ✓ Direct check: $(t\ln t)' = \ln t + 1$, $(t\ln t)'' = 1/t$; $t^2/t - t(\ln t + 1) + t\ln t = 0$. ✓

Nonlinear second-order equations: two reductions

Nonlinear second-order equations rarely have closed-form solutions, but two structural features reduce the order by one.

- y **missing**, $F(t, y', y'') = 0$. Put $v = y'$; then $F(t, v, v') = 0$ is first order. Integrate v afterwards to get y.
- t **missing (autonomous)**, $F(y, y', y'') = 0$. Put $v = y'$ and regard v as a function of y. By the chain rule $y'' = \dfrac{dv}{dt} = \dfrac{dv}{dy}\dfrac{dy}{dt} = v\dfrac{dv}{dy}$, so $F\left(y, v, v\dfrac{dv}{dy}\right) = 0$ is first order in the variables (y, v) — an equation in the **phase plane** (§11.9).

For a conservative system $y'' = -U'(y)$ the second reduction gives $v\,dv = -U'(y)\,dy$, i.e. the **energy integral** $\frac{1}{2}v^2 + U(y) = E$: kinetic plus potential energy is constant.

Worked Example 11.19 — The pendulum energy integral

A pendulum obeys $\ddot\theta + (g/\ell)\sin\theta = 0$. It is released from rest at $\theta_0 = 90^\circ$ with $g/\ell = 9.81\ \text{s}^{-2}$. Find the angular speed at the bottom.

Step 1 (t missing). With $\omega = \dot\theta$ as a function of θ: $\omega\,\dfrac{d\omega}{d\theta} = -\dfrac{g}{\ell}\sin\theta$.

Step 2 (separate). $\tfrac12\omega^2 = \dfrac{g}{\ell}\cos\theta + E$. At release $\omega = 0$, $\theta = \theta_0$, so $E = -(g/\ell)\cos\theta_0$:

$$\omega^2 = \frac{2g}{\ell}\big(\cos\theta - \cos\theta_0\big).$$

Step 3. At $\theta = 0$: $\omega = \sqrt{2\cdot 9.81\cdot(1-0)} = 4.43\ \text{rad/s}$.

Check. The small-angle linearisation $\ddot\theta + (g/\ell)\theta = 0$ would give $\omega_{\max} = \theta_0\sqrt{g/\ell} = 1.571\cdot 3.132 = 4.92\ \text{rad/s}$, about 11% too high — at 90° amplitude the linear model is no longer accurate. The first-order equation in (θ,ω) can be separated once more to give the period as an integral (an elliptic integral), which has no elementary closed form.

Engineering note — constant coefficients live in Chapter 12

When p and q are constants, $y = e^{st}$ reduces $L[y] = 0$ to the algebraic **characteristic equation** $s^2 + ps + q = 0$, and the three root cases give the overdamped, critically damped and underdamped responses of RLC circuits. That theory, with damping ratio, natural frequency and forced response, is the subject of Ch. 12. The methods of this section — Wronskian, reduction of order, Cauchy–Euler — are what you use when the coefficients are **not** constant: tapered transmission lines, graded doping profiles, time-varying circuit elements, fields in curvilinear coordinates.

11.5 Higher-order ODEs

Motivation

Each independent energy store adds one to the order of a network's equation, so an nth-order filter, a multi-stage amplifier with n dominant poles, or a chain of n coupled resonators leads to an nth-order ODE. Fourth-order equations govern the bending of beams and cantilevers (MEMS accelerometers and resonators), and higher-order equations appear whenever a system of first-order equations is collapsed into a single equation for one output. The theory of §11.4 carries over almost word for word; the new ingredients are bookkeeping (an $n \times n$ Wronskian) and the systematic reduction to a first-order system, which is how such equations are actually analysed and computed.

The nth-order linear equation

Linear nth-order ODE

$$L[y] = y^{(n)} + p_{n-1}(t)\,y^{(n-1)} + \cdots + p_1(t)\,y' + p_0(t)\,y = r(t),$$

with $p_0,\dots,p_{n-1}, r$ continuous on an interval I. An **initial-value problem** prescribes $y(t_0), y'(t_0), \dots, y^{(n-1)}(t_0)$.

Structure of the nth-order homogeneous equation

1. **Existence and uniqueness.** For every $t_0 \in I$ and every vector of initial data, the IVP has exactly one solution, defined on all of I.
2. **Dimension.** The solutions of $L[y] = 0$ form a vector space of dimension n. Any n linearly independent solutions $y_1,\dots,y_n$ form a **fundamental set**, and the general solution is $y = c_1y_1 + \cdots + c_ny_n$.
3. **Wronskian.** With

$$W(t) = \det\begin{pmatrix} y_1 & y_2 & \cdots & y_n \\ y_1' & y_2' & \cdots & y_n' \\ \vdots & \vdots & & \vdots \\ y_1^{(n-1)} & y_2^{(n-1)} & \cdots & y_n^{(n-1)} \end{pmatrix},$$

Abel's formula reads $W(t) = W(t_0)\exp\!\Big(-\int_{t_0}^{t} p_{n-1}(s)\,ds\Big)$, so W is never zero or always zero on I, and the solutions are independent exactly when $W \neq 0$.

Proof sketch. Parts 1 and 2 follow exactly as in §11.4, with the initial-data map now onto $\mathbb{R}^n$. For Abel's formula, differentiate the determinant row by row: W' is the sum of n determinants, in each of which one row is differentiated. Differentiating row $k < n$ produces a copy of row $k+1$, so those determinants have two equal rows and vanish. Only the last row survives, becoming $\big(y_1^{(n)},\dots,y_n^{(n)}\big)$. Substituting $y_k^{(n)} = -p_{n-1}y_k^{(n-1)} - \cdots - p_0y_k$ and subtracting multiples of the earlier rows leaves $-p_{n-1}$ times the original last row. Hence $W' = -p_{n-1}W$. $\square$

The general solution of $L[y] = r$ contains n arbitrary constants, and n independent conditions are needed to fix them.

Worked Example 11.20 — A third-order constant-coefficient equation

Solve $y''' - y' = 0$ and verify independence of the solutions.

Step 1. With constant coefficients, $y = e^{st}$ gives $s^3 - s = s(s-1)(s+1) = 0$, so $y = c_1 + c_2 e^{t} + c_3 e^{-t}$.

Step 2 (Wronskian).

$$W = \det \begin{pmatrix} 1 & e^{t} & e^{-t} \\ 0 & e^{t} & -e^{-t} \\ 0 & e^{t} & e^{-t} \end{pmatrix} = 1 \cdot \left(e^{t}e^{-t} + e^{t}e^{-t} \right) = 2 \neq 0.$$

Check. The coefficient of y'' is $p_2 = 0$, so Abel predicts a constant W. ✓

Worked Example 11.21 — A third-order Cauchy–Euler IVP

Solve $t^3 y''' + t^2 y'' - 2ty' + 2y = 0$ for $t > 0$ with $y(1) = 0$, $y'(1) = 0$, $y''(1) = 6$.

Step 1 (indicial equation). For $y = t^m$, $t^3 y''' = m(m-1)(m-2)t^m$, $t^2 y'' = m(m-1)t^m$, $ty' = mt^m$:

$$m(m-1)(m-2) + m(m-1) - 2m + 2 = m^3 - 2m^2 - m + 2 = (m-2)(m-1)(m+1) = 0.$$

So $y = c_1 t + c_2 t^2 + c_3 t^{-1}$.

Step 2 (Wronskian, two ways). Directly,

$$W = \det \begin{pmatrix} t & t^2 & t^{-1} \\ 1 & 2t & -t^{-2} \\ 0 & 2 & 2t^{-3} \end{pmatrix} = \frac{6}{t}.$$

In standard form (divide by t^3) the coefficient of y'' is $p_2 = 1/t$, so Abel gives $W \propto e^{-\ln t} = 1/t$. ✓ It is nonzero on $t > 0$.

Step 3 (fit). With $y' = c_1 + 2c_2 t - c_3 t^{-2}$ and $y'' = 2c_2 + 2c_3 t^{-3}$, at $t = 1$:

$$c_1 + c_2 + c_3 = 0, \qquad c_1 + 2c_2 - c_3 = 0, \qquad 2c_2 + 2c_3 = 6.$$

The third gives $c_2 + c_3 = 3$, so $c_1 = -3$; then $2c_2 - c_3 = 3$, so $c_2 = 2$, $c_3 = 1$.

$$y = 2t^2 - 3t + \frac{1}{t}.$$

Check. $y(1) = 2 - 3 + 1 = 0$, $y'(1) = 4 - 3 - 1 = 0$, $y''(1) = 4 + 2 = 6$. ✓ The determinant of the 3×3 fitting system is $W(1) = 6 \neq 0$, which is why a unique fit was guaranteed.

Reduction to a first-order system

Companion form

Define the **state** $x_1 = y,\ x_2 = y',\ \dots,\ x_n = y^{(n-1)}$. Then $L[y] = r$ is equivalent to the first-order system

$$\dot{\mathbf{x}} = \mathbf{A}(t)\,\mathbf{x} + \mathbf{b}\,r(t), \qquad \mathbf{A} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -p_0 & -p_1 & -p_2 & \cdots & -p_{n-1} \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}.$$

For constant coefficients, $\det(s\mathbf{I} - \mathbf{A}) = s^n + p_{n-1}s^{n-1} + \cdots + p_0$, the characteristic polynomial of the scalar equation.

The first $n-1$ rows just say "the derivative of each state is the next state"; the last row is the ODE solved for $y^{(n)}$. The initial data $y(t_0), \dots, y^{(n-1)}(t_0)$ are precisely $\mathbf{x}(t_0)$, and the Wronskian matrix is a fundamental matrix of the system (§11.9).

The conversion matters for three reasons:

- **Theory.** Existence, uniqueness and continuous dependence need only be proved once, for first-order systems (§11.7).
- **Computation.** Every numerical ODE solver (Ch. 22) — Runge–Kutta, SPICE's transient engine, MATLAB's `ode45` — accepts only first-order systems.
- **Modelling.** The physical state of a circuit (capacitor voltages, inductor currents) is a first-order system from the start; the companion form is one particular choice of state, and Ch. 12 shows how to choose others.

Worked Example 11.22 — Companion form

Write $y''' + 2y'' - y' + 3y = \sin t$ as a first-order system and confirm the characteristic polynomial.

Step 1. States $x_1 = y$, $x_2 = y'$, $x_3 = y''$. Then $\dot{x}_1 = x_2$, $\dot{x}_2 = x_3$, and from the equation $\dot{x}_3 = y''' = -3x_1 + x_2 - 2x_3 + \sin t$.

Step 2.

$$\frac{d}{dt}\begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -3 & 1 & -2 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}\sin t.$$

Check. Expanding along the first column, $\det(s\mathbf{I} - \mathbf{A}) = s\big(s(s+2) - 1\big) + 3 \cdot 1 = s^3 + 2s^2 - s + 3$. ✓

Operator factorisation

Write $D = d/dt$. A constant-coefficient operator is a polynomial in D, and polynomials in D **commute** and **factor** like ordinary polynomials: $D^2 - 3D + 2 = (D-1)(D-2)$. A factored equation can be solved as a chain of first-order linear equations, each by the integrating factor of §11.3. This is the cleanest way to see where the extra factors t^k for repeated roots come from.

Worked Example 11.23 — Solving by successive first-order steps

Find a particular solution of $y''' - 3y'' + 3y' - y = e^t$.

Step 1 (factor). The operator is $(D-1)^3$. Put $u = (D-1)^2 y$ and $w = (D-1)y$, so the equation is $(D-1)u = e^t$, then $(D-1)w = u$, then $(D-1)y = w$.

Step 2 (three integrating factors). Each step is $z' - z = g$, with solution $z = e^t \int e^{-t} g\,dt$ (constants dropped, since we need only one particular solution):

- $u = e^t \int e^{-t} e^t\,dt = te^t$;
- $w = e^t \int e^{-t} te^t\,dt = \tfrac{1}{2}t^2 e^t$;
- $y_p = e^t \int \tfrac{1}{2}t^2\,dt = \tfrac{1}{6}t^3 e^t$.

Check. Symbolic substitution of $y_p = \tfrac{1}{6}t^3 e^t$ returns exactly e^t. ✓

Interpretation. The input e^t coincides with a triple root of the characteristic polynomial, and each coincident factor contributes one power of t. This is *resonance* in its purest form; Ch. 12 turns the observation into the modification rule of undetermined coefficients.

Variable-coefficient operators can sometimes be factored too, but the factors no longer commute: $(D+t)D\,y = y'' + ty'$ whereas $D(D+t)\,y = y'' + ty' + y$. Factor in the right order.

Reduction of order for nth-order equations

If one solution y_1 of $L[y] = 0$ is known, substituting $y = v\,y_1$ again cancels all terms in v itself (because $L[y_1] = 0$), leaving an equation of order $n-1$ for $w = v'$. Each known solution therefore lowers the order by one. In practice this is used mostly for $n = 2$; for higher orders it is a theoretical tool showing that knowledge of solutions can be traded for reduced work.

Common pitfall — too few or too many conditions

An nth-order equation needs exactly n conditions. Fewer leaves free constants; more over-determines the problem, which usually has no solution. When a model gives you "too many" conditions, one of them is either redundant or signals that the order of the model is wrong — a classic symptom of an ignored parasitic element.

Engineering note — where higher order comes from

Each independent energy-storage element (a capacitor or inductor that cannot be merged with another by series/parallel combination, and is not in a loop of capacitors or a cutset of inductors) adds one to the order. A third-order Butterworth low-pass filter obeys a third-order ODE; a fourth-order Euler–Bernoulli beam equation $EI\,w'''' = q$ describes a MEMS cantilever. In practice engineers rarely solve high-order ODEs as single equations. They factor the characteristic polynomial (Ch. 12), work with transfer functions (Ch. 14), or integrate the first-order system numerically.

11.6 Homogeneous and nonhomogeneous equations

Motivation

A circuit left to itself after a switching event obeys a homogeneous equation; the same circuit driven by a source obeys a nonhomogeneous one. Linearity lets us treat the two effects separately and add the results — the mathematical content of the superposition theorem of circuit analysis. This section makes that precise and gives a method, **variation of parameters**, that produces a particular solution for *any* continuous input and *any* linear equation whose homogeneous solutions are known — including variable-coefficient equations where the guessing methods of Ch. 12 fail.

Homogeneous and nonhomogeneous linear equations

With $L[y] = y^{(n)} + p_{n-1}y^{(n-1)} + \cdots + p_0 y$, the equation $L[y] = 0$ is **homogeneous** and $L[y] = r(t)$ with $r \not\equiv 0$ is **nonhomogeneous**. The function $r(t)$ is called the *forcing*, *input* or *source term*. The general solution y_h of $L[y] = 0$ is the **complementary function**; any single solution y_p of $L[y] = r$ is a **particular solution**.

Common pitfall — two meanings of "homogeneous"

In §11.2, "homogeneous" meant $y' = F(y/t)$, a scaling property of a first-order equation. For linear equations it means "no forcing term". The two ideas are unrelated. In this book "homogeneous" means the linear sense unless stated otherwise.

Structure of solutions

Structure theorem

Let y_p be **any** particular solution of $L[y] = r$ on I and $y_h = c_1 y_1 + \cdots + c_n y_n$ the general solution of $L[y] = 0$. Then every solution of $L[y] = r$ on I has the form

$$y = y_h + y_p = c_1 y_1 + \cdots + c_n y_n + y_p.$$

Proof. If y is any solution, $L[y - y_p] = L[y] - L[y_p] = r - r = 0$, so $y - y_p$ is a homogeneous solution, i.e. equals $c_1 y_1 + \cdots + c_n y_n$ for some constants. Conversely every such sum is a solution. $\square$

Geometrically, the solution set of $L[y] = r$ is an **affine subspace**: the n-dimensional solution space of $L[y] = 0$ translated by y_p — the same picture as the solution set of a consistent linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ in Ch. 8. Different choices of y_p just shift the constants c_k.

Superposition of inputs

If $L[y_a] = r_a$ and $L[y_b] = r_b$, then $L[\alpha y_a + \beta y_b] = \alpha r_a + \beta r_b$ for any constants α, β.

A complicated input can therefore be split into simple pieces, a particular solution found for each, and the results added. This is the basis of the Fourier method (Ch. 15): split a periodic input into sinusoids, solve for each, and sum.

Worked Example 11.24 — Splitting the input

Find the general solution of $y'' + 4y = 8 + 5e^{t}$.

Step 1 (homogeneous). $s^2 + 4 = 0$ gives $y_h = c_1 \cos 2t + c_2 \sin 2t$.

Step 2 (input 8). A constant $y_{p1} = A$ gives $4A = 8$, so $y_{p1} = 2$.

Step 3 (input $5e^{t}$). Try $y_{p2} = Be^{t}$: $Be^{t} + 4Be^{t} = 5e^{t}$, so $B = 1$.

Step 4. $y = c_1 \cos 2t + c_2 \sin 2t + 2 + e^{t}$.

Check. $y_p'' + 4y_p = e^{t} + 8 + 4e^{t} = 8 + 5e^{t}$. ✓

The guesses in steps 2–3 are the method of **undetermined coefficients**, which works for constant-coefficient equations with inputs built from polynomials, exponentials and sinusoids. It is developed with all its special cases in Ch. 12. Here we need a method with no such restrictions.

Variation of parameters

The idea (due to Lagrange) is to look for a particular solution of the same form as y_h but with the constants replaced by functions: $y_p = u_1(t)y_1(t) + u_2(t)y_2(t)$. Two unknown functions are more freedom than one equation needs, so we may impose one extra condition of our choosing — and we choose it to keep second derivatives of u_k out of the calculation.

Variation of parameters (second order)

Let y_1, y_2 be a fundamental set for $y'' + p(t)y' + q(t)y = 0$ on I, with Wronskian $W = y_1y_2' - y_1'y_2$. Then a particular solution of $y'' + p(t)y' + q(t)y = r(t)$ is

$$y_p(t) = -y_1(t)\int \frac{y_2(t)\,r(t)}{W(t)}\,dt + y_2(t)\int \frac{y_1(t)\,r(t)}{W(t)}\,dt.$$

Derivation. With $y_p = u_1y_1 + u_2y_2$,

$$y_p' = u_1y_1' + u_2y_2' + \underbrace{(u_1'y_1 + u_2'y_2)}_{\text{set to } 0}.$$

Imposing $u_1'y_1 + u_2'y_2 = 0$, differentiate again: $y_p'' = u_1y_1'' + u_2y_2'' + u_1'y_1' + u_2'y_2'$. Substituting into the equation and grouping,

$$u_1\underbrace{(y_1'' + py_1' + qy_1)}_{0} + u_2\underbrace{(y_2'' + py_2' + qy_2)}_{0} + u_1'y_1' + u_2'y_2' = r.$$

So u_1', u_2' satisfy the linear system

$$\begin{pmatrix} y_1 & y_2 \\ y_1' & y_2' \end{pmatrix} \begin{pmatrix} u_1' \\ u_2' \end{pmatrix} = \begin{pmatrix} 0 \\ r \end{pmatrix},$$

whose determinant is the Wronskian, nonzero on I. Cramer's rule (Ch. 8) gives $u_1' = -y_2 r/W$ and $u_2' = y_1 r/W$. Integrating gives the formula. □

General order. For $L[y] = r$ of order n, impose $\sum u_k' y_k^{(j)} = 0$ for $j = 0, \dots, n-2$; the last equation becomes $\sum u_k' y_k^{(n-1)} = r$. Cramer's rule gives $u_k' = r\, W_k/W$, where W_k is W with its kth column replaced by $(0, \dots, 0, 1)^{\mathsf{T}}$.

Common pitfall — use the standard form

The $r(t)$ in the formula is the right side **after** dividing by the coefficient of y''. For $t^2 y'' - 2ty' + 2y = t^3$ it is $r = t$, not t^3. Using the raw right side is the single most common error in variation of parameters.

Worked Example 11.25 — An input undetermined coefficients cannot handle

Find a particular solution of $y'' + y = \sec t$ on $|t| < \pi/2$.

Step 1. $y_1 = \cos t$, $y_2 = \sin t$, $W = \cos^2 t + \sin^2 t = 1$.

Step 2.

$$u_1 = -\int \sin t \sec t \, dt = -\int \tan t \, dt = \ln|\cos t|,$$
$$u_2 = \int \cos t \sec t \, dt = t.$$

Step 3. $y_p = \cos t \, \ln(\cos t) + t \sin t$.

Check. $y_p' = -\sin t \ln\cos t - \sin t + \sin t + t\cos t = -\sin t \ln\cos t + t\cos t$, and $y_p'' = -\cos t \ln\cos t + \dfrac{\sin^2 t}{\cos t} + \cos t - t\sin t$. Adding y_p: $\dfrac{\sin^2 t}{\cos t} + \cos t = \dfrac{1}{\cos t} = \sec t$. ✓ The input has no finite family of derivatives, so no guess of undetermined-coefficients type can succeed.

Worked Example 11.26 — Variable coefficients with initial conditions

Solve $t^2 y'' - 2ty' + 2y = t^3$, $t > 0$, with $y(1) = 0$, $y'(1) = 0$.

Step 1 (homogeneous). From Example 11.16, $y_1 = t$, $y_2 = t^2$, $W = t^2$.

Step 2 (standard form). $y'' - \dfrac{2}{t}y' + \dfrac{2}{t^2}y = t$, so $r = t$.

Step 3 (parameters). $u_1' = -\dfrac{y_2 r}{W} = -\dfrac{t^2 \cdot t}{t^2} = -t$, so $u_1 = -\tfrac{1}{2}t^2$; $u_2' = \dfrac{y_1 r}{W} = \dfrac{t \cdot t}{t^2} = 1$, so $u_2 = t$.

Step 4. $y_p = -\tfrac{1}{2}t^2 \cdot t + t \cdot t^2 = \tfrac{1}{2}t^3$, and $y = c_1 t + c_2 t^2 + \tfrac{1}{2}t^3$.

Step 5 (conditions). $y(1) = c_1 + c_2 + \tfrac{1}{2} = 0$ and $y'(1) = c_1 + 2c_2 + \tfrac{3}{2} = 0$ give $c_2 = -1$, $c_1 = \tfrac{1}{2}$:

$$y = \tfrac{1}{2}t - t^2 + \tfrac{1}{2}t^3 = \tfrac{1}{2}\, t\,(t-1)^2.$$

Check. With $y = \tfrac{1}{2}(t^3 - 2t^2 + t)$: $y' = \tfrac{1}{2}(3t^2 - 4t + 1)$, $y'' = 3t - 2$. Then $t^2(3t-2) - t(3t^2 - 4t + 1) + (t^3 - 2t^2 + t) = t^3$. ✓

The Green's-function (impulse-response) form

Variation of parameters can be written as a single integral that builds in zero initial conditions. Taking definite integrals from t_0,

$$y_p(t) = \int_{t_0}^{t} G(t,s)\, r(s)\, ds, \qquad G(t,s) = \frac{y_1(s)\, y_2(t) - y_1(t)\, y_2(s)}{W(s)}.$$

Properties of the causal Green's function

For fixed s, $G(t,s)$ as a function of t solves the homogeneous equation with $G(s,s) = 0$ and $\partial G/\partial t\,(s,s) = 1$. Consequently y_p above is the unique solution of $L[y] = r$ with $y(t_0) = y'(t_0) = 0$, and the solution with general initial data is $y_h + y_p$ with y_h fitted to those data.

Why. $G(\cdot, s)$ is a combination of y_1, y_2, so it solves $L[y] = 0$; $G(s,s) = 0$ by inspection, and $\partial_t G(s,s) = [y_1(s)y_2'(s) - y_1'(s)y_2(s)]/W(s) = 1$. Differentiating y_p under the integral sign (Leibniz rule, Ch. 5) then gives $y_p' = \int \partial_t G\, r\, ds$ and $y_p'' = r(t) + \int \partial_t^2 G\, r\, ds$, so $L[y_p] = r$. □

Physically, $G(t,s)$ is the response at time t to a unit **impulse** of input applied at time s: the impulse leaves position unchanged and kicks the velocity by 1. The integral says the response to a general input is the superposition of responses to the impulses $r(s)\, ds$ that make it up. When the coefficients are constant, $G(t,s) = g(t-s)$ depends only on the elapsed time, and y_p is the **convolution** $g * r$ — the impulse-response description of a linear time-invariant system used throughout Ch. 12, Ch. 14 and Ch. 16.

Worked Example 11.27 — The undamped oscillator: step and resonant inputs

For $y'' + \omega_0^2 y = r(t)$ with $y(0) = y'(0) = 0$, find the response to (a) a step $r = F$, (b) a resonant input $r = \cos \omega_0 t$.

Step 1 (Green's function). $y_1 = \cos \omega_0 t$, $y_2 = \sin \omega_0 t$, $W = \omega_0$. Then

$$G(t, s) = \frac{\cos \omega_0 s \sin \omega_0 t - \cos \omega_0 t \sin \omega_0 s}{\omega_0} = \frac{\sin \omega_0 (t - s)}{\omega_0}.$$

Step 2 (step). $y = \dfrac{F}{\omega_0} \displaystyle\int_0^t \sin \omega_0 (t - s)\, ds = \frac{F}{\omega_0^2}\big(1 - \cos \omega_0 t\big)$.

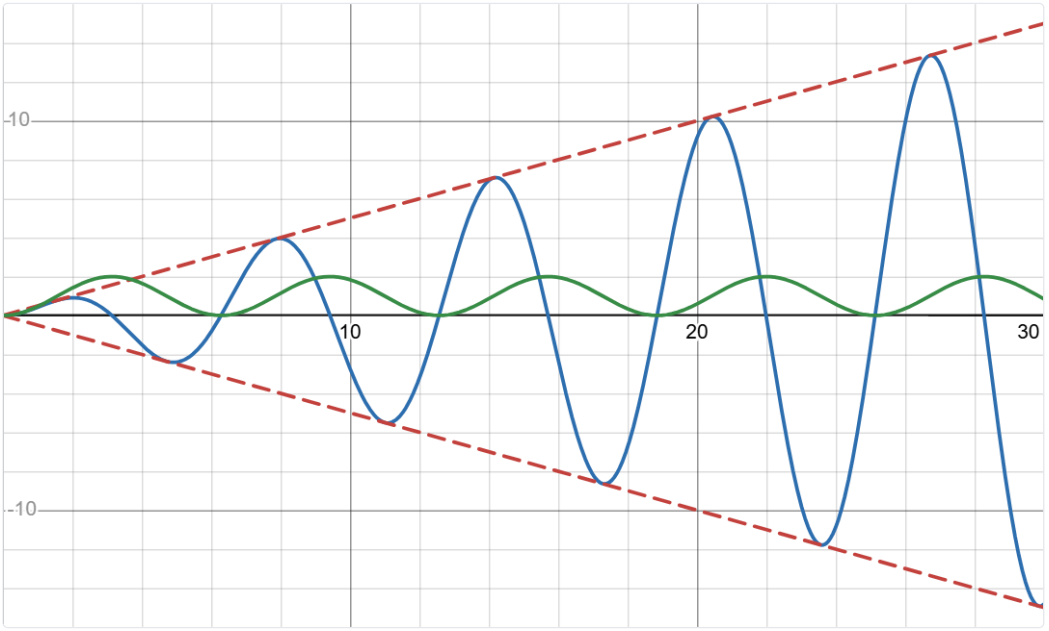
Step 3 (resonant input). Using $\sin A \cos B = \tfrac{1}{2}[\sin(A + B) + \sin(A - B)]$,

$$y = \frac{1}{\omega_0} \int_0^t \sin \omega_0 (t - s) \cos \omega_0 s \, ds = \frac{1}{2\omega_0} \int_0^t \big[\sin \omega_0 t + \sin \omega_0 (t - 2s)\big]\, ds = \frac{t \sin \omega_0 t}{2\omega_0}.$$

(The second integrand integrates to zero over $[0, t]$.)

Check. For (b), $y' = \dfrac{\sin \omega_0 t}{2\omega_0} + \dfrac{t}{2} \cos \omega_0 t$ and $y'' = \cos \omega_0 t - \dfrac{\omega_0 t}{2} \sin \omega_0 t$, so $y'' + \omega_0^2 y = \cos \omega_0 t$; $y(0) = y'(0) = 0$. ✓

Interpretation. The step response oscillates about the new equilibrium F/ω_0^2 forever (no damping). The resonant response grows linearly without bound — the envelope $t/(2\omega_0)$ — which is why lossless resonators driven at their natural frequency are dangerous, and why real circuits always contain the resistance that Ch. 12 uses to limit the peak.



Example 11.27 with $\omega_0 = 1$: resonant response $\frac{1}{2} t \sin t$ (blue) inside its linearly growing envelope (red dashed), and the bounded step response $1 - \cos t$ (green).

Engineering note — natural and forced response

In circuit language y_h is the **natural response** (shape set by the circuit, amplitude set by initial conditions) and y_p a **forced response** (shape set by the source). For stable circuits y_h decays and y_p — chosen as the steady periodic solution — is what a meter reads after the transient. Ch. 12 develops this vocabulary for constant-coefficient circuits; the structure theorem here is what guarantees that the decomposition is always possible and complete.

11.7 Initial-value problems

Motivation

An engineer who simulates a circuit is solving an initial-value problem: the state at $t = 0$ is known (capacitor voltages, inductor currents), and the simulator marches forward. Three questions must have good answers before the result means anything. Does a solution **exist**? Is it **unique** — or could the same initial state lead to different futures? Does it depend **continuously** on the data, so that small errors in component values or initial conditions produce small errors in the answer? A problem with all three properties is called **well-posed**. This section states when that is guaranteed, sketches why, and shows what goes wrong when the hypotheses fail.

Initial-value problem (IVP)

For a first-order system, find $\mathbf{y}(t)$ with

$$\mathbf{y}' = \mathbf{f}(t, \mathbf{y}), \qquad \mathbf{y}(t_0) = \mathbf{y}_0.$$

For an nth-order scalar equation, the data are $y(t_0), y'(t_0), \dots, y^{(n-1)}(t_0)$ — all at the **same** point t_0 — which is the same thing after the companion-form reduction of §11.5.

We state results for scalar first-order equations $y' = f(t, y)$; with $|\cdot|$ replaced by a vector norm $\|\cdot\|$ everything holds verbatim for systems, and hence for nth-order equations.

The Lipschitz condition

Lipschitz condition

$f(t, y)$ is **Lipschitz in** y on a region R with constant K if

$$|f(t, y) - f(t, z)| \le K\,|y - z| \quad \text{for all } (t, y), (t, z) \in R.$$

By the mean-value theorem, if $\partial f/\partial y$ is continuous on a closed rectangle then f is Lipschitz there with $K = \max|\partial f/\partial y|$. So the practical test is: **is $\partial f/\partial y$ bounded near the initial point?** The function $f = y^{2/3}$ fails at $y = 0$ (its derivative $\tfrac{2}{3}y^{-1/3}$ is unbounded); $f = |y|$ is Lipschitz with $K = 1$ even though it is not differentiable at 0.

Existence and uniqueness

Picard–Lindelöf

Let f be continuous on the rectangle $R = \{|t - t_0| \le a,\ |y - y_0| \le b\}$ and Lipschitz in y there. Let $M = \max_R |f|$ and $h = \min(a, b/M)$. Then the IVP $y' = f(t, y)$, $y(t_0) = y_0$ has **exactly one** solution on $|t - t_0| \le h$.

Proof sketch. **(1) Integral equation.** A continuous y solves the IVP if and only if

$$y(t) = y_0 + \int_{t_0}^{t} f\big(s, y(s)\big)\, ds,$$

by the fundamental theorem of calculus. This form needs no derivatives and builds in the initial condition.

(2) Picard iteration. Start from $y_0(t) \equiv y_0$ and define $y_{k+1}(t) = y_0 + \int_{t_0}^{t} f(s, y_k(s))\, ds$. The choice $h \le b/M$ keeps every iterate inside R: $|y_{k+1} - y_0| \le M|t - t_0| \le b$.

(3) Convergence. By the Lipschitz condition, $|y_{k+1}(t) - y_k(t)| \le K \int_{t_0}^{t} |y_k - y_{k-1}|\, ds$. Starting from $|y_1 - y_0| \le M|t - t_0|$ and inducting,

$$|y_{k+1}(t) - y_k(t)| \le \frac{M K^k |t - t_0|^{k+1}}{(k+1)!}.$$

The right side is the general term of a convergent exponential series, so y_k converges uniformly to a continuous limit y, and passing to the limit in the iteration shows that y satisfies the integral equation.

(4) Uniqueness. If y and z both solve it, $u = |y - z|$ satisfies $u(t) \le K \int_{t_0}^{t} u\, ds$ with $u(t_0) = 0$, and Grönwall's inequality (below) forces $u \equiv 0$. $\square$

Two weaker or complementary statements are worth knowing:

- **Peano's theorem.** Continuity of f alone guarantees that *at least one* solution exists near t_0, but not that it is unique.
- **Continuation.** A solution can be continued as long as it stays in a region where the hypotheses hold. The maximal solution either exists for all $t \ge t_0$ or leaves every bounded region — for a scalar equation on all of $\mathbb{R}^2$, it **blows up** ($|y| \to \infty$) in finite time. There is no third option such as "stops for no reason".

Worked Example 11.28 — Picard iterates for $y' = y$

Compute the Picard iterates for $y' = y$, $y(0) = 1$.

Step 1. $y_0 = 1$.

Step 2. $y_1 = 1 + \int_0^t 1\, ds = 1 + t$; $y_2 = 1 + \int_0^t (1 + s)\, ds = 1 + t + \tfrac{t^2}{2}$; and by induction

$$y_k(t) = \sum_{m=0}^{k} \frac{t^m}{m!}.$$

Step 3. The iterates are the Taylor partial sums of e^t and converge to $y = e^t$ for every t (Ch. 4).

Check against the error bound. On $|t| \le 1$ with $K = 1$, the bound on $|y_5 - y_4|$ at $t = 1$ is $MK^4/5!$ with $M \le e$ in a suitable rectangle, i.e. about 0.023; the actual difference is $1/5! = 0.0083$. ✓ The iteration is a constructive proof and, for simple f, a usable approximation method.

Worked Example 11.29 — How long is the guaranteed interval?

For $y' = 1 + y^2$, $y(0) = 0$, find the interval of existence promised by Picard–Lindelöf and compare with the true solution.

Step 1. $f = 1 + y^2$ is continuous with $f_y = 2y$ bounded on any rectangle, so the theorem applies for every a, b. Take a large; on $|y| \le b$, $M = 1 + b^2$, so $h = b/(1 + b^2)$.

Step 2 (best choice). $\dfrac{d}{db}\dfrac{b}{1+b^2} = \dfrac{1 - b^2}{(1+b^2)^2} = 0$ at $b = 1$, giving $h = \tfrac{1}{2}$.

Step 3 (true solution). Separating, $\arctan y = t$, so $y = \tan t$, which exists on $(-\pi/2, \pi/2)$ and blows up at $|t| = \pi/2 \approx 1.571$.

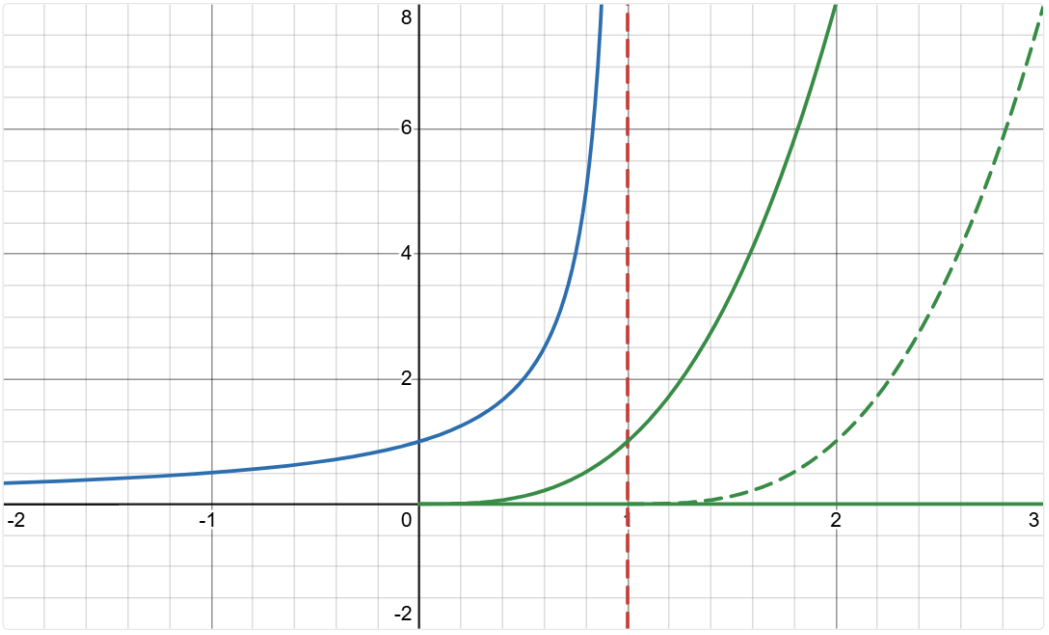
Interpretation. The theorem is conservative — it guarantees $|t| \le 0.5$ where the truth is $|t| < 1.571$ — but it is *local by nature*: no choice of rectangle could guarantee all t, because the solution genuinely escapes. Applying the theorem again from $t = 0.5$ extends the solution step by step until the blow-up.

When the hypotheses fail

Worked Example 11.30 — Blow-up and non-uniqueness

(a) Finite-time blow-up. $y' = y^2$, $y(0) = 1$. Here $f = y^2$ is smooth everywhere, and separation gives $y = 1/(1 - t)$. The solution exists only for $t < 1$, although the equation itself is defined everywhere. The cause is the superlinear growth of f: $K = 2|y|$ grows without bound as y grows.

(b) Non-uniqueness. $y' = 3y^{2/3}$, $y(0) = 0$. Both $y \equiv 0$ and $y = t^3$ are solutions: $(t^3)' = 3t^2 = 3(t^3)^{2/3}$. In fact, for any $c \ge 0$ the function equal to 0 for $t \le c$ and $(t - c)^3$ for $t > c$ is also a solution — infinitely many futures from the same initial state. Uniqueness fails because $\partial f/\partial y = 2y^{-1/3}$ is unbounded at $y = 0$; existence still holds (Peano).



Blue: $y = 1/(1 - t)$ escapes to infinity at $t = 1$ (red dashed asymptote). Green: three different solutions of $y' = 3y^{2/3}$ leave the same initial point $(0, 0)$ — $y = 0$, $y = t^3$, and y that waits until $t = 1$ before departing.

Continuous dependence and Grönwall's inequality

Grönwall's inequality

If $u(t) \ge 0$ is continuous and $u(t) \le \alpha + K\int_{t_0}^{t} u(s)\,ds$ for $t \ge t_0$, with constants $\alpha \ge 0$, $K \ge 0$, then $u(t) \le \alpha\, e^{K(t - t_0)}$.

Sketch. Let $U(t) = \alpha + K\int_{t_0}^{t} u\,ds$. Then $U' = Ku \le KU$, so $(e^{-K(t-t_0)}U)' \le 0$ and $U(t) \le U(t_0)e^{K(t-t_0)} = \alpha e^{K(t-t_0)}$; finally $u \le U$. □

Continuous dependence on initial data

If f is Lipschitz in y with constant K and y, z solve $y' = f(t, y)$ with initial values y_0, z_0, then

$$|y(t) - z(t)| \le |y_0 - z_0|\, e^{K|t - t_0|}.$$

Proof. Subtract the two integral equations and use the Lipschitz bound: $|y - z| \le |y_0 - z_0| + K\int |y - z|\,ds$. Apply Grönwall. With $y_0 = z_0$ this is the uniqueness proof. □

The bound is a worst case: errors *may* grow like e^{Kt}. For a stable system they actually shrink — for $y' = -y/\tau$ two solutions approach each other like $e^{-t/\tau}$ — but for an unstable one (an oscillator start-up, a latch near its metastable point, Example 11.2) the exponential growth of small differences is real and is exactly what limits predictability. A similar estimate shows continuous dependence on parameters in f: a small change in a component value changes the solution by a small amount on any finite time interval.

Linear equations: global existence

Linear IVPs

If $p_0, \dots, p_{n-1}, r$ (or $\mathbf{A}(t), \mathbf{f}(t)$ for a system) are continuous on an open interval I containing t_0, the linear IVP has exactly one solution, and it exists on **all** of I.

Why linear equations cannot blow up. For $\mathbf{y}' = \mathbf{A}(t)\mathbf{y} + \mathbf{f}(t)$ the Lipschitz constant on any closed subinterval $J \subset I$ is $K = \max_J \|\mathbf{A}\|$, the same for *all* $\mathbf{y}$ — no rectangle in y is needed. Grönwall then bounds $\|\mathbf{y}(t)\|$ by $\big(\|\mathbf{y}_0\| + \int_J \|\mathbf{f}\|\big) e^{K|t-t_0|}$ on J, so the solution stays bounded on every closed subinterval and, by the continuation property, extends across all of I. The only places a linear solution can misbehave are where the *coefficients* do — the singular points — and those are visible in the equation before solving it.

Worked Example 11.31 — Fitting circuit initial conditions

In a series RLC circuit with $R = 4\ \Omega$, $L = 1$ H, $C = \frac{1}{3}$ F, the capacitor holds $v_C(0^-) = 2$ V and the inductor current is $i(0^-) = 0$. At $t = 0$ a 10 V source is switched into the loop. Find $v_C(t)$ for $t > 0$.

Step 1 (equation). KVL: $Li' + Ri + v_C = 10$ with $i = C\dot{v}_C$ gives $LC\ddot{v}_C + RC\dot{v}_C + v_C = 10$, i.e. $\ddot{v}_C + 4\dot{v}_C + 3v_C = 30$.

Step 2 (initial data at 0^+). Capacitor voltage and inductor current are continuous: $v_C(0^+) = 2$ V and $i(0^+) = 0$, hence $\dot{v}_C(0^+) = i(0^+)/C = 0$.

Step 3 (general solution). The constant input gives $y_p = 10$; the homogeneous equation has $s^2 + 4s + 3 = (s+1)(s+3)$, so $v_C = 10 + Ae^{-t} + Be^{-3t}$.

Step 4 (fit). $A + B = -8$ and $-A - 3B = 0$, so $B = 4$, $A = -12$:

$$v_C(t) = 10 - 12e^{-t} + 4e^{-3t}\ \text{V}.$$

Check. $v_C(0) = 10 - 12 + 4 = 2$, $\dot{v}_C(0) = 12 - 12 = 0$. ✓ At $t = 1$ s: $v_C = 10 - 4.415 + 0.199 = 5.78$ V. The coefficients are constant, so this is the unique solution for all $t > 0$.

Engineering note — initial conditions in circuits

A capacitor voltage cannot jump unless the current is infinite, and an inductor current cannot jump unless the voltage is infinite. The natural initial conditions for a circuit are therefore $v_C(0^-)$ and $i_L(0^-)$, the stored energies just before a switching event — exactly one number per state variable, which is why state variables make the IVP automatically well-posed. Derivatives such as $\dot{v}_C(0^+) = i_C(0^+)/C$ follow from the circuit at $t = 0^+$. When an idealised circuit violates the rule (a capacitor switched directly across a voltage source, an inductor current interrupted), the model needs impulses — handled systematically by the Laplace transform in Ch. 14.

Common pitfall — trusting a simulator at a non-Lipschitz point

Models with square-root or fractional-power laws (ideal square-law MOSFET at threshold, some magnetic and friction models) can be non-Lipschitz at a point. At such points a numerical integrator may follow any of several solutions depending on step size and round-off, and the result can change with solver settings. Smoothing the model (e.g. replacing $|v|^{1/2}$ by $(v^2 + \varepsilon^2)^{1/4}$) restores uniqueness.

11.8 Boundary-value problems

Motivation

When the independent variable is **position** rather than time, conditions are naturally given at two places: the potential on both electrodes, the voltage at the source and load ends of a line, the temperature at both ends of a heat sink, the clamped and free ends of a cantilever. These are **boundary-value problems** (BVPs). They behave very differently from IVPs — existence and uniqueness are no longer automatic — and their homogeneous versions, the **eigenvalue problems**, produce the modes (standing waves, resonant frequencies, orthogonal function sets) on which separation of variables (Ch. 13) and Fourier series (Ch. 15) are built.

Two-point boundary-value problem

A second-order ODE on $a \le x \le b$ with one condition at **each end**. Common boundary conditions:

- **Dirichlet:** $y(a) = \alpha$, $y(b) = \beta$ (value prescribed — e.g. electrode potential);
- **Neumann:** $y'(a) = \alpha$, $y'(b) = \beta$ (slope prescribed — e.g. zero field or zero heat flux);
- **Robin (mixed):** $c_1 y(a) + c_2 y'(a) = \alpha$ (a linear combination — e.g. convective cooling, or a line terminated in a resistance).

The BVP is **homogeneous** if the equation and both boundary conditions are homogeneous (zero right sides).

Solvability: one, none or infinitely many

For a linear equation $y'' + p(x)y' + q(x)y = r(x)$ with fundamental set y_1, y_2 and particular solution y_p, write $y = c_1 y_1 + c_2 y_2 + y_p$ and impose the two boundary conditions. For Dirichlet conditions this gives the 2×2 system

$$\begin{pmatrix} y_1(a) & y_2(a) \\ y_1(b) & y_2(b) \end{pmatrix} \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} = \begin{pmatrix} \alpha - y_p(a) \\ \beta - y_p(b) \end{pmatrix}.$$

Everything now follows from linear algebra (Ch. 8): if the determinant $D = y_1(a)y_2(b) - y_2(a)y_1(b)$ is nonzero there is exactly one solution for every right side; if $D = 0$ there is either none or infinitely many, depending on whether the right side lies in the column space.

Fredholm alternative (two-point BVPs)

For a linear second-order BVP, exactly one of the following holds:

1. The homogeneous BVP has only the trivial solution $y \equiv 0$. Then the nonhomogeneous BVP has **exactly one** solution for every r, α, β.
2. The homogeneous BVP has a nontrivial solution. Then the nonhomogeneous BVP has **either no solution or infinitely many**, depending on the data.

Proof. The homogeneous BVP corresponds to a zero right side, and it has a nontrivial solution exactly when $D = 0$. Apply the corresponding statement for 2×2 linear systems. □

An IVP never meets case 2, because its "determinant" is the Wronskian at t_0, which is never zero. A BVP meets it whenever the interval length is "tuned" to a natural oscillation of the equation — the spatial analogue of resonance.

Worked Example 11.32 — Three possible outcomes

The equation $y'' + y = 0$ has general solution $y = c_1 \cos x + c_2 \sin x$.

1. $y(0) = 0$, $y(\pi/2) = 1$: $c_1 = 0$ and $c_2 = 1$, so the **unique** solution is $y = \sin x$. Here $D = \cos 0 \sin \frac{\pi}{2} - \sin 0 \cos \frac{\pi}{2} = 1 \neq 0$.
2. $y(0) = 0$, $y(\pi) = 1$: $c_1 = 0$, then $c_2 \sin \pi = 0 \neq 1$, so there is **no solution**.
3. $y(0) = 0$, $y(\pi) = 0$: $c_1 = 0$ and c_2 is arbitrary, so there are **infinitely many** solutions $y = c_2 \sin x$.

In cases 2 and 3, $D = \cos 0 \sin \pi - \sin 0 \cos \pi = 0$: the interval $[0, \pi]$ is exactly half a period of the natural solution $\sin x$, so the homogeneous problem has the nontrivial solution $\sin x$.

Worked Example 11.33 — A Poisson-type BVP

In one dimension the potential between two plates with a space-charge density obeys Poisson's equation $V'' = -\rho/\varepsilon$. As a dimensionless model, solve $y'' = 6x$ with $y(0) = 0$, $y(1) = 2$.

Step 1. Integrate twice: $y = x^3 + c_1 x + c_0$.

Step 2. $y(0) = c_0 = 0$ and $y(1) = 1 + c_1 = 2$, so $c_1 = 1$:

$$y = x^3 + x.$$

Check. $y'' = 6x$, $y(0) = 0$, $y(1) = 2$. ✓ Uniqueness is guaranteed because $y'' = 0$ with $y(0) = y(1) = 0$ has only $y \equiv 0$ (a straight line through two zeros).

Green's function for a BVP

As for IVPs (§11.6), the solution of a uniquely solvable BVP with homogeneous boundary conditions can be written as an integral against a kernel.

Green's function for $-y'' = f$, $y(0) = y(1) = 0$

$$y(x) = \int_0^1 G(x, s)\, f(s)\, ds, \qquad G(x, s) = \begin{cases} x(1 - s), & 0 \le x \le s, \\ s(1 - x), & s \le x \le 1. \end{cases}$$

Construction. For fixed s, G must satisfy $-G'' = 0$ for $x \neq s$ (so it is linear on each side), vanish at $x = 0$ and $x = 1$, be continuous at $x = s$, and have a slope that drops by 1 at $x = s$ (the response to a unit point source, since $-G'' = \delta(x - s)$). The linear pieces Ax and $B(1 - x)$ with $As = B(1 - s)$ and $-B - A = -1$ give $A = 1 - s$, $B = s$. □

G is **symmetric**, $G(x, s) = G(s, x)$ — the reciprocity principle of electrostatics and of passive networks: the potential at x due to a unit charge at s equals the potential at s due to a unit charge at x.

Worked Example 11.34 — Using the Green's function

Solve $-y'' = 1$, $y(0) = y(1) = 0$ (uniform space charge between grounded plates).

Step 1. Split the integral at $s = x$:

$$y(x) = \int_0^x s(1 - x)\, ds + \int_x^1 x(1 - s)\, ds = (1 - x)\frac{x^2}{2} + x\frac{(1 - x)^2}{2} = \frac{x(1 - x)}{2}.$$

Check. $y'' = -1$ ✓, $y(0) = y(1) = 0$ ✓. The maximum $1/8$ occurs midway between the plates, as symmetry demands.

Eigenvalue problems and Sturm–Liouville theory

A homogeneous BVP containing a parameter λ normally has only the trivial solution; for special values of λ — **eigenvalues** — it has nontrivial solutions, the **eigenfunctions**. This is the infinite-dimensional analogue of $\mathbf{A}\mathbf{v} = \lambda\mathbf{v}$ (Ch. 10).

The model eigenvalue problem

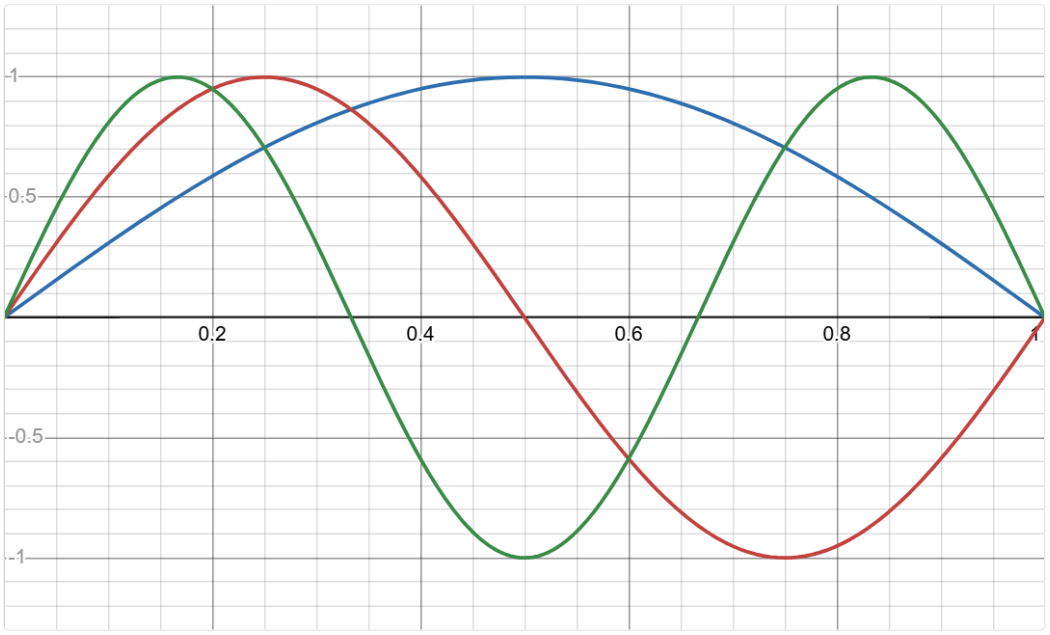
$$y'' + \lambda y = 0, \qquad y(0) = 0, \quad y(L) = 0$$

has nontrivial solutions only for

$$\lambda_n = \left(\frac{n\pi}{L}\right)^2, \qquad y_n(x) = \sin\frac{n\pi x}{L}, \qquad n = 1, 2, 3, \dots$$

Derivation. Consider the sign of λ.

- $\lambda = -k^2 < 0$: $y = c_1 \cosh kx + c_2 \sinh kx$. Then $y(0) = c_1 = 0$ and $y(L) = c_2 \sinh kL = 0$ forces $c_2 = 0$, since $\sinh kL \neq 0$.
- $\lambda = 0$: $y = c_1 + c_2 x$, and both conditions give $c_1 = c_2 = 0$.
- $\lambda = k^2 > 0$: $y = c_1 \cos kx + c_2 \sin kx$. $y(0) = 0$ gives $c_1 = 0$; $y(L) = c_2 \sin kL = 0$ with $c_2 \neq 0$ requires $kL = n\pi$. $\square$



The first three eigenfunctions $\sin(n\pi x/L)$ for $L = 1$: the nth has $n - 1$ interior zeros. They are the standing-wave shapes of a string fixed at both ends and the voltage patterns on a lossless line section shorted at both ends.

The model problem is one member of a large family with the same properties.

Regular Sturm–Liouville problem

$$\big(P(x)\,y'\big)' + Q(x)\,y + \lambda\,w(x)\,y = 0, \qquad a < x < b,$$

$$\alpha_1 y(a) + \alpha_2 y'(a) = 0, \qquad \beta_1 y(b) + \beta_2 y'(b) = 0,$$

with P, P', Q, w continuous on $[a, b]$, $P > 0$ and $w > 0$ there, and each pair (α_1, α_2), (β_1, β_2) not both zero. The function w is the **weight**.

Any equation $y'' + p(x)y' + q(x)y + \lambda s(x)y = 0$ can be put in this form by multiplying by $P = e^{\int p\,dx}$: then $Py'' + Py'p = (Py')'$, and $Q = Pq$, $w = Ps$.

Properties of regular Sturm–Liouville problems

1. All eigenvalues are **real**, and they form an increasing sequence $\lambda_1 < \lambda_2 < \cdots \to \infty$.
2. Each eigenvalue is **simple**: its eigenfunctions are multiples of one function y_n, which can be taken real.
3. Eigenfunctions for different eigenvalues are **orthogonal with weight** w:

$$\langle y_m, y_n \rangle_w = \int_a^b y_m(x)\,y_n(x)\,w(x)\,dx = 0, \qquad m \neq n.$$

4. The nth eigenfunction has exactly $n - 1$ zeros in (a, b).
5. The eigenfunctions are **complete**: any square-integrable f on $[a, b]$ has a convergent (in the mean-square sense) expansion $f = \sum c_n y_n$ with $c_n = \langle f, y_n \rangle_w / \langle y_n, y_n \rangle_w$.

Proof of orthogonality (and reality). Write $\mathcal{S}[y] = (Py')' + Qy$. For any two functions satisfying the boundary conditions, **Lagrange's identity**

$$u\,\mathcal{S}[v] - v\,\mathcal{S}[u] = \big(P(uv' - vu')\big)'$$

(verify by expanding) integrates to

$$\int_a^b \big(u\,\mathcal{S}[v] - v\,\mathcal{S}[u]\big)\,dx = \Big[P(uv' - vu')\Big]_a^b = 0,$$

because at each end the boundary condition makes the vectors (u, u') and (v, v') both orthogonal to the nonzero vector (α_1, α_2) (resp. (β_1, β_2)), hence parallel, so $uv' - vu' = 0$ there. The operator is **self-adjoint** — the function-space counterpart of a symmetric matrix. Now take $u = y_m, v = y_n$ with $\mathcal{S}[y_k] = -\lambda_k w y_k$: the identity gives $(\lambda_m - \lambda_n)\int_a^b y_m y_n w\,dx = 0$, so the integral vanishes when $\lambda_m \neq \lambda_n$. Applying the same identity to $u = y$, $v = \bar{y}$ for a possibly complex eigenpair gives $(\lambda - \bar{\lambda})\int |y|^2 w\,dx = 0$, so λ is real. □

Parts 1, 2, 4 and 5 need more machinery (comparison theorems and functional analysis) and are quoted. Part 3 is what makes coefficients of an eigenfunction expansion computable one at a time — exactly as with the orthogonal eigenvectors of a symmetric matrix.

Worked Example 11.35 — Neumann conditions

Find the eigenvalues and eigenfunctions of $y'' + \lambda y = 0$, $y'(0) = 0$, $y'(L) = 0$.

Step 1 ($\lambda < 0$). $y = c_1 \cosh kx + c_2 \sinh kx$: $y'(0) = kc_2 = 0$, then $y'(L) = kc_1 \sinh kL = 0$ forces $c_1 = 0$. No eigenvalues.

Step 2 ($\lambda = 0$). $y = c_1 + c_2 x$: $y' = c_2 = 0$, leaving $y = c_1$. So $\lambda_0 = 0$ **is** an eigenvalue with eigenfunction $y_0 = 1$.

Step 3 ($\lambda = k^2 > 0$). $y'(0) = kc_2 = 0$; $y'(L) = -kc_1 \sin kL = 0$ needs $kL = n\pi$.

Result. $\lambda_n = (n\pi/L)^2$, $y_n = \cos(n\pi x/L)$, $n = 0, 1, 2, \ldots$ — the cosine set of Fourier series. The constant mode $n = 0$ is the "DC term"; it exists because insulating (zero-flux) ends allow any uniform level.

Worked Example 11.36 — A Robin condition with transcendental eigenvalues

Find the eigenvalues of $y'' + \lambda y = 0$, $y(0) = 0$, $y'(1) + y(1) = 0$.

Step 1. For $\lambda \leq 0$ one checks as before that only $y \equiv 0$ survives (for $\lambda = -k^2$, the condition becomes $k\cosh k + \sinh k = 0$, impossible for $k > 0$; for $\lambda = 0$, $y = c_2 x$ gives $2c_2 = 0$).

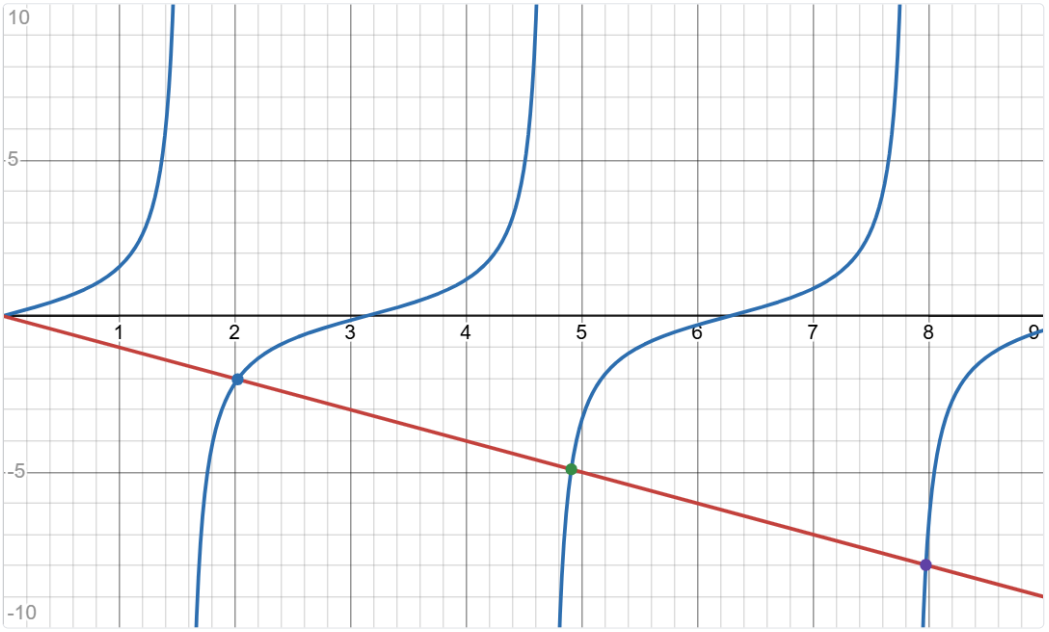
Step 2. For $\lambda = k^2 > 0$, $y(0) = 0$ gives $y = \sin kx$, and the Robin condition gives $k\cos k + \sin k = 0$, i.e.

$$\tan k = -k.$$

Step 3 (solve numerically). The roots are the intersections of $y = \tan k$ with $y = -k$, one in each interval $\left((n - \tfrac{1}{2})\pi, n\pi\right)$. Newton's method (Ch. 22) gives

$$k_1 = 2.0288, \quad k_2 = 4.9132, \quad k_3 = 7.9787, \qquad \lambda_n = k_n^2 = 4.116,\ 24.14,\ 63.66.$$

Check. $\tan(2.0288) = -2.0288$ to four figures. ✓ For large n, $k_n \to (n - \tfrac{1}{2})\pi$ from above: $(3 - 0.5)\pi = 7.854$ versus 7.979. The eigenfunctions $\sin k_n x$ are orthogonal on $[0, 1]$ even though the k_n are not equally spaced — guaranteed by the Sturm–Liouville theorem, not by any trigonometric identity.



Graphical solution of $\tan k = -k$ (Example 11.36): the eigenvalues of a Robin problem are the intersections of $\tan k$ (blue) with the line $-k$ (red), approaching $(n - \tfrac{1}{2})\pi$ as n grows.

Worked Example 11.37 — A weighted Sturm–Liouville problem

Solve $x^2y'' + xy' + \lambda y = 0$ on $1 < x < e$ with $y(1) = y(e) = 0$, and identify the weight.

Step 1 (SL form). Dividing by x: $xy'' + y' + (\lambda/x)y = 0$, i.e. $(xy')' + \lambda \dfrac{1}{x}\, y = 0$. So $P = x$, $Q = 0$, $w = 1/x$.

Step 2 (solve). This is Cauchy–Euler (§11.4) with indicial equation $m^2 + \lambda = 0$. For $\lambda = k^2 > 0$, $y = c_1 \cos(k \ln x) + c_2 \sin(k \ln x)$. $y(1) = c_1 = 0$; $y(e) = c_2 \sin k = 0$ needs $k = n\pi$. (As in the model problem, $\lambda \le 0$ gives only the trivial solution.)

Step 3. $\lambda_n = n^2\pi^2$, $y_n = \sin(n\pi \ln x)$.

Check (orthogonality with weight). With $u = \ln x$, $du = dx/x$:

$$\int_1^e \sin(m\pi \ln x)\sin(n\pi \ln x)\,\frac{dx}{x} = \int_0^1 \sin(m\pi u)\sin(n\pi u)\,du = 0, \quad m \neq n. \checkmark$$

Without the weight $1/x$ the integral is *not* zero — orthogonality is always relative to the weight of the SL form.

Common pitfall — forgetting $\lambda \le 0$

Always check $\lambda < 0$, $\lambda = 0$ and $\lambda > 0$ separately. Dirichlet problems have no zero eigenvalue, but Neumann and periodic problems do, and some Robin conditions (with the "wrong" sign) produce a negative eigenvalue. Missing the $\lambda_0 = 0$ mode loses the average value of every Fourier-cosine expansion.

Engineering note — eigenvalues are resonances

In a separation-of-variables solution of the wave equation on a line or in a cavity, $\lambda_n = (n\pi/L)^2$ becomes $(\omega_n/c)^2$: the eigenvalues fix the **resonant frequencies** $\omega_n = n\pi c/L$, and the eigenfunctions are the **mode shapes**. The Fredholm alternative is the precise statement of what happens if a structure is driven exactly at one of them: no steady solution exists unless the drive is orthogonal to that mode. Ch. 13 uses these results directly.

11.9 Systems of differential equations

Motivation

Real networks have several state variables that interact: two coupled resonators, a multi-loop filter, a motor with electrical and mechanical dynamics, a transistor amplifier with several internal capacitances. Writing each state's rate of change in terms of all states gives a **system** of first-order equations. Systems are also the universal form: every nth-order equation is one (§11.5), every simulator integrates one, and the geometry of systems — trajectories in a state space, equilibria, modes — is the clearest way to understand dynamics. This section gives the general theory and the eigenvector method for constant coefficients; the matrix exponential and the full state-variable formulation of circuits are developed in Ch. 12.

Linear first-order system

$$\dot{\mathbf{x}}(t) = \mathbf{A}(t)\,\mathbf{x}(t) + \mathbf{f}(t), \qquad \mathbf{x}(t) \in \mathbb{R}^n,$$

with $\mathbf{A}(t)$ an $n \times n$ matrix and $\mathbf{f}(t)$ an input vector, both continuous on I. The system is **homogeneous** if $\mathbf{f} \equiv \mathbf{0}$. An IVP adds $\mathbf{x}(t_0) = \mathbf{x}_0$. By §11.7, the IVP has a unique solution on all of I.

Structure theory

Everything in §11.4–§11.6 has a matrix counterpart.

- **Dimension.** Solutions of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ form an n-dimensional vector space.
- **Fundamental matrix.** A matrix $\mathbf{\Phi}(t)$ whose n columns are independent solutions satisfies $\dot{\mathbf{\Phi}} = \mathbf{A}\mathbf{\Phi}$ and $\det \mathbf{\Phi} \neq 0$. The general homogeneous solution is $\mathbf{x} = \mathbf{\Phi}(t)\mathbf{c}$, and the IVP solution is $\mathbf{x}(t) = \mathbf{\Phi}(t)\mathbf{\Phi}(t_0)^{-1}\mathbf{x}_0$.
- **Liouville's formula** (Abel's formula for systems):

$$\det \mathbf{\Phi}(t) = \det \mathbf{\Phi}(t_0)\, \exp\!\left(\int_{t_0}^{t} \operatorname{tr} \mathbf{A}(s)\, ds \right).$$

For the companion matrix of §11.5, $\operatorname{tr}\mathbf{A} = -p_{n-1}$ and $\mathbf{\Phi}$ is the Wronskian matrix, so this reproduces Abel's formula.

- **Variation of parameters.** Seeking $\mathbf{x}_p = \mathbf{\Phi}(t)\mathbf{u}(t)$ gives $\mathbf{\Phi}\dot{\mathbf{u}} = \mathbf{f}$, so

$$\mathbf{x}(t) = \mathbf{\Phi}(t)\mathbf{\Phi}(t_0)^{-1}\mathbf{x}_0 + \mathbf{\Phi}(t)\int_{t_0}^{t} \mathbf{\Phi}(s)^{-1}\mathbf{f}(s)\, ds.$$

The first term is the zero-input response, the second the zero-state response — the matrix version of §11.3's formula.

Derivation of variation of parameters. $\dot{\mathbf{x}}_p = \dot{\mathbf{\Phi}}\mathbf{u} + \mathbf{\Phi}\dot{\mathbf{u}} = \mathbf{A}\mathbf{\Phi}\mathbf{u} + \mathbf{\Phi}\dot{\mathbf{u}}$. Setting this equal to $\mathbf{A}\mathbf{x}_p + \mathbf{f} = \mathbf{A}\mathbf{\Phi}\mathbf{u} + \mathbf{f}$ leaves $\mathbf{\Phi}\dot{\mathbf{u}} = \mathbf{f}$; $\mathbf{\Phi}$ is invertible, so $\dot{\mathbf{u}} = \mathbf{\Phi}^{-1}\mathbf{f}$. $\square$

Constant coefficients: the eigenvector method

For constant $\mathbf{A}$, try $\mathbf{x} = \mathbf{v}e^{\lambda t}$ with a constant vector $\mathbf{v} \neq \mathbf{0}$. Then $\dot{\mathbf{x}} = \lambda \mathbf{v} e^{\lambda t}$ and $\mathbf{A}\mathbf{x} = \mathbf{A}\mathbf{v}e^{\lambda t}$, so we need

$$\mathbf{A}\mathbf{v} = \lambda\mathbf{v}:$$

an eigenvalue problem (Ch. 10). Each eigenpair gives a **mode** — a solution that keeps its shape $\mathbf{v}$ and only scales by $e^{\lambda t}$.

Eigen-solution of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$

If $\mathbf{A}$ has n linearly independent eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ with eigenvalues $\lambda_1, \dots, \lambda_n$, then

$$\mathbf{x}(t) = c_1\mathbf{v}_1 e^{\lambda_1 t} + \cdots + c_n\mathbf{v}_n e^{\lambda_n t},$$

and the constants are found from $\mathbf{x}(0) = \sum c_k\mathbf{v}_k$, i.e. by solving $\mathbf{V}\mathbf{c} = \mathbf{x}_0$ with $\mathbf{V} = [\mathbf{v}_1 \cdots \mathbf{v}_n]$.

Independence of the eigensolutions follows from Liouville or directly: at $t = 0$ the fundamental matrix is $\mathbf{V}$, which is invertible. Three cases arise.

Complex eigenvalues. If $\mathbf{A}$ is real and $\lambda = \alpha + j\beta$ with eigenvector $\mathbf{v} = \mathbf{a} + j\mathbf{b}$, then $\bar{\lambda}, \bar{\mathbf{v}}$ is also an eigenpair, and the real and imaginary parts of $\mathbf{v}e^{\lambda t}$ are two real independent solutions:

$$e^{\alpha t}\big(\mathbf{a}\cos\beta t - \mathbf{b}\sin\beta t\big), \qquad e^{\alpha t}\big(\mathbf{a}\sin\beta t + \mathbf{b}\cos\beta t\big).$$

(Real and imaginary parts of a complex solution of a real linear system are solutions, because $\mathbf{A}$ is real.)

Repeated eigenvalues with too few eigenvectors (defective A). If λ is a double eigenvalue with only one eigenvector $\mathbf{v}$, a second solution is

$$\mathbf{x}_2 = (t\,\mathbf{v} + \mathbf{w})\,e^{\lambda t}, \qquad (\mathbf{A} - \lambda\mathbf{I})\mathbf{w} = \mathbf{v},$$

where $\mathbf{w}$ is a **generalised eigenvector**. (Substituting: $\dot{\mathbf{x}}_2 = (\mathbf{v} + \lambda t\mathbf{v} + \lambda\mathbf{w})e^{\lambda t}$, and $\mathbf{A}\mathbf{x}_2 = (\lambda t\mathbf{v} + \lambda\mathbf{w} + \mathbf{v})e^{\lambda t}$.) This is the matrix origin of the $te^{\lambda t}$ terms of repeated characteristic roots. The general treatment via $e^{\mathbf{A}t}$ and Jordan form is in Ch. 12.

Worked Example 11.38 — A symmetric 2×2 system

Solve $\dot{x}_1 = -3x_1 + x_2$, $\dot{x}_2 = x_1 - 3x_2$ with $x_1(0) = 2$, $x_2(0) = 0$.

Step 1 (eigenvalues). $\mathbf{A} = \begin{pmatrix} -3 & 1 \\ 1 & -3 \end{pmatrix}$, $\det(\mathbf{A} - \lambda\mathbf{I}) = (\lambda+3)^2 - 1 = 0$, so $\lambda_1 = -2$, $\lambda_2 = -4$.

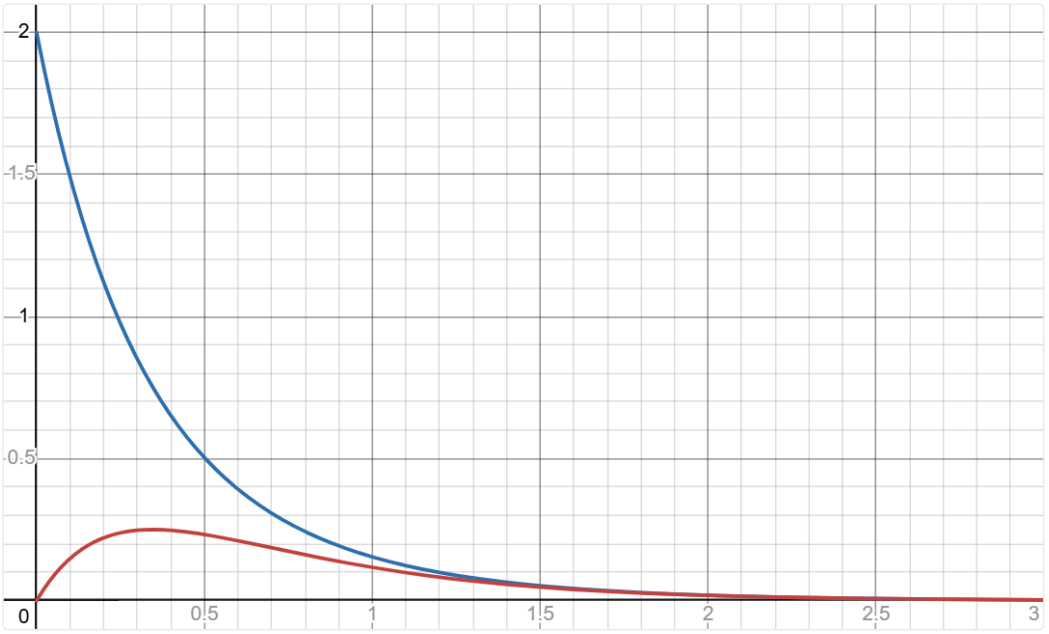
Step 2 (eigenvectors). For $\lambda_1 = -2$: $\begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}\mathbf{v} = \mathbf{0}$ gives $\mathbf{v}_1 = (1, 1)^{\mathsf{T}}$. For $\lambda_2 = -4$: $\mathbf{v}_2 = (1, -1)^{\mathsf{T}}$. (Orthogonal, as for any symmetric matrix.)

Step 3 (fit). $c_1 + c_2 = 2$, $c_1 - c_2 = 0$, so $c_1 = c_2 = 1$:

$$x_1 = e^{-2t} + e^{-4t}, \qquad x_2 = e^{-2t} - e^{-4t}.$$

Check. $\dot{x}_1 = -2e^{-2t} - 4e^{-4t}$ and $-3x_1 + x_2 = -2e^{-2t} - 4e^{-4t}$. ✓ Liouville: $\operatorname{tr}\mathbf{A} = -6$, and $\det\mathbf{\Phi} \propto e^{-2t}e^{-4t} = e^{-6t}$. ✓

Modes. The symmetric mode $(1, 1)$ (both states equal) decays with time constant 0.5; the antisymmetric mode $(1, -1)$ decays twice as fast. Any initial state is a mixture of the two.



Example 11.38: x_1 (blue) and x_2 (red). The fast mode e^{-4t} dies first, after which $x_1 \approx x_2$ and both follow the slow mode e^{-2t}.

Worked Example 11.39 — Complex eigenvalues

Solve $\dot{\mathbf{x}} = \begin{pmatrix} -1 & -4 \\ 1 & -1 \end{pmatrix}\mathbf{x}$, $\mathbf{x}(0) = (1,0)^{\mathsf{T}}$.

Step 1. $\det(\mathbf{A} - \lambda\mathbf{I}) = (\lambda+1)^2 + 4 = 0$, so $\lambda = -1 \pm 2j$.

Step 2. For $\lambda = -1 + 2j$: $(\mathbf{A} - \lambda\mathbf{I}) = \begin{pmatrix} -2j & -4 \\ 1 & -2j \end{pmatrix}$; the second row gives $v_1 = 2jv_2$, so $\mathbf{v} = (2j, 1)^{\mathsf{T}}$, i.e. $\mathbf{a} = (0,1)^{\mathsf{T}}$, $\mathbf{b} = (2,0)^{\mathsf{T}}$.

Step 3 (real solutions).

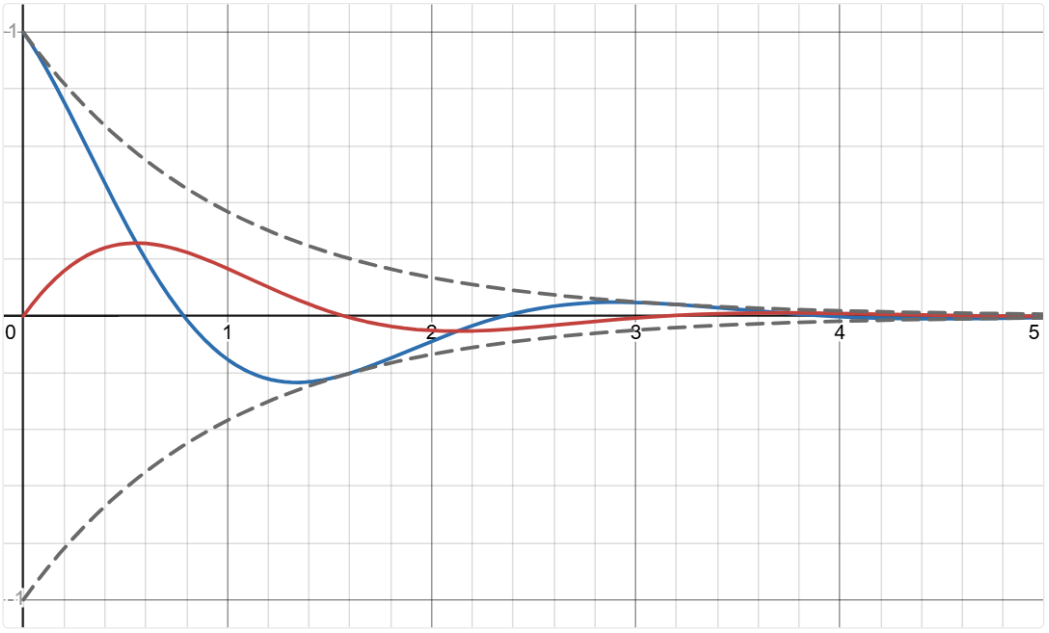
$$\mathbf{x} = e^{-t}\left[c_1\begin{pmatrix} -2\sin 2t \\ \cos 2t \end{pmatrix} + c_2\begin{pmatrix} 2\cos 2t \\ \sin 2t \end{pmatrix}\right].$$

Step 4 (fit). At $t = 0$: $(2c_2, c_1) = (1,0)$, so $c_1 = 0$, $c_2 = \tfrac{1}{2}$:

$$x_1 = e^{-t}\cos 2t, \qquad x_2 = \tfrac{1}{2}e^{-t}\sin 2t.$$

Check. $\dot{x}_1 = -e^{-t}\cos 2t - 2e^{-t}\sin 2t = -x_1 - 4x_2$ ✓; $\dot{x}_2 = -\tfrac{1}{2}e^{-t}\sin 2t + e^{-t}\cos 2t = x_1 - x_2$ ✓.

In the phase plane the state spirals into the origin (a stable focus), turning at 2 rad/s and shrinking by e^{-1} per second — the behaviour of an underdamped RLC tank.



Example 11.39: $x_1 = e^{-t}\cos 2t$ (blue) and $x_2 = \tfrac{1}{2}e^{-t}\sin 2t$ (red), a quarter-period apart inside the decaying envelope $\pm e^{-t}$ set by $\operatorname{Re}\lambda = -1$.

Worked Example 11.40 — A defective matrix

Solve $\dot{\mathbf{x}} = \begin{pmatrix} 1 & -1 \\ 1 & 3 \end{pmatrix}\mathbf{x}$, $\mathbf{x}(0) = (1,1)^{\mathsf{T}}$.

Step 1. $\operatorname{tr}\mathbf{A} = 4$, $\det\mathbf{A} = 4$, so $\lambda^2 - 4\lambda + 4 = (\lambda-2)^2$: a double eigenvalue $\lambda = 2$.

Step 2. $\mathbf{A} - 2\mathbf{I} = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}$ has rank 1, so there is only one eigenvector, $\mathbf{v} = (1,-1)^{\mathsf{T}}$.

Step 3 (generalised eigenvector). $(\mathbf{A} - 2\mathbf{I})\mathbf{w} = \mathbf{v}$: $-w_1 - w_2 = 1$; take $\mathbf{w} = (-1,0)^{\mathsf{T}}$.

Step 4. $\mathbf{x} = c_1\mathbf{v}e^{2t} + c_2(t\mathbf{v} + \mathbf{w})e^{2t}$. At $t = 0$: $c_1\mathbf{v} + c_2\mathbf{w} = (c_1 - c_2, -c_1) = (1,1)$, so $c_1 = -1$, $c_2 = -2$:

$$\mathbf{x}(t) = e^{2t}\begin{pmatrix} 1 - 2t \\ 1 + 2t \end{pmatrix}.$$

Check. $\dot{x}_1 = e^{2t}(2 - 4t - 2) = -4te^{2t}$ and $x_1 - x_2 = -4te^{2t}$ ✓; $\dot{x}_2 = e^{2t}(2 + 4t + 2) = (4+4t)e^{2t}$ and $x_1 + 3x_2 = (4+4t)e^{2t}$ ✓.

The phase plane for 2×2 systems

Plotting x_2 against x_1 — the **phase plane** — shows all trajectories at once. For $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ with $\det\mathbf{A} \neq 0$ the origin is the only equilibrium, and its type depends only on the eigenvalues, which in turn depend only on $T = \operatorname{tr}\mathbf{A}$ and $\Delta = \det\mathbf{A}$ through $\lambda^2 - T\lambda + \Delta = 0$:

Condition	Eigenvalues	Equilibrium type	Stability
$\Delta < 0$	real, opposite signs	saddle	unstable
$\Delta > 0, T^2 > 4\Delta, T < 0$	real, both negative	node	asymptotically stable

Condition	Eigenvalues	Equilibrium type	Stability
$\Delta > 0, T^2 > 4\Delta, T > 0$	real, both positive	node	unstable
$\Delta > 0, T^2 < 4\Delta, T < 0$	complex, $\operatorname{Re}\lambda < 0$	spiral (focus)	asymptotically stable
$\Delta > 0, T^2 < 4\Delta, T > 0$	complex, $\operatorname{Re}\lambda > 0$	spiral	unstable
$\Delta > 0, T = 0$	purely imaginary	centre	stable, not asymptotically

So a 2×2 linear system is asymptotically stable exactly when $\operatorname{tr}\mathbf{A} < 0$ and $\det\mathbf{A} > 0$ — the two-state case of the Routh–Hurwitz criterion. Examples 11.38, 11.39 and 11.40 are a stable node ($T = -6$, $\Delta = 8$), a stable spiral ($T = -2$, $\Delta = 5$) and an unstable degenerate node ($T = 4$, $\Delta = 4 = T^2/4$).

Nonlinear systems and linearisation

For an autonomous nonlinear system $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$, an **equilibrium** $\mathbf{x}^*$ satisfies $\mathbf{F}(\mathbf{x}^*) = \mathbf{0}$. Setting $\mathbf{x} = \mathbf{x}^* + \boldsymbol{\eta}$ and expanding to first order (Ch. 6),

$$\dot{\boldsymbol{\eta}} \approx \mathbf{J}\,\boldsymbol{\eta}, \qquad \mathbf{J} = \left.\frac{\partial \mathbf{F}}{\partial \mathbf{x}}\right|_{\mathbf{x}^*},$$

where $\mathbf{J}$ is the Jacobian matrix.

Linearisation (Hartman–Grobman, informal)

If no eigenvalue of $\mathbf{J}$ has zero real part (the equilibrium is **hyperbolic**), then near $\mathbf{x}^*$ the trajectories of the nonlinear system look like those of $\dot{\boldsymbol{\eta}} = \mathbf{J}\boldsymbol{\eta}$: same type (node, saddle, spiral) and same stability. If some eigenvalue has zero real part (for example a linear centre), the linearisation is inconclusive and the nonlinear terms decide.

Worked Example 11.41 — Equilibria of a damped pendulum

The damped pendulum $\ddot{\theta} + 0.5\dot{\theta} + \sin\theta = 0$ becomes, with $x_1 = \theta$, $x_2 = \dot{\theta}$,

$$\dot{x}_1 = x_2, \qquad \dot{x}_2 = -\sin x_1 - 0.5x_2.$$

Classify the equilibria $(0,0)$ and $(\pi,0)$.

Step 1 (Jacobian). $\mathbf{J} = \begin{pmatrix} 0 & 1 \\ -\cos x_1 & -0.5 \end{pmatrix}$.

Step 2 (hanging down, $(0,0)$). $\mathbf{J} = \begin{pmatrix} 0 & 1 \\ -1 & -0.5 \end{pmatrix}$: $T = -0.5$, $\Delta = 1$, $T^2 < 4\Delta$. Eigenvalues $-0.25 \pm 0.968j$: a **stable spiral** — the pendulum swings with decaying amplitude.

Step 3 (inverted, $(\pi,0)$). $\mathbf{J} = \begin{pmatrix} 0 & 1 \\ 1 & -0.5 \end{pmatrix}$: $\Delta = -1 < 0$, a **saddle**. Eigenvalues $\left(-0.5 \pm \sqrt{4.25}\right)/2 = 0.781,\ -1.281$. The unstable direction is the eigenvector for 0.781: almost every small disturbance topples the pendulum.

Check. Both equilibria are hyperbolic, so the nonlinear pendulum has the same local behaviour. The same analysis applied to a phase-locked loop (whose phase-error equation has exactly this form) shows that the loop locks at one equilibrium and is repelled from the other.

Engineering note — small-signal analysis is linearisation

The small-signal model of a transistor circuit is the Jacobian of the large-signal equations at the DC operating point: $g_m = \partial i_C/\partial v_{BE}$, r_π, r_o are entries of $\mathbf{J}$. Hartman–Grobman is the mathematical warrant for trusting small-signal stability analysis — and the warning that when a pole sits on the $j\omega$-axis (an oscillator at the edge of start-up), the linear model cannot predict the amplitude; nonlinear terms must be kept (compare Example 11.13).

11.10 Applications to electrical circuits

From a circuit to a differential equation

Every lumped-circuit ODE is built from two ingredients.

1. **Element laws.** $v_R = Ri$; $v_L = L\,\dfrac{di}{dt}$; $i_C = C\,\dfrac{dv}{dt}$; plus any nonlinear laws such as a diode $i = I_S\left(e^{v/V_T} - 1\right)$, a saturating inductor $v = \dfrac{d\lambda(i)}{dt}$, or a time-varying element $i = \dfrac{d}{dt}\big(C(t)v\big)$.
2. **Kirchhoff's laws.** KVL around loops and KCL at nodes — linear algebraic constraints (Ch. 8).

The natural unknowns are the **state variables**: capacitor voltages and inductor currents. They carry the stored energy ($\tfrac12 Cv^2$, $\tfrac12 Li^2$), they are continuous in time (§11.7), and their values at one instant, together with the sources thereafter, determine everything else. The number of independent state variables is the **order** of the circuit.

A systematic procedure.

1. Choose the state variables: one v_C per independent capacitor, one i_L per independent inductor.
2. Express each $C\,\dot{v}_C$ as a capacitor current and each $L\,\dot{i}_L$ as an inductor voltage.
3. Use KVL, KCL and the resistive element laws to write those currents and voltages in terms of the states and the sources.

4. The result is $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x}, t)$ — linear, $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}(t)$, if all elements are linear and time-invariant.
5. Eliminate states if a single higher-order equation for one output is wanted (§11.5 in reverse).

Ch. 12 refines steps 1–4 into the formal state-variable method and solves the resulting constant-coefficient systems completely. The table below shows which method of *this* chapter each common circuit leads to.

Circuit	Equation	Type (this chapter)
Series RC, source v_s	$RC\,\dot{v}_C + v_C = v_s(t)$	linear first order (§11.3)
Series RL	$L\,\dot{i} + Ri = v_s(t)$	linear first order (§11.3)
C discharging into nonlinear load $i = g(v)$	$C\,\dot{v} = -g(v)$	separable (§11.2)
RC with time-varying $C(t)$ or $R(t)$	$R\,\dfrac{d}{dt}(Cv) + v = v_s$	linear, variable coefficient (§11.3)
Series RLC	$LC\,\ddot{v}_C + RC\,\dot{v}_C + v_C = v_s$	linear second order (§11.4, Ch. 12)
Multi-loop or multi-node network	$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$	linear system (§11.9)
Negative-resistance oscillator	$\ddot{v} - \mu(1 - v^2)\dot{v} + v = 0$	nonlinear system (§11.9)
Distributed line or electrode at DC	$V'' = rg\,V$ on $0 < x < \ell$	boundary-value problem (§11.8)

Worked Example 11.42 — RC charging

A 10 kΩ resistor and a 10 μF capacitor (initially uncharged) are connected to a 5 V source at $t = 0$. Find $v_C(t)$, its value at $t = 0.2$ s, and the time to reach 4.5 V.

Step 1. KVL: $RC\,\dot{v}_C + v_C = 5$, with $\tau = RC = 10^4 \cdot 10^{-5} = 0.1$ s.

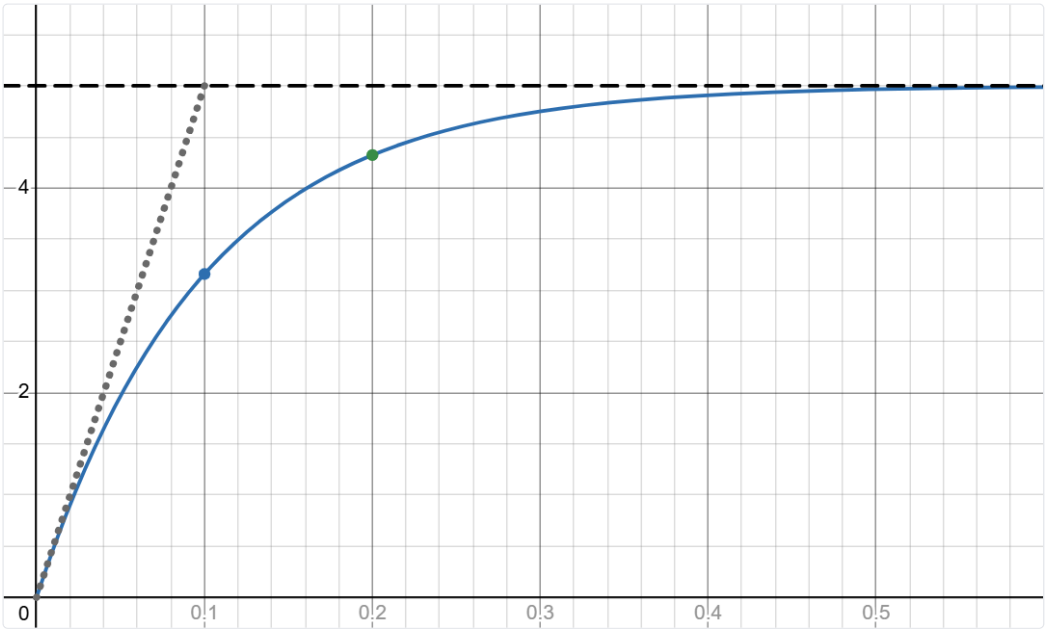
Step 2. By §11.3 with $v_C(0) = 0$:

$$v_C(t) = 5\left(1 - e^{-t/0.1}\right)\ \text{V}.$$

Step 3. At $t = 0.2$ s: $v_C = 5(1 - e^{-2}) = 5(0.8647) = 4.32$ V.

Step 4. $5(1 - e^{-t/\tau}) = 4.5$ gives $e^{-t/\tau} = 0.1$, so $t = \tau \ln 10 = 0.230$ s.

Check. Units: $\Omega \cdot \text{F} = (\text{V/A})(\text{A s/V}) = \text{s}$. ✓ Initial slope $\dot{v}_C(0) = 5/\tau = 50$ V/s equals $i(0)/C = (5/10^4)/10^{-5} = 50$ V/s. ✓



RC charging with $\tau = 0.1$ s: 63% of the final value after one time constant, 86% after two and over 98% after 4τ. The dotted initial tangent reaches the final value exactly at $t = \tau$.

Worked Example 11.43 — A two-loop network as a system

Loop 1 contains the source $v(t)$, $R_1 = 2\ \Omega$ and $L_1 = 1$ H. Loop 2 contains $R_3 = 2\ \Omega$ and $L_2 = 1$ H. The loops share $R_2 = 1\ \Omega$. Find the mesh currents when $v = 8$ V is switched on at $t = 0$ with both inductors initially unenergised.

Step 1 (KVL). With mesh currents i_1, i_2 (which here are also the inductor currents, hence states):

$$L_1\dot{i}_1 + R_1 i_1 + R_2(i_1 - i_2) = v(t),$$
$$L_2\dot{i}_2 + R_3 i_2 + R_2(i_2 - i_1) = 0.$$

Step 2 (state form).

$$\frac{d}{dt}\begin{pmatrix} i_1 \\ i_2 \end{pmatrix} = \begin{pmatrix} -3 & 1 \\ 1 & -3 \end{pmatrix}\begin{pmatrix} i_1 \\ i_2 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \end{pmatrix} v(t).$$

The matrix is that of Example 11.38: eigenvalues -2 and -4 s^{-1} (the network's **natural frequencies**), modes $(1,1)$ and $(1,-1)$.

Step 3 (particular solution). For constant input, try a constant: $\mathbf{0} = \mathbf{A}\mathbf{x}_p + \mathbf{b}\cdot 8$, so $\mathbf{x}_p = -8\mathbf{A}^{-1}\mathbf{b}$. With $\mathbf{A}^{-1} = \frac{1}{8}\begin{pmatrix} -3 & -1 \\ -1 & -3 \end{pmatrix}$, $\mathbf{x}_p = (3,1)^{\mathsf{T}}$ A.

Step 4 (fit zero initial state). $\mathbf{x} = (3,1)^{\mathsf{T}} + c_1(1,1)^{\mathsf{T}}e^{-2t} + c_2(1,-1)^{\mathsf{T}}e^{-4t}$, with $c_1 + c_2 = -3$ and $c_1 - c_2 = -1$, so $c_1 = -2$, $c_2 = -1$:

$$i_1 = 3 - 2e^{-2t} - e^{-4t}\ \text{A}, \qquad i_2 = 1 - 2e^{-2t} + e^{-4t}\ \text{A}.$$

Check. $i_1(0) = i_2(0) = 0$ ✓. DC check with inductors as shorts: loop 1, $2(3) + 1(3-1) = 8$ ✓; loop 2, $2(1) + 1(1-3) = 0$ ✓. Settling is governed by the slow mode e^{-2t}: within 1% of DC after about $t = \ln(200)/2 \approx 2.6$ s.

Worked Example 11.44 — A leaky line at DC: a boundary-value problem

A long cable (or a buried grounding conductor) has series resistance $r = 0.1\ \Omega/\text{m}$ and leakage conductance $g = 10^{-5}$ S/m to ground, length $\ell = 1$ km. A DC voltage V_0 is applied at $x = 0$ and the far end is open. Find $V(x)$, the far-end voltage and the input resistance.

Step 1 (model). On a short piece dx: the series drop is $dV = -rI\,dx$ and the leakage is $dI = -gV\,dx$. Hence $V' = -rI$, $I' = -gV$, and eliminating I,

$$V'' = \alpha^2 V, \qquad \alpha = \sqrt{rg} = \sqrt{10^{-6}} = 10^{-3}\ \text{m}^{-1}.$$

Step 2 (boundary conditions). $V(0) = V_0$ (Dirichlet). The open end carries no current: $I(\ell) = -V'(\ell)/r = 0$, i.e. $V'(\ell) = 0$ (Neumann).

Step 3 (solve). Using the basis $\cosh\alpha(\ell - x)$, $\sinh\alpha(\ell - x)$ — chosen so the Neumann condition at $x = \ell$ is easy — the condition $V'(\ell) = 0$ kills the sinh term, and $V(0) = V_0$ fixes the amplitude:

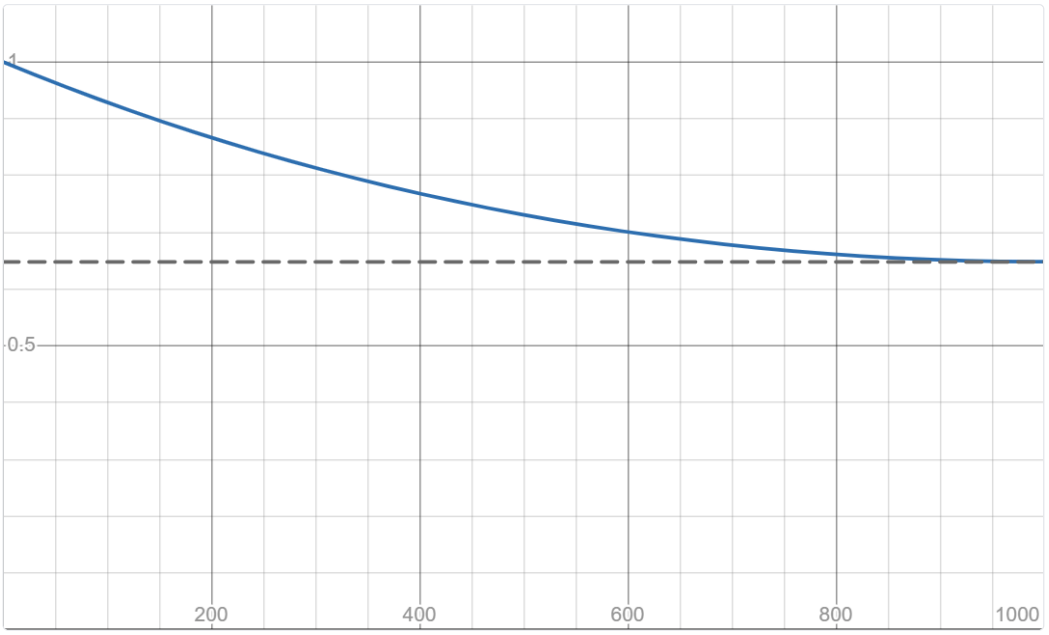
$$V(x) = V_0\,\frac{\cosh\alpha(\ell - x)}{\cosh\alpha\ell}.$$

The homogeneous problem ($V_0 = 0$) has only the trivial solution, since cosh never vanishes, so by the Fredholm alternative this is the unique solution.

Step 4 (numbers). $\alpha\ell = 1$: far-end voltage $V(\ell) = V_0/\cosh 1 = 0.648\,V_0$. Input current $I(0) = -V'(0)/r = V_0\alpha\tanh(\alpha\ell)/r$, so

$$R_{\text{in}} = \frac{r}{\alpha\tanh\alpha\ell} = \frac{0.1}{10^{-3}\cdot 0.7616} = 131\ \Omega.$$

Check. Two limits confirm the formula. For a very long line ($\alpha\ell \to \infty$), $\tanh \to 1$ and $R_{\text{in}} \to \sqrt{r/g} = 100\ \Omega$, the characteristic resistance. For a very short line, $\tanh\alpha\ell \approx \alpha\ell$ and $R_{\text{in}} \approx 1/(g\ell)$, the total leakage resistance in parallel to ground, as expected when series drop is negligible. Our line is finite and open-ended, so less leakage path is available than on an infinite line and $R_{\text{in}} = 131\ \Omega$ exceeds $100\ \Omega$. ✓ Directly: $V'' = \alpha^2 V$ holds since $\big(\cosh\alpha(\ell - x)\big)'' = \alpha^2\cosh\alpha(\ell - x)$, and $V'(\ell) = -\alpha V_0\sinh 0/\cosh\alpha\ell = 0$. ✓ The same equation, with α complex, describes AC voltage along a transmission line (Ch. 13).



Normalised DC voltage V/V_0 along the 1 km leaky line of Example 11.44. The curve meets the open end with zero slope (zero current); the far end sits at $1/\cosh 1 = 0.648$ of the input.

Worked Example 11.45 — Start-up of a negative-resistance oscillator

An LC tank in parallel with a nonlinear negative conductance (a tunnel diode, or a cross-coupled transistor pair) gives, in normalised units, the **van der Pol equation**

$$\ddot{v} - \mu\,(1 - v^2)\,\dot{v} + v = 0, \qquad \mu = 0.5.$$

Show that the oscillator starts by itself.

Step 1 (system). $x_1 = v$, $x_2 = \dot{v}$: $\dot{x}_1 = x_2$, $\dot{x}_2 = -x_1 + \mu(1 - x_1^2)x_2$. The only equilibrium is the origin.

Step 2 (linearise). $\mathbf{J} = \begin{pmatrix} 0 & 1 \\ -1 - 2\mu x_1 x_2 & \mu(1 - x_1^2) \end{pmatrix}$, which at the origin is $\begin{pmatrix} 0 & 1 \\ -1 & \mu \end{pmatrix}$: $T = 0.5 > 0$, $\Delta = 1$, $T^2 < 4\Delta$.

Step 3 (classify). Eigenvalues $\lambda = \tfrac{1}{2}\left(\mu \pm \sqrt{\mu^2 - 4}\right) = 0.25 \pm 0.968j$: an **unstable spiral**. Any noise voltage grows as $e^{0.25t}$ while oscillating at ≈ 0.97 (normalised) rad/s. The equilibrium is hyperbolic, so the nonlinear circuit does the same near the origin.

Step 4 (amplitude). Growth cannot continue forever, because for $|v| > 1$ the term $\mu(1 - v^2)$ becomes *positive damping*. Averaging the energy balance over a cycle leads to an amplitude equation of exactly the Bernoulli form of Example 11.13, whose stable equilibrium gives the steady amplitude (≈ 2 for small μ). Linear analysis predicts *whether* an oscillator starts; nonlinear analysis predicts *how large* it gets.

Common pitfall — dependent energy stores

Two capacitors in parallel (or a loop consisting only of capacitors and voltage sources), or two inductors in series (or a cutset of only inductors and current sources), do not add an order: their states are linked by an algebraic constraint. Counting them as independent gives a singular $\mathbf{A}$ or an inconsistent set of initial conditions, and in a simulator can produce "impulsive" currents at switching instants.

Engineering note — what comes next

This chapter *sets up* circuit equations and gives the general solution structure, plus the methods that survive nonlinear and time-varying elements. The systematic constant-coefficient theory — characteristic roots, damping ratio, natural and forced response, steady-state AC, state-variable form and $e^{\mathbf{A}t}$ — is Ch. 12. s-domain impedance methods that solve the same IVPs algebraically, impulses included, are Ch. 14. Nonlinear circuits beyond the reach of separation or linearisation are integrated numerically (Ch. 22), with the existence and uniqueness theory of §11.7 as the guarantee that the numerical answer means something.

Summary

Topic	Key formula / fact
Autonomous stability	$y' = f(y)$, $f(y^*) = 0$: stable if $f'(y^*) < 0$, unstable if $f'(y^*) > 0$
Exact equation	$M_y = N_t \Rightarrow \Phi(t, y) = C$ with $\Phi_t = M$, $\Phi_y = N$
Integrating factor for exactness	$(M_y - N_t)/N = R(t) \Rightarrow \mu = e^{\int R\,dt}$
Separable	$y' = g(t)h(y) \Rightarrow \int dy/h(y) = \int g\,dt + C$; check roots of h
Scale-invariant substitution	$y' = F(y/t)$: $v = y/t$, $tv' = F(v) - v$

Topic	Key formula / fact
Linear first order	$y' + py = r$: $y = y_0 e^{-P(t)} + \int_{t_0}^{t} e^{-[P(t)-P(s)]} r(s)\,ds$, $P = \int_{t_0}^{t} p$
Bernoulli	$y' + py = qy^n$: $v = y^{1-n}$, $v' + (1-n)pv = (1-n)q$
Riccati	known y_1: $y = y_1 + 1/v$, $v' = -(q_1 + 2q_2 y_1)v - q_2$
Wronskian / Abel	$W = y_1 y_2' - y_1' y_2$; $W(t) = W(t_0) e^{-\int_{t_0}^{t} p\,ds}$ (order n: use p_{n-1})
Reduction of order	$y_2 = y_1 \int e^{-\int p\,dt} / y_1^2\,dt$
Cauchy–Euler	$t^2 y'' + aty' + by = 0$: $y = t^m$, $m^2 + (a-1)m + b = 0$; $t = e^x$ gives constant coefficients
Energy integral	$y'' = -U'(y)$: $\tfrac{1}{2}(y')^2 + U(y) = E$
Companion form	$x_k = y^{(k-1)}$; $\det(s\mathbf{I} - \mathbf{A}) = s^n + p_{n-1}s^{n-1} + \cdots + p_0$
Structure theorem	$y = y_h + y_p$; y_h has n free constants
Variation of parameters	$y_p = -y_1 \int y_2 r/W\,dt + y_2 \int y_1 r/W\,dt$ (r from standard form)
Causal Green's function	$G(t,s) = [y_1(s)y_2(t) - y_1(t)y_2(s)]/W(s)$; $y_p = \int_{t_0}^{t} G\,r\,ds$
Picard–Lindelöf	f continuous, Lipschitz in y: unique solution on $\lvert t - t_0\rvert \le \min(a, b/M)$
Continuous dependence	$\lvert y - z\rvert \le \lvert y_0 - z_0\rvert e^{K\lvert t-t_0\rvert}$
Linear IVP	unique solution on the whole interval where coefficients are continuous
BVP solvability	unique $\iff$ homogeneous BVP has only $y \equiv 0$ (Fredholm alternative)
Model eigenvalue problem	$y'' + \lambda y = 0$, $y(0) = y(L) = 0$: $\lambda_n = (n\pi/L)^2$, $y_n = \sin(n\pi x/L)$
Sturm–Liouville	$(Py')' + Qy + \lambda w y = 0$: real simple eigenvalues, $\int y_m y_n w\,dx = 0$ for $m \ne n$
Systems	$\mathbf{x} = \mathbf{\Phi}\mathbf{\Phi}_0^{-1}\mathbf{x}_0 + \mathbf{\Phi}\int \mathbf{\Phi}^{-1}\mathbf{f}\,ds$; $\det\mathbf{\Phi} \propto e^{\int \operatorname{tr}\mathbf{A}}$
Eigenvector method	$\mathbf{x} = \sum c_k \mathbf{v}_k e^{\lambda_k t}$; defective: $(t\mathbf{v} + \mathbf{w})e^{\lambda t}$, $(\mathbf{A} - \lambda\mathbf{I})\mathbf{w} = \mathbf{v}$
2×2 stability	asymptotically stable $\iff$ $\operatorname{tr}\mathbf{A} < 0$ and $\det\mathbf{A} > 0$
Linearisation	$\dot{\boldsymbol{\eta}} = \mathbf{J}\boldsymbol{\eta}$, valid locally when no eigenvalue of $\mathbf{J}$ has zero real part
Circuit element laws	$v_L = L\,di/dt$, $i_C = C\,dv/dt$; states v_C, i_L are continuous; order = number of independent stores

Chapter 12 — Linear Differential Equations

> **Prerequisites:** Ch. 2 (Complex Numbers), Ch. 4 (Differential Calculus), Ch. 8 and Ch. 10 (Matrices, Eigenvalues), Ch. 11 (Ordinary Differential Equations)
>
> **Learning outcomes:** After this chapter you can
>
> - write a linear constant-coefficient ODE in operator form $P(D)y = r(t)$ and use linearity, superposition and time invariance to simplify it;
> - find the homogeneous solution from the roots of the characteristic polynomial in all cases (distinct, repeated, complex), and classify a second-order system as overdamped, critically damped, underdamped or undamped;
> - split a response into natural and forced parts, or into zero-input and zero-state parts, and fit initial conditions correctly;
> - find particular solutions by undetermined coefficients, the complex-exponential (phasor) method and the resonance rule;
> - separate transient from steady-state behaviour, compute frequency response, settling time and overshoot;
> - solve coupled linear equations by elimination and by modal decomposition, and write any linear lumped system as $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u$ with solution through the matrix exponential $e^{\mathbf{A}t}$.

Chapter 11 laid out the general theory of ordinary differential equations: the structure theorem $y = y_h + y_p$, the Wronskian, variation of parameters, existence and uniqueness, and the eigenvector method for first-order systems. This chapter specialises to the case that dominates electrical engineering: **linear equations with constant coefficients**. Every circuit built from ideal resistors, capacitors, inductors, coupled inductors, controlled sources and op-amps operating linearly is described by such equations; so are small-signal models of amplifiers, linearised motors, filters, control loops and transmission-line sections.

Constant coefficients change the mathematics fundamentally. Instead of searching for unknown functions, we search for **roots of a polynomial**. Calculus problems become algebra problems, and the algebra has a clear physical reading: the roots are the natural frequencies of the system, their real parts say how fast energy dissipates, and their imaginary parts say how fast it sloshes between storage elements. The same polynomial reappears as the denominator of the transfer function in Chapter 14 and as the characteristic polynomial of the state matrix in Section 12.7.

The chapter proceeds in eight sections. Sections 12.1–12.2 build the homogeneous theory. Sections 12.3–12.5 add forcing and interpret the result physically. Sections 12.6–12.7 move to several interacting unknowns and to the state-space form that modern analysis and simulation software uses. Section 12.8 pulls everything together on RLC circuits and an electromechanical system.

12.1 Constant-coefficient equations

Motivation

Write Kirchhoff's voltage law around a series loop containing a resistor R, an inductor L, a capacitor C and a source $v_s(t)$. Using the element laws $v_R = Ri$, $v_L = L\,di/dt$, $i = C\,dv_C/dt$:

$$LC\,\frac{d^2 v_C}{dt^2} + RC\,\frac{dv_C}{dt} + v_C = v_s(t).$$

The coefficients LC, RC and 1 are fixed by the component values; they do not depend on time or on v_C. That is the defining feature of the class studied here. The same form arises for a mass–spring–damper ($m\ddot{x} + b\dot{x} + kx = F$), a torsional shaft, a thermal network or the linearised dynamics of a phase-locked loop. Because the form is universal, a single toolkit solves all of them.

Definitions

Linear constant-coefficient ODE

A **linear ordinary differential equation of order n with constant coefficients** is

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 y' + a_0 y = r(t), \qquad a_n \neq 0,$$

where $a_0, \dots, a_n$ are real (occasionally complex) constants and $r(t)$ is a given **forcing function**, **input** or **excitation**. The equation is **homogeneous** if $r(t) \equiv 0$ and **nonhomogeneous** (or *forced*) otherwise. Dividing by a_n gives the **monic** form with $a_n = 1$.

Three words carry the content of the definition:

- *Linear*: y and its derivatives appear only to the first power and are never multiplied together or placed inside a nonlinear function.
- *Constant coefficient*: the a_k do not vary with t. Physically, the components do not age, heat up or switch during the interval considered.
- *Order n*: the highest derivative present. For lumped circuits n equals the number of independent energy-storage elements (capacitors and inductors that cannot be combined into one equivalent element).

The differential operator D

It is efficient to treat differentiation as an algebraic object. Let $D = d/dt$, so $Dy = y'$, $D^2 y = y''$ and in general $D^k y = y^{(k)}$, with $D^0 = 1$ (the identity).

Operator polynomial

For the polynomial $P(s) = a_n s^n + \cdots + a_1 s + a_0$, the **operator polynomial** $P(D)$ acts on a sufficiently differentiable function y by

$$P(D)\,y = a_n D^n y + \cdots + a_1 D y + a_0 y.$$

The equation of the definition above is then simply $P(D)\,y = r(t)$. The polynomial $P(s)$ is called the **characteristic polynomial** of the equation.

The key fact that makes D behave like a number is that constant-coefficient operators **commute** and **factor** exactly like the polynomials that define them.

Algebra of constant-coefficient operators

If $P(s)$ and $Q(s)$ are polynomials with constant coefficients, then for any sufficiently differentiable y

$$P(D)\big[Q(D)\,y\big] = Q(D)\big[P(D)\,y\big] = (PQ)(D)\,y.$$

In particular, if $P(s) = a_n(s - s_1)(s - s_2)\cdots(s - s_n)$ then $P(D) = a_n(D - s_1)(D - s_2)\cdots(D - s_n)$, with the factors in any order.

Proof sketch. By linearity it suffices to check monomials: $D^j(D^k y) = D^{j+k}y = D^k(D^j y)$. Constants pass through D because $D(cy) = cDy$ when c is constant. Expanding both sides term by term gives the same coefficients as polynomial multiplication. □

Common Pitfall

The commuting property fails as soon as a coefficient depends on t. For example $D(t\,y) = y + t\,Dy \neq t\,Dy$. So $(D + t)(D - t) \neq (D - t)(D + t)$, and the factor-and-solve techniques of this chapter do **not** apply to variable-coefficient equations such as Cauchy–Euler or Bessel equations (see Ch. 11).

Linearity and superposition

Superposition

$P(D)$ is a linear operator: for constants c_1, c_2 and functions y_1, y_2,

$$P(D)\,(c_1 y_1 + c_2 y_2) = c_1 P(D) y_1 + c_2 P(D) y_2.$$

Consequently:

1. any linear combination of solutions of the homogeneous equation $P(D)y = 0$ is again a solution;
2. if $P(D)y_1 = r_1$ and $P(D)y_2 = r_2$, then $P(D)(c_1 y_1 + c_2 y_2) = c_1 r_1 + c_2 r_2$;
3. the general solution of $P(D)y = r$ is $y = y_h + y_p$, where y_h is the general homogeneous solution (n arbitrary constants) and y_p is any one particular solution.

Item 3 is the structure theorem of Ch. 11; it is restated here because everything that follows is a recipe for finding y_h (Section 12.2) and y_p (Section 12.4) when coefficients are constant.

Time invariance

Constant coefficients bring a second structural property that variable-coefficient equations lack.

Time invariance (shift property)

If $y(t)$ solves $P(D)y = r(t)$, then for any fixed t_0 the shifted function $y(t - t_0)$ solves $P(D)y = r(t - t_0)$.

Proof. Let $w(t) = y(t - t_0)$. By the chain rule $w^{(k)}(t) = y^{(k)}(t - t_0)$, so $P(D)w(t) = \big[P(D)y\big](t - t_0) = r(t - t_0)$. The coefficients do not change under the shift because they are constants. □

Linearity plus time invariance is the defining pair of properties of an **LTI system** (linear time-invariant). Everything in signal processing that relies on convolution, transfer functions and frequency response depends on both. A circuit with a time-varying element (a switched capacitor, a mixer, a varactor driven by a pump) is linear but not time-invariant, and its equations do not have constant coefficients.

The exponential as eigenfunction

Why should exponentials be the building blocks? Apply D to e^{st}, where s is any complex constant:

$$D\,e^{st} = s\,e^{st}, \qquad D^k e^{st} = s^k e^{st}, \qquad P(D)\,e^{st} = P(s)\,e^{st}.$$

So e^{st} is an **eigenfunction** of every constant-coefficient operator, with eigenvalue $P(s)$. An LTI system therefore maps an exponential input into the same exponential, merely scaled by a complex number. This single identity drives the characteristic equation (Section 12.2), the phasor method (Section 12.4), frequency response (Section 12.5) and, after integration against e^{-st}, the Laplace transform (Ch. 14).

A useful generalisation handles exponentials multiplied by other functions.

Exponential shift theorem

For any constant a and sufficiently differentiable f,

$$P(D)\left[e^{at}f(t)\right] = e^{at}\,P(D+a)\,f(t).$$

Proof. For one factor, $D\left[e^{at}f\right] = ae^{at}f + e^{at}f' = e^{at}(D+a)f$. Applying this k times gives $D^k\left[e^{at}f\right] = e^{at}(D+a)^k f$, and summing with coefficients a_k gives the result. □

The shift theorem lets us "pull an exponential through" an operator. It explains at once why repeated roots produce factors of t (Section 12.2) and why resonant forcing produces $t\,e^{at}$ terms (Section 12.4).

Real solutions from complex ones

When the coefficients a_k are real and $y = u + jv$ is a complex-valued solution of $P(D)y = r$ with r real, then taking real and imaginary parts gives $P(D)u = r$ and $P(D)v = 0$. More generally:

Real and imaginary parts

If the coefficients of P are real and $P(D)z = w(t)$ with z, w complex, then

$$P(D)\ \mathrm{Re}\{z\} = \mathrm{Re}\{w\}, \qquad P(D)\ \mathrm{Im}\{z\} = \mathrm{Im}\{w\}.$$

This is the justification for solving with complex exponentials $e^{j\omega t}$ and then taking real parts, which is precisely what phasor analysis does.

Worked examples

Example 12.1 — First-order RC charging

A capacitor C charges through a resistor R from a DC source V_0 switched on at $t = 0$; the capacitor is initially uncharged. Find $v_C(t)$.

Model. KVL gives $Ri + v_C = V_0$ and $i = C\,dv_C/dt$, so

$$RC\,\frac{dv_C}{dt} + v_C = V_0, \qquad v_C(0) = 0.$$

With $\tau = RC$ (units: $\Omega \cdot \mathrm{F} = \mathrm{s}$) the operator form is $(\tau D + 1)v_C = V_0$, with characteristic polynomial $P(s) = \tau s + 1$ and root $s_1 = -1/\tau$.

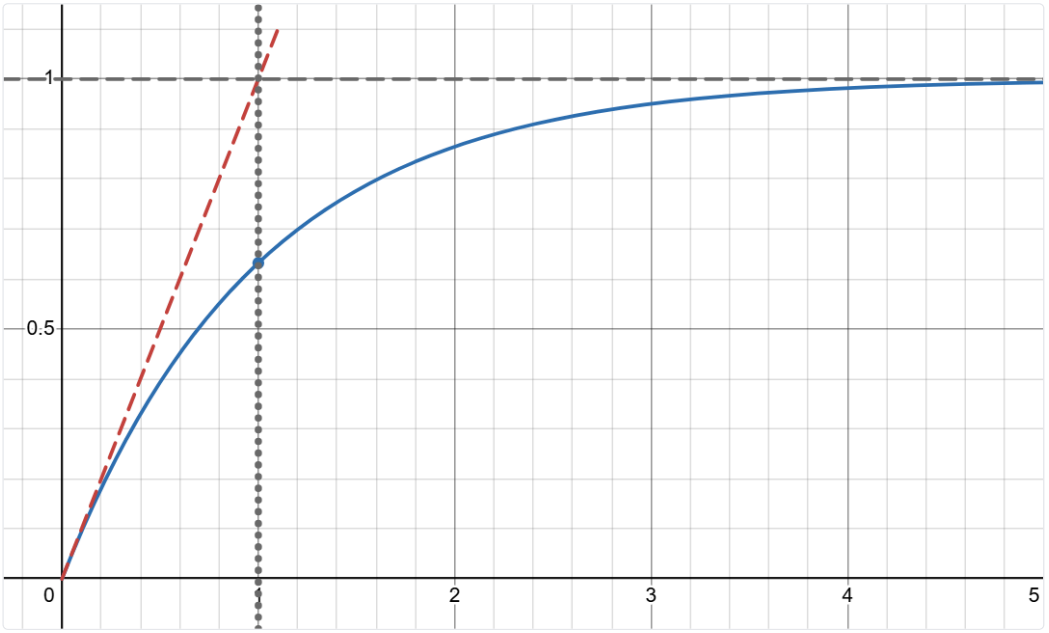
Homogeneous part. $v_h = Ae^{-t/\tau}$.

Particular part. The input is constant, so try a constant $v_p = K$: then $0 + K = V_0$, $K = V_0$.

Initial condition. $v_C = V_0 + Ae^{-t/\tau}$; $v_C(0) = V_0 + A = 0$ gives $A = -V_0$:

$$v_C(t) = V_0\left(1 - e^{-t/\tau}\right), \qquad t \ge 0.$$

Check. At $t = \tau$, $v_C = V_0(1 - e^{-1}) = 0.632\,V_0$; at $t = 5\tau$, $v_C = 0.9933\,V_0$. Substituting: $\tau \cdot (V_0/\tau)e^{-t/\tau} + V_0 - V_0e^{-t/\tau} = V_0$. ✓ With $R = 10\ \mathrm{k\Omega}$, $C = 100\ \mathrm{nF}$, $\tau = 1\ \mathrm{ms}$, the capacitor is within 1% of V_0 after 4.6 ms (since $e^{-4.6} = 0.010$).



Normalised RC charging curve v_C/V_0 against t/τ; the initial tangent (red) reaches the final value exactly at $t = \tau$.

Example 12.2 — Deriving and factoring a second-order operator

Show that $y'' + y' - 2y = 0$ factors as $(D-1)(D+2)y = 0$ and verify directly that e^{t} and e^{-2t} are solutions.

Factoring. $P(s) = s^2 + s - 2 = (s-1)(s+2)$, so by the operator algebra theorem $P(D) = (D-1)(D+2) = (D+2)(D-1)$.

Check by expansion. $(D-1)(D+2)y = (D-1)(y' + 2y) = y'' + 2y' - y' - 2y = y'' + y' - 2y$. ✓

Solutions. $(D-1)e^{t} = e^{t} - e^{t} = 0$, so $(D+2)(D-1)e^{t} = (D+2)\,0 = 0$. Likewise $(D+2)e^{-2t} = 0$, so $(D-1)(D+2)e^{-2t} = 0$. Alternatively, using the eigenfunction identity, $P(D)e^{st} = P(s)e^{st}$ vanishes exactly when $P(s) = 0$, i.e. $s = 1$ or $s = -2$.

The general solution is $y = c_1 e^{t} + c_2 e^{-2t}$; the e^{t} term grows, so this system is unstable.

Example 12.3 — Using the exponential shift theorem

Evaluate $P(D)\left[te^{-3t}\right]$ for $P(D) = D^2 + 6D + 9$, and interpret.

By the shift theorem with $a = -3$, $f = t$:

$$P(D)\left[e^{-3t}t\right] = e^{-3t}P(D-3)\,t = e^{-3t}\left[(D-3)^2 + 6(D-3) + 9\right]t = e^{-3t}D^2 t = 0.$$

The operator $(D-3)^2 + 6(D-3) + 9$ simplifies to D^2 because $P(s) = (s+3)^2$, so $P(s-3) = s^2$. Hence te^{-3t} is a solution of $y'' + 6y' + 9y = 0$, alongside e^{-3t}. This is the repeated-root case of Section 12.2, obtained here without any guesswork.

Direct check. $y = te^{-3t}$, $y' = (1-3t)e^{-3t}$, $y'' = (-6+9t)e^{-3t}$. Then $y'' + 6y' + 9y = (-6 + 9t + 6 - 18t + 9t)e^{-3t} = 0$. ✓

Example 12.4 — Series RLC in operator form

For the series RLC loop of the motivation with $R = 100\ \Omega$, $L = 10$ mH, $C = 1\ \mu$F, write the equation for v_C in monic operator form and find its characteristic polynomial.

Divide $LC\,v_C'' + RC\,v_C' + v_C = v_s$ by $LC = 10^{-8}\ \text{s}^2$:

$$\left(D^2 + \frac{R}{L}D + \frac{1}{LC}\right)v_C = \frac{1}{LC}v_s, \qquad P(s) = s^2 + 10^4 s + 10^8.$$

Dimensional check: R/L has units $\Omega/\text{H} = \text{s}^{-1}$ and $1/LC$ has units s^{-2}, matching D and D^2. The roots, $s = -5000 \pm j\,8660\ \text{s}^{-1}$, are found in Section 12.2 and the full step response in Section 12.8.

Engineering Note

Circuit simulators (SPICE) never form the single nth-order equation; they assemble first-order equations for every node and storage element (modified nodal analysis), which is the state-space viewpoint of Section 12.7. Hand analysis, by contrast, almost always reduces to one equation $P(D)y = r$, because the polynomial $P(s)$ is where the design insight lives: its roots set rise time, ringing and stability.

12.2 Characteristic equations

Motivation

Section 12.1 showed that e^{st} solves $P(D)y = 0$ whenever $P(s) = 0$. Solving a homogeneous constant-coefficient ODE therefore reduces to finding the n roots of a degree-n polynomial and handling two complications: roots may be **repeated**, and roots of a real polynomial may be **complex**. This section treats both and then studies the second-order case in detail, because nearly every practical design specification (damping, overshoot, ringing frequency, quality factor) is phrased in terms of a dominant pair of roots.

The characteristic equation

Characteristic equation and natural frequencies

For $P(D)y = 0$ with $P(s) = a_n s^n + \cdots + a_0$, the algebraic equation

$$P(s) = a_n s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0 = 0$$

is the **characteristic (auxiliary) equation**. Its roots $s_1, \ldots, s_n$ (counted with multiplicity) are the **characteristic roots**, also called the **natural frequencies**, **modes** or **poles** of the system. They have units of s^{-1} when t is in seconds.

One obtains the characteristic equation mechanically by replacing $y^{(k)}$ with s^k. By the fundamental theorem of algebra, a degree-n polynomial has exactly n complex roots counted with multiplicity, and when the coefficients are real, non-real roots occur in **conjugate pairs** $\sigma \pm j\omega$.

Case 1: distinct real roots

Distinct roots

If $P(s)$ has n distinct roots $s_1, \dots, s_n$, then $e^{s_1 t}, \dots, e^{s_n t}$ form a fundamental set of solutions of $P(D)y = 0$, and the general solution is

$$y_h(t) = c_1 e^{s_1 t} + c_2 e^{s_2 t} + \cdots + c_n e^{s_n t}.$$

Proof sketch. Each is a solution by the eigenfunction identity. Independence follows from the Wronskian at $t = 0$, which is the Vandermonde determinant $\prod_{i<k}(s_k - s_i) \neq 0$ for distinct roots (Ch. 8). By the theory of Ch. 11, n independent solutions of an nth-order linear equation span all solutions. □

The theorem holds for distinct complex roots too; Case 3 converts the complex exponentials into real functions.

Case 2: repeated roots

If s_1 is a root of multiplicity m, the list of exponentials contains $e^{s_1 t}$ only once, so we are $m - 1$ solutions short. The exponential shift theorem supplies them.

Repeated roots

If s_1 is a root of $P(s)$ of multiplicity m, then

$$e^{s_1 t},\ t e^{s_1 t},\ t^2 e^{s_1 t},\ \dots,\ t^{m-1} e^{s_1 t}$$

are m linearly independent solutions of $P(D)y = 0$. Collecting such blocks over all distinct roots gives a fundamental set of n solutions.

Derivation. Write $P(s) = (s - s_1)^m Q(s)$. Then $P(D) = Q(D)(D - s_1)^m$, and by the shift theorem

$$(D - s_1)^m \left[e^{s_1 t} t^k\right] = e^{s_1 t}\left(D + s_1 - s_1\right)^m t^k = e^{s_1 t} D^m t^k = 0 \quad \text{for } k < m,$$

because the mth derivative of a polynomial of degree $k < m$ vanishes. Applying $Q(D)$ to zero still gives zero. Independence: a relation $\sum_k c_k t^k e^{s_1 t} = 0$ for all t forces the polynomial $\sum c_k t^k$ to vanish identically, so all $c_k = 0$; mixing different roots is handled by the generalised Vandermonde argument. □

There is a second, intuitive derivation. For a double root, consider two nearby distinct roots s_1 and $s_1 + \varepsilon$. The combination $\left(e^{(s_1+\varepsilon)t} - e^{s_1 t}\right)/\varepsilon$ is a solution for every $\varepsilon \neq 0$, and as $\varepsilon \to 0$ it tends to $\partial e^{st}/\partial s\big|_{s_1} = t e^{s_1 t}$. Repeated roots are the limit of merging modes, and the factor t records the merger.

Case 3: complex-conjugate roots

For real coefficients, a complex root $s = \sigma + j\omega$ ($\omega > 0$) comes paired with $\bar{s} = \sigma - j\omega$. The complex solutions $e^{(\sigma \pm j\omega)t}$ are legitimate but inconvenient. Using Euler's formula (Ch. 2),

$$e^{(\sigma \pm j\omega)t} = e^{\sigma t}(\cos \omega t \pm j \sin \omega t),$$

and by the real/imaginary-parts theorem of Section 12.1, the real and imaginary parts are themselves real solutions.

Complex roots

If $\sigma \pm j\omega$ is a pair of simple complex-conjugate roots of a real polynomial $P(s)$, the corresponding contribution to y_h is

$$e^{\sigma t}\left(A \cos \omega t + B \sin \omega t\right) = M e^{\sigma t} \cos(\omega t - \varphi),$$

with real constants A, B, or equivalently amplitude $M = \sqrt{A^2 + B^2}$ and phase $\varphi = \operatorname{atan2}(B, A)$. If the pair has multiplicity m, multiply by $1, t, \dots, t^{m-1}$ as in Case 2.

The real part σ sets the **envelope** $e^{\sigma t}$ (decay if $\sigma < 0$, growth if $\sigma > 0$), and the imaginary part ω sets the **oscillation frequency** in rad/s. A root located in the complex s-plane can be read at a glance: distance to the left of the imaginary axis is decay rate, height above the real axis is ringing frequency.

Common Pitfall

Writing the complex-root solution as $c_1 e^{\sigma t} \cos \omega t + c_2 e^{\sigma t} \cos \omega t$ (the same function twice) or forgetting the $e^{\sigma t}$ envelope are the two most common errors. Each conjugate *pair* contributes exactly two real functions, $e^{\sigma t} \cos \omega t$ and $e^{\sigma t} \sin \omega t$. Also note: one pair accounts for two roots, so a cubic with one complex pair has one more real root to find.

Summary of the root-to-solution map

Root(s) of $P(s)$	Contribution to y_h
real s_1, simple	$c_1 e^{s_1 t}$
real s_1, multiplicity m	$(c_1 + c_2 t + \cdots + c_m t^{m-1}) e^{s_1 t}$
$\sigma \pm j\omega$, simple	$e^{\sigma t}(A \cos \omega t + B \sin \omega t)$
$\sigma \pm j\omega$, multiplicity m	$e^{\sigma t}\left[(A_1 + \cdots + A_m t^{m-1}) \cos \omega t + (B_1 + \cdots + B_m t^{m-1}) \sin \omega t\right]$
$s = 0$, multiplicity m	$c_1 + c_2 t + \cdots + c_m t^{m-1}$
$\pm j\omega$ (purely imaginary)	$A \cos \omega t + B \sin \omega t$ (sustained oscillation)

Stability from the roots

Stability of a homogeneous LTI equation

The equation $P(D)y = 0$ is

- **asymptotically stable** if every solution tends to 0 as $t \to \infty$;
- **marginally stable** if every solution stays bounded but some do not decay;
- **unstable** if some solution is unbounded.

Root criterion

$P(D)y = 0$ is asymptotically stable if and only if every characteristic root satisfies $\operatorname{Re}\{s_k\} < 0$ (all roots in the open left half-plane). It is marginally stable if all roots satisfy $\operatorname{Re}\{s_k\} \le 0$ and those on the imaginary axis are simple. Otherwise it is unstable.

Reason. $|t^k e^{st}| = t^k e^{\sigma t}$, which tends to zero for any k when $\sigma < 0$ (exponential decay beats polynomial growth), stays bounded when $\sigma = 0$ and $k = 0$, and grows otherwise. $\square$

For a real polynomial of degree two, stability is equivalent to all coefficients having the same sign. For degree three, $s^3 + a_2 s^2 + a_1 s + a_0$ is stable if and only if $a_2, a_1, a_0 > 0$ and $a_2 a_1 > a_0$. For higher degrees, the **Routh–Hurwitz criterion** tests stability from the coefficients without computing roots; positive coefficients are necessary but not sufficient beyond degree two. Detailed Routh tables belong to control theory; the point here is that stability is a property of the characteristic polynomial alone.

The standard second-order form

Every stable second-order equation with real coefficients can be written

$$y'' + 2\zeta\omega_n\, y' + \omega_n^2\, y = \omega_n^2\, K\, u(t),$$

where

- $\omega_n > 0$ is the **undamped natural frequency** (rad/s),
- $\zeta \ge 0$ is the **damping ratio** (dimensionless),
- K is the DC gain (irrelevant for the homogeneous problem).

The characteristic equation $s^2 + 2\zeta\omega_n s + \omega_n^2 = 0$ has roots

$$s_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{\zeta^2 - 1}.$$

The product of the roots is ω_n^2, so both roots lie on (or, when real, on either side of) a circle of radius ω_n in the s-plane; the sum is $-2\zeta\omega_n$. The damping ratio alone decides the character of the response.

Damping cases

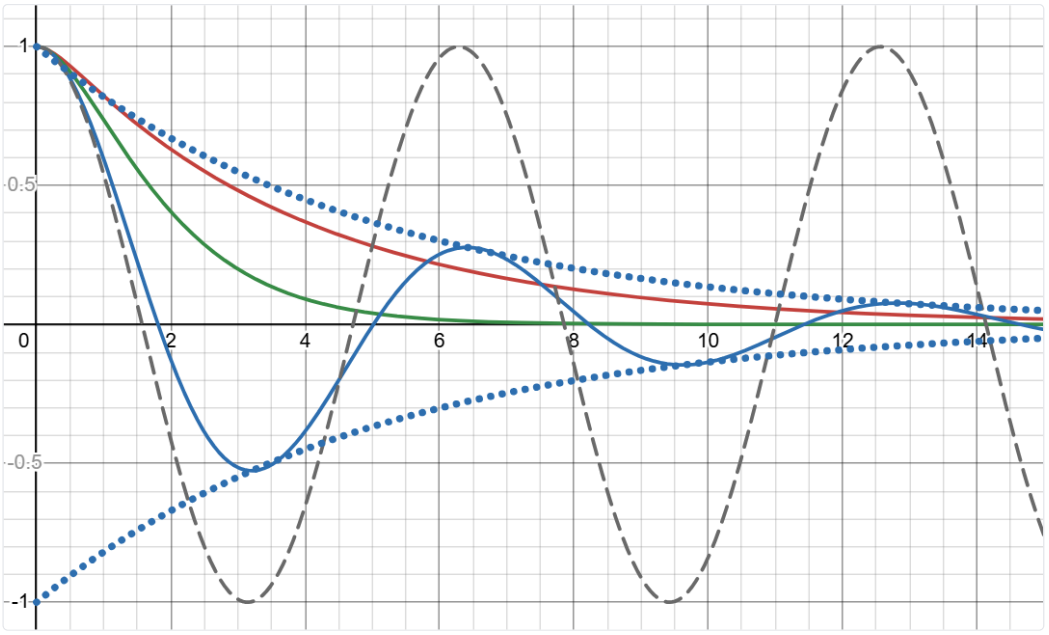
Case	Condition	Roots	Homogeneous solution
Overdamped	$\zeta > 1$	two distinct negative reals $-\alpha_1, -\alpha_2$	$c_1 e^{-\alpha_1 t} + c_2 e^{-\alpha_2 t}$
Critically damped	$\zeta = 1$	double root $-\omega_n$	$(c_1 + c_2 t)e^{-\omega_n t}$
Underdamped	$0 < \zeta < 1$	$-\alpha \pm j\omega_d$	$e^{-\alpha t}(A\cos\omega_d t + B\sin\omega_d t)$
Undamped	$\zeta = 0$	$\pm j\omega_n$	$A\cos\omega_n t + B\sin\omega_n t$

In the underdamped case, $\alpha = \zeta\omega_n$ is the **decay rate** (neper frequency) and $\omega_d = \omega_n\sqrt{1-\zeta^2}$ is the **damped natural frequency**. Note $\alpha^2 + \omega_d^2 = \omega_n^2$.

The geometric picture is useful. As ζ increases from 0, the root pair starts on the imaginary axis at $\pm j\omega_n$, travels along the circle of radius ω_n into the left half-plane, meets on the real axis at $-\omega_n$ when $\zeta = 1$, and then splits along the real axis, one root heading towards 0 and the other towards $-\infty$. The angle θ between a complex root and the negative real axis satisfies $\cos\theta = \zeta$.

Consider the response from $y(0) = 1$, $y'(0) = 0$ with $\omega_n = 1$:

- $\zeta = 2$: roots $-2 \pm \sqrt{3} = -0.2679,\ -3.7321$; $y = 1.0774\,e^{-0.2679t} - 0.0774\,e^{-3.7321t}$.
- $\zeta = 1$: $y = (1 + t)e^{-t}$.
- $\zeta = 0.2$: $\omega_d = 0.9798$; $y = e^{-0.2t}\big(\cos 0.9798t + 0.2041\sin 0.9798t\big)$.
- $\zeta = 0$: $y = \cos t$.



Free response from $y(0) = 1$, $y'(0) = 0$ with $\omega_n = 1$: overdamped $\zeta = 2$ (red), critically damped $\zeta = 1$ (green), underdamped $\zeta = 0.2$ (blue, with its $e^{-0.2t}$ envelope dotted) and undamped $\zeta = 0$ (grey). Critical damping returns to zero fastest without crossing it.

Three features of the graph are worth stating as facts:

1. **Critical damping is the fastest non-oscillatory return.** The overdamped response is dominated by its slow root -0.268; increasing damping beyond $\zeta = 1$ actually slows the system down, because the slow root moves towards the origin ($s_1 \approx -\omega_n/(2\zeta)$ for large ζ).
2. **An underdamped response crosses zero infinitely often**, at intervals of π/ω_d, while its envelope decays with time constant $1/\alpha$.
3. **An overdamped or critically damped response crosses zero at most once.** Since $c_1 e^{-\alpha_1 t} + c_2 e^{-\alpha_2 t} = 0$ means $e^{(\alpha_2 - \alpha_1)t} = -c_2/c_1$, there is at most one solution t.

Fitting initial conditions

The n constants in y_h are fixed by n initial conditions $y(0), y'(0), \dots, y^{(n-1)}(0)$. For distinct roots this gives a Vandermonde system:

$$\begin{bmatrix} 1 & 1 & \cdots & 1 \\ s_1 & s_2 & \cdots & s_n \\ \vdots & & & \vdots \\ s_1^{n-1} & s_2^{n-1} & \cdots & s_n^{n-1} \end{bmatrix} \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_n \end{bmatrix} = \begin{bmatrix} y(0) \\ y'(0) \\ \vdots \\ y^{(n-1)}(0) \end{bmatrix}.$$

For second order with distinct roots and data $y_0 = y(0)$, $v_0 = y'(0)$ the solution is

$$c_1 = \frac{v_0 - s_2 y_0}{s_1 - s_2}, \qquad c_2 = \frac{s_1 y_0 - v_0}{s_1 - s_2}.$$

For the underdamped case, $y = e^{-\alpha t}(A \cos \omega_d t + B \sin \omega_d t)$ gives $A = y_0$ and $-\alpha A + \omega_d B = v_0$, so

$$A = y_0, \qquad B = \frac{v_0 + \alpha y_0}{\omega_d}.$$

For the critically damped case $y = (c_1 + c_2 t) e^{-\omega_n t}$: $c_1 = y_0$, $c_2 = v_0 + \omega_n y_0$.

Worked examples

Example 12.5 — Overdamped: distinct real roots

Solve $y'' + 5y' + 6y = 0$, $y(0) = 1$, $y'(0) = 0$.

Characteristic equation. $s^2 + 5s + 6 = (s+2)(s+3) = 0$, roots $s_1 = -2$, $s_2 = -3$. (Here $\omega_n = \sqrt{6} = 2.449$, $\zeta = 5/(2\sqrt{6}) = 1.021$: just overdamped.)

Constants. $c_1 = (v_0 - s_2 y_0)/(s_1 - s_2) = (0 + 3)/1 = 3$, $c_2 = (s_1 y_0 - v_0)/(s_1 - s_2) = -2$.

$$y(t) = 3e^{-2t} - 2e^{-3t}.$$

Check. $y(0) = 1$ ✓, $y'(0) = -6 + 6 = 0$ ✓. Substituting: $y'' = 12e^{-2t} - 18e^{-3t}$, $5y' = -30e^{-2t} + 30e^{-3t}$, $6y = 18e^{-2t} - 12e^{-3t}$; sum $= 0$ ✓. At $t = 1$: $y = 3(0.13534) - 2(0.04979) = 0.3064$.

Example 12.6 — Critically damped: repeated root

Solve $y'' + 4y' + 4y = 0$, $y(0) = 1$, $y'(0) = 0$.

$s^2 + 4s + 4 = (s+2)^2$: double root $s = -2$, so $y = (c_1 + c_2 t)e^{-2t}$. Then $c_1 = 1$ and $c_2 = v_0 + \omega_n y_0 = 0 + 2 = 2$:

$$y(t) = (1 + 2t)e^{-2t}.$$

Check. $y' = 2e^{-2t} - 2(1+2t)e^{-2t} = -4te^{-2t}$, so $y'(0) = 0$ ✓; $y'' = (-4 + 8t)e^{-2t}$; $y'' + 4y' + 4y = (-4 + 8t - 16t + 4 + 8t)e^{-2t} = 0$ ✓. Notice $y' < 0$ for all $t > 0$: the response decays monotonically without overshoot.

Example 12.7 — Underdamped: complex roots

Solve $y'' + 2y' + 10y = 0$, $y(0) = 1$, $y'(0) = 0$, and express the result in amplitude–phase form.

$s^2 + 2s + 10 = 0$ gives $s = -1 \pm \sqrt{1 - 10} = -1 \pm j3$. So $\alpha = 1$, $\omega_d = 3$, $\omega_n = \sqrt{10} = 3.162$, $\zeta = 1/\sqrt{10} = 0.316$.

$A = y_0 = 1$, $B = (v_0 + \alpha y_0)/\omega_d = 1/3$:

$$y(t) = e^{-t}\left(\cos 3t + \tfrac{1}{3}\sin 3t\right) = \frac{\sqrt{10}}{3}\,e^{-t}\cos(3t - 0.3218).$$

Here $M = \sqrt{1 + 1/9} = 1.0541$ and $\varphi = \arctan(1/3) = 0.3218$ rad $= 18.43°$.

Check. $y'(0) = -1 \cdot 1 + 3 \cdot \tfrac{1}{3} = 0$ ✓. The oscillation period is $2\pi/3 = 2.094$ s and the envelope falls by a factor $e^{-2.094} = 0.123$ per period; this ratio, $e^{-2\pi\zeta/\sqrt{1-\zeta^2}}$, is the basis of the **logarithmic decrement** method of measuring damping from a recorded ring-down.

Example 12.8 — Higher order with mixed roots

Find the general solution of $y^{(4)} + 2y'' + y = 0$ and of $y''' - y'' + y' - y = 0$.

First equation. $s^4 + 2s^2 + 1 = (s^2+1)^2$, so $\pm j$ are double roots. The table gives

$$y = (A_1 + A_2 t)\cos t + (B_1 + B_2 t)\sin t.$$

The $t\cos t$ and $t\sin t$ terms grow without bound, so the system is unstable even though all roots lie on the imaginary axis: repeated imaginary-axis roots violate the marginal-stability condition.

Second equation. Factor by grouping: $s^3 - s^2 + s - 1 = s^2(s-1) + (s-1) = (s-1)(s^2+1)$. Roots $1, \pm j$:

$$y = c_1 e^{t} + A\cos t + B\sin t.$$

Check of factorisation. $(s-1)(s^2+1) = s^3 + s - s^2 - 1$ ✓.

Example 12.9 — Stability of a cubic without computing roots

A third-order active filter has characteristic polynomial $s^3 + 2s^2 + 3s + K$, where $K > 0$ is a gain. For what K is it stable? What happens at the boundary?

By the cubic criterion, stability requires $2 \cdot 3 > K$, i.e. $0 < K < 6$. At $K = 6$: $s^3 + 2s^2 + 3s + 6 = s^2(s+2) + 3(s+2) = (s+2)(s^2+3)$, with roots -2 and $\pm j\sqrt{3}$. The homogeneous solution contains $A\cos\sqrt{3}\,t + B\sin\sqrt{3}\,t$, an undamped oscillation at $\sqrt{3} = 1.732$ rad/s. This is exactly how an oscillator is designed: the loop gain is set so that a root pair sits on the imaginary axis. For $K > 6$ the pair crosses into the right half-plane and the oscillation grows until nonlinearity limits it.

Engineering Note

Designers frequently specify ζ rather than component values. $\zeta = 1/\sqrt{2} \approx 0.707$ gives the second-order Butterworth response (maximally flat frequency response, about 4.3% step overshoot); $\zeta = 1$ is used where overshoot is forbidden, such as in a precision positioning stage or an ADC driver that must not exceed the converter's input range; $\zeta \approx 0.5$–0.6 is common in control loops that trade some overshoot for speed. A probe ringing on an oscilloscope is a lightly damped pair formed by ground-lead inductance and input capacitance; the fix (a shorter ground lead or a damping resistor) raises ζ.

12.3 Natural and forced responses

Motivation

When a source drives a circuit, the response always contains two ingredients with completely different origins. One is dictated by the *circuit*: the exponentials $e^{s_k t}$ whose rates are the characteristic roots, the same no matter what drives it. The other is dictated by the *source*: a DC input produces a DC component, a sinusoid produces a sinusoid at the same frequency. Engineers call these the **natural response** and the **forced response**. Recognising which is which tells you immediately which part of a waveform you can change by redesigning the circuit and which part only by changing the input.

There is a second, independent way to split the same response, according to *cause*: the part due to energy initially stored in capacitors and inductors, and the part due to the source. Both splittings are useful, they are not the same, and confusing them is a frequent source of errors.

Natural and forced decomposition

Natural and forced response

For $P(D)y = r(t)$ with general solution $y = y_h + y_p$:

- the **natural response** $y_n(t)$ is the homogeneous part, a combination of the characteristic modes $t^k e^{s_k t}$ with constants fixed by the initial conditions;
- the **forced response** $y_f(t)$ is a particular solution chosen to have the same functional form as the input (constant for constant input, sinusoid for sinusoid, and so on), containing **no** natural modes unless resonance forces them in (Section 12.4).

Then $y = y_n + y_f$.

The forced response is sometimes defined loosely as "any particular solution". The convention adopted here, that y_f is the particular solution built from the input's own functional form, makes y_f unique whenever the input's exponent does not coincide with a characteristic root. For example, for $y' + 2y = 4$ both $y_p = 2$ and $y_p = 2 + 7e^{-2t}$ are particular solutions, but only $y_f = 2$ is the forced response.

Procedure for the complete response

1. Find the characteristic roots and write the natural response with n undetermined constants.
2. Find the forced response y_f (Section 12.4).
3. Write $y = y_n + y_f$ and impose the n initial conditions **on the complete** y, not on y_n alone.

Common Pitfall

The constants in y_n must be fitted after adding y_f. Fitting y_n to the initial conditions first and then adding y_f gives a function that satisfies the ODE but violates the initial conditions, unless y_f and its derivatives happen to vanish at $t = 0$.

Zero-input and zero-state decomposition

Zero-input and zero-state response

- The **zero-input response** y_{zi} solves $P(D)y = 0$ with the actual initial conditions: the response to stored energy alone, with the source switched off.
- The **zero-state response** y_{zs} solves $P(D)y = r(t)$ with **all initial conditions zero**: the response to the source alone, starting from rest.

By linearity $y = y_{zi} + y_{zs}$.

Relation between the two decompositions

The zero-input response consists purely of natural modes. The zero-state response contains the whole forced response plus some natural modes:

$$y_{zs} = y_f + y_{n,\text{zs}}, \qquad y_n = y_{zi} + y_{n,\text{zs}}.$$

Thus the natural response is generally **not** the zero-input response; the source itself excites the natural modes when it is switched on.

The zero-state response is the one that a transfer function or a convolution integral computes: it is linear in the input, and doubling the input doubles it. The complete response is **not** linear in the input when initial conditions are nonzero; it is *affine* (y_{zi} is an offset that does not scale). That is why "linear system" in signal-processing usage tacitly assumes the system starts at rest.

The impulse response

A special natural response deserves a name. Let $h(t)$ be the zero-state response to a unit impulse $r(t) = \delta(t)$. For $t > 0$ the input is zero, so h is purely natural; the impulse merely sets its initial conditions.

Impulse response of $P(D)y = \delta(t)$

With $P(s) = a_n s^n + \cdots + a_0$, the impulse response is the solution of the homogeneous equation for $t > 0$ with

$$h(0^+) = h'(0^+) = \cdots = h^{(n-2)}(0^+) = 0, \qquad h^{(n-1)}(0^+) = \frac{1}{a_n},$$

and $h(t) = 0$ for $t < 0$. The zero-state response to any input applied at $t = 0$ is then the convolution

$$y_{zs}(t) = \int_0^t h(t - \tau)\, r(\tau)\, d\tau.$$

Derivation sketch. Integrate $a_n y^{(n)} + \cdots + a_0 y = \delta(t)$ from 0^- to 0^+. If y and its first $n-2$ derivatives are continuous and $y^{(n-1)}$ has a jump, only the highest term picks up the integral of δ, giving $a_n\left[y^{(n-1)}(0^+) - 0\right] = 1$. The lower-order terms integrate to zero over the vanishing interval because they are bounded. The convolution formula follows from writing $r(t) = \int r(\tau)\delta(t-\tau)\,d\tau$ and using linearity and time invariance: each slice $r(\tau)\,d\tau\,\delta(t-\tau)$ produces $r(\tau)\,d\tau\,h(t-\tau)$, and summing the slices gives the integral. □

The impulse response is the bridge to Ch. 14 (where $\mathcal{L}\{h\} = 1/P(s)$) and to Ch. 16 (where its Fourier transform is the frequency response). The convolution theorem is developed there; here it is enough that the zero-state response is fully determined by h.

Worked examples

Example 12.10 — First order: both decompositions

Solve $y' + 2y = 4$, $y(0) = 5$, and give the natural/forced and zero-input/zero-state splits.

Natural/forced. Root $s = -2$: $y_n = Ae^{-2t}$. Forced: constant $y_f = K$ with $2K = 4$, $K = 2$. Then $y = 2 + Ae^{-2t}$ and $y(0) = 5$ gives $A = 3$:

$$y = \underbrace{2}_{y_f} + \underbrace{3e^{-2t}}_{y_n}.$$

Zero-input/zero-state. y_{zi}: $y' + 2y = 0$, $y(0) = 5$, so $y_{zi} = 5e^{-2t}$. y_{zs}: $y' + 2y = 4$, $y(0) = 0$, so $y_{zs} = 2(1 - e^{-2t})$. Sum: $5e^{-2t} + 2 - 2e^{-2t} = 2 + 3e^{-2t}$ ✓.

The natural response $3e^{-2t}$ is the zero-input response $5e^{-2t}$ plus the natural part of the zero-state response, $-2e^{-2t}$, exactly as the relation theorem says.

Example 12.11 — Second-order step from rest

Solve $y'' + 3y' + 2y = 10$, $y(0) = 0$, $y'(0) = 0$.

Natural. $s^2 + 3s + 2 = (s + 1)(s + 2)$: $y_n = c_1 e^{-t} + c_2 e^{-2t}$.

Forced. $y_f = K$, $2K = 10$, $K = 5$.

Initial conditions on the complete response. $y = 5 + c_1 e^{-t} + c_2 e^{-2t}$:

$$\begin{aligned} y(0) &= 5 + c_1 + c_2 = 0, \\ y'(0) &= -c_1 - 2c_2 = 0, \end{aligned} \quad \Rightarrow \quad c_1 = -10,\ c_2 = 5.$$

$$y(t) = 5 - 10e^{-t} + 5e^{-2t}.$$

Check. $y(0) = 0$ ✓, $y'(0) = 10 - 10 = 0$ ✓; numerically $y(1.5) = 5 - 2.2313 + 0.2489 = 3.0176$, matching a numerical ODE solver to 10 digits. Since the system starts at rest, this complete response *is* the zero-state response.

Example 12.12 — Same system, stored energy and source together

Solve $y'' + 3y' + 2y = 10$ with $y(0) = 2$, $y'(0) = 1$, and decompose it.

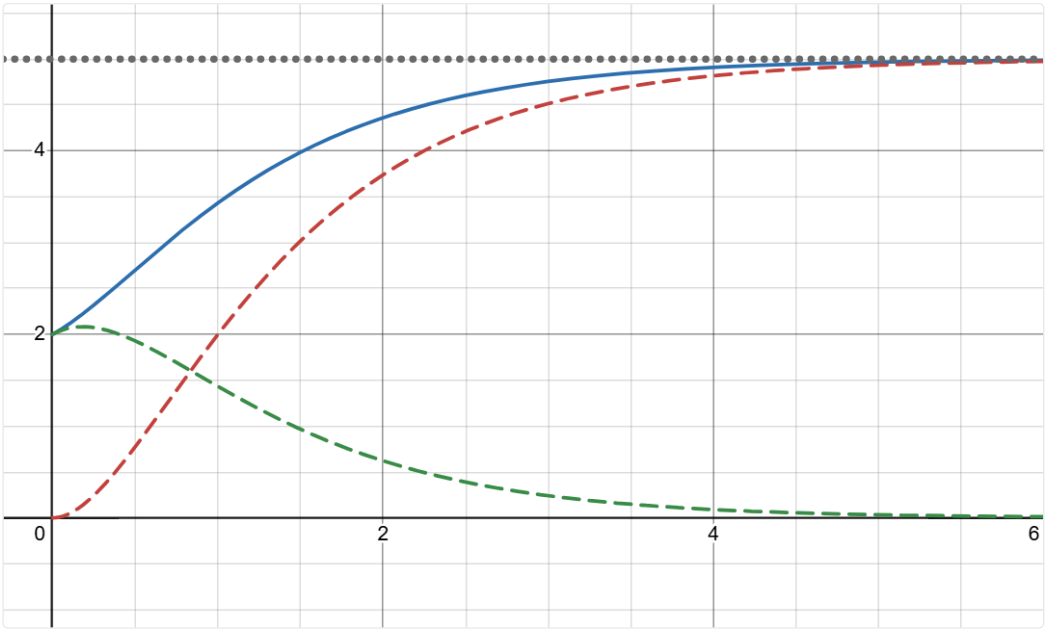
Complete response. $y = 5 + c_1 e^{-t} + c_2 e^{-2t}$; $5 + c_1 + c_2 = 2$ and $-c_1 - 2c_2 = 1$ give $c_2 = 2$, $c_1 = -5$:

$$y = 5 - 5e^{-t} + 2e^{-2t}, \qquad y_f = 5, \quad y_n = -5e^{-t} + 2e^{-2t}.$$

Zero-input. $c_1 + c_2 = 2$, $-c_1 - 2c_2 = 1$: $c_2 = -3$, $c_1 = 5$, so $y_{zi} = 5e^{-t} - 3e^{-2t}$.

Zero-state. From Example 12.11, $y_{zs} = 5 - 10e^{-t} + 5e^{-2t}$.

Consistency. $y_{zi} + y_{zs} = 5 - 5e^{-t} + 2e^{-2t}$ ✓, and $y(1.5) = 3.9839$ agrees with a numerical solver. If the source were doubled to 20, y_{zs} would double but y_{zi} would not, so the complete response would become $10 - 15e^{-t} + 7e^{-2t}$, not twice the original.



Example 12.12: the complete response (blue) is the sum of the zero-input response (green, decays to zero) and the zero-state response (red, rises from rest to the forced value 5).

Example 12.13 — Impulse response and convolution

Find the impulse response of $y'' + 3y' + 2y = r(t)$ and use convolution to recover the unit-step response.

Impulse response. For $t > 0$, $h = c_1 e^{-t} + c_2 e^{-2t}$ with $h(0^+) = 0$, $h'(0^+) = 1/a_2 = 1$: $c_1 + c_2 = 0$, $-c_1 - 2c_2 = 1$, so $c_1 = 1$, $c_2 = -1$:

$$h(t) = \left(e^{-t} - e^{-2t}\right) u(t).$$

Step response by convolution. With $r = u(t)$,

$$y_{zs}(t) = \int_0^t \left(e^{-(t-\tau)} - e^{-2(t-\tau)}\right) d\tau = \left(1 - e^{-t}\right) - \tfrac{1}{2}\left(1 - e^{-2t}\right) = \tfrac{1}{2} - e^{-t} + \tfrac{1}{2}e^{-2t}.$$

Multiplying by 10 reproduces Example 12.11 ✓. Note also that the step response is the integral of the impulse response, and h is the derivative of the step response: the derivative of $\frac{1}{2} - e^{-t} + \frac{1}{2}e^{-2t}$ is $e^{-t} - e^{-2t}$ ✓. Because $u' = \delta$, linearity and time invariance force the two responses to be related by the same derivative.

Example 12.14 — Natural response excited by switching a sinusoid

An RL branch obeys $L\,i' + R\,i = V_m \cos \omega t$ for $t \geq 0$ with $i(0) = 0$. Show that a natural component appears unless the switching instant is chosen carefully.

With $\tau = L/R$, the forced response (Section 12.4) is $i_f = I_m \cos(\omega t - \theta)$ with $I_m = V_m/\sqrt{R^2 + \omega^2 L^2}$ and $\theta = \arctan(\omega L/R)$. The natural response is $A e^{-t/\tau}$, and $i(0) = 0$ gives $A = -I_m \cos\theta$:

$$i(t) = I_m\left[\cos(\omega t - \theta) - \cos\theta\, e^{-t/\tau}\right].$$

If instead the source is switched on at a phase ψ, i.e. $V_m \cos(\omega t + \psi)$, then $A = -I_m \cos(\psi - \theta)$, which vanishes when $\psi = \theta \pm \pi/2$. Switching at that point on the wave produces no transient at all; switching at $\psi = \theta$ produces the largest. This is the origin of the **DC offset** in fault currents and transformer inrush: in a highly inductive circuit ($\theta \to 90^\circ$), switching at a voltage zero gives a natural component as large as the forced amplitude, and the first current peak approaches $2I_m$.

Engineering Note

On a bench, the zero-input response is what you see when you charge a circuit and then disconnect the source (a "ring-down" or discharge test); it measures the natural frequencies directly. The zero-state response is what a network analyser or a step-response test measures, because the instrument starts from rest. Datasheet specifications such as rise time, overshoot and settling time always refer to the zero-state step response.

12.4 Complementary and particular solutions

Motivation and vocabulary

The general solution $y = y_c + y_p$ of $P(D)y = r$ has two parts that mathematicians name differently from engineers:

Mathematics	Engineering	Found by
complementary function y_c	natural response y_n (before fitting ICs)	characteristic roots (Section 12.2)
particular integral y_p	forced response y_f	this section

Section 12.2 settled y_c completely. This section gives methods for y_p. For the inputs that occur most often in practice (constants, polynomials, exponentials, sinusoids and products of these) the **method of undetermined coefficients** is fast and purely algebraic. For sinusoids specifically, the **complex-exponential method** is faster still and leads straight to phasors. For arbitrary inputs, variation of parameters (Ch. 11) and convolution (Section 12.3) always work, and the Laplace transform (Ch. 14) automates the whole procedure.

Why guessing works: the annihilator idea

Undetermined coefficients looks like guesswork, but it rests on a precise fact. The admissible inputs are exactly the functions that are themselves solutions of some constant-coefficient homogeneous equation.

Annihilator

A constant-coefficient operator $Q(D)$ **annihilates** $r(t)$ if $Q(D)\,r = 0$. Examples:

$r(t)$	**Annihilator** $Q(D)$
t^k (or any polynomial of degree k)	D^{k+1}
e^{at}	$D - a$
$t^k e^{at}$	$(D - a)^{k+1}$
$\cos \omega t$, $\sin \omega t$	$D^2 + \omega^2$
$e^{\sigma t}\cos \omega t$, $e^{\sigma t}\sin \omega t$	$(D - \sigma)^2 + \omega^2$

If $P(D)y = r$ and $Q(D)r = 0$, apply $Q(D)$ to both sides: $Q(D)P(D)\,y = 0$. So every solution y of the forced equation solves a *higher-order homogeneous* equation whose characteristic polynomial is $Q(s)P(s)$. Its solutions are known from Section 12.2. Those coming from the roots of P are already in y_c; the remaining ones, coming from the roots of Q, give the form of y_p. If a root of Q coincides with a root of P, the multiplicities add, and the repeated-root rule automatically introduces extra factors of t. That is the whole theory behind the resonance (modification) rule below.

The method of undetermined coefficients

Trial forms for y_p

Let $r(t) = e^{at}\big[p_k(t)\cos\omega t + q_k(t)\sin\omega t\big]$, where p_k, q_k are polynomials of degree at most k (either may be zero; $\omega = 0$ covers pure exponentials and polynomials, $a = 0$ covers pure sinusoids). Let m be the multiplicity of $s_0 = a + j\omega$ as a root of $P(s)$ ($m = 0$ if it is not a root). Then there is a particular solution of the form

$$y_p = t^m e^{at}\big[A_k(t)\cos\omega t + B_k(t)\sin\omega t\big],$$

with A_k, B_k polynomials of degree k whose coefficients are determined by substitution.

Common cases in table form (with $m = 0$, i.e. no resonance):

Input $r(t)$	Trial y_p
constant K	A
t^k	$A_k t^k + \cdots + A_1 t + A_0$
e^{at}	Ae^{at}
$\cos\omega t$ or $\sin\omega t$	$A\cos\omega t + B\sin\omega t$
$e^{at}\cos\omega t$	$e^{at}(A\cos\omega t + B\sin\omega t)$
te^{at}	$(A_1 t + A_0)e^{at}$

Modification (resonance) rule

If any term of the trial form is a solution of the homogeneous equation, multiply the **entire** trial form by t^m, where m is the multiplicity of the corresponding characteristic root. After the modification no term of y_p duplicates a term of y_c.

Common Pitfall

Three errors account for most failures:

1. **Dropping a companion term.** For $r = \sin\omega t$ the trial must contain *both* $\cos\omega t$ and $\sin\omega t$; for $r = t^2$ it must contain t^2, t and 1.
2. **Multiplying only part of the trial.** For $r = te^{-t}$ with a simple root -1, the trial is $t(A_1 t + A_0)e^{-t}$, not $(A_1 t^2 + A_0)e^{-t}$.
3. **Ignoring resonance.** Substituting Ae^{at} when $P(a) = 0$ gives the impossible equation $0 = 1$; that is the signal to multiply by t.

A closed-form shortcut for exponential inputs

For $r(t) = e^{at}$ the eigenfunction identity gives the answer without solving any equations:

Exponential input formula

If $P(a) \neq 0$, then $P(D)y = e^{at}$ has the particular solution

$$y_p = \frac{e^{at}}{P(a)}.$$

If a is a root of multiplicity m, then

$$y_p = \frac{t^m e^{at}}{P^{(m)}(a)}.$$

Proof. The first case is immediate from $P(D)e^{at} = P(a)e^{at}$. For the second, write $P(s) = (s-a)^m Q(s)$ with $Q(a) \neq 0$. By the shift theorem,

$$P(D)\big[e^{at}t^m\big] = e^{at}P(D+a)\,t^m = e^{at}\,Q(D+a)\,D^m t^m = e^{at}\,Q(D+a)\,m! = m!\,Q(a)\,e^{at},$$

since $D^m t^m = m!$ is a constant and $Q(D+a)$ acting on a constant multiplies it by $Q(a)$. Finally, differentiating $P(s) = (s-a)^m Q(s)$ m times and setting $s = a$ gives $P^{(m)}(a) = m!\,Q(a)$. $\square$

For a constant input K (the case $a = 0$), the formula gives $y_p = K/P(0) = K/a_0$: the DC gain is $1/a_0$. This is the formal version of the circuit-analysis rule "at DC, capacitors are open circuits and inductors are short circuits", which amounts to setting every derivative to zero.

The complex-exponential (phasor) method

For a sinusoidal input $r(t) = R_m\cos(\omega t + \psi)$ write $r = \mathrm{Re}\{\mathbf{R}\,e^{j\omega t}\}$ with complex amplitude (phasor) $\mathbf{R} = R_m e^{j\psi}$. Solve the complex equation $P(D)z = \mathbf{R}e^{j\omega t}$ with the exponential formula, $z = \mathbf{R}e^{j\omega t}/P(j\omega)$, and take the real part.

Sinusoidal forced response

If $P(j\omega) \neq 0$ and P has real coefficients, the forced response to $R_m \cos(\omega t + \psi)$ is

$$y_f(t) = \operatorname{Re}\left\{ \frac{\mathbf{R}}{P(j\omega)} e^{j\omega t} \right\} = \frac{R_m}{|P(j\omega)|} \cos\big(\omega t + \psi - \angle P(j\omega)\big).$$

The output phasor is $\mathbf{Y} = \mathbf{R}/P(j\omega)$.

The quantity $H(j\omega) = 1/P(j\omega)$ (more generally $N(j\omega)/P(j\omega)$ when derivatives of the input appear on the right-hand side) is the **frequency response**. Section 12.5 studies it as a function of ω. The method reduces sinusoidal steady-state analysis to complex arithmetic, which is why AC circuit theory uses impedances R, $j\omega L$ and $1/(j\omega C)$: each is the eigenvalue of an element law acting on $e^{j\omega t}$.

Superposition of inputs

If $r = r_1 + r_2 + \dots$, find a particular solution for each term separately and add them. Each term may need its own resonance modification. This is valid only for the *particular* parts; the complementary function is written once, with n constants, and fitted to the initial conditions at the end.

When undetermined coefficients fails

The method requires r to have a finite-dimensional family of derivatives. It fails for inputs such as $\tan t$, $1/t$, $\ln t$, e^{t^2} or a general measured waveform. Then use:

- **variation of parameters**, which works for any continuous r once y_c is known (derived in Ch. 11);
- **convolution** with the impulse response (Section 12.3);
- **Laplace transforms** for piecewise inputs such as pulses, ramps and delayed steps (Ch. 14);
- **numerical integration** for anything else (Ch. 22).

Worked examples

Example 12.15 — Polynomial input

Find a particular solution of $y'' + 3y' + 2y = 4t^2$.

No root of $s^2 + 3s + 2$ is zero, so $m = 0$ and the trial is $y_p = At^2 + Bt + C$. Then $y_p' = 2At + B$, $y_p'' = 2A$, and

$$2A + 3(2At + B) + 2(At^2 + Bt + C) = 2A\,t^2 + (6A + 2B)\,t + (2A + 3B + 2C).$$

Matching coefficients with $4t^2 + 0t + 0$:

$$2A = 4, \qquad 6A + 2B = 0, \qquad 2A + 3B + 2C = 0 \quad \Rightarrow \quad A = 2,\ B = -6,\ C = 7.$$

$$y_p = 2t^2 - 6t + 7.$$

Check. $y_p'' = 4$, $3y_p' = 12t - 18$, $2y_p = 4t^2 - 12t + 14$; sum $= 4t^2$ ✓. Note that the constant and linear terms are essential even though the input contains only t^2.

Example 12.16 — Sinusoid by the complex-exponential method

Find the forced response of $y'' + 2y' + 5y = 10\cos t$.

$P(s) = s^2 + 2s + 5$ and $P(j1) = -1 + 2j + 5 = 4 + 2j$, which is nonzero (the roots are $-1 \pm 2j$). The output phasor is

$$\mathbf{Y} = \frac{10}{4 + 2j} = \frac{10(4 - 2j)}{20} = 2 - j.$$

$$y_f = \operatorname{Re}\{(2 - j)(\cos t + j \sin t)\} = 2\cos t + \sin t = \sqrt{5}\cos(t - 0.4636).$$

Check by substitution. $y_f' = -2\sin t + \cos t$, $y_f'' = -2\cos t - \sin t$. Then $y_f'' + 2y_f' + 5y_f = (-2 + 2 + 10)\cos t + (-1 - 4 + 5)\sin t = 10\cos t$ ✓. The amplitude $\sqrt{5} = 10/|4 + 2j| = 10/\sqrt{20}$ ✓, and the phase lag is $\arctan(2/4) = 26.57^\circ$.

The same result by undetermined coefficients requires solving $4A + 2B = 10$, $-2A + 4B = 0$ (from the cos and sin coefficients), giving $A = 2$, $B = 1$, the same answer with more algebra.

Example 12.17 — Pure resonance

Solve $y'' + 4y = 3\cos 2t$, $y(0) = 0$, $y'(0) = 0$.

Complementary. Roots $\pm 2j$: $y_c = c_1 \cos 2t + c_2 \sin 2t$.

Particular. The input frequency 2 coincides with a simple root ($m = 1$), so use the formula with $P'(s) = 2s$: the complex equation $P(D)z = 3e^{j2t}$ has

$$z_p = \frac{3\,t\,e^{j2t}}{P'(2j)} = \frac{3t\,e^{j2t}}{4j} = -\frac{3j}{4}\,t\,(\cos 2t + j\sin 2t),$$

whose real part is $y_p = \frac{3}{4}\,t\sin 2t$.

Initial conditions. $y(0) = c_1 = 0$; $y'(0) = 2c_2 + \left[\frac{3}{4}\sin 2t + \frac{3}{2}t\cos 2t\right]_{t=0} = 2c_2 = 0$. So

$$y(t) = \tfrac{3}{4}\,t\sin 2t.$$

Check. $y'' = 3\cos 2t - 3t\sin 2t$, so $y'' + 4y = 3\cos 2t - 3t\sin 2t + 3t\sin 2t = 3\cos 2t$ ✓. The amplitude grows linearly without bound: a lossless resonator driven at its natural frequency absorbs energy every cycle. Any real resonator has some damping, which caps the amplitude at a finite value (Section 12.5).

Example 12.18 — Mixed input with resonance and a full IVP

Solve $y'' - y' - 2y = e^{2t} + 3$, $y(0) = 0$, $y'(0) = 0$.

Complementary. $s^2 - s - 2 = (s-2)(s+1)$: $y_c = c_1 e^{2t} + c_2 e^{-t}$.

Particular, term by term.

- For e^{2t}: $a = 2$ is a simple root, $P'(s) = 2s - 1$, $P'(2) = 3$, so $y_{p1} = \frac{1}{3}te^{2t}$.
- For 3: $y_{p2} = 3/P(0) = 3/(-2) = -\frac{3}{2}$.

Initial conditions. $y = c_1 e^{2t} + c_2 e^{-t} + \frac{1}{3}te^{2t} - \frac{3}{2}$:

$$\begin{aligned} y(0) &= c_1 + c_2 - \tfrac{3}{2} = 0, \\ y'(0) &= 2c_1 - c_2 + \tfrac{1}{3} = 0, \end{aligned} \qquad \Rightarrow \qquad c_1 = \tfrac{7}{18}, \quad c_2 = \tfrac{10}{9}.$$

$$y(t) = \tfrac{7}{18}e^{2t} + \tfrac{10}{9}e^{-t} + \tfrac{1}{3}te^{2t} - \tfrac{3}{2}.$$

Check. At $t = 1$ the formula gives 4.24530, agreeing with a numerical solution to nine significant figures. Verifying y_{p1} directly: with $w = te^{2t}$, $w' = (1 + 2t)e^{2t}$, $w'' = (4 + 4t)e^{2t}$, and $w'' - w' - 2w = (4 + 4t - 1 - 2t - 2t)e^{2t} = 3e^{2t}$ ✓, so $w/3$ is correct.

Example 12.19 — Exponential times polynomial via the shift theorem

Find a particular solution of $y'' + y = te^t$.

Write $y_p = e^t f(t)$. By the shift theorem, $(D^2+1)\left[e^t f\right] = e^t\left[(D+1)^2 + 1\right]f = e^t\left(D^2 + 2D + 2\right)f$. We need $(D^2 + 2D + 2)f = t$. Try $f = At + B$: $2A + 2At + 2B = t$, so $A = \frac{1}{2}$, $B = -\frac{1}{2}$:

$$y_p = \tfrac{1}{2}(t-1)e^t.$$

Check. $y_p' = \frac{1}{2}te^t$, $y_p'' = \frac{1}{2}(t+1)e^t$; $y_p'' + y_p = \frac{1}{2}(t + 1 + t - 1)e^t = te^t$ ✓. The shift theorem reduces an exponential-times-polynomial problem to a pure polynomial problem, which is often less error-prone than substituting $(At + B)e^t$ directly.

Example 12.20 — Damped sinusoidal input

Find the forced response of $y'' + 4y' + 13y = e^{-2t}\cos 3t$, and explain the result.

The characteristic roots are $-2 \pm 3j$, and the input is $\mathrm{Re}\{e^{(-2+3j)t}\}$ with exponent $s_0 = -2 + 3j$, a simple root. So $m = 1$ and, with $P'(s) = 2s + 4$, $P'(s_0) = 6j$:

$$y_p = \mathrm{Re}\left\{\frac{t\,e^{(-2+3j)t}}{6j}\right\} = \mathrm{Re}\left\{-\frac{j}{6}\,t\,e^{-2t}(\cos 3t + j\sin 3t)\right\} = \frac{1}{6}\,t\,e^{-2t}\sin 3t.$$

Check. Using the shift theorem with $y_p = e^{-2t}g$: $P(D-2) = (D-2)^2 + 4(D-2) + 13 = D^2 + 9$, so we need $g'' + 9g = \cos 3t$, which by Example 12.17's pattern has $g = \frac{1}{6}t\sin 3t$ ✓. The input is itself a natural mode of the system, so it resonates even though it decays.

12.5 Transient and steady-state behavior

Motivation

Switch on a sinusoidal generator connected to a filter and watch the output on an oscilloscope. For a short time the waveform is irregular; then it settles into a clean sinusoid at the generator frequency, with a fixed amplitude and phase. The irregular part is the **transient**; the clean sinusoid is the **steady state**. Almost all AC circuit analysis, filter design and frequency-response measurement concerns the steady state, but the transient decides how long one must wait before the steady-state formulas apply, how large the switching surges are, and whether the steady state exists at all.

Definitions

Transient and steady-state response

Suppose the response of $P(D)y = r(t)$ can be written $y = y_{tr} + y_{ss}$ where

$$\lim_{t\to\infty} y_{tr}(t) = 0$$

and y_{ss} persists (for example constant, periodic, or growing like the input). Then y_{tr} is the **transient response** and y_{ss} is the **steady-state response**.

Transient = natural, steady state = forced (for stable systems)

If $P(D)y = 0$ is asymptotically stable (all characteristic roots satisfy $\mathrm{Re}\{s_k\} < 0$), then for any input of the undetermined-coefficients class:

1. the natural response y_n decays to zero for every set of initial conditions, so $y_{tr} = y_n$ and $y_{ss} = y_f$;
2. the steady state is **independent of the initial conditions**;
3. if the input is bounded, the steady state is bounded (bounded-input, bounded-output stability).

Reason. Every term of y_n has the form $t^k e^{s_k t}$ with $\mathrm{Re}\{s_k\} < 0$ and tends to zero. Initial conditions enter only through the constants of y_n. If the input contains no natural modes (stable roots never coincide with a pure sinusoid or constant, which have exponents on the imaginary axis), y_f has the same bounded form as the input. □

When the system is not asymptotically stable, the split fails in instructive ways:

- **Unstable** ($\mathrm{Re}\{s_k\} > 0$ for some root): the natural response grows; the "steady state" of the formula y_f exists on paper but is never observed, because any perturbation excites the growing mode. An unstable amplifier oscillates or latches instead of amplifying.
- **Marginally stable** (simple roots on the imaginary axis): the natural response never decays, so the initial conditions are remembered forever. A lossless LC tank rings indefinitely; an integrator ($s = 0$) holds its initial value.
- **Resonance with a marginal root**: a constant input to an integrator, or a sinusoid at an LC tank's natural frequency, produces a growing y_f (t or $t\sin\omega t$, Example 12.17) and there is no bounded steady state.

How fast does the transient die?

The slowest-decaying mode dominates the late transient. With the root closest to the imaginary axis at real part $-\sigma_{\min}$, the transient is bounded by a multiple of $e^{-\sigma_{\min} t}$ for large t (times a polynomial factor if that root is repeated).

Time constant and settling time

- For a first-order mode $e^{-t/\tau}$, the **time constant** is $\tau = 1/\sigma$.
- The **2% settling time** t_s is the time after which the response stays within 2% of its final value. For a first-order system $t_s = \tau \ln 50 \approx 3.9\tau$, usually rounded to 4τ. For an underdamped second-order system the envelope $e^{-\zeta\omega_n t}/\sqrt{1-\zeta^2}$ gives

$$t_s \approx \frac{\ln\!\left(50/\sqrt{1-\zeta^2}\right)}{\zeta\omega_n} \approx \frac{4}{\zeta\omega_n}.$$

For the 1% and 0.1% criteria replace $\ln 50 = 3.91$ by $\ln 100 = 4.61$ and $\ln 1000 = 6.91$. A rule worth memorising: **each time constant buys about 8.7 dB (a factor e)**, so reaching 16-bit accuracy ($2^{-16} \approx 1.5 \times 10^{-5}$) takes about 11τ.

Sinusoidal steady state and frequency response

For a stable system driven by $\cos\omega t$, Section 12.4 gave the steady state directly from the complex number $P(j\omega)$. In general, when the input enters through derivatives as well, the ODE reads $P(D)y = N(D)r$, and the same argument gives:

Frequency response

For the stable LTI equation $P(D)y = N(D)r$ with input $r = R_m\cos(\omega t + \psi)$, the steady-state output is

$$y_{ss}(t) = R_m\,|H(j\omega)|\cos\big(\omega t + \psi + \angle H(j\omega)\big), \qquad H(j\omega) = \frac{N(j\omega)}{P(j\omega)}.$$

$|H(j\omega)|$ is the **gain** (magnitude response) and $\angle H(j\omega)$ is the **phase shift**. In phasor form $\mathbf{Y} = H(j\omega)\,\mathbf{R}$.

The frequency response is the transfer function $H(s) = N(s)/P(s)$ of Ch. 14 evaluated on the imaginary axis. Here it arises without any transform: it is simply the eigenvalue of the system for the eigenfunction $e^{j\omega t}$.

First-order low-pass. For $\tau y' + y = r$, $H(j\omega) = 1/(1 + j\omega\tau)$:

$$|H| = \frac{1}{\sqrt{1+(\omega\tau)^2}}, \qquad \angle H = -\arctan(\omega\tau).$$

At the **corner frequency** $\omega_c = 1/\tau$ the gain is $1/\sqrt{2}$ (-3 dB) and the phase is $-45°$; well above it the gain falls as $1/(\omega\tau)$, i.e. -20 dB per decade.

Second-order low-pass. For $y'' + 2\zeta\omega_n y' + \omega_n^2 y = \omega_n^2 r$, with normalised frequency $\nu = \omega/\omega_n$,

$$H(j\omega) = \frac{1}{1 - \nu^2 + j\,2\zeta\nu}, \qquad |H| = \frac{1}{\sqrt{(1-\nu^2)^2 + (2\zeta\nu)^2}}, \qquad \angle H = -\operatorname{atan2}\left(2\zeta\nu,\ 1-\nu^2\right).$$

Resonant peak of a second-order system

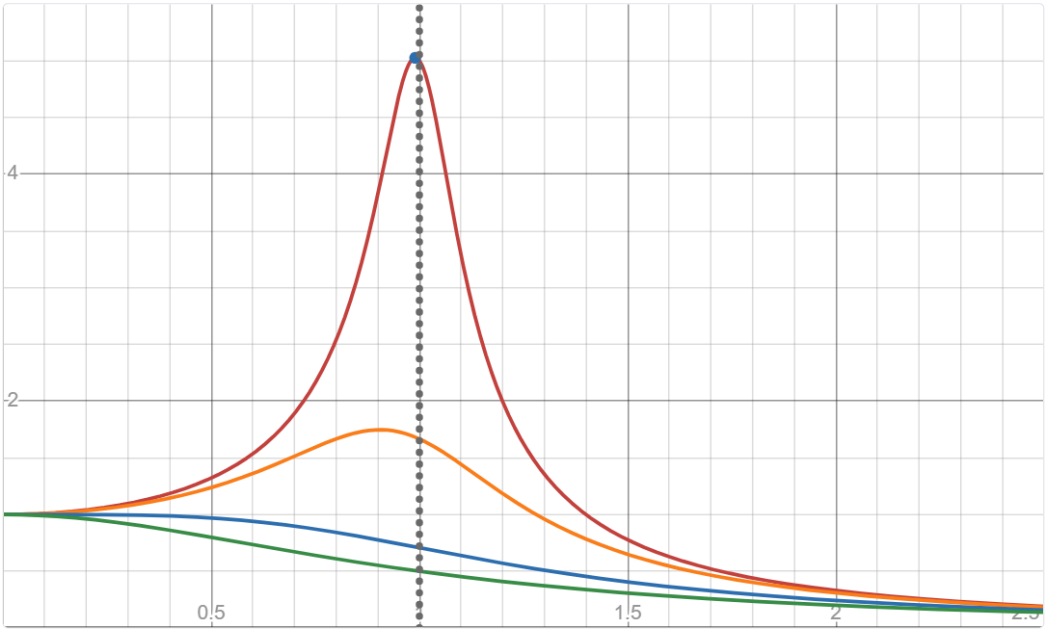
For $0 < \zeta < 1/\sqrt{2}$, $|H(j\omega)|$ has a maximum at the **resonant frequency** and with the **peak value**

$$\omega_r = \omega_n\sqrt{1 - 2\zeta^2}, \qquad M_r = \frac{1}{2\zeta\sqrt{1-\zeta^2}}.$$

For $\zeta \geq 1/\sqrt{2}$ there is no peak; the gain decreases monotonically. At $\omega = \omega_n$ the phase is exactly $-90°$ and the gain is $1/(2\zeta)$ for every ζ.

Derivation. Maximising $|H|$ means minimising $g(\nu^2) = (1-\nu^2)^2 + 4\zeta^2\nu^2$. With $x = \nu^2$, $g'(x) = -2(1-x) + 4\zeta^2 = 0$ gives $x = 1 - 2\zeta^2$, which is positive only if $\zeta^2 < 1/2$. Substituting, $g = 4\zeta^4 + 4\zeta^2(1-2\zeta^2) = 4\zeta^2(1-\zeta^2)$, so $M_r = 1/\sqrt{g} = 1/\left(2\zeta\sqrt{1-\zeta^2}\right)$. □

For light damping $M_r \approx 1/(2\zeta) = Q$, the **quality factor**, and the half-power (-3 dB) bandwidth of the peak is approximately $2\zeta\omega_n = \omega_n/Q$. For $\zeta = 0.1$ the exact peak is $M_r = 5.025$ at $\nu = 0.990$, and the exact half-power bandwidth is $0.202\,\omega_n$, close to the approximation $0.2\,\omega_n$.



Magnitude response $|H|$ against $\nu = \omega/\omega_n$ for $\zeta = 0.1$ (red), 0.3 (orange), 0.707 (blue, maximally flat) and 1 (green). Light damping produces a tall, narrow resonant peak just below ω_n.

Steady state for periodic inputs

A periodic input can be expanded in a Fourier series (Ch. 15), $r(t) = c_0 + \sum_k |c_k|\cos(k\omega_0 t + \psi_k)$. By superposition the steady state is

$$y_{ss}(t) = H(0)\,c_0 + \sum_k |c_k|\,|H(jk\omega_0)|\cos\left(k\omega_0 t + \psi_k + \angle H(jk\omega_0)\right).$$

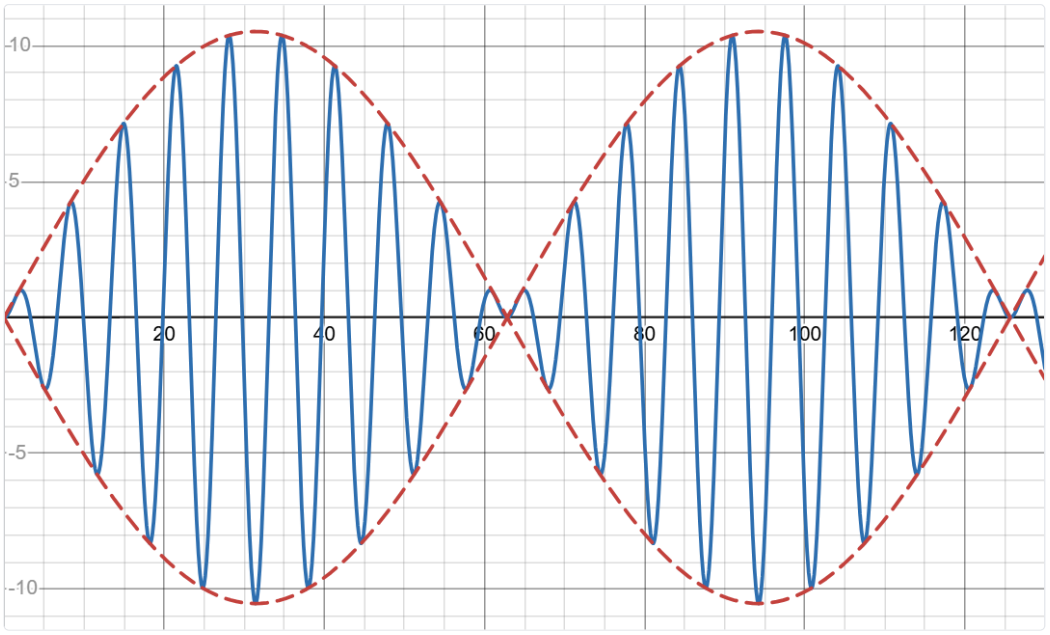
Each harmonic is scaled and shifted by the frequency response at its own frequency. A low-pass system attenuates the high harmonics, which is why a square wave through an RC filter comes out rounded. A lightly damped system can selectively amplify one harmonic that falls near its resonant peak.

Beats: the approach to resonance

For an undamped system driven near, but not at, its natural frequency, the "transient" never decays, and the sum of natural and forced responses produces **beats**. For $y'' + \omega_0^2 y = \cos\omega t$ with $y(0) = y'(0) = 0$ and $\omega \neq \omega_0$:

$$y = \frac{\cos\omega t - \cos\omega_0 t}{\omega_0^2 - \omega^2} = \frac{2}{\omega_0^2 - \omega^2}\,\sin\left(\frac{(\omega_0 - \omega)t}{2}\right)\sin\left(\frac{(\omega_0 + \omega)t}{2}\right),$$

using $\cos A - \cos B = -2\sin\frac{A+B}{2}\sin\frac{A-B}{2}$. The fast oscillation at the average frequency is modulated by a slow envelope at half the difference frequency. As $\omega \to \omega_0$, the envelope period grows without bound and, near $t = 0$, $y \to \frac{t\sin\omega_0 t}{2\omega_0}$, the resonant solution of Example 12.17. With damping, the beat pattern is a transient: it decays and leaves the steady-state sinusoid.



Beats for $\omega_0 = 1, \omega = 0.9$: the response (blue) oscillates near 0.95 rad/s inside a slow envelope $\pm 10.5\sin(0.05t)$ (red), with beat period $2\pi/0.1 = 62.8$.

Worked examples

Example 12.21 — RC low-pass switched onto a sinusoid

Solve $\tau y' + y = \cos \omega t$, $y(0) = 0$, identify transient and steady state, and evaluate for $\omega\tau = 1$.

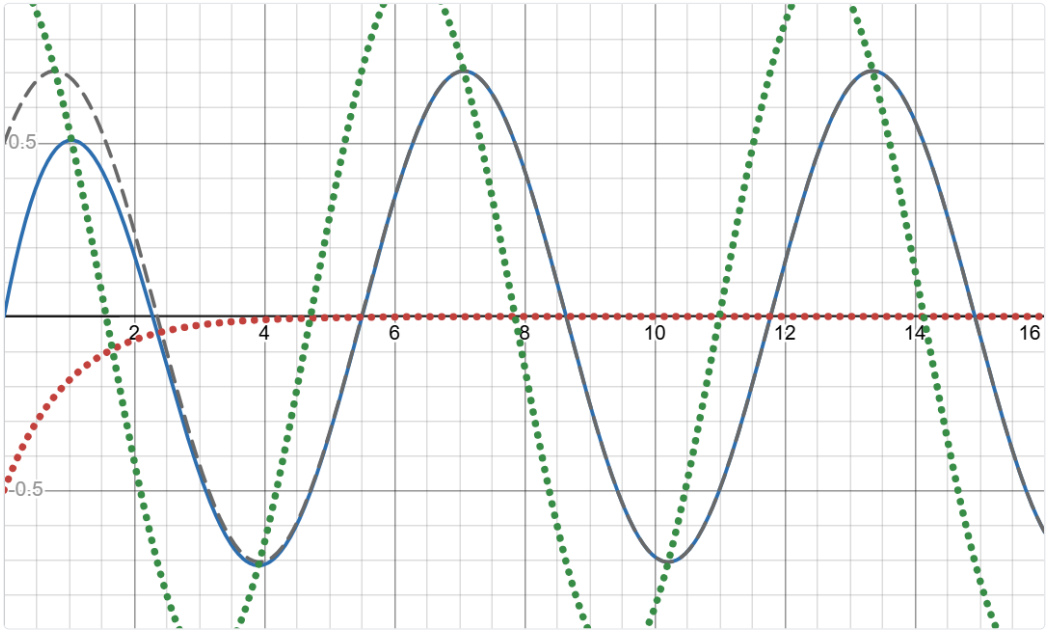
Steady state. $H(j\omega) = 1/(1 + j\omega\tau)$:

$$y_{ss} = \frac{1}{\sqrt{1+\omega^2\tau^2}}\cos\left(\omega t - \arctan\omega\tau\right) = \frac{\cos\omega t + \omega\tau\sin\omega t}{1+\omega^2\tau^2}.$$

Transient. $y_{tr} = Ae^{-t/\tau}$ with $y(0) = 0$: $A = -y_{ss}(0) = -1/(1+\omega^2\tau^2)$.

$$y(t) = \frac{\cos\omega t + \omega\tau\sin\omega t - e^{-t/\tau}}{1+\omega^2\tau^2}.$$

At $\omega\tau = 1$. $y = \tfrac{1}{2}\left(\cos\omega t + \sin\omega t - e^{-t/\tau}\right)$, with steady-state amplitude 0.7071 (-3 dB) and lag 45°. Check: $y(0) = \tfrac{1}{2}(1 + 0 - 1) = 0$ ✓. After 4τ the transient is $0.5e^{-4} = 0.009$, under 1.3% of the steady-state amplitude.



Example 12.21 with $\tau = 1, \omega = 1$: input $\cos t$ (green), complete response (blue), steady state (grey dashed) and transient (red). The output merges with the steady state within a few time constants, attenuated by 0.707 and lagging by 45°.

Example 12.22 — Second-order: transient, steady state and settling

Solve $y'' + 2y' + 5y = 10\cos t$, $y(0) = 0$, $y'(0) = 0$, and estimate when the transient is negligible.

Steady state (Example 12.16): $y_{ss} = 2\cos t + \sin t$.

Transient. Roots $-1 \pm 2j$: $y_{tr} = e^{-t}(A\cos 2t + B\sin 2t)$. Conditions on the complete response:

$$y(0) = 2 + A = 0 \Rightarrow A = -2, \qquad y'(0) = 1 + (-A + 2B) = 0 \Rightarrow B = -\tfrac{3}{2}.$$

$$y(t) = 2\cos t + \sin t - e^{-t}\left(2\cos 2t + \tfrac{3}{2}\sin 2t\right).$$

Check. At $t = 3$ the formula gives -1.91361, matching a numerical solver. The transient amplitude is $\sqrt{4 + 2.25}\,e^{-t} = 2.5e^{-t}$; it falls below 2% of the steady amplitude $\sqrt{5} = 2.236$ when $2.5e^{-t} < 0.0447$, i.e. $t > 4.0$. The transient oscillates at 2 rad/s (the natural frequency ω_d), not at the input frequency 1 rad/s: natural modes always ring at their own frequency.

Example 12.23 — Harmonics of a periodic input

The input $r(t) = \cos t + \cos 3t$ (the first two terms of a crude approximation to a pulse train) drives $y' + y = r$. Find the steady state.

With $\tau = 1$: at $\omega = 1$, $|H| = 1/\sqrt{2} = 0.7071$, $\angle H = -45°$; at $\omega = 3$, $|H| = 1/\sqrt{10} = 0.3162$, $\angle H = -71.57°$.

$$y_{ss} = 0.7071\cos(t - 45°) + 0.3162\cos(3t - 71.57°).$$

The third harmonic is attenuated more (ratio 0.447) and delayed by a different time: 45° at 1 rad/s is a delay of 0.785 s, whereas 71.57° at 3 rad/s is a delay of 0.416 s. Because different harmonics are delayed differently, the output waveform has a different *shape* from the input. This is phase distortion, which a linear-phase filter avoids.

Example 12.24 — No steady state: unstable and marginal systems

(a) $y'' - y = \cos t$; (b) $y'' + y' = 1$.

(a) Roots ± 1. The forced response is $y_f = \cos t / P(j) = \cos t/(-1 - 1) = -\frac{1}{2}\cos t$, but $y_n = c_1 e^t + c_2 e^{-t}$. Unless the initial conditions make $c_1 = 0$ exactly (a set of measure zero, destroyed by any noise), $c_1 e^t$ dominates. The formula y_f is not a physically meaningful steady state.

(b) Roots $0, -1$. The constant input matches the root $s = 0$ ($m = 1$): $y_p = t/P'(0) = t/1 = t$. The response grows as a ramp; the system integrates the constant input. In circuit terms, a capacitor charged by a constant current has no DC steady state. A DC steady state exists only if $P(0) = a_0 \neq 0$.

Common Pitfall

Phasor and impedance calculations silently assume the system is stable and that enough time has passed. Applying $H(j\omega)$ to an unstable circuit, or reading a "steady-state" measurement before 4–5 time constants of the slowest mode have elapsed, gives wrong answers. In very lightly damped circuits (Q in the hundreds, as in crystal oscillators or high-Q filters) the settling time $t_s \approx 8Q/\omega_n$ can be surprisingly long.

Engineering Note

A network analyser measures $H(j\omega)$ by sweeping a sinusoid and waiting at each frequency for the transient to die. Its IF bandwidth and dwell time are chosen from exactly the settling-time estimate above; narrow-band high-Q devices need slow sweeps. Similarly, a switching power supply's "load-step response" specification is a transient measurement: the regulator's dominant poles decide how quickly the output voltage recovers after a sudden change in current.

12.6 Coupled differential equations

Motivation

Real networks have more than one loop or node, and the unknowns interact. Two mesh currents share a resistor; two coils share magnetic flux through mutual inductance M; a motor's current produces torque and its speed produces a back-EMF that opposes the current. Each such interaction gives a system of simultaneous linear ODEs in several unknowns. This section treats them with two tools: **elimination**, which reduces the system to a single higher-order equation of the kind already solved, and **modal decomposition**, which changes variables so that the system splits into independent scalar equations. The general first-order matrix form $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}$ and its eigenvector solution appear in Ch. 11; here the emphasis is on equations as they arise from circuits, often second order and with derivatives on several unknowns in one equation.

Operator-matrix form

Coupled linear system with constant coefficients

A system of k linear constant-coefficient ODEs in unknowns $y_1, \dots, y_k$ can be written

$$\begin{bmatrix} P_{11}(D) & \cdots & P_{1k}(D) \\ \vdots & & \vdots \\ P_{k1}(D) & \cdots & P_{kk}(D) \end{bmatrix} \begin{bmatrix} y_1 \\ \vdots \\ y_k \end{bmatrix} = \begin{bmatrix} r_1(t) \\ \vdots \\ r_k(t) \end{bmatrix}, \qquad \text{briefly} \qquad \mathbf{P}(D)\,\mathbf{y} = \mathbf{r},$$

where each $P_{il}(D)$ is a polynomial in D. The polynomial $\Delta(s) = \det \mathbf{P}(s)$ is the **characteristic polynomial of the system**.

Because constant-coefficient operators commute (Section 12.1), the entries of $\mathbf{P}(D)$ can be manipulated like the entries of a matrix of polynomials. In particular **Cramer's rule** holds in operator form:

Elimination by operator determinants

If $\Delta(s) = \det \mathbf{P}(s)$ is not identically zero, every solution of $\mathbf{P}(D)\mathbf{y} = \mathbf{r}$ satisfies, for each component,

$$\Delta(D)\, y_i = \det \mathbf{P}_i(D),$$

where $\mathbf{P}_i$ is $\mathbf{P}$ with its ith column replaced by $\mathbf{r}$ (expanded along that column so that operators act on the r_l). Each y_i therefore has natural modes given by the roots of $\Delta(s)$. The general solution of the system contains exactly $\deg \Delta$ independent arbitrary constants.

Proof sketch. Multiply the system on the left by the adjugate operator matrix $\operatorname{adj}\mathbf{P}(D)$. Since entries commute, $\operatorname{adj}\mathbf{P}\cdot\mathbf{P} = \Delta(D)\,\mathbf{I}$, giving $\Delta(D)\mathbf{y} = \operatorname{adj}\mathbf{P}(D)\,\mathbf{r}$, which is the column-replacement formula. The count of constants is a standard result (each component individually appears to need $\deg\Delta$ constants, but the original equations tie them together so that only $\deg\Delta$ in total are free). $\square$

Common Pitfall

After eliminating, each component y_i satisfies a degree-$\deg\Delta$ equation, so writing each with its own $\deg\Delta$ constants gives $k\cdot\deg\Delta$ constants, far too many. The surplus constants are **not** free: substitute back into one of the original equations to express them in terms of the others, or, more simply, solve for one unknown and *compute* the others from the original equations (as in Example 12.25). Also: if $\Delta(s)\equiv 0$ the system is degenerate (dependent equations or a redundant variable) and must be reformulated.

The degree of Δ equals the number of independent energy-storage elements, i.e. the order of the system. For two coupled inductors, Δ has degree 2 unless the coupling is perfect ($M^2 = L_1L_2$), in which case the two inductors behave as one and the degree drops to 1.

Modal decomposition

The second method changes variables. Suppose the system can be written $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ (first order) or $\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0}$ (second order, undamped, as for LC ladders or spring–mass chains). If $\mathbf{A}$ is diagonalisable, $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$ (Ch. 10), then the **modal coordinates** $\mathbf{q} = \mathbf{V}^{-1}\mathbf{x}$ satisfy

$$\dot{\mathbf{q}} = \mathbf{\Lambda}\mathbf{q}, \qquad \text{i.e.} \qquad \dot{q}_k = \lambda_k q_k \quad \text{independently for each } k.$$

The system has split into scalar first-order equations, each with solution $q_k = q_k(0)e^{\lambda_k t}$, and $\mathbf{x} = \mathbf{V}\mathbf{q} = \sum_k q_k(0)\,\mathbf{v}_k e^{\lambda_k t}$. Each eigenvector $\mathbf{v}_k$ is a **mode shape**: the fixed pattern of relative amplitudes in which the unknowns move together at the rate λ_k.

For the second-order form $\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0}$ (taking $\mathbf{M} = \mathbf{I}$, or after scaling) with $\mathbf{K}$ symmetric positive definite, the eigenvalues κ_k of $\mathbf{K}$ are positive and the modes are **normal modes** $\mathbf{v}_k\cos(\omega_k t + \varphi_k)$ with $\omega_k = \sqrt{\kappa_k}$. Symmetric matrices have orthogonal eigenvectors, which is what makes the decoupling exact and the mode shapes physically distinct.

With forcing, the same change of variables gives $\dot{q}_k = \lambda_k q_k + g_k(t)$ with $\mathbf{g} = \mathbf{V}^{-1}\mathbf{f}$: each mode is driven only by its own projection of the input. A mode whose projection is zero is not excited at all.

Sinusoidal steady state of coupled systems

For a stable coupled system driven sinusoidally at frequency ω, replace every D by $j\omega$: the phasor amplitudes satisfy the complex linear algebraic system

$$\mathbf{P}(j\omega)\,\mathbf{Y} = \mathbf{R},$$

solvable by Cramer's rule or Gaussian elimination (Ch. 8). This is exactly mesh or nodal analysis with impedances. Its determinant $\det\mathbf{P}(j\omega) = \Delta(j\omega)$ is small near the natural frequencies (resonances), while a numerator determinant can vanish at some frequency, making one output zero: an **antiresonance** or transmission zero.

Worked examples

Example 12.25 — Elimination for a first-order pair

Solve $x' = -2x + y$, $y' = x - 2y$, with $x(0) = 1$, $y(0) = 0$.

Eliminate y. From the first equation $y = x' + 2x$. Substituting into the second: $x'' + 2x' = x - 2(x' + 2x)$, i.e.

$$x'' + 4x' + 3x = 0, \qquad s^2 + 4s + 3 = (s+1)(s+3).$$

(Operator check: $\Delta(s) = \det \begin{bmatrix} s+2 & -1 \\ -1 & s+2 \end{bmatrix} = (s+2)^2 - 1 = s^2 + 4s + 3$ ✓.)

Initial data for x. $x(0) = 1$ and $x'(0) = -2x(0) + y(0) = -2$. With $x = c_1 e^{-t} + c_2 e^{-3t}$: $c_1 + c_2 = 1$, $-c_1 - 3c_2 = -2$, so $c_1 = c_2 = \tfrac{1}{2}$.

Recover y from the original equation (no new constants):

$$x = \tfrac{1}{2}\left(e^{-t} + e^{-3t}\right), \qquad y = x' + 2x = \tfrac{1}{2}\left(e^{-t} - e^{-3t}\right).$$

Modal view. $\mathbf{A} = \begin{bmatrix} -2 & 1 \\ 1 & -2 \end{bmatrix}$ has eigenpairs $\lambda = -1$, $\mathbf{v} = (1,1)$ and $\lambda = -3$, $\mathbf{v} = (1,-1)$. The solution is $\tfrac{1}{2}(1,1)e^{-t} + \tfrac{1}{2}(1,-1)e^{-3t}$: the sum $x + y = e^{-t}$ decays slowly and the difference $x - y = e^{-3t}$ decays fast. Check: $y(0) = 0$ ✓, and $y' = \tfrac{1}{2}(-e^{-t} + 3e^{-3t})$ equals $x - 2y = \tfrac{1}{2}(e^{-t} + e^{-3t}) - (e^{-t} - e^{-3t}) = \tfrac{1}{2}(-e^{-t} + 3e^{-3t})$ ✓.

Example 12.26 — Mutually coupled coils with a step input

Two coils with $L_1 = L_2 = 1$ H, mutual inductance $M = 0.5$ H and winding resistances $R_1 = R_2 = 1\ \Omega$ are coupled. A 1 V step is applied to coil 1 at $t = 0$; coil 2 is short-circuited. Both currents start at zero. Find $i_1(t)$ and $i_2(t)$.

Equations.

$$\begin{aligned} L_1 i_1' + M i_2' + R_1 i_1 &= 1, \\ M i_1' + L_2 i_2' + R_2 i_2 &= 0, \end{aligned} \qquad \begin{bmatrix} D+1 & 0.5D \\ 0.5D & D+1 \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}.$$

Characteristic polynomial. $\Delta(s) = (s+1)^2 - 0.25s^2 = 0.75s^2 + 2s + 1$, roots $s = (-2 \pm 1)/1.5$: $s_1 = -\tfrac{2}{3}$, $s_2 = -2\ \text{s}^{-1}$.

Cramer. $\Delta(D)\, i_1 = (D+1)[1] - 0.5D[0] = 1$ and $\Delta(D)\, i_2 = (D+1)[0] - 0.5D[1] = 0$. So the forced values are $i_{1f} = 1/\Delta(0) = 1$ and $i_{2f} = 0$, as expected (at DC the coils are shorts and only R_1 limits i_1).

Initial derivatives. At $t = 0^+$, $\begin{bmatrix} 1 & 0.5 \\ 0.5 & 1 \end{bmatrix} \mathbf{i}' = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$, so $i_1'(0) = \tfrac{4}{3}$, $i_2'(0) = -\tfrac{2}{3}$ A/s.

Fit. $i_1 = 1 + ae^{-2t/3} + be^{-2t}$ with $1 + a + b = 0$, $-\tfrac{2}{3}a - 2b = \tfrac{4}{3}$: $a = b = -\tfrac{1}{2}$. For $i_2 = ce^{-2t/3} + de^{-2t}$: $c + d = 0$, $-\tfrac{2}{3}c - 2d = -\tfrac{2}{3}$: $c = -\tfrac{1}{2}$, $d = \tfrac{1}{2}$.

$$i_1 = 1 - \tfrac{1}{2}e^{-2t/3} - \tfrac{1}{2}e^{-2t}, \qquad i_2 = -\tfrac{1}{2}e^{-2t/3} + \tfrac{1}{2}e^{-2t}\ \text{A}.$$

Interpretation. The sum $i_1 + i_2$ sees inductance $L + M = 1.5$ H (time constant 1.5 s, rate $2/3$), the difference $i_1 - i_2$ sees $L - M = 0.5$ H (rate 2): these are the modal coordinates. The secondary current is negative (Lenz's law: it opposes the change in flux), peaks, and returns to zero. A numerical eigen-solution of the matrix form gives the same eigenvalues -0.6667 and -2 and the same coefficients.

Example 12.27 — Coupled resonators and energy exchange

Two identical LC resonators coupled through a capacitor (or two masses joined by springs) obey, in suitable units,

$$x_1'' = -2x_1 + x_2, \qquad x_2'' = x_1 - 2x_2,$$

with $x_1(0) = 1$, $x_2(0) = 0$, $x_1'(0) = x_2'(0) = 0$. Find the normal modes and the motion.

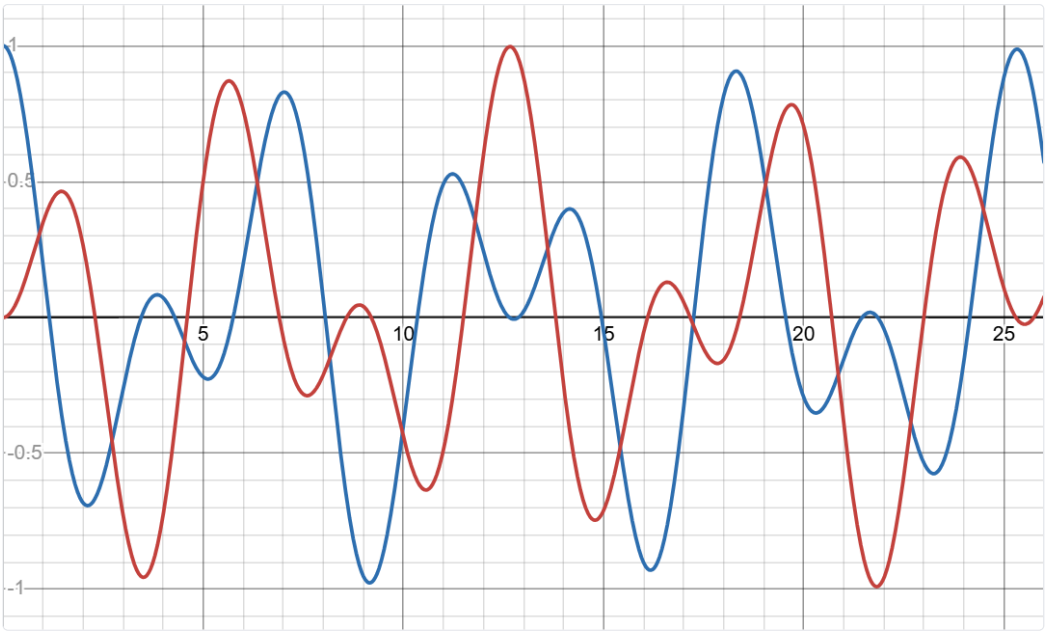
Normal modes. $\mathbf{K} = \begin{bmatrix} 2 & -1 \\ -1 & 2 \end{bmatrix}$ has eigenvalues 1 and 3 with eigenvectors $(1,1)$ and $(1,-1)$. So the in-phase mode oscillates at $\omega_1 = 1$ and the anti-phase mode at $\omega_2 = \sqrt{3} = 1.732$.

Modal coordinates. $q_1 = (x_1 + x_2)/2$, $q_2 = (x_1 - x_2)/2$ satisfy $q_1'' = -q_1$, $q_2'' = -3q_2$, with $q_1(0) = q_2(0) = \tfrac{1}{2}$ and zero initial velocities. Hence $q_1 = \tfrac{1}{2}\cos t$, $q_2 = \tfrac{1}{2}\cos\sqrt{3}t$, and

$$x_1 = q_1 + q_2 = \tfrac{1}{2}\left(\cos t + \cos\sqrt{3}\,t\right), \qquad x_2 = q_1 - q_2 = \tfrac{1}{2}\left(\cos t - \cos\sqrt{3}\,t\right).$$

Check. $x_1'' = \tfrac{1}{2}(-\cos t - 3\cos\sqrt{3}t)$ and $-2x_1 + x_2 = -\cos t - \cos\sqrt{3}t + \tfrac{1}{2}\cos t - \tfrac{1}{2}\cos\sqrt{3}t = \tfrac{1}{2}(-\cos t - 3\cos\sqrt{3}t)$ ✓.

By the sum-to-product identity, $x_1 = \cos\!\left(\tfrac{\sqrt{3}-1}{2}t\right)\cos\!\left(\tfrac{\sqrt{3}+1}{2}t\right)$ and $x_2 = \sin\!\left(\tfrac{\sqrt{3}-1}{2}t\right)\sin\!\left(\tfrac{\sqrt{3}+1}{2}t\right)$. The energy moves completely from resonator 1 to resonator 2 and back, with the transfer taking $\pi/(\sqrt{3}-1) = 4.29$ time units. With weak coupling the two mode frequencies are close and the exchange is slow; this is the mechanism behind coupled-resonator bandpass filters and wireless power transfer.



Example 12.27: displacement of resonator 1 (blue) and resonator 2 (red). Energy passes back and forth between them as the two normal modes drift in and out of phase.

Example 12.28 — Driven coupled resonators and an antiresonance

Drive the system of Example 12.27 with a force on the first coordinate: $x_1'' + 2x_1 - x_2 = \cos\omega t$, $x_2'' - x_1 + 2x_2 = 0$. Find the steady-state phasor amplitudes and show that x_1 can be made to stand still.

Replace D^2 by $-\omega^2$ (strictly, the undamped system has no decaying transient; in practice a small loss makes the transient decay and leaves this steady state):

$$\begin{bmatrix} 2-\omega^2 & -1 \\ -1 & 2-\omega^2 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad \Rightarrow \quad X_1 = \frac{2-\omega^2}{(2-\omega^2)^2 - 1}, \qquad X_2 = \frac{1}{(2-\omega^2)^2-1}.$$

The denominator $(2-\omega^2)^2 - 1 = (1-\omega^2)(3-\omega^2)$ vanishes at the natural frequencies $\omega = 1$ and $\sqrt{3}$ (resonances). The numerator of X_1 vanishes at $\omega = \sqrt{2}$: there $X_1 = 0$ and $X_2 = 1/(0-1) = -1$. The driven coordinate does not move; the second resonator, tuned to $\omega = \sqrt{2}$ on its own ($x_2'' + 2x_2 = x_1$), oscillates in antiphase and exactly cancels the drive. This is the principle of the mechanical vibration absorber and of the parallel-resonant **wave trap** in power-line carrier systems: a resonator tuned to an unwanted frequency blocks it.

Engineering Note

In nodal analysis of an RLC network the operator matrix $\mathbf{P}(s)$ is the admittance matrix $\mathbf{Y}(s)$, and $\Delta(s) = \det \mathbf{Y}(s)$, after clearing denominators, is the characteristic polynomial of the network. Circuit simulators find natural frequencies ("pole-zero analysis") by locating the zeros of this determinant, and they find transfer-function zeros from the cofactors, exactly the numerator determinants of Cramer's rule.

12.7 State-variable formulation

Motivation

A single nth-order equation is ideal for hand analysis of small systems, but it scales badly. Eliminating variables from a ten-node network is painful; systems with several inputs and outputs do not fit a scalar equation at all; and numerical ODE solvers only accept first-order systems. The **state-variable** (state-space) formulation writes any linear lumped system as a single first-order *vector* equation. It handles any number of inputs and outputs, it is what simulators and control-design software use internally, and its solution has a closed form, the **matrix exponential**, which is the exact matrix analogue of e^{at} for the scalar equation $\dot{x} = ax$.

State, state equation, output equation

State

The **state** of a system at time t_0 is the smallest set of numbers $x_1(t_0), \dots, x_n(t_0)$ which, together with the input $u(t)$ for $t \geq t_0$, determines the system's behaviour for all $t \geq t_0$. The vector $\mathbf{x} = (x_1, \dots, x_n)^{\mathsf{T}}$ is the **state vector**; n is the **order**.

Linear time-invariant state-space model

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \mathbf{A}\,\mathbf{x}(t) + \mathbf{B}\,\mathbf{u}(t) \quad \text{(state equation)}\\ \mathbf{y}(t) &= \mathbf{C}\,\mathbf{x}(t) + \mathbf{D}\,\mathbf{u}(t) \quad \text{(output equation)}\end{aligned}$$

with $\mathbf{x} \in \mathbb{R}^n$ (state), $\mathbf{u} \in \mathbb{R}^p$ (inputs), $\mathbf{y} \in \mathbb{R}^q$ (outputs), and constant matrices $\mathbf{A}$ ($n \times n$, the **system** or **state matrix**), $\mathbf{B}$ ($n \times p$, input matrix), $\mathbf{C}$ ($q \times n$, output matrix), $\mathbf{D}$ ($q \times p$, feedthrough matrix).

The letter $\mathbf{D}$ for the feedthrough matrix is universal in control texts; context distinguishes it from the operator $D = d/dt$.

Choosing state variables

From a circuit. The natural state variables are the **capacitor voltages** and **inductor currents**: they are continuous in time (finite current cannot change a capacitor voltage instantaneously, finite voltage cannot change an inductor current), they define the stored energy $\tfrac{1}{2}Cv_C^2 + \tfrac{1}{2}Li_L^2$, and the element laws already give their derivatives:

$$\frac{dv_C}{dt} = \frac{i_C}{C}, \qquad \frac{di_L}{dt} = \frac{v_L}{L}.$$

The recipe: (1) choose every independent v_C and i_L as a state; (2) using KCL, KVL and resistor laws, express each i_C and v_L in terms of the states and the sources; (3) divide by C or L. The result is $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ directly, with no elimination.

From an nth-order ODE. For $y^{(n)} + a_{n-1}y^{(n-1)} + \cdots + a_1 y' + a_0 y = u$ choose the **phase variables** $x_1 = y$, $x_2 = y'$, ..., $x_n = y^{(n-1)}$. Then $\dot{x}_k = x_{k+1}$ for $k < n$ and $\dot{x}_n = -a_0 x_1 - \cdots - a_{n-1}x_n + u$:

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-1} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}, \quad \mathbf{D} = 0.$$

This is the **companion** (controllable canonical) form. Its characteristic polynomial $\det(s\mathbf{I} - \mathbf{A})$ equals $s^n + a_{n-1}s^{n-1} + \cdots + a_0 = P(s)$, so the eigenvalues of $\mathbf{A}$ are exactly the characteristic roots of the ODE. When the right-hand side contains input derivatives, $P(D)y = (b_{n-1}D^{n-1} + \cdots + b_0)u$, keep the same $\mathbf{A}$ and $\mathbf{B}$, solve $P(D)w = u$ for an auxiliary variable w with states $w, w', \ldots$, and take $y = b_0 w + b_1 w' + \ldots$, i.e. $\mathbf{C} = [\,b_0 \;\; b_1 \;\; \cdots \;\; b_{n-1}\,]$.

State representations are not unique

If $\mathbf{T}$ is any invertible $n \times n$ matrix and $\mathbf{z} = \mathbf{T}^{-1}\mathbf{x}$, then

$$\dot{\mathbf{z}} = \mathbf{T}^{-1}\mathbf{A}\mathbf{T}\,\mathbf{z} + \mathbf{T}^{-1}\mathbf{B}\,\mathbf{u}, \qquad \mathbf{y} = \mathbf{C}\mathbf{T}\,\mathbf{z} + \mathbf{D}\mathbf{u}$$

describes the same input–output behaviour. Similar matrices have the same eigenvalues, so the natural frequencies, stability and transfer function are invariant; only the internal coordinates change. Choosing $\mathbf{T} = \mathbf{V}$ (eigenvectors) gives the **modal** (diagonal) form of Section 12.6.

The matrix exponential

For the scalar equation $\dot{x} = ax$ the solution is $x = e^{at}x(0)$. To mimic this for $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$, define the exponential of a matrix by the same power series.

Matrix exponential

For a square matrix $\mathbf{A}$ and real t,

$$e^{\mathbf{A}t} = \mathbf{I} + \mathbf{A}t + \frac{\mathbf{A}^2t^2}{2!} + \frac{\mathbf{A}^3t^3}{3!} + \cdots = \sum_{k=0}^{\infty} \frac{\mathbf{A}^k t^k}{k!}.$$

In control theory $\boldsymbol{\Phi}(t) = e^{\mathbf{A}t}$ is called the **state-transition matrix**.

The series converges absolutely for every $\mathbf{A}$ and t, because $\|\mathbf{A}^k t^k/k!\| \le (\|\mathbf{A}\|\,|t|)^k/k!$ and the scalar exponential series converges.

Properties of $e^{\mathbf{A}t}$

1. $e^{\mathbf{A}\cdot 0} = \mathbf{I}$.
2. $\dfrac{d}{dt}e^{\mathbf{A}t} = \mathbf{A}e^{\mathbf{A}t} = e^{\mathbf{A}t}\mathbf{A}$.
3. $e^{\mathbf{A}(t+\tau)} = e^{\mathbf{A}t}e^{\mathbf{A}\tau}$ (semigroup property).
4. $\left(e^{\mathbf{A}t}\right)^{-1} = e^{-\mathbf{A}t}$; in particular $e^{\mathbf{A}t}$ is always invertible, with $\det e^{\mathbf{A}t} = e^{t\,\mathrm{tr}\,\mathbf{A}}$.
5. If $\mathbf{A} = \mathbf{V}\boldsymbol{\Lambda}\mathbf{V}^{-1}$, then $e^{\mathbf{A}t} = \mathbf{V}e^{\boldsymbol{\Lambda}t}\mathbf{V}^{-1}$ with $e^{\boldsymbol{\Lambda}t} = \mathrm{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_n t})$.
6. $e^{(\mathbf{A}+\mathbf{B})t} = e^{\mathbf{A}t}e^{\mathbf{B}t}$ **if** $\mathbf{AB} = \mathbf{BA}$, but not in general.

Proof sketches. (2): differentiate the series term by term, $\frac{d}{dt}\frac{\mathbf{A}^k t^k}{k!} = \mathbf{A}\frac{\mathbf{A}^{k-1}t^{k-1}}{(k-1)!}$; $\mathbf{A}$ commutes with its own powers. (3): both sides satisfy $\dot{\mathbf{X}} = \mathbf{A}\mathbf{X}$ in t with value $e^{\mathbf{A}\tau}$ at $t = 0$, so they are equal by uniqueness. (4) follows from (3) with $\tau = -t$. (5): $\mathbf{A}^k = \mathbf{V}\boldsymbol{\Lambda}^k\mathbf{V}^{-1}$, so each term of the series factors. (6): the binomial expansion of $(\mathbf{A}+\mathbf{B})^k$ needs commuting factors. $\square$

Common Pitfall

$e^{\mathbf{A}t}$ is **not** the matrix of entry-wise exponentials $[e^{a_{ik}t}]$, except when $\mathbf{A}$ is diagonal. And $e^{\mathbf{A}t}e^{\mathbf{B}t} \neq e^{(\mathbf{A}+\mathbf{B})t}$ unless $\mathbf{A}$ and $\mathbf{B}$ commute; this matters, for example, in piecewise-linear switched circuits, where each switching interval has its own state matrix and the transition matrices must be multiplied in time order.

Solving the state equation

Solution of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$

The unique solution with $\mathbf{x}(0) = \mathbf{x}_0$ is

$$\mathbf{x}(t) = \underbrace{e^{\mathbf{A}t}\mathbf{x}_0}_{\text{zero-input}} + \underbrace{\int_0^t e^{\mathbf{A}(t-\tau)}\mathbf{B}\,\mathbf{u}(\tau)\,d\tau}_{\text{zero-state}},$$

and the output is $\mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u}$.

Derivation (integrating factor). Multiply the state equation by $e^{-\mathbf{A}t}$ and use property 2:

$$e^{-\mathbf{A}t}\big(\dot{\mathbf{x}} - \mathbf{A}\mathbf{x}\big) = \frac{d}{dt}\Big(e^{-\mathbf{A}t}\mathbf{x}\Big) = e^{-\mathbf{A}t}\mathbf{B}\mathbf{u}.$$

Integrate from 0 to t: $e^{-\mathbf{A}t}\mathbf{x}(t) - \mathbf{x}_0 = \int_0^t e^{-\mathbf{A}\tau}\mathbf{B}\mathbf{u}(\tau)\,d\tau$. Multiply by $e^{\mathbf{A}t}$ and use property 3. Uniqueness follows from the general theory (Ch. 11). $\square$

The formula is the vector version of the first-order integrating-factor solution, and it displays the zero-input/zero-state decomposition of Section 12.3 explicitly. The matrix $e^{\mathbf{A}t}\mathbf{B}$ is the **impulse response** of the states, and $\mathbf{C}e^{\mathbf{A}t}\mathbf{B} + \mathbf{D}\delta(t)$ is the impulse response from input to output.

Constant (step) input

If $\mathbf{u}(t) = \mathbf{u}_0$ is constant for $t \geq 0$ and $\mathbf{A}$ is invertible,

$$\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}_0 + \mathbf{A}^{-1}\big(e^{\mathbf{A}t} - \mathbf{I}\big)\mathbf{B}\mathbf{u}_0.$$

If moreover $\mathbf{A}$ is stable (all eigenvalues in the open left half-plane), $e^{\mathbf{A}t} \to \mathbf{0}$ and the steady state is $\mathbf{x}_{ss} = -\mathbf{A}^{-1}\mathbf{B}\mathbf{u}_0$, the solution of $\mathbf{0} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}_0$.

Proof. $\int_0^t e^{\mathbf{A}(t-\tau)}\,d\tau = \int_0^t e^{\mathbf{A}\sigma}\,d\sigma = \mathbf{A}^{-1}\big(e^{\mathbf{A}t} - \mathbf{I}\big)$, by integrating the series term by term (or because the derivative of the right side is $e^{\mathbf{A}t}$). $\square$

Stability in state space. The eigenvalues of $\mathbf{A}$ are the characteristic roots: $\det(s\mathbf{I} - \mathbf{A})$ is the characteristic polynomial. The system is asymptotically stable if and only if every eigenvalue of $\mathbf{A}$ has negative real part, which is the root criterion of Section 12.2 in matrix language.

Frequency response in state space. For $\mathbf{u} = \mathbf{U}e^{j\omega t}$, try $\mathbf{x} = \mathbf{X}e^{j\omega t}$: $j\omega\mathbf{X} = \mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{U}$, so $\mathbf{X} = (j\omega\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}\mathbf{U}$ and

$$\mathbf{H}(j\omega) = \mathbf{C}\big(j\omega\mathbf{I} - \mathbf{A}\big)^{-1}\mathbf{B} + \mathbf{D}.$$

Replacing $j\omega$ by s gives the transfer-function matrix of Ch. 14, where it is also shown that $\mathcal{L}\{e^{\mathbf{A}t}\} = (s\mathbf{I} - \mathbf{A})^{-1}$, the **resolvent**. That identity provides a fourth way to compute $e^{\mathbf{A}t}$: invert $s\mathbf{I} - \mathbf{A}$ and take inverse Laplace transforms entry by entry.

Computing $e^{\mathbf{A}t}$ by hand

Four methods cover practical needs.

1. Diagonalisation (property 5), when $\mathbf{A}$ has n independent eigenvectors.

2. Cayley–Hamilton / Sylvester interpolation. Every square matrix satisfies its own characteristic equation, so $\mathbf{A}^n$ and all higher powers are combinations of $\mathbf{I}, \mathbf{A}, \dots, \mathbf{A}^{n-1}$. Hence

$$e^{\mathbf{A}t} = \alpha_0(t)\mathbf{I} + \alpha_1(t)\mathbf{A} + \cdots + \alpha_{n-1}(t)\mathbf{A}^{n-1},$$

where the scalar functions $\alpha_k(t)$ are fixed by requiring $e^{\lambda t} = \alpha_0 + \alpha_1\lambda + \cdots + \alpha_{n-1}\lambda^{n-1}$ at every eigenvalue λ (and, for a repeated eigenvalue of multiplicity m, also the first $m-1$ derivatives of this identity with respect to λ). For 2×2 matrices this gives closed forms:

$$e^{\mathbf{A}t} = \frac{e^{\lambda_1 t}(\mathbf{A} - \lambda_2\mathbf{I}) - e^{\lambda_2 t}(\mathbf{A} - \lambda_1\mathbf{I})}{\lambda_1 - \lambda_2} \quad (\lambda_1 \neq \lambda_2), \qquad e^{\mathbf{A}t} = e^{\lambda t}\big[\mathbf{I} + (\mathbf{A} - \lambda\mathbf{I})t\big] \quad (\lambda_1 = \lambda_2 = \lambda).$$

The repeated-eigenvalue formula follows because $(\mathbf{A} - \lambda\mathbf{I})^2 = \mathbf{0}$ by Cayley–Hamilton, so $e^{\mathbf{A}t} = e^{\lambda t}e^{(\mathbf{A}-\lambda\mathbf{I})t}$ and the second series terminates after two terms.

3. Jordan / nilpotent splitting. If $\mathbf{A} = \lambda\mathbf{I} + \mathbf{N}$ with $\mathbf{N}$ nilpotent ($\mathbf{N}^m = \mathbf{0}$), then since $\lambda\mathbf{I}$ commutes with everything, $e^{\mathbf{A}t} = e^{\lambda t}\big(\mathbf{I} + \mathbf{N}t + \cdots + \mathbf{N}^{m-1}t^{m-1}/(m-1)!\big)$. This is the matrix origin of the $t^k e^{\lambda t}$ terms of Section 12.2.

4. Laplace transform: $e^{\mathbf{A}t} = \mathcal{L}^{-1}\{(s\mathbf{I} - \mathbf{A})^{-1}\}$ (Ch. 14).

For complex eigenvalues $\sigma \pm j\omega$ of a real matrix, the useful real canonical block is

$$\mathbf{A} = \begin{bmatrix} \sigma & \omega \\ -\omega & \sigma \end{bmatrix} = \sigma\mathbf{I} + \omega\mathbf{J}, \quad \mathbf{J} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \qquad e^{\mathbf{A}t} = e^{\sigma t}\begin{bmatrix} \cos\omega t & \sin\omega t \\ -\sin\omega t & \cos\omega t \end{bmatrix},$$

because $\mathbf{J}^2 = -\mathbf{I}$ makes the series for $e^{\omega\mathbf{J}t}$ split exactly like Euler's formula. Geometrically: a rotation at angular rate ω combined with a uniform contraction at rate $-\sigma$.

Worked examples

Example 12.29 — Companion form of a third-order equation

Write $y''' + 6y'' + 11y' + 6y = u$ in state-space form and confirm the eigenvalues.

With $x_1 = y$, $x_2 = y'$, $x_3 = y''$:

$$\dot{\mathbf{x}} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -6 & -11 & -6 \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} u, \qquad y = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} \mathbf{x}.$$

Expanding $\det(s\mathbf{I} - \mathbf{A})$ along the first column: $s\big[s(s+6)+11\big] + 6 = s^3 + 6s^2 + 11s + 6 = (s+1)(s+2)(s+3)$. Eigenvalues $-1, -2, -3$: stable, overdamped, slowest time constant 1 s. If the equation were instead $y''' + 6y'' + 11y' + 6y = 2u' + 5u$, the same $\mathbf{A}$ and $\mathbf{B}$ would be kept with $\mathbf{C} = [\,5 \;\; 2 \;\; 0\,]$.

Example 12.30 — $e^{\mathbf{A}t}$ three ways

Compute $e^{\mathbf{A}t}$ for $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix}$ (the companion matrix of $y'' + 3y' + 2y$).

Eigenvalues. $\det(s\mathbf{I} - \mathbf{A}) = s^2 + 3s + 2$: $\lambda_1 = -1$, $\lambda_2 = -2$.

Sylvester formula. $\mathbf{A} - \lambda_2 \mathbf{I} = \mathbf{A} + 2\mathbf{I} = \begin{bmatrix} 2 & 1 \\ -2 & -1 \end{bmatrix}$, $\mathbf{A} - \lambda_1 \mathbf{I} = \mathbf{A} + \mathbf{I} = \begin{bmatrix} 1 & 1 \\ -2 & -2 \end{bmatrix}$, $\lambda_1 - \lambda_2 = 1$:

$$e^{\mathbf{A}t} = e^{-t} \begin{bmatrix} 2 & 1 \\ -2 & -1 \end{bmatrix} - e^{-2t} \begin{bmatrix} 1 & 1 \\ -2 & -2 \end{bmatrix} = \begin{bmatrix} 2e^{-t} - e^{-2t} & e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix}.$$

Diagonalisation check. Eigenvectors $\mathbf{v}_1 = (1, -1)$, $\mathbf{v}_2 = (1, -2)$; $\mathbf{V} = \begin{bmatrix} 1 & 1 \\ -1 & -2 \end{bmatrix}$, $\mathbf{V}^{-1} = \begin{bmatrix} 2 & 1 \\ -1 & -1 \end{bmatrix}$. Then $\mathbf{V}\,\mathrm{diag}(e^{-t}, e^{-2t})\mathbf{V}^{-1}$ reproduces the same matrix.

Sanity checks. At $t = 0$ the matrix is $\mathbf{I}$ ✓. The derivative at $t = 0$ is $\begin{bmatrix} -2+2 & -1+2 \\ 2-4 & 1-4 \end{bmatrix} = \mathbf{A}$ ✓. Entry $(1,1)$ is the zero-input y for $y(0) = 1$, $y'(0) = 0$, and $(1,2)$ is the impulse response $e^{-t} - e^{-2t}$ of Example 12.13 ✓. At $t = 0.7$ the entries are 0.74657, 0.24999, -0.49998, -0.00339, identical to a numerical `expm` to all printed digits.

Example 12.31 — Repeated and complex eigenvalues

(a) $\mathbf{A} = \begin{bmatrix} -2 & 1 \\ 0 & -2 \end{bmatrix}$; (b) $\mathbf{A} = \begin{bmatrix} -1 & 2 \\ -2 & -1 \end{bmatrix}$.

(a) Double eigenvalue -2 with only one eigenvector, so $\mathbf{A}$ is not diagonalisable. Write $\mathbf{A} = -2\mathbf{I} + \mathbf{N}$ with $\mathbf{N} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, $\mathbf{N}^2 = \mathbf{0}$:

$$e^{\mathbf{A}t} = e^{-2t}(\mathbf{I} + \mathbf{N}t) = e^{-2t} \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix}.$$

The te^{-2t} entry is the matrix counterpart of a critically damped response.

(b) This is the real canonical block with $\sigma = -1$, $\omega = 2$ (eigenvalues $-1 \pm 2j$):

$$e^{\mathbf{A}t} = e^{-t} \begin{bmatrix} \cos 2t & \sin 2t \\ -\sin 2t & \cos 2t \end{bmatrix}.$$

At $t = 0.5$: $e^{-0.5}\cos 1 = 0.32771$, $e^{-0.5}\sin 1 = 0.51038$, matching numerical computation. Trajectories spiral into the origin, the phase-plane picture of an underdamped system (Ch. 11).

Example 12.32 — Forced solution by the matrix formula

For $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u$ with $\mathbf{A}$ from Example 12.30, $\mathbf{B} = (0, 1)^{\mathsf{T}}$, $u = 1$ for $t \geq 0$ and $\mathbf{x}_0 = \mathbf{0}$, find $\mathbf{x}(t)$.

$\mathbf{A}^{-1} = \tfrac{1}{2}\begin{bmatrix} -3 & -1 \\ 2 & 0 \end{bmatrix}$, so $\mathbf{A}^{-1}\mathbf{B} = (-\tfrac{1}{2}, 0)^{\mathsf{T}}$. Since $\mathbf{A}^{-1}$ commutes with $e^{\mathbf{A}t}$:

$$\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{A}^{-1}\mathbf{B} - \mathbf{A}^{-1}\mathbf{B} = -\tfrac{1}{2}\begin{bmatrix} 2e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} \end{bmatrix} + \begin{bmatrix} \tfrac{1}{2} \\ 0 \end{bmatrix} = \begin{bmatrix} \tfrac{1}{2} - e^{-t} + \tfrac{1}{2}e^{-2t} \\ e^{-t} - e^{-2t} \end{bmatrix}.$$

The first state is the unit-step response of $y'' + 3y' + 2y = u$ found by scalar methods in Example 12.13 ✓, and the second state is its derivative ✓. The steady state $-\mathbf{A}^{-1}\mathbf{B} = (\tfrac{1}{2}, 0)$ is the DC gain $1/P(0) = 1/2$ ✓.

Example 12.33 — Exact discretisation for simulation

A digital controller samples the system of Example 12.32 every $T = 0.1$ s and holds u constant between samples (zero-order hold). Derive the exact discrete-time model.

Over one interval $[kT, (k+1)T]$ with $u = u[k]$ constant, the step-input formula with $\mathbf{x}_0 = \mathbf{x}[k]$ gives

$$\mathbf{x}[k+1] = \mathbf{\Phi}\,\mathbf{x}[k] + \mathbf{\Gamma}\,u[k], \qquad \mathbf{\Phi} = e^{\mathbf{A}T}, \quad \mathbf{\Gamma} = \mathbf{A}^{-1}\big(e^{\mathbf{A}T} - \mathbf{I}\big)\mathbf{B}.$$

Numerically, from Example 12.30 with $t = 0.1$:

$$\mathbf{\Phi} = \begin{bmatrix} 0.99094 & 0.08611 \\ -0.17221 & 0.73262 \end{bmatrix}, \qquad \mathbf{\Gamma} = \begin{bmatrix} 0.004528 \\ 0.086107 \end{bmatrix}.$$

Iterating ten steps from rest with $u[k] = 1$ gives $x_1[10] = 0.199788$, equal to the exact continuous value $\tfrac{1}{2} - e^{-1} + \tfrac{1}{2}e^{-2} = 0.199788$. The discretisation is exact at the sample instants, not an approximation like Euler's method; this is how simulators and digital-control design tools convert continuous models into difference equations (Ch. 17). The eigenvalues of $\mathbf{\Phi}$ are $e^{\lambda_k T} = e^{-0.1}, e^{-0.2}$: continuous poles map to discrete poles by $z = e^{sT}$.

Engineering Note

The state-space model is the native language of modern tools. SPICE assembles nodal equations that are a (descriptor) state-space system; MATLAB/Python control libraries store models as $(\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D})$; Kalman filters, observers, optimal (LQR) controllers and model-order reduction all operate on these matrices. Numerically, $e^{\mathbf{A}T}$ is computed by scaling and squaring with a Padé approximant (the `expm` routine), not by summing the raw series, which suffers from cancellation when $\|\mathbf{A}T\|$ is large.

12.8 Applications to RLC circuits and dynamic systems

This section applies the whole chapter to the circuits and systems that motivated it. The methods are those of Sections 12.1–12.7; the new ingredients are the circuit-specific steps of **obtaining initial conditions** from the physics of switching and **interpreting** the parameters α, ω_n, ζ and Q in terms of component values.

Initial conditions at a switching instant

A switch operating at $t = 0$ changes the circuit, so the equation valid for $t > 0$ needs initial values at $t = 0^+$. They come from two continuity principles, both consequences of finite power:

Continuity of state variables

In a circuit with finite voltages and currents (no impulsive sources and no loops of capacitors or cut-sets of inductors forced to change state instantaneously):

$$v_C(0^+) = v_C(0^-), \qquad i_L(0^+) = i_L(0^-).$$

Reason. $v_C(0^+) - v_C(0^-) = \frac{1}{C}\int_{0^-}^{0^+} i_C\,dt = 0$ when i_C is bounded; similarly for i_L with v_L. Equivalently, stored energy $\tfrac{1}{2}Cv_C^2$ or $\tfrac{1}{2}Li_L^2$ cannot jump without infinite power. □

All other quantities (resistor currents, inductor voltages, capacitor currents) **may** jump. The derivative initial conditions needed for a second-order equation are found from these jump-allowed quantities at $t = 0^+$:

$$\frac{dv_C}{dt}(0^+) = \frac{i_C(0^+)}{C}, \qquad \frac{di_L}{dt}(0^+) = \frac{v_L(0^+)}{L},$$

where $i_C(0^+)$ and $v_L(0^+)$ are computed by KCL/KVL on the $t = 0^+$ circuit with the known $v_C(0^+)$ and $i_L(0^+)$. In practice, the values before switching come from the DC steady state of the old circuit, in which capacitors are open circuits and inductors are short circuits.

The complete procedure for a switched linear circuit is therefore:

1. Find $v_C(0^-), i_L(0^-)$ from the pre-switching circuit (usually its DC steady state).
2. Carry them across: $v_C(0^+) = v_C(0^-), i_L(0^+) = i_L(0^-)$.
3. Find the derivative initial values from the $t = 0^+$ circuit.
4. Find the final (forced) value from the post-switching steady state.
5. Find the characteristic roots of the post-switching circuit.
6. Assemble $y = y_f + y_n$ and fit the constants.

The series RLC circuit

For the series loop (source v_s, all elements carrying the same current i), with v_C as unknown:

$$v_C'' + \frac{R}{L}v_C' + \frac{1}{LC}v_C = \frac{1}{LC}v_s.$$

Comparing with the standard form $y'' + 2\alpha y' + \omega_n^2 y$:

$$\alpha = \frac{R}{2L}, \qquad \omega_n = \frac{1}{\sqrt{LC}}, \qquad \zeta = \frac{\alpha}{\omega_n} = \frac{R}{2}\sqrt{\frac{C}{L}}, \qquad Q = \frac{1}{2\zeta} = \frac{1}{R}\sqrt{\frac{L}{C}}.$$

The **critical resistance** $R_{\text{crit}} = 2\sqrt{L/C}$ separates underdamped ($R < R_{\text{crit}}$) from overdamped ($R > R_{\text{crit}}$) behaviour. The quantity $Z_0 = \sqrt{L/C}$ is the **characteristic impedance** of the LC pair; damping depends on how the series resistance compares with it. In the series circuit, *more* resistance means *more* damping.

Underdamped step response of the standard second-order system

For $y'' + 2\zeta\omega_n y' + \omega_n^2 y = \omega_n^2 V u(t)$ from rest, with $0 < \zeta < 1$, $\alpha = \zeta\omega_n$, $\omega_d = \omega_n\sqrt{1-\zeta^2}$:

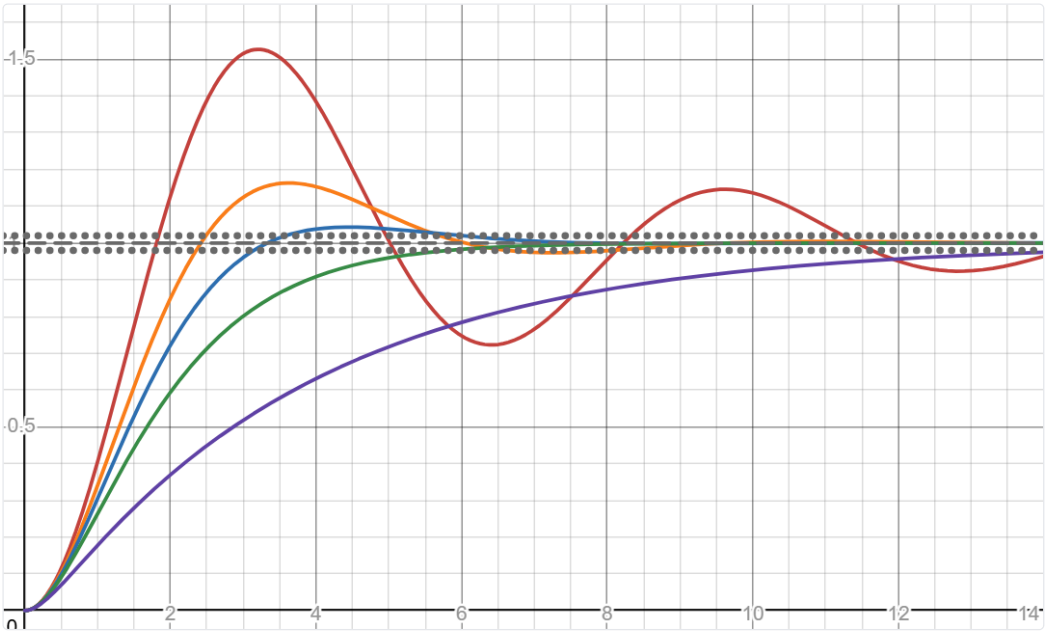
$$y(t) = V\left[1 - e^{-\alpha t}\left(\cos\omega_d t + \frac{\alpha}{\omega_d}\sin\omega_d t\right)\right] = V\left[1 - \frac{e^{-\alpha t}}{\sqrt{1-\zeta^2}}\cos(\omega_d t - \varphi)\right], \quad \sin\varphi = \zeta.$$

Its derivative is $y'(t) = V\dfrac{\omega_n^2}{\omega_d}e^{-\alpha t}\sin\omega_d t$. The response has

- **peak time** $t_p = \pi/\omega_d$,
- **maximum (percent) overshoot** $M_p = e^{-\pi\zeta/\sqrt{1-\zeta^2}}$,
- **2% settling time** $t_s \approx 4/\alpha$.

Derivation. The forced value is V. With $y = V + e^{-\alpha t}(A\cos\omega_d t + B\sin\omega_d t)$, $y(0) = 0$ gives $A = -V$, and $y'(0) = -\alpha A + \omega_d B = 0$ gives $B = \alpha A/\omega_d = -V\alpha/\omega_d$. Differentiating, the cosine terms cancel and $y' = V\left(\alpha^2/\omega_d + \omega_d\right)e^{-\alpha t}\sin\omega_d t = V(\omega_n^2/\omega_d)e^{-\alpha t}\sin\omega_d t$. This vanishes first (for $t > 0$) at $\omega_d t = \pi$, the peak. There $\cos\pi = -1$, $\sin\pi = 0$, so $y(t_p) = V(1 + e^{-\alpha\pi/\omega_d})$, and $\alpha/\omega_d = \zeta/\sqrt{1-\zeta^2}$. □

The overshoot depends **only on** ζ: 16.3% at $\zeta = 0.5$, 4.3% at $\zeta = 0.707$, 52.7% at $\zeta = 0.2$, and zero for $\zeta \geq 1$. Inverting, a measured overshoot gives the damping ratio: $\zeta = -\ln M_p/\sqrt{\pi^2 + \ln^2 M_p}$.



Normalised step responses against $\omega_n t$ for $\zeta = 0.2$ (red), 0.5 (orange), 0.707 (blue), 1 (green) and 2 (purple), with the $\pm 2\%$ band dotted. Lower damping rises faster but overshoots and rings; heavy damping is sluggish.

The parallel RLC circuit

For R, L, C in parallel driven by a current source i_s, take the common voltage v (or the inductor current) as unknown. KCL, $v/R + i_L + Cv' = i_s$ with $v = Li_L'$, gives

$$i_L'' + \frac{1}{RC}i_L' + \frac{1}{LC}i_L = \frac{1}{LC}i_s, \qquad \alpha = \frac{1}{2RC}, \qquad \zeta = \frac{1}{2R}\sqrt{\frac{L}{C}}, \qquad Q = R\sqrt{\frac{C}{L}}.$$

The parallel circuit is the **dual** of the series one: here a *larger* resistance means *less* damping, since a large parallel resistor draws little current and dissipates little energy. An ideal tank with $R \to \infty$ is undamped.

Worked examples

Example 12.34 — Series RLC step response with numbers

$R = 100\ \Omega$, $L = 10$ mH, $C = 1\ \mu$F; a 10 V step is applied at $t = 0$ with the circuit at rest. Find $v_C(t)$, $i(t)$, the peak voltage and its time, and the settling time.

Parameters. $\omega_n = 1/\sqrt{10^{-8}} = 10^4$ rad/s; $\alpha = R/2L = 5000\ \text{s}^{-1}$; $\zeta = 0.5$; $\omega_d = 10^4\sqrt{0.75} = 8660$ rad/s; $Q = 1$; $R_{\text{crit}} = 2\sqrt{L/C} = 200\ \Omega$, so the circuit is underdamped.

Initial conditions. $v_C(0^+) = 0$ and $i(0^+) = 0$ (continuity), so $v_C'(0^+) = i/C = 0$.

Response.

$$v_C(t) = 10\left[1 - e^{-5000t}\left(\cos 8660t + 0.5774 \sin 8660t\right)\right]\ \text{V},$$

$$i(t) = C\,v_C' = C \cdot 10 \cdot \frac{\omega_n^2}{\omega_d} e^{-5000t} \sin 8660t = \frac{10}{L\omega_d} e^{-5000t} \sin 8660t = 0.1155\, e^{-5000t} \sin 8660t\ \text{A}.$$

Specifications. $t_p = \pi/\omega_d = 362.8\ \mu$s; $M_p = e^{-\pi \cdot 0.5/0.866} = 0.163$, so $v_{C,\max} = 11.63$ V; $t_s \approx 4/\alpha = 0.8$ ms.

Checks. Dimension of $10/(L\omega_d)$: $\text{V}/(\text{H}\cdot\text{s}^{-1}) = \text{V}/\Omega = \text{A}$ ✓. The capacitor voltage exceeds the supply: the inductor keeps current flowing after v_C reaches 10 V. A designer who needs no overshoot would raise R to at least 200 Ω.

Example 12.35 — Source-free parallel RLC

A parallel RLC circuit with $R = 250\ \Omega$, $L = 10$ mH, $C = 1\ \mu$F has $v(0) = 10$ V on the capacitor and $i_L(0) = 0$. Find $v(t)$.

Parameters. $\omega_n = 10^4$ rad/s, $\alpha = 1/(2RC) = 2000\ \text{s}^{-1}$, $\zeta = 0.2$, $\omega_d = \sqrt{10^8 - 4 \times 10^6} = 9798$ rad/s.

Derivative initial condition. KCL at $t = 0^+$: $i_C = -v/R - i_L = -10/250 - 0 = -0.04$ A, so $v'(0^+) = i_C/C = -4 \times 10^4$ V/s.

Fit. $v = e^{-2000t}(A\cos\omega_d t + B\sin\omega_d t)$ with $A = 10$ and $-2000A + 9798B = -40000$, giving $B = -2.041$:

$$v(t) = e^{-2000t}\left(10\cos 9798t - 2.041 \sin 9798t\right)\ \text{V}.$$

Check. At $t = 100\ \mu$s the formula gives 3.1741 V; a numerical integration of the state equations $v' = -(v/R + i_L)/C$, $i_L' = v/L$ gives 3.1741 V ✓. With $Q = R\sqrt{C/L} = 2.5$, the ringing decays by a factor $e^{-2\pi\zeta/\sqrt{1-\zeta^2}} = 0.277$ per cycle.

Example 12.36 — Switching a source: critically damped transition

A series RLC circuit with $R = 4\ \Omega$, $L = 1$ H, $C = 0.25$ F has been driven by 5 V DC for a long time. At $t = 0$ the source steps to 15 V. Find $v_C(t)$.

Before switching (DC steady state): $i(0^-) = 0$, $v_C(0^-) = 5$ V.

At 0^+. $v_C(0^+) = 5$, $i(0^+) = 0$, so $v_C'(0^+) = i/C = 0$.

After switching. $\omega_n = 1/\sqrt{0.25} = 2$ rad/s, $\zeta = \frac{R}{2}\sqrt{C/L} = 2 \times 0.5 = 1$: critically damped, double root -2. Forced value 15 V.

Fit. $v_C = 15 + (A + Bt)e^{-2t}$: $15 + A = 5$ gives $A = -10$; $v_C'(0) = B - 2A = 0$ gives $B = -20$:

$$v_C(t) = 15 - 10(1 + 2t)e^{-2t}\ \text{V}, \qquad i(t) = Cv_C' = 0.25 \cdot 40\, t\, e^{-2t} = 10\, t\, e^{-2t}\ \text{A}.$$

Check. $v_C' = -20e^{-2t} + 20(1 + 2t)e^{-2t} = 40te^{-2t}$ ✓. The current peaks at $t = 0.5$ s with $i = 5e^{-1} = 1.84$ A, and v_C rises monotonically from 5 V to 15 V without overshoot, as critical damping guarantees. Only the *change* of input (10 V) appears in the transient: the zero-input part (initial 5 V) and the zero-state part combine into a single natural response.

Example 12.37 — DC motor: an electromechanical coupled system

A permanent-magnet DC motor has armature resistance $R = 2\ \Omega$, inductance $L = 0.5$ H, torque/back-EMF constant $K = 0.1\ \text{N m/A} = 0.1\ \text{V s/rad}$, rotor inertia $J = 0.02\ \text{kg m}^2$ and viscous friction $b = 0.01\ \text{N m s}$. A 12 V step is applied at rest. Find the current and speed.

Coupled equations. Electrical (KVL with back-EMF $K\omega$) and mechanical (Newton with motor torque Ki):

$$L\,i' + R\,i + K\omega = v, \qquad J\,\omega' + b\,\omega = K\,i.$$

State-space form. With $\mathbf{x} = (i, \omega)^{\mathsf{T}}$:

$$\dot{\mathbf{x}} = \begin{bmatrix} -R/L & -K/L \\ K/J & -b/J \end{bmatrix}\mathbf{x} + \begin{bmatrix} 1/L \\ 0 \end{bmatrix} v = \begin{bmatrix} -4 & -0.2 \\ 5 & -0.5 \end{bmatrix}\mathbf{x} + \begin{bmatrix} 2 \\ 0 \end{bmatrix} v.$$

Eigenvalues. $\operatorname{tr}\mathbf{A} = -4.5$, $\det\mathbf{A} = 2 + 1 = 3$: $\lambda^2 + 4.5\lambda + 3 = 0$, $\lambda = (-4.5 \pm \sqrt{8.25})/2 = -0.8139,\ -3.6861\ \text{s}^{-1}$. Both real and negative: stable, overdamped. The slow root is mostly mechanical (inertia), the fast one mostly electrical.

Steady state. $\mathbf{x}_{ss} = -\mathbf{A}^{-1}\mathbf{B}\,v$: from $\omega' = 0$, $i = b\omega/K = 0.1\omega$; from $i' = 0$, $2i + 0.1\omega = 12$, so $0.3\omega = 12$, $\omega_{ss} = 40$ rad/s, $i_{ss} = 4$ A.

Complete solution (eigenvector expansion of $\mathbf{x} - \mathbf{x}_{ss}$, fitted to $\mathbf{x}(0) = \mathbf{0}$):

$$\begin{aligned} i(t) &= 4 - 7.222\,e^{-3.686t} + 3.222\,e^{-0.814t}\ \text{A}, \\ \omega(t) &= 40 + 11.334\,e^{-3.686t} - 51.334\,e^{-0.814t}\ \text{rad/s}. \end{aligned}$$

Checks. $i(0) = 4 - 7.222 + 3.222 = 0$ ✓, $\omega(0) = 0$ ✓; $i'(0) = 7.222(3.686) - 3.222(0.814) = 24.0 = 12/L$ ✓ (initially the full voltage appears across L); $\omega'(0) = -11.334(3.686) + 51.334(0.814) = 0.0$ ✓ (no current, no torque at $t = 0$). The starting current overshoots to 5.30 A at $t = 0.81$ s, before back-EMF builds up; the speed settles within 2% after about 5.1 s, governed by the slow root ($4/0.814 = 4.9$ s).

Example 12.38 — RLC in state-variable form with a sinusoidal drive

Write the series RLC circuit of Example 12.34 in state form with states v_C and i_L, and find the steady-state capacitor voltage for $v_s = 10\cos(10^4 t)$ V.

State equations. $Cv_C' = i_L$ and $Li_L' = v_s - Ri_L - v_C$:

$$\frac{d}{dt}\begin{bmatrix} v_C \\ i_L \end{bmatrix} = \begin{bmatrix} 0 & 1/C \\ -1/L & -R/L \end{bmatrix}\begin{bmatrix} v_C \\ i_L \end{bmatrix} + \begin{bmatrix} 0 \\ 1/L \end{bmatrix} v_s, \qquad \det(s\mathbf{I} - \mathbf{A}) = s^2 + \frac{R}{L}s + \frac{1}{LC}.$$

Frequency response at $\omega = \omega_n$. $H(j\omega) = \mathbf{C}(j\omega\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$ with $\mathbf{C} = [1\ \ 0]$ reduces to $\omega_n^2/(\omega_n^2 - \omega^2 + j2\zeta\omega_n\omega)$. At $\omega = \omega_n$ this is $1/(j2\zeta) = -jQ = -j$. So

$$v_{C,ss}(t) = 10\cos(10^4 t - 90^\circ) = 10\sin(10^4 t)\ \text{V}.$$

At resonance the capacitor voltage is Q times the source amplitude and lags it by exactly 90°. For a high-Q circuit ($Q = 50$, say) the capacitor would see $50\times$ the source voltage, which is why resonant circuits need components rated well above the drive level.

Analogies and generality

The same mathematics governs mechanical, thermal and hydraulic systems through the standard analogies:

Electrical (series)	Mechanical (translation)	Mechanical (rotation)
voltage v	force F	torque T
current i	velocity $\dot{x}$	angular velocity ω
inductance L	mass m	inertia J
resistance R	damping b	rotational damping b
elastance $1/C$	stiffness k	torsional stiffness k
$\zeta = \frac{R}{2}\sqrt{C/L}$	$\zeta = \frac{b}{2\sqrt{km}}$	$\zeta = \frac{b}{2\sqrt{kJ}}$

Any lumped linear system, of whatever physical type, reduces to $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$, and its behaviour is read from the eigenvalues of $\mathbf{A}$. Distributed systems such as transmission lines and heat conduction lead to partial differential equations (Ch. 13); after separation of variables, each spatial mode again obeys a constant-coefficient ODE of exactly the type studied here.

Common Pitfall

Three errors dominate switched-circuit problems: (1) assuming i_C or v_L is continuous (they are not; only v_C and i_L are); (2) using the *pre*-switching circuit's α and ω_n for the *post*-switching transient; (3) setting $v_C'(0^+) = 0$ by habit, when it equals $i_C(0^+)/C$, which is often nonzero (Example 12.35).

Engineering Note

The parameters of this section are design handles. A switching converter's output LC filter is designed for a chosen ω_n (well below the switching frequency) and a damping ratio set by the load resistance and capacitor ESR; a light load (large parallel R) gives low damping and visible ringing on load steps. A gate-drive loop is a series RLC (trace inductance, gate capacitance, gate resistor) and the gate resistor is chosen near $R_{\text{crit}} = 2\sqrt{L/C}$ to suppress ringing without slowing the edge too much. A PLL's loop filter is chosen to give $\zeta \approx 0.7$ for the closed loop.

Summary

Topic	Key formula / fact
Operator form	$P(D)y = r$, $P(s) = a_n s^n + \cdots + a_0$; $P(D)e^{st} = P(s)e^{st}$
Exponential shift	$P(D)[e^{at}f] = e^{at}P(D+a)f$
Distinct roots	$y_h = \sum c_k e^{s_k t}$
Repeated root s_1 (mult. m)	$(c_1 + c_2 t + \cdots + c_m t^{m-1})e^{s_1 t}$
Complex pair $\sigma \pm j\omega$	$e^{\sigma t}(A\cos\omega t + B\sin\omega t)$
Stability	all roots $\mathrm{Re}\{s_k\} < 0$; cubic $s^3 + a_2 s^2 + a_1 s + a_0$: $a_i > 0$, $a_2 a_1 > a_0$
Standard 2nd order	$y'' + 2\zeta\omega_n y' + \omega_n^2 y$; $s = -\zeta\omega_n \pm \omega_n\sqrt{\zeta^2 - 1}$
Damping cases	$\zeta > 1$ over, $\zeta = 1$ critical, $0 < \zeta < 1$ under ($\omega_d = \omega_n\sqrt{1-\zeta^2}$), $\zeta = 0$ undamped
Complete response	$y = y_n + y_f = y_{zi} + y_{zs}$; fit ICs to the complete y
Impulse response	homogeneous with $h^{(n-1)}(0^+) = 1/a_n$; $y_{zs} = \int_0^t h(t-\tau)r(\tau)\,d\tau$
Exponential input	$y_p = e^{at}/P(a)$; resonant: $y_p = t^m e^{at}/P^{(m)}(a)$
DC gain	$y_p = K/P(0) = K/a_0$
Sinusoidal steady state	$\mathbf{Y} = H(j\omega)\mathbf{R}$, $H = N(j\omega)/P(j\omega)$
Resonant peak	$\omega_r = \omega_n\sqrt{1-2\zeta^2}$, $M_r = 1/(2\zeta\sqrt{1-\zeta^2})$, $Q = 1/(2\zeta)$
Settling time (2%)	$t_s \approx 4\tau$ (1st order), $t_s \approx 4/(\zeta\omega_n)$ (2nd order)
Step overshoot	$M_p = e^{-\pi\zeta/\sqrt{1-\zeta^2}}$, $t_p = \pi/\omega_d$
Coupled systems	$\Delta(s) = \det\mathbf{P}(s)$; $\Delta(D)y_i = \det\mathbf{P}_i(D)$; deg Δ constants
State space	$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$, $\mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u}$
Matrix exponential	$e^{\mathbf{A}t} = \sum \mathbf{A}^k t^k/k! = \mathbf{V}e^{\mathbf{\Lambda}t}\mathbf{V}^{-1}$
State solution	$\mathbf{x} = e^{\mathbf{A}t}\mathbf{x}_0 + \int_0^t e^{\mathbf{A}(t-\tau)}\mathbf{B}\mathbf{u}(\tau)\,d\tau$
Step input	$\mathbf{x} = e^{\mathbf{A}t}\mathbf{x}_0 + \mathbf{A}^{-1}(e^{\mathbf{A}t} - \mathbf{I})\mathbf{B}\mathbf{u}_0$; $\mathbf{x}_{ss} = -\mathbf{A}^{-1}\mathbf{B}\mathbf{u}_0$
2×2 Sylvester	$e^{\mathbf{A}t} = [e^{\lambda_1 t}(\mathbf{A} - \lambda_2\mathbf{I}) - e^{\lambda_2 t}(\mathbf{A} - \lambda_1\mathbf{I})]/(\lambda_1 - \lambda_2)$
Discretisation (ZOH)	$\mathbf{\Phi} = e^{\mathbf{A}T}$, $\mathbf{\Gamma} = \mathbf{A}^{-1}(e^{\mathbf{A}T} - \mathbf{I})\mathbf{B}$
Series RLC	$\alpha = R/2L$, $\omega_n = 1/\sqrt{LC}$, $\zeta = \frac{R}{2}\sqrt{C/L}$, $Q = \frac{1}{R}\sqrt{L/C}$
Parallel RLC	$\alpha = 1/(2RC)$, $\zeta = \frac{1}{2R}\sqrt{L/C}$, $Q = R\sqrt{C/L}$
Switching	$v_C(0^+) = v_C(0^-)$, $i_L(0^+) = i_L(0^-)$; $v_C'(0^+) = i_C(0^+)/C$, $i_L'(0^+) = v_L(0^+)/L$

Chapter 13 — Partial Differential Equations

Prerequisites: Ch. 6 (Multivariable Calculus), Ch. 7 (Vector Calculus), Ch. 11 and Ch. 12 (Ordinary and Linear Differential Equations); Ch. 15 (Fourier Series) is used heavily from Section 13.4 on and may be read in parallel.

Learning outcomes: After this chapter you can

- derive the telegrapher's equations of a transmission line and recognise the wave, diffusion and Laplace equations as its limiting cases;
- classify a second-order linear PDE as elliptic, parabolic or hyperbolic, find its characteristics and say what kind of auxiliary data makes the problem well posed;
- state Dirichlet, Neumann, Robin and periodic boundary conditions, homogenise non-homogeneous ones, and translate circuit terminations into boundary conditions;
- solve the heat, wave and Laplace equations on intervals, rectangles, disks and annuli by separation of variables and Fourier-series expansion;
- use d'Alembert's solution, characteristics and the method of images to follow pulses and reflections on lines and strings;
- apply these solutions to electrostatic fields, semiconductor diffusion, skin effect and transient heat transfer, and estimate how many series terms a given accuracy needs.

An ordinary differential equation describes a quantity that depends on one variable — usually time. Most physical quantities in electrical engineering depend on *where* as well as *when*: the voltage along a cable, the temperature across a power transistor die, the potential between the plates of a capacitor, the concentration of boron atoms below a silicon surface, the current density inside a conductor carrying high-frequency current. Each of these obeys a **partial differential equation** (PDE), a relation between an unknown function of several variables and its partial derivatives.

This chapter concentrates on the three classical second-order linear PDEs — the **heat (diffusion) equation**, the **wave equation** and **Laplace's equation** — because between them they cover almost every field problem met in an EE curriculum, and because they are the prototypes of the three types into which all second-order linear PDEs fall. The main solution technique is **separation of variables**, which turns one PDE into several ODEs (Ch. 11, Ch. 12) and then reassembles the solution as a **Fourier series** (Ch. 15). For infinite domains we also use d'Alembert's travelling-wave solution and similarity solutions built from the error function. Transform methods for PDEs (Laplace transform in time, Fourier transform in space) are touched on only briefly here; they are developed in Ch. 14 and Ch. 16, and numerical (finite-difference) solution in Ch. 22.

Motivation: the transmission line

We start with one physical system that contains all three classical equations as special cases. A two-conductor transmission line (coaxial cable, twisted pair, microstrip trace) is described by four constants **per unit length**: series resistance R (Ω/m), series inductance L ($\mathrm{H/m}$), shunt conductance G ($\mathrm{S/m}$) and shunt capacitance C ($\mathrm{F/m}$). Let $v(x,t)$ be the voltage between the conductors and $i(x,t)$ the current in the forward conductor at position x and time t.

Cut out a short piece of length Δx. Its equivalent circuit is a series $R\Delta x$, $L\Delta x$ followed by a shunt $G\Delta x$, $C\Delta x$. Kirchhoff's voltage law around the piece gives

$$v(x,t) - v(x+\Delta x,t) = R\,\Delta x\, i(x,t) + L\,\Delta x\,\frac{\partial i}{\partial t}(x,t),$$

and Kirchhoff's current law at the node $x+\Delta x$ gives

$$i(x,t) - i(x+\Delta x,t) = G\,\Delta x\, v(x+\Delta x,t) + C\,\Delta x\,\frac{\partial v}{\partial t}(x+\Delta x,t).$$

Divide by Δx and let $\Delta x \to 0$. The left-hand sides become $-\partial v/\partial x$ and $-\partial i/\partial x$:

Telegrapher's equations

$$\frac{\partial v}{\partial x} = -R\,i - L\,\frac{\partial i}{\partial t}, \qquad \frac{\partial i}{\partial x} = -G\,v - C\,\frac{\partial v}{\partial t}.$$

These are two coupled *first-order* PDEs. To get a single equation for v, differentiate the first with respect to x and substitute the second (the mixed partials $i_{xt} = i_{tx}$ commute for smooth i, Ch. 6):

$$\frac{\partial^2 v}{\partial x^2} = -R\frac{\partial i}{\partial x} - L\frac{\partial}{\partial t}\frac{\partial i}{\partial x} = R\Big(Gv + C\frac{\partial v}{\partial t}\Big) + L\Big(G\frac{\partial v}{\partial t} + C\frac{\partial^2 v}{\partial t^2}\Big).$$

Telegrapher's (transmission-line) equation

$$\frac{\partial^2 v}{\partial x^2} = LC\,\frac{\partial^2 v}{\partial t^2} + (RC + GL)\,\frac{\partial v}{\partial t} + RG\,v.$$

The current $i(x,t)$ satisfies the same equation.

Dimensional check: LC has units $\mathrm{s^2/m^2}$, so $LC\,v_{tt}$ has units $\mathrm{V/m^2}$, as does v_{xx}. RC and GL have units $\mathrm{s/m^2}$, and RG has units $\mathrm{m^{-2}}$. Every term is in $\mathrm{V/m^2}$.

Three limiting cases give the three classical equations:

1. **Lossless line** ($R = G = 0$): $v_{xx} = LC\,v_{tt}$, or

$$\frac{\partial^2 v}{\partial t^2} = c^2\frac{\partial^2 v}{\partial x^2}, \qquad c = \frac{1}{\sqrt{LC}}.$$

This is the **wave equation**. Signals travel undistorted at speed c. For a coaxial cable with polyethylene dielectric, $c \approx 2\times10^8\ \mathrm{m/s}$. 2. **RC line** ($L = G = 0$): the long submarine telegraph cables analysed by Kelvin in the 1850s, and on-chip interconnect today, are dominated by R and C. Then

$$\frac{\partial v}{\partial t} = \frac{1}{RC}\frac{\partial^2 v}{\partial x^2}.$$

This is the **diffusion (heat) equation** with diffusivity $1/(RC)$ in m^2/s. Signals do not travel; they *spread*, and the delay grows as the square of the length. 3. **DC steady state, lossless shunt** ($\partial/\partial t = 0$, $G = 0$): $v_{xx} = 0$, so v is linear in x. In two or three space dimensions the analogous statement $\nabla^2 V = 0$ is **Laplace's equation**, which governs electrostatic potential in charge-free regions.

The rest of the chapter studies each of these, first in general and then with the specific techniques that solve them.

13.1 Classification of PDEs

Basic vocabulary

Partial differential equation

A **partial differential equation** for an unknown function $u(x_1, \dots, x_n)$ of $n \geq 2$ independent variables is a relation

$$F\big(x_1, \dots, x_n,\ u,\ u_{x_1}, \dots, u_{x_n},\ u_{x_1x_1},\ u_{x_1x_2}, \dots\big) = 0$$

among the variables, the function and finitely many of its partial derivatives. Subscripts denote partial derivatives: $u_x = \partial u/\partial x$, $u_{xt} = \partial^2 u/\partial t\,\partial x$.

- The **order** is the order of the highest derivative present.
- The PDE is **linear** if F is linear in u and all its derivatives, with coefficients that depend only on the independent variables.
- A linear PDE is **homogeneous** if every term contains u or one of its derivatives; a term depending only on the independent variables (a *source* or *forcing* term) makes it **non-homogeneous**.
- The PDE is **quasilinear** if it is linear in the highest-order derivatives, with coefficients that may depend on u and lower derivatives.

So the telegrapher's equation is second order, linear and homogeneous. The heat equation with internal Joule heating, $u_t = \alpha u_{xx} + q(x)/(\rho c_p)$, is linear but non-homogeneous. The inviscid Burgers equation $u_t + u\,u_x = 0$, which describes shock formation, is first order and quasilinear but not linear. Poisson's equation $\nabla^2 V = -\rho_v/\varepsilon$ is linear, second order and non-homogeneous whenever the charge density ρ_v is non-zero.

Linearity is what makes the methods of this chapter work, through the same principle that underlies circuit analysis.

Superposition principle

Let $\mathcal{L}$ be a linear differential operator, so that $\mathcal{L}[c_1 u_1 + c_2 u_2] = c_1\mathcal{L}[u_1] + c_2\mathcal{L}[u_2]$ for constants c_1, c_2.

1. If $u_1, \dots, u_N$ solve the homogeneous equation $\mathcal{L}[u] = 0$, so does every linear combination $\sum c_k u_k$.
2. If u_p solves $\mathcal{L}[u] = f$, then every solution has the form $u = u_p + u_h$ with $\mathcal{L}[u_h] = 0$.
3. Under convergence conditions (uniform convergence of the series and of the series of the derivatives that appear in $\mathcal{L}$), an *infinite* series $\sum_{k=1}^{\infty} c_k u_k$ of solutions of $\mathcal{L}[u] = 0$ is again a solution.

Part 3 is the one that separation of variables relies on, and it is the reason convergence of Fourier series (Ch. 15) matters to us.

Second-order linear equations in two variables

The general second-order linear PDE in two independent variables x and y (one of which may be time) is

$$a_{11}\,u_{xx} + 2a_{12}\,u_{xy} + a_{22}\,u_{yy} + b_1\,u_x + b_2\,u_y + c_0\,u = f,$$

where the coefficients may depend on (x, y). The factor 2 in front of a_{12} is a convention that makes the formulas below clean. The second-order part, the **principal part**, controls the qualitative behaviour of solutions: how information travels, whether solutions are smooth, and what boundary data are appropriate. Associate with it the quadratic form $a_{11}\xi^2 + 2a_{12}\xi\eta + a_{22}\eta^2$, i.e. the symmetric matrix

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{pmatrix}.$$

Type of a second-order linear PDE

Let the **discriminant** be $\Delta = a_{12}^2 - a_{11}a_{22} = -\det \mathbf{A}$. At a point (x, y) the equation is

- **hyperbolic** if $\Delta > 0$ (eigenvalues of $\mathbf{A}$ of opposite sign),
- **parabolic** if $\Delta = 0$ (one eigenvalue zero),
- **elliptic** if $\Delta < 0$ (eigenvalues of the same sign).

If the coefficients vary, the type can change from region to region.

The names come from the conic $a_{11}\xi^2 + 2a_{12}\xi\eta + a_{22}\eta^2 = 1$, which is a hyperbola, parabola or ellipse in the three cases. The lower-order terms do not affect the type.

The three prototypes:

Equation	Standard form	a_{11}, a_{12}, a_{22}	Δ	Type
Wave	$u_{tt} - c^2 u_{xx} = 0$ (variables x, t)	$-c^2,\ 0,\ 1$	$c^2 > 0$	hyperbolic
Heat	$u_t - \alpha u_{xx} = 0$	$-\alpha,\ 0,\ 0$	0	parabolic
Laplace	$u_{xx} + u_{yy} = 0$	$1,\ 0,\ 1$	$-1 < 0$	elliptic

The telegrapher's equation $v_{xx} - LC\, v_{tt} - (RC + GL)v_t - RGv = 0$ has $a_{11} = 1$, $a_{12} = 0$, $a_{22} = -LC$, so $\Delta = LC > 0$: it is hyperbolic whenever $L \neq 0$. The loss terms are lower order and do not change the type — they cause attenuation and dispersion, but signals still have a finite front speed $1/\sqrt{LC}$. In the RC limit $L = 0$ the second-order time derivative disappears, $\Delta = 0$, and the type jumps to parabolic: information then spreads instantly (though with exponentially small amplitude) to all x.

What the type tells you

	Elliptic	Parabolic	Hyperbolic
Prototype physics	equilibrium, steady state, electrostatics	diffusion, heat conduction, RC lines	waves, lossless lines, vibrations
Typical data	boundary values on a closed curve	initial value + boundary values	initial value and initial velocity + boundary values
Speed of information	— (no time)	infinite	finite, along characteristics
Smoothness	solutions as smooth as the coefficients, even with rough boundary data	rough initial data smoothed instantly for $t > 0$	discontinuities propagate, never smoothed
Time reversal	—	ill posed backwards	reversible

Characteristics and canonical forms

The type can be understood through **characteristic curves**. Ask: along which curves $y = y(x)$ is it impossible to determine the second derivatives of u from the values of u and its first derivatives on the curve? Writing $d(u_x) = u_{xx}\,dx + u_{xy}\,dy$ and $d(u_y) = u_{xy}\,dx + u_{yy}\,dy$ together with the PDE gives a 3×3 linear system for (u_{xx}, u_{xy}, u_{yy}). Its determinant vanishes when

$$a_{11}\,(dy)^2 - 2a_{12}\,dx\,dy + a_{22}\,(dx)^2 = 0, \qquad \text{i.e.} \qquad \frac{dy}{dx} = \frac{a_{12} \pm \sqrt{\Delta}}{a_{11}}.$$

Characteristics

The solution curves of $dy/dx = (a_{12} \pm \sqrt{\Delta})/a_{11}$ are the **characteristics** of the PDE. A hyperbolic equation has two real families, a parabolic equation one, and an elliptic equation none (the roots are complex).

Data given on a characteristic cannot be continued off it uniquely; this is why initial data for the wave equation are given on a line $t = 0$ that is *not* characteristic, and why discontinuities in hyperbolic problems travel *along* characteristics.

Changing to characteristic coordinates simplifies the principal part.

Canonical forms

With constant coefficients (or locally, with variable ones) there is a change of variables $\xi = \xi(x, y)$, $\eta = \eta(x, y)$ that reduces the principal part to

- hyperbolic: $u_{\xi\eta} + (\text{lower order}) = 0$, with $\xi = \text{const}$, $\eta = \text{const}$ the two characteristic families;
- parabolic: $u_{\eta\eta} + (\text{lower order}) = 0$, with $\xi = \text{const}$ the single characteristic family and η any independent function;
- elliptic: $u_{\xi\xi} + u_{\eta\eta} + (\text{lower order}) = 0$, with ξ, η the real and imaginary parts of the complex characteristic.

Proof sketch (hyperbolic, constant coefficients). Let $m_1 \neq m_2$ be the real roots of $a_{11}m^2 - 2a_{12}m + a_{22} = 0$; these are exactly the characteristic slopes. Since $m_1 + m_2 = 2a_{12}/a_{11}$ and $m_1 m_2 = a_{22}/a_{11}$, the principal part factors as

$$a_{11}\partial_x^2 + 2a_{12}\partial_x\partial_y + a_{22}\partial_y^2 = a_{11}(\partial_x + m_1\partial_y)(\partial_x + m_2\partial_y).$$

Put $\xi = y - m_1 x$ and $\eta = y - m_2 x$. By the chain rule, $\partial_x + m_1\partial_y = (m_1 - m_2)\,\partial_\eta$ and $\partial_x + m_2\partial_y = (m_2 - m_1)\,\partial_\xi$ (each factor kills functions of "its own" characteristic variable). The principal part is therefore $-a_{11}(m_1 - m_2)^2\,\partial_\xi\partial_\eta$, a non-zero constant times $\partial_\xi\partial_\eta$. $\square$

Example 13.1 — Classifying and solving a constant-coefficient equation

Classify $u_{xx} + 4u_{xy} + 3u_{yy} = 0$ and find its general solution.

Type. $a_{11} = 1$, $2a_{12} = 4 \Rightarrow a_{12} = 2$, $a_{22} = 3$. $\Delta = 4 - 3 = 1 > 0$: hyperbolic everywhere.

Characteristics. $dy/dx = (2 \pm 1)/1$, so $dy/dx = 3$ or 1. The families are $y - 3x = \text{const}$ and $y - x = \text{const}$.

Canonical form. Put $\xi = y - x$, $\eta = y - 3x$. Then $u_x = -u_\xi - 3u_\eta$, $u_y = u_\xi + u_\eta$, and

$$\begin{aligned} u_{xx} &= u_{\xi\xi} + 6u_{\xi\eta} + 9u_{\eta\eta}, \\ u_{xy} &= -u_{\xi\xi} - 4u_{\xi\eta} - 3u_{\eta\eta}, \\ u_{yy} &= u_{\xi\xi} + 2u_{\xi\eta} + u_{\eta\eta}. \end{aligned}$$

So $u_{xx} + 4u_{xy} + 3u_{yy} = (1 - 4 + 3)u_{\xi\xi} + (6 - 16 + 6)u_{\xi\eta} + (9 - 12 + 3)u_{\eta\eta} = -4u_{\xi\eta}$. The PDE becomes $u_{\xi\eta} = 0$.

General solution. Integrating in η gives $u_\xi = h(\xi)$; integrating in ξ gives $u = F(\xi) + G(\eta)$:

$$u(x, y) = F(y - x) + G(y - 3x)$$

for arbitrary twice-differentiable F, G.

Check. For $u = G(y - 3x)$: $u_{xx} = 9G''$, $u_{xy} = -3G''$, $u_{yy} = G''$, and $9 - 12 + 3 = 0$. For $u = F(y - x)$: $1 - 4 + 3 = 0$. ✓

Notice the analogy with ODEs: a second-order ODE has two arbitrary *constants*; a second-order PDE in two variables typically has two arbitrary *functions*. This is why PDE solutions are pinned down by functions (initial profiles, boundary profiles) rather than by numbers.

Example 13.2 — A parabolic equation

Classify $u_{xx} + 2u_{xy} + u_{yy} = 0$ and find its general solution.

$a_{11} = a_{12} = a_{22} = 1$, $\Delta = 1 - 1 = 0$: parabolic. The single characteristic family is $dy/dx = 1$, i.e. $\xi = y - x$. Take $\eta = x$ as the second variable. Then $\partial_x = -\partial_\xi + \partial_\eta$, $\partial_y = \partial_\xi$, and the principal part $(\partial_x + \partial_y)^2$ becomes ∂_η^2. The PDE is $u_{\eta\eta} = 0$, so $u = F(\xi) + \eta\, G(\xi)$:

$$u(x, y) = F(y - x) + x\, G(y - x).$$

Check the second piece: with $u = xG(y - x)$, $u_{xx} = -2G' + xG''$, $u_{xy} = G' - xG''$, $u_{yy} = xG''$. Then $u_{xx} + 2u_{xy} + u_{yy} = (-2G' + 2G') + (x - 2x + x)G'' = 0$. ✓

The repeated factor x is the PDE analogue of the repeated-root solution te^{rt} of a constant-coefficient ODE (Ch. 12).

Example 13.3 — A PDE that changes type

The **Tricomi equation** $y\, u_{xx} + u_{yy} = 0$ models transonic flow. Here $a_{11} = y$, $a_{12} = 0$, $a_{22} = 1$, so $\Delta = -y$.

- For $y > 0$: $\Delta < 0$, elliptic (subsonic region).
- For $y = 0$: parabolic (sonic line).
- For $y < 0$: hyperbolic, with characteristics $dy/dx = \pm\sqrt{-y}/y$, i.e. $\tfrac{2}{3}(-y)^{3/2} = \pm x + \text{const}$.

The same physical device can therefore require different kinds of boundary data in different regions — an important warning when setting up numerical solvers.

Example 13.4 — Classifying the RC-line and the lossy line

(a) On-chip interconnect with $R = 2 \times 10^5\ \Omega/\text{m}$ (that is, $0.2\ \Omega/\mu\text{m}$) and $C = 2 \times 10^{-10}\ \text{F/m}$ ($0.2\ \text{fF}/\mu\text{m}$) and negligible L: $v_t = v_{xx}/(RC)$ with $RC = 4 \times 10^{-5}\ \text{s/m}^2$. Parabolic, diffusivity $1/(RC) = 2.5 \times 10^4\ \text{m}^2/\text{s}$. A diffusive "front" travels a distance ℓ in a time of order $RC\ell^2$; for $\ell = 1$ mm this is 4×10^{-11} s $= 40$ ps, for $\ell = 10$ mm it is 4 ns — a hundred times longer for ten times the length.

(b) If the same line has $L = 4 \times 10^{-7}\ \text{H/m}$, the equation is hyperbolic with front speed $1/\sqrt{LC} = 1/\sqrt{8 \times 10^{-17}} \approx 1.12 \times 10^8\ \text{m/s}$. The ratio of the loss term to the inertial term at frequency ω is $RC\,\omega/(LC\,\omega^2) = R/(\omega L)$; with $\omega = 2\pi \times 1$ GHz, $\omega L \approx 2.5 \times 10^3\ \Omega/\text{m}$, so $R/(\omega L) \approx 80$ and the line behaves diffusively at 1 GHz despite being formally hyperbolic. Type tells you the *ultimate* (high-frequency) behaviour; the size of the terms tells you what you will actually see.

Common pitfall — type is a property of the principal part only

Do not include first-order or zeroth-order terms when computing Δ. $u_t = \alpha u_{xx} - \beta u_x$ (diffusion with drift, as for minority carriers in an electric field) is just as parabolic as the plain heat equation. Also remember the factor 2: in $u_{xx} + 4u_{xy} + 3u_{yy}$, $a_{12} = 2$, not 4.

Engineering note — choosing a numerical method by type

Field solvers exploit the type. Elliptic problems (electrostatic capacitance extraction) are solved as one large sparse linear system for all unknowns at once. Parabolic problems (thermal transients, process simulation of diffusion) march in time but need implicit schemes to avoid tiny time steps. Hyperbolic problems (FDTD electromagnetic simulation, signal-integrity of long lines) march in time with a step limited by the Courant condition $c\,\Delta t \le \Delta x$, which is a statement that the numerical domain of dependence must contain the characteristic one (Ch. 22).

13.2 Boundary and initial conditions

A PDE on its own has far too many solutions — Example 13.1 produced two *arbitrary functions*. To single out the physically relevant one we must say what happens on the boundary of the region and, for evolution equations, at the initial instant. Getting these auxiliary conditions right is half the modelling work, and the wrong kind or the wrong number of conditions produces either no solution or a meaningless one.

Initial conditions

For an equation that is kth order in time, we prescribe the function and its first $k-1$ time derivatives at $t=0$, exactly as for an ODE.

- Heat equation (u_t first order in t): one initial condition, $u(x,0)=f(x)$ — the initial temperature profile.
- Wave and telegrapher's equations (u_{tt}): two, $u(x,0)=f(x)$ and $u_t(x,0)=g(x)$ — initial displacement and initial velocity. On a transmission line, specifying $v(x,0)$ and $i(x,0)$ is equivalent, because the second telegrapher equation gives v_t from i_x and v: $C\,v_t=-i_x-Gv$.
- Laplace's equation has no time variable and takes no initial condition.

Boundary conditions

Let the spatial region be Ω with boundary $\partial\Omega$ and outward unit normal $\hat{\mathbf{n}}$, and write $\partial u/\partial n=\hat{\mathbf{n}}\cdot\nabla u$ for the outward normal derivative. In one dimension $\Omega=(0,L)$, $\partial\Omega=\{0,L\}$, and $\partial u/\partial n$ is $-u_x$ at $x=0$ and $+u_x$ at $x=L$.

Classical boundary conditions

- **Dirichlet (first kind):** the value is prescribed, $u=h$ on $\partial\Omega$. *Examples:* an electrode held at a fixed potential; a surface clamped to a heat sink at fixed temperature; a short-circuited transmission-line end, $v(\ell,t)=0$.
- **Neumann (second kind):** the normal derivative is prescribed, $\partial u/\partial n=h$. *Examples:* a thermally insulated surface, $\partial u/\partial n=0$ (no heat flux); a prescribed heat flux $-k\,\partial u/\partial n=q_s$; the free end of a string; an open-circuited line end, $i(\ell,t)=0$, which by the first telegrapher equation (lossless case) means $v_x(\ell,t)=-L\,i_t=0$.
- **Robin (third kind, mixed):** a linear combination, $\beta\,u+\partial u/\partial n=h$. *Example:* Newton cooling at a surface in contact with a fluid at temperature u_∞, $-k\,\partial u/\partial n=h_c(u-u_\infty)$, where h_c is the convective heat-transfer coefficient ($\mathrm{W\,m^{-2}K^{-1}}$).
- **Periodic:** on an interval that represents a closed loop (angle ϕ around a ring or a cylinder), $u(-\pi)=u(\pi)$ and $u_\phi(-\pi)=u_\phi(\pi)$.

A boundary condition is **homogeneous** if $h\equiv 0$, so that the zero function satisfies it and sums of functions satisfying it also satisfy it.

Different parts of the boundary may carry different kinds of condition. For a rectangle one might hold one edge at a potential (Dirichlet) while the others are insulating symmetry planes (Neumann).

Initial–boundary-value problem

An **initial–boundary-value problem** (IBVP) consists of an evolution PDE on $\Omega\times(0,\infty)$, initial conditions at $t=0$, and boundary conditions on $\partial\Omega$ for all $t>0$. A **boundary-value problem** (BVP) consists of a steady-state PDE (typically elliptic) on Ω with conditions on $\partial\Omega$.

The model problem for the heat equation on a rod of length L with ends held at zero temperature is

$$\begin{aligned} &u_t=\alpha\,u_{xx}, && 0<x<L,\ t>0,\\ &u(0,t)=0,\quad u(L,t)=0, && t>0,\\ &u(x,0)=f(x), && 0\le x\le L. \end{aligned}$$

Well-posedness

Well-posed problem (Hadamard)

A problem is **well posed** if

1. a solution **exists**,
2. the solution is **unique**, and
3. the solution **depends continuously on the data**: small changes in the initial and boundary data produce small changes in the solution.

Condition 3 is the one engineers care most about, because measured data always carry error. A problem that fails it is **ill posed**, and any computed answer is at the mercy of noise.

The right auxiliary data depend on the type:

Type	Well-posed data	Ill-posed data
Elliptic (Laplace)	one condition (D, N or R) at each point of a *closed* boundary	Cauchy data (u and u_n) on part of the boundary only
Parabolic (heat)	initial value + one condition at each boundary point, solved *forward* in time	solving *backward* in time from a final state
Hyperbolic (wave)	u and u_t at $t=0$ + one condition at each boundary point	boundary values on a closed curve in the (x,t) plane

Example 13.5 — Hadamard's example: an ill-posed Laplace problem

Consider $u_{xx} + u_{yy} = 0$ for $y > 0$ with **Cauchy data** on the line $y = 0$: $u(x,0) = 0$, $u_y(x,0) = \dfrac{\sin(nx)}{n}$.

Try $u = X(x)Y(y)$ with $X = \sin(nx)$; then $Y'' = n^2 Y$, $Y(0) = 0$, $Y'(0) = 1/n$, so $Y = \sinh(ny)/n^2$:

$$u_n(x,y) = \frac{\sin(nx)\,\sinh(ny)}{n^2}.$$

As $n \to \infty$ the data tend to zero uniformly ($|u_y(x,0)| \le 1/n$), and the zero data have solution $u \equiv 0$. But at $y = 1$, $\max_x |u_n| = \sinh(n)/n^2 \approx e^n/(2n^2)$; for $n = 20$ this is about 6.1×10^5. Data of size 0.05 produce a solution of size 6×10^5. Continuous dependence fails: Laplace's equation with Cauchy data is ill posed.

Engineering meaning: trying to reconstruct the potential deep inside a region from measurements of V and $\partial V/\partial n$ on one face (an "inverse" problem, as in impedance tomography) amplifies measurement noise exponentially and needs regularisation.

Backward heat conduction is ill posed for the same reason: a mode $\sin(n\pi x/L)$ decays like $e^{-\alpha(n\pi/L)^2 t}$ forward in time, so running time backwards multiplies high-frequency noise by $e^{+\alpha(n\pi/L)^2 t}$ (see Section 13.4).

How many conditions?

A useful rule: a PDE that is of order 2 in a spatial variable needs **one condition at each end** of that variable's interval; a PDE of order k in time needs k **initial** conditions. Heat equation on $(0, L)$: two boundary conditions + one initial condition. Wave equation on $(0, L)$: two boundary conditions + two initial conditions. Laplace on a rectangle: one condition on each of the four sides. On an infinite interval the boundary conditions are replaced by a growth or decay condition ("u bounded as $|x| \to \infty$").

Compatibility

The initial and boundary data must agree where they meet. For the model heat problem, continuity at the corner $(x,t) = (0,0)$ requires $f(0) = 0$. If $f(0) \neq 0$ (a rod at 100 °C suddenly clamped to 0 °C ends), the solution still exists and is smooth for $t > 0$, but the series solution converges non-uniformly near the corner and the boundary condition is attained only as $t \to 0^+$. For the wave equation, incompatible data produce a discontinuity (a "kink") that travels along the characteristic from the corner and never smooths out.

Homogenising non-homogeneous boundary conditions

Separation of variables (Section 13.3) needs **homogeneous** boundary conditions. When the boundary data are constant (or independent of time), subtract a steady-state solution.

Steady-state subtraction

Suppose $u_t = \alpha u_{xx}$ on $0 < x < L$ with $u(0,t) = T_1$, $u(L,t) = T_2$ (constants) and $u(x,0) = f(x)$. Let $u_s(x)$ be the steady state: $u_s'' = 0$, $u_s(0) = T_1$, $u_s(L) = T_2$, so

$$u_s(x) = T_1 + (T_2 - T_1)\frac{x}{L}.$$

Then the **transient** $w = u - u_s$ satisfies $w_t = \alpha w_{xx}$, $w(0,t) = w(L,t) = 0$, $w(x,0) = f(x) - u_s(x)$ — a problem with homogeneous boundary conditions.

The proof is one line: u_s is independent of t and has $u_s'' = 0$, so it satisfies the PDE, and subtracting it removes the boundary values. The same idea works for Laplace's equation (split a problem with data on all four sides into four problems with data on one side each, Section 13.6), for the wave equation, and for time-dependent boundary data (subtract any function $\psi(x,t)$ that matches the boundary data; the price is a source term $-\psi_t + \alpha\psi_{xx}$ in the PDE for w, handled by eigenfunction expansion in Section 13.7).

Example 13.6 — Homogenising a Neumann–Dirichlet problem

A rod $0 < x < L$ has its end $x = 0$ held at T_0 and receives a constant heat flux q_s (W/m^2) into the end $x = L$: $k\,u_x(L,t) = q_s$. Find a steady state that removes both boundary conditions.

Steady state: $u_s'' = 0 \Rightarrow u_s = A + Bx$. $u_s(0) = T_0 \Rightarrow A = T_0$. $k u_s'(L) = q_s \Rightarrow B = q_s/k$. So

$$u_s(x) = T_0 + \frac{q_s}{k}\,x.$$

Then $w = u - u_s$ satisfies $w(0,t) = 0$, $w_x(L,t) = 0$, $w(x,0) = f(x) - T_0 - q_s x/k$.

Check units: q_s/k has units $(\mathrm{W/m^2})/(\mathrm{W\,m^{-1}K^{-1}}) = \mathrm{K/m}$, a temperature gradient. ✓ Numerically, a copper rod ($k = 400$ W m^{-1}K^{-1}, $L = 0.1$ m) receiving $q_s = 10^5$ W/m^2 (10 W/cm^2) settles with its hot end $q_s L/k = 25$ K above T_0.

Pitfall: with Neumann conditions at **both** ends, $k u_x(0,t) = q_0$, $k u_x(L,t) = q_L$, a linear steady state exists only if $q_0 = q_L$ (net heat flow in = out). Otherwise energy accumulates and there is no steady state. Subtract instead

$$\psi(x,t) = \frac{q_L - q_0}{2kL}\,x^2 + \frac{q_0}{k}\,x + \frac{(q_L - q_0)\,\alpha}{kL}\,t,$$

which matches both flux conditions and satisfies $\psi_t = \alpha\psi_{xx}$ (both sides equal $\alpha(q_L - q_0)/(kL)$), so the uniform temperature rises linearly in time.

Example 13.7 — Circuit terminations as boundary conditions

A lossless line of length ℓ ($R = G = 0$) is driven at $x = 0$ and terminated at $x = \ell$. Express the termination as a condition on $v(x,t)$ alone.

The telegrapher's equation $v_x = -L\, i_t$ links i and v.

- **Short circuit:** $v(\ell, t) = 0$ — Dirichlet.
- **Open circuit:** $i(\ell, t) = 0$ for all t, so $i_t(\ell, t) = 0$ and $v_x(\ell, t) = 0$ — Neumann.
- **Resistor R_L:** $v(\ell, t) = R_L\, i(\ell, t)$. Differentiate in time: $v_t = R_L i_t = -(R_L/L)\, v_x$. So

$$v_x(\ell, t) + \frac{L}{R_L}\, v_t(\ell, t) = 0,$$

a boundary condition that involves a *time* derivative. It is homogeneous, but it is not of the Robin type in x alone; we solve it with travelling waves in Section 13.5 and find the reflection coefficient $\Gamma = (R_L - Z_0)/(R_L + Z_0)$.

- **Source with internal resistance R_s at $x = 0$:** $v(0,t) = v_s(t) - R_s\, i(0,t)$ — non-homogeneous, time-dependent.

Check limits: $R_L \to \infty$ gives $v_x = 0$ (open). $R_L \to 0$ forces $v_t(\ell, t) = 0$, i.e. $v(\ell, t)$ stays at its initial value 0 (short). ✓ Dimensional check: L/R_L has units $(\mathrm{H/m})/\Omega = \mathrm{s/m}$, so $(L/R_L)v_t$ has units $\mathrm{V/m}$, like v_x. ✓

Common pitfall — Neumann data alone do not fix the solution

For the steady state (Laplace) with pure Neumann conditions on the whole boundary, u is determined only up to an additive constant, and a solution exists only if the net flux vanishes: $\oint_{\partial\Omega} \partial u/\partial n \, ds = 0$ (by the divergence theorem, Ch. 7). In a field solver this shows up as a singular matrix; fix one node's potential (a "ground" reference) to remove the null space, exactly as you choose a ground node in nodal circuit analysis.

Engineering note — symmetry planes are Neumann boundaries

A plane of mirror symmetry in a thermal or electrostatic problem carries zero normal flux, so it can be replaced by an insulating (Neumann, $\partial u/\partial n = 0$) boundary. A plane of *antisymmetry* (potential $+V$ on one side mirrored by $-V$ on the other) is an equipotential at 0, a Dirichlet boundary. Modelling half or a quarter of a symmetric device this way cuts the solver's work by $2\times$ or $4\times$.

Uniqueness by the energy method

Uniqueness for linear problems reduces to showing that the *difference* of two solutions, which solves the problem with zero data, is zero.

Uniqueness for the heat IBVP

The problem $u_t = \alpha u_{xx} + q(x,t)$ on $0 < x < L$, $u(x,0) = f(x)$, with Dirichlet, Neumann or Robin ($\beta \geq 0$) conditions at each end, has at most one smooth solution.

Proof. Let w be the difference of two solutions. Then $w_t = \alpha w_{xx}$ with zero initial value and homogeneous boundary conditions. Define the "energy" $E(t) = \frac{1}{2}\int_0^L w^2\, dx \geq 0$. Then, integrating by parts,

$$E'(t) = \int_0^L w\, w_t\, dx = \alpha \int_0^L w\, w_{xx}\, dx = \alpha \big[w\, w_x\big]_0^L - \alpha \int_0^L w_x^2\, dx.$$

The boundary term is zero for Dirichlet and Neumann conditions and ≤ 0 for Robin conditions with $\beta \geq 0$ (at $x = L$, $w_x = -\beta w$ gives $w\, w_x = -\beta w^2 \leq 0$; at $x = 0$ the sign flip of the outward normal gives the same conclusion). Hence $E'(t) \leq 0$. Since $E(0) = 0$ and $E \geq 0$, $E(t) = 0$ for all t, so $w \equiv 0$. □

The same argument with $E = \frac{1}{2}\int (w_t^2 + c^2 w_x^2)\, dx$ proves uniqueness for the wave equation (there E is conserved, not just non-increasing), and with $E = \int |\nabla w|^2\, dV$ for Laplace's equation.

13.3 Separation of variables

Separation of variables is the workhorse method for linear PDEs on simple domains (intervals, rectangles, disks, boxes, cylinders, spheres). Its idea is to look for solutions in which the dependence on each variable is *independent* of the others,

$$u(x,t) = X(x)\, T(t),$$

so that the PDE splits into ODEs, one per variable. Each product solution is too special to match arbitrary data, but because the problem is linear we can superpose infinitely many of them and choose the coefficients to match the data. The method is the PDE counterpart of **modal analysis**: a coupled system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ is solved by expanding in the eigenvectors of $\mathbf{A}$ (Ch. 10, Ch. 11); here the "matrix" is the differential operator d^2/dx^2 with its boundary conditions, and the "eigenvectors" are functions.

The procedure

Separation of variables — the five steps

1. **Homogenise.** Make the PDE and the boundary conditions in all but one variable homogeneous (Section 13.2).
2. **Separate.** Substitute $u = X(x)T(t)$ (or $X(x)Y(y)$, $R(r)\Phi(\phi)$), divide by XT and put all x-dependence on one side. A function of x equal to a function of t must be a constant, the **separation constant** $-\lambda$.
3. **Solve the eigenvalue problem.** The homogeneous boundary conditions become conditions on X alone, giving a **Sturm–Liouville problem** $X'' + \lambda X = 0$ plus boundary conditions. Find all **eigenvalues** λ_n for which a non-trivial solution exists and the corresponding **eigenfunctions** X_n.
4. **Solve the remaining ODE** for each λ_n, giving $T_n(t)$ and the **product solutions** $u_n = X_n(x)T_n(t)$.
5. **Superpose and match.** Write $u = \sum_n c_n X_n(x) T_n(t)$ and determine c_n from the remaining (initial or non-homogeneous boundary) data using orthogonality of the X_n — a Fourier-series computation (Section 13.7).

Separating the heat equation

Take $u_t = \alpha u_{xx}$ on $0 < x < L$ with $u(0,t) = u(L,t) = 0$. Substituting $u = X(x)T(t)$ gives $X\,T' = \alpha X''\,T$. Dividing by αXT:

$$\frac{T'(t)}{\alpha\,T(t)} = \frac{X''(x)}{X(x)}.$$

The left side depends only on t, the right only on x. If we change x while holding t fixed, the left side does not change, so neither can the right; hence both equal a constant, which we call $-\lambda$:

$$X'' + \lambda X = 0, \qquad T' + \alpha\lambda\,T = 0.$$

The boundary conditions $u(0,t) = X(0)T(t) = 0$ for all t force $X(0) = 0$ (otherwise $T \equiv 0$ and $u \equiv 0$). Likewise $X(L) = 0$. This is the eigenvalue problem already met in Ch. 11:

Dirichlet eigenvalue problem

The problem $X'' + \lambda X = 0$, $X(0) = X(L) = 0$ has non-trivial solutions only for

$$\lambda_n = \left(\frac{n\pi}{L}\right)^2, \qquad X_n(x) = \sin\frac{n\pi x}{L}, \qquad n = 1, 2, 3, \ldots$$

Proof. Consider the sign of λ.

- $\lambda < 0$: write $\lambda = -\mu^2$, $\mu > 0$. Then $X = A\cosh\mu x + B\sinh\mu x$. $X(0) = A = 0$; $X(L) = B\sinh\mu L = 0$ with $\sinh\mu L \neq 0$, so $B = 0$. Trivial.
- $\lambda = 0$: $X = A + Bx$; $X(0) = 0 \Rightarrow A = 0$, $X(L) = BL = 0 \Rightarrow B = 0$. Trivial.
- $\lambda > 0$: $\lambda = \mu^2$, $X = A\cos\mu x + B\sin\mu x$. $X(0) = A = 0$. $X(L) = B\sin\mu L = 0$, so a non-zero B requires $\sin\mu L = 0$, i.e. $\mu L = n\pi$. □

With λ_n known, $T_n = e^{-\alpha\lambda_n t}$, and the product solutions are

$$u_n(x,t) = e^{-\alpha(n\pi/L)^2 t}\,\sin\frac{n\pi x}{L}.$$

Each is a spatial sine pattern that keeps its shape and decays exponentially, faster for higher n. Section 13.4 assembles them into the full solution.

Common eigenvalue problems

The boundary conditions change the eigenfunctions. The following table covers nearly every case met in practice for $X'' + \lambda X = 0$ on $0 < x < L$ (on $-\pi < \phi < \pi$ for the periodic case).

Boundary conditions	Eigenvalues λ_n	Eigenfunctions X_n	n
$X(0) = 0,\ X(L) = 0$ (D–D)	$(n\pi/L)^2$	$\sin(n\pi x/L)$	$1, 2, \ldots$
$X'(0) = 0,\ X'(L) = 0$ (N–N)	$(n\pi/L)^2$	$\cos(n\pi x/L)$	$0, 1, 2, \ldots$
$X(0) = 0,\ X'(L) = 0$ (D–N)	$\big((2n-1)\pi/(2L)\big)^2$	$\sin\big((2n-1)\pi x/(2L)\big)$	$1, 2, \ldots$
$X'(0) = 0,\ X(L) = 0$ (N–D)	$\big((2n-1)\pi/(2L)\big)^2$	$\cos\big((2n-1)\pi x/(2L)\big)$	$1, 2, \ldots$
periodic on $(-\pi, \pi)$	n^2	1; $\cos n\phi$, $\sin n\phi$ (two per $n \geq 1$)	$0, 1, 2, \ldots$
$X(0) = 0,\ X'(L) + hX(L) = 0$ (D–R, $h > 0$)	μ_n^2, $\tan(\mu_n L) = -\mu_n/h$	$\sin(\mu_n x)$	$1, 2, \ldots$

Note that N–N admits $\lambda_0 = 0$ with the **constant** eigenfunction $X_0 = 1$. Physically, an insulated rod can hold any uniform temperature forever; this mode carries the average.

Sturm–Liouville theory

All the problems in the table are instances of a general theory that guarantees the properties we need.

Regular Sturm–Liouville problem

On $a < x < b$, the problem

$$\big(p(x)\,X'\big)' + q(x)\,X + \lambda\, w(x)\,X = 0,$$

$$\beta_1 X(a) + \beta_2 X'(a) = 0, \qquad \gamma_1 X(b) + \gamma_2 X'(b) = 0,$$

with p, p', q, w continuous, $p > 0$ and $w > 0$ on $[a,b]$, and $(\beta_1,\beta_2) \neq (0,0)$, $(\gamma_1,\gamma_2) \neq (0,0)$, is a **regular Sturm–Liouville problem**. w is the **weight function**.

$X'' + \lambda X = 0$ is the case $p = w = 1$, $q = 0$. Bessel's equation, which arises for the circular disk and cylinder, is the case $p = r$, $q = -n^2/r$, $w = r$ on $0 < r < a$ (singular at $r = 0$, but the conclusions below still hold with a boundedness condition there).

Sturm–Liouville theorem

For a regular Sturm–Liouville problem:

1. All eigenvalues are **real**, and they form an infinite increasing sequence $\lambda_1 < \lambda_2 < \lambda_3 < \cdots \to \infty$.
2. Each eigenvalue has a single eigenfunction (up to a constant factor), and the nth eigenfunction has exactly $n-1$ zeros in (a,b).
3. Eigenfunctions for different eigenvalues are **orthogonal with weight** w:

$$\langle X_m, X_n \rangle_w = \int_a^b X_m(x)\,X_n(x)\,w(x)\,dx = 0, \qquad m \neq n.$$

4. The eigenfunctions are **complete**: any square-integrable f on (a,b) has an expansion $f = \sum c_n X_n$ converging in the mean-square sense, with **generalised Fourier coefficients**

$$c_n = \frac{\langle f, X_n\rangle_w}{\langle X_n, X_n\rangle_w} = \frac{\int_a^b f\,X_n\,w\,dx}{\int_a^b X_n^2\,w\,dx}.$$

If f is piecewise smooth, the series converges to $\tfrac12[f(x^+) + f(x^-)]$ at each interior point, exactly as for ordinary Fourier series (Ch. 15).

Proof of orthogonality and reality. Let $\mathcal{S}[X] = (pX')' + qX$. For any two functions X, Y satisfying the boundary conditions, **Lagrange's identity** gives

$$\int_a^b \big(Y\,\mathcal{S}[X] - X\,\mathcal{S}[Y]\big)\,dx = \Big[p\,(YX' - XY')\Big]_a^b = 0,$$

the boundary term vanishing because at each end both X and Y satisfy the same homogeneous condition, so the vectors (X, X') and (Y, Y') are both orthogonal to (β_1,β_2) and are therefore parallel, making $YX' - XY' = 0$. (This "self-adjointness" is the analogue of a symmetric matrix, $\mathbf{y}^{\mathsf T}\mathbf{A}\mathbf{x} = \mathbf{x}^{\mathsf T}\mathbf{A}\mathbf{y}$.) Now if $\mathcal{S}[X_m] = -\lambda_m w X_m$ and $\mathcal{S}[X_n] = -\lambda_n w X_n$, then

$$0 = \int_a^b \big(X_n\mathcal{S}[X_m] - X_m\mathcal{S}[X_n]\big)\,dx = (\lambda_n - \lambda_m)\int_a^b X_m X_n\,w\,dx,$$

so $\lambda_m \neq \lambda_n$ forces orthogonality. If λ were complex with eigenfunction X, then $\bar\lambda$ would be an eigenvalue with eigenfunction $\bar X$, and the same identity would give $(\lambda - \bar\lambda)\int |X|^2 w\,dx = 0$, so $\lambda = \bar\lambda$ is real. $\square$

The Rayleigh quotient tells us the sign of the eigenvalues. Multiplying $(pX')' + qX = -\lambda w X$ by X and integrating by parts,

$$\lambda = \frac{-\big[pXX'\big]_a^b + \int_a^b \big(pX'^2 - qX^2\big)dx}{\int_a^b X^2 w\,dx}.$$

For $X'' + \lambda X = 0$ with Dirichlet, Neumann or Robin ($h \geq 0$) conditions, $q = 0$ and the boundary term $-[XX']_0^L$ is zero (Dirichlet, Neumann) or non-negative (Robin: $X'(L) = -hX(L)$ gives $-X(L)X'(L) = hX(L)^2 \geq 0$), so $\lambda \geq 0$: there are no negative eigenvalues, and the case analysis "$\lambda < 0$" in the proof above could have been skipped. Physically, $\lambda \geq 0$ says that no mode of a passive diffusion grows.

Example 13.8 — A Dirichlet–Neumann eigenvalue problem

A rod $0 < x < L$ is held at 0 at $x = 0$ and insulated at $x = L$. Find the eigenvalues and eigenfunctions and verify orthogonality of the first two.

$X'' + \lambda X = 0$, $X(0) = 0$, $X'(L) = 0$. From the Rayleigh quotient, $\lambda \geq 0$; $\lambda = 0$ gives $X = Bx$ with $X'(L) = B = 0$, trivial. For $\lambda = \mu^2 > 0$, $X(0) = 0$ gives $X = B\sin\mu x$, and $X'(L) = B\mu\cos\mu L = 0$ requires $\cos\mu L = 0$:

$$\mu_n = \frac{(2n-1)\pi}{2L}, \qquad X_n = \sin\frac{(2n-1)\pi x}{2L}, \qquad n = 1, 2, \ldots$$

The first eigenfunction is a quarter sine wave: zero at the clamped end, flat at the insulated end.

Orthogonality check with $L = 1$: $\int_0^1 \sin(\pi x/2)\sin(3\pi x/2)\,dx = \tfrac12\int_0^1[\cos(\pi x) - \cos(2\pi x)]dx = \tfrac12[0 - 0] = 0$. ✓ Normalisation: $\int_0^L X_n^2\,dx = L/2$.

Example 13.9 — A Robin eigenvalue problem (convective cooling)

A rod $0 < x < 1$ is held at 0 at $x = 0$ and loses heat by convection at $x = 1$: $X'(1) + hX(1) = 0$ with $h = 1$. Find the first three eigenvalues.

As before, $X = \sin \mu x$ (the $\lambda \le 0$ cases are trivial since $h > 0$). The Robin condition gives $\mu \cos \mu + h \sin \mu = 0$, i.e.

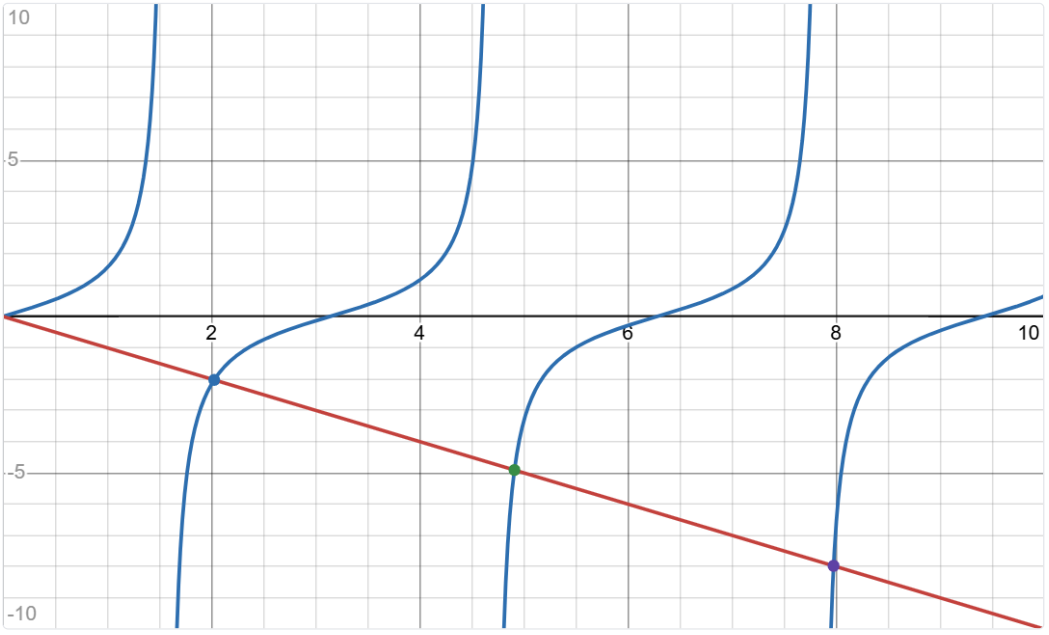
$$\tan \mu = -\frac{\mu}{h}.$$

This is **transcendental**: the eigenvalues must be found numerically, from the intersections of $y = \tan \mu$ with the line $y = -\mu/h$. One root lies in each interval $\big((n - \tfrac{1}{2})\pi,\ n\pi\big)$. Newton's method or bisection (Ch. 22) on $g(\mu) = \sin \mu + \mu \cos \mu$ gives

$$\mu_1 = 2.0288, \qquad \mu_2 = 4.9132, \qquad \mu_3 = 7.9787.$$

For large n, $\mu_n \approx (n - \tfrac{1}{2})\pi + \dfrac{h}{(n - \tfrac{1}{2})\pi}$; for $n = 3$ this gives $7.8540 + 0.1273 = 7.9813$, close to the exact 7.9787.

Limits. $h \to 0$ (insulated end) gives $\cos \mu = 0$, $\mu_1 = \pi/2 = 1.571$; $h \to \infty$ (end held at zero) gives $\sin \mu = 0$, $\mu_1 = \pi$. The Robin value 2.029 lies between, as it must. The eigenfunctions $\sin \mu_n x$ are orthogonal on $(0, 1)$ by the Sturm–Liouville theorem even though the μ_n are not equally spaced — a fact that is far from obvious by direct integration.



The Robin eigenvalues of Example 13.9 are the intersections of $y = \tan \mu$ (blue) with $y = -\mu/h$ (red, $h = 1$); they approach $(n - \tfrac{1}{2})\pi$ from above.

Separating other equations

Example 13.10 — Separating the lossy telegrapher's equation

A line of length ℓ is short-circuited at both ends, $v(0, t) = v(\ell, t) = 0$. Separate $v_{xx} = LC\, v_{tt} + (RC + GL) v_t + RGv$.

With $v = X(x)T(t)$:

$$\frac{X''}{X} = \frac{LC\, T'' + (RC + GL)\, T' + RG\, T}{T} = -\lambda.$$

The X problem is the Dirichlet problem: $\lambda_n = (n\pi/\ell)^2$, $X_n = \sin(n\pi x/\ell)$. The T equation becomes

$$T'' + \Big(\frac{R}{L} + \frac{G}{C}\Big) T' + \frac{RG + (n\pi/\ell)^2}{LC}\, T = 0,$$

a **damped harmonic oscillator** — the equation of a series RLC circuit (Ch. 12). Each spatial mode of the line behaves like its own resonant circuit with undamped natural frequency $\omega_n = \sqrt{(RG + (n\pi/\ell)^2)/(LC)}$ and damping coefficient $\zeta_n \omega_n = \tfrac{1}{2}(R/L + G/C)$.

Numbers. $\ell = 1$ m, $L = 250$ nH/m, $C = 100$ pF/m (so $c = 2 \times 10^8$ m/s, $Z_0 = 50\ \Omega$), $R = 0.5\ \Omega$/m, $G = 0$. For $n = 1$: $\omega_1 = \pi/\sqrt{LC} = \pi \times 2 \times 10^8 = 6.28 \times 10^8$ rad/s, i.e. $f_1 = 100$ MHz (half a wavelength fits in the line). Decay rate $R/(2L) = 10^6\ \text{s}^{-1}$, so the mode's quality factor is $Q = \omega_1/(2 \cdot 10^6) \approx 314$. This is the principle of a shorted-stub resonator.

Example 13.11 — Separating Laplace's equation in polar coordinates

In polar coordinates (r, ϕ), Laplace's equation is (Ch. 7)

$$u_{rr} + \frac{1}{r}u_r + \frac{1}{r^2}u_{\phi\phi} = 0.$$

Put $u = R(r)\Phi(\phi)$ and multiply by $r^2/(R\Phi)$:

$$\frac{r^2R'' + rR'}{R} = -\frac{\Phi''}{\Phi} = \lambda.$$

On a full disk or annulus ϕ is an angle, so Φ must be 2π-periodic: $\lambda = n^2$, $\Phi = a_n\cos n\phi + b_n \sin n\phi$, $n = 0, 1, 2, \ldots$. The radial equation $r^2R'' + rR' - n^2R = 0$ is a **Cauchy–Euler** equation (Ch. 11): try $R = r^m$ to get $m^2 = n^2$, so

$$R = \begin{cases} C_0 + D_0 \ln r, & n = 0, \\ C_n r^n + D_n r^{-n}, & n \geq 1. \end{cases}$$

These product solutions are used in Section 13.6.

When separation fails

Separation of variables needs three things: a separable PDE, a domain whose boundary consists of coordinate curves ($x = $ const, $r = $ const, …), and homogeneous conditions on all but one pair of opposite boundaries (or a way to split the problem so this holds).

- **Non-separable PDE.** $u_{xx} + (x + y)u_{yy} = 0$ gives $X''Y + (x + y)XY'' = 0$, and $(x + y)$ cannot be split into a function of x times or plus a function of y after division. Equations with coefficients that are products, $a(x)b(y)$, often *do* separate.
- **Non-separable domain.** An L-shaped region, a microstrip cross-section with a finite-width strip, or a region bounded by a curve that is not a coordinate line requires conformal mapping (Ch. 18) or numerical methods.
- **Non-homogeneous conditions on every side.** Split by superposition into several problems with one non-homogeneous side each (Section 13.6).

Common pitfall — choosing the sign of the separation constant

Writing the constant as $+\lambda$ rather than $-\lambda$ is not an error, but it changes which case gives the oscillatory solution, and students then reject the right case. Always examine all three cases $\lambda < 0$, $\lambda = 0$, $\lambda > 0$ (or use the Rayleigh quotient to rule some out), and remember that N–N and periodic problems *do* have a zero eigenvalue. Losing the $\lambda_0 = 0$ constant mode loses the average value of the solution.

Engineering note — modes are the natural "coordinates" of a distributed system

A distributed system (line, plate, membrane, cavity) has infinitely many degrees of freedom, but separation of variables shows that it behaves like an infinite set of *independent* lumped systems, one per eigenfunction. Engineers routinely truncate to the first few modes: a thermal model of a heat sink with one or two exponential time constants, a cavity resonator described by its lowest mode, a loudspeaker cone by its first bending modes. Sturm–Liouville orthogonality is what makes the modes decouple.

13.4 Heat equation

Derivation

Consider a rod (or a slab, or a wire) in which heat flows only along x. Let $u(x, t)$ be the temperature, ρ the density, c_p the specific heat capacity, k the thermal conductivity and $g(x, t)$ the heat generated per unit volume per unit time (Joule heating J^2/σ in a conductor, for example). Two physical laws are needed.

1. **Conservation of energy** for the slice $(x, x + \Delta x)$ of cross-section A: the rate of increase of stored heat equals heat flowing in minus heat flowing out plus heat generated:

$$\frac{\partial}{\partial t}\int_x^{x+\Delta x} \rho c_p\, u\, A\, ds = A\, q(x, t) - A\, q(x + \Delta x, t) + \int_x^{x+\Delta x} g\, A\, ds,$$

where q is the heat flux ($\mathrm{W/m^2}$) in the $+x$ direction. 2. **Fourier's law of conduction**: heat flows down the temperature gradient, $q = -k\, u_x$.

Divide by $A\,\Delta x$, let $\Delta x \to 0$ and substitute Fourier's law:

$$\rho c_p\, u_t = (k\, u_x)_x + g.$$

Heat (diffusion) equation

For constant k, ρ, c_p,

$$\frac{\partial u}{\partial t} = \alpha\,\frac{\partial^2 u}{\partial x^2} + \frac{g}{\rho c_p}, \qquad \alpha = \frac{k}{\rho c_p},$$

where α is the **thermal diffusivity** ($\mathrm{m^2/s}$). In three dimensions, $u_t = \alpha\nabla^2 u + g/(\rho c_p)$.

The same equation, with different letters, governs every process in which a conserved quantity flows down its own gradient:

Process	Quantity u	Flux law	Diffusivity
Heat conduction	temperature T	Fourier, $q = -kT_x$	$\alpha = k/(\rho c_p)$
Impurity diffusion	concentration N	Fick, $J = -DN_x$	D
Minority carriers (no field)	excess density Δn	$J_n = qD_n\,\Delta n_x$	D_n (plus recombination term $-\Delta n/\tau_n$)
RC transmission line	voltage v	Ohm, $i = -v_x/R$	$1/(RC)$
Magnetic field in a conductor	H or $\mathbf{J}$	Faraday + Ohm	$1/(\mu\sigma)$

Typical diffusivities: copper $\alpha \approx 1.1 \times 10^{-4}\ \mathrm{m^2/s}$, silicon 8.8×10^{-5}, FR-4 circuit board $\approx 1.5 \times 10^{-7}$, water $1.4 \times 10^{-7}\ \mathrm{m^2/s}$.

A diffusion process has one intrinsic scale: in time t, the quantity spreads over a distance of order $\sqrt{\alpha t}$; equivalently, crossing a distance L takes a time of order L^2/α. Doubling the thickness of a heat spreader quadruples its thermal settling time.

Solution on a finite interval with Dirichlet conditions

Section 13.3 gave the product solutions $e^{-\alpha\lambda_n t}\sin(n\pi x/L)$ of the model problem. Superposing them,

$$u(x,t) = \sum_{n=1}^{\infty} b_n\, e^{-\alpha(n\pi/L)^2 t} \sin\frac{n\pi x}{L},$$

and imposing $u(x,0) = f(x)$ gives $f(x) = \sum b_n \sin(n\pi x/L)$: the b_n are the coefficients of the **Fourier sine series** of f on $(0,L)$ (the half-range expansion of Ch. 15). Multiplying by $\sin(m\pi x/L)$ and integrating, orthogonality kills every term except $n = m$, and $\int_0^L \sin^2(m\pi x/L)\,dx = L/2$.

Heat equation on $(0,L)$, zero Dirichlet ends

If f is piecewise smooth on $[0,L]$, the IBVP $u_t = \alpha u_{xx}$, $u(0,t) = u(L,t) = 0$, $u(x,0) = f(x)$ has the unique solution

$$u(x,t) = \sum_{n=1}^{\infty} b_n\, e^{-\alpha n^2\pi^2 t/L^2}\, \sin\frac{n\pi x}{L}, \qquad b_n = \frac{2}{L}\int_0^L f(x)\sin\frac{n\pi x}{L}\,dx.$$

For $t > 0$ the series converges, together with all its derivatives, uniformly in x, and u is infinitely differentiable.

The convergence statement for $t > 0$ is easy: $|b_n| \le \frac{2}{L}\int_0^L |f|\,dx = M$, so the nth term of the series for any derivative $\partial_x^p \partial_t^q u$ is bounded by $M\,(n\pi/L)^{p+2q}\alpha^q e^{-\alpha n^2\pi^2 t/L^2}$, and the exponential beats any power: the Weierstrass M-test applies. At $t = 0$ the series is just the Fourier sine series of f, whose convergence is governed by the theory of Ch. 15 (pointwise to the mid-value at jumps, with Gibbs overshoot).

Properties of heat-equation solutions

1. **Exponential decay and the dominant mode.** For large t the $n = 1$ term dominates:

$$u(x,t) \approx b_1 e^{-t/\tau_1}\sin\frac{\pi x}{L}, \qquad \tau_1 = \frac{L^2}{\pi^2\alpha}.$$

The ratio of the second surviving term to the first decays like $e^{-(n_2^2-1)t/\tau_1}$, so after about one time constant the profile *is* a half sine wave. τ_1 is the **thermal time constant** of the rod. 2. **Smoothing.** Mode n is damped by $e^{-n^2 t/\tau_1}$. High spatial frequencies (sharp corners, jumps) die almost instantly; a discontinuous initial temperature becomes smooth for every $t > 0$. The heat operator is a spatial *low-pass filter* whose bandwidth shrinks as $1/\sqrt{t}$. 3. **Maximum principle.**

Maximum principle for the heat equation

If $u_t = \alpha u_{xx}$ in $0 < x < L$, $0 < t \le T$, then the maximum (and minimum) of u over the closed rectangle $[0,L]\times[0,T]$ is attained either at $t = 0$ or on the ends $x = 0$, $x = L$.

Physical meaning: without sources, a point in the interior cannot become hotter than the hottest initial or boundary temperature. *Proof idea:* if u had an interior maximum at (x_0,t_0), then $u_{xx} \le 0$ and $u_t \ge 0$ there; perturbing to $v = u + \varepsilon x^2$ makes the inequality $v_t - \alpha v_{xx} = -2\alpha\varepsilon < 0$ strict, contradicting $v_t \ge 0 \ge v_{xx}$ at its maximum. The principle gives uniqueness and continuous dependence on the data at once: two solutions whose data differ by at most ε differ everywhere by at most ε.

4. **Irreversibility.** Running the series backwards, $e^{+\alpha n^2\pi^2|t|/L^2}$ multiplies the nth coefficient. An error of 10^{-6} in b_{10} grows by $e^{100\,|t|/\tau_1}$; at $|t| = \tau_1$ that is $e^{100} \approx 3 \times 10^{43}$. You cannot reconstruct an earlier temperature profile from a later one.

Example 13.12 — Cooling of a uniformly heated rod

A rod of length $L = 1$ (nondimensional units, $\alpha = 1$) starts at a uniform $u = 100$ and has both ends plunged into ice at 0. Find $u(x,t)$ and the midpoint temperature at $t = 0.05,\ 0.1,\ 0.2$.

Coefficients.

$$b_n = 2\int_0^1 100\sin(n\pi x)\,dx = \frac{200}{n\pi}\bigl(1-\cos n\pi\bigr) = \begin{cases} \dfrac{400}{n\pi}, & n \text{ odd},\\[2mm] 0, & n \text{ even}. \end{cases}$$

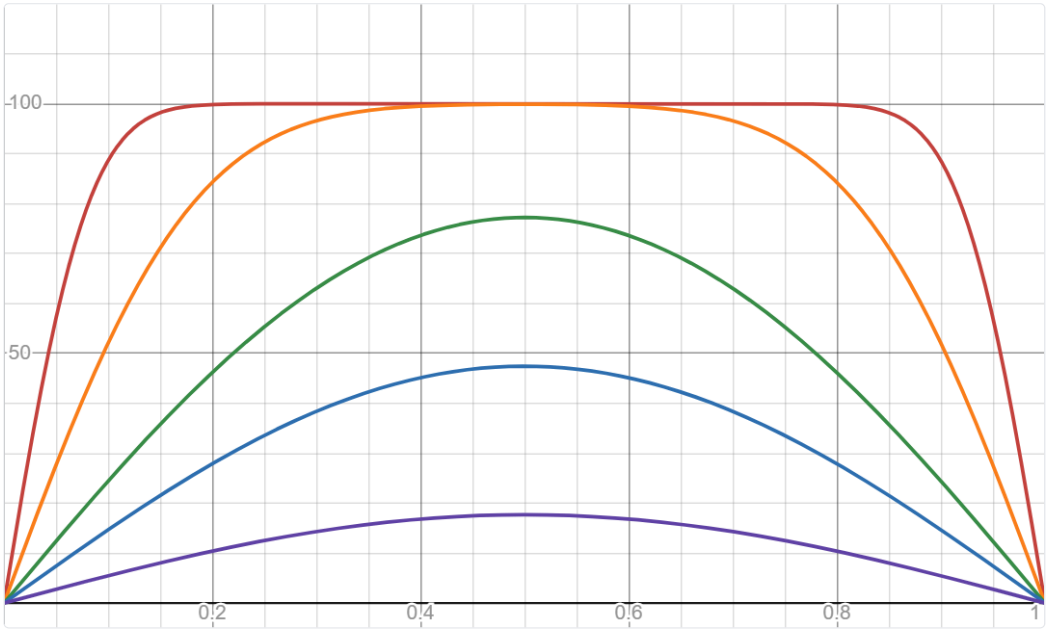
Solution.

$$u(x,t) = \frac{400}{\pi}\sum_{n\ \text{odd}} \frac{1}{n}\,e^{-n^2\pi^2 t}\sin(n\pi x).$$

Midpoint. At $x = \tfrac12$, $\sin(n\pi/2) = (-1)^{(n-1)/2}$ for odd n. Summing 1000 terms:

t	$u(\tfrac12,t)$ **(series)**	**one-term** $\tfrac{400}{\pi}e^{-\pi^2 t}$
0.01	99.92	115.36
0.05	77.23	77.73
0.1	47.45	47.45
0.2	17.69	17.69
0.5	0.916	0.916

For $t \ge 0.1$ the one-term approximation is accurate to four figures; for very small t it is useless (it even exceeds the initial temperature, violating the maximum principle) and many terms are needed. The time constant is $\tau_1 = 1/\pi^2 = 0.101$.



Snapshots of Example 13.12 at $t = 0.002$ (red), 0.01, 0.05, 0.1 and 0.2 (purple): the flat-topped profile first rounds off near the cold ends, then relaxes to a decaying half sine wave.

Example 13.13 — Thermal time constant of a copper bus bar

A copper bar of length $L = 0.10$ m ($\alpha = 1.11 \times 10^{-4}$ m^2/s), insulated along its sides, is at 100 °C above ambient when both ends are suddenly clamped to ambient. Estimate its time constant and the time for the centre excess temperature to fall to 1 K.

$\tau_1 = L^2/(\pi^2\alpha) = 0.01/(9.870 \times 1.11 \times 10^{-4}) = 9.13$ s.

From Example 13.12 (rescaled: x/L and $t/(L^2/\alpha)$ are the nondimensional variables), the centre excess temperature for $t \gtrsim \tau_1$ is $\frac{400}{\pi}e^{-t/\tau_1}$ K. Setting it equal to 1:

$$t = \tau_1 \ln\frac{400}{\pi} = 9.13 \times 4.847 = 44.2\ \text{s}.$$

For a 1 m bar the time constant is 100 times longer, 15 min — the L^2 law in action.

Insulated ends: the Neumann problem

If both ends are insulated, $u_x(0,t) = u_x(L,t) = 0$, the eigenfunctions are $\cos(n\pi x/L)$, $n = 0, 1, 2, \ldots$ (Section 13.3), and

$$u(x,t)=\frac{a_0}{2}+\sum_{n=1}^{\infty}a_n\,e^{-\alpha n^2\pi^2 t/L^2}\cos\frac{n\pi x}{L},\qquad a_n=\frac{2}{L}\int_0^L f(x)\cos\frac{n\pi x}{L}\,dx,$$

a Fourier **cosine** series. As $t\to\infty$, $u\to a_0/2=\frac{1}{L}\int_0^L f\,dx$, the **average** initial temperature: no heat escapes, so the total heat content $\int_0^L \rho c_p u\,dx$ is conserved and simply redistributes.

Example 13.14 — Equalisation in an insulated rod

An insulated rod with $L=1$, $\alpha=1$ starts with the linear profile $u(x,0)=x$. Find $u(x,t)$ and the end temperatures at $t=0.1$.

$a_0=2\int_0^1 x\,dx=1$. For $n\ge 1$, integrating by parts,

$$a_n=2\int_0^1 x\cos(n\pi x)\,dx=2\Big[\frac{x\sin n\pi x}{n\pi}\Big]_0^1-\frac{2}{n\pi}\int_0^1\sin n\pi x\,dx=\frac{2(\cos n\pi-1)}{n^2\pi^2},$$

which is $-4/(n^2\pi^2)$ for odd n and 0 for even n. So

$$u(x,t)=\frac{1}{2}-\frac{4}{\pi^2}\sum_{n\ \text{odd}}\frac{1}{n^2}e^{-n^2\pi^2 t}\cos n\pi x.$$

Checks. At $t=0$, $x=0$: $\frac12-\frac{4}{\pi^2}\sum_{\text{odd}}1/n^2=\frac12-\frac{4}{\pi^2}\cdot\frac{\pi^2}{8}=0$. ✓ At $t=0.1$: $u(0,0.1)=0.3489$, $u(1,0.1)=0.6511$; they sum to 1 by the antisymmetry of $\cos n\pi x$ (n odd) about $x=\frac12$. Both ends are converging to the average $\frac12$ with time constant $1/\pi^2$.

The coefficients decay like $1/n^2$ (compared with $1/n$ in Example 13.12) because the even periodic extension of $f(x)=x$ is continuous — a general rule from Ch. 15: smoother extension, faster coefficient decay.

Non-homogeneous boundary conditions

Example 13.15 — A rod heated at one end

A rod with $L=1$, $\alpha=1$, initially at 0, has $u(0,t)=0$ and $u(1,t)=100$ for $t>0$. Find $u(x,t)$ and $u(\frac12,t)$.

Steady state. $u_s=100x$.

Transient. $w=u-100x$ satisfies the model problem with $w(x,0)=-100x$. Its sine coefficients:

$$b_n=2\int_0^1(-100x)\sin n\pi x\,dx=-200\Big[-\frac{x\cos n\pi x}{n\pi}\Big]_0^1-200\int_0^1\frac{\cos n\pi x}{n\pi}dx=\frac{200(-1)^n}{n\pi}.$$

Solution.

$$u(x,t)=100x+\frac{200}{\pi}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}e^{-n^2\pi^2 t}\sin n\pi x.$$

Midpoint values (4000 terms): $u(\frac12,0)=0.008$ (the truncated series of a function that is 0 there; the error is the slowly converging $1/n$ tail), $u(\frac12,0.05)=11.38$, $u(\frac12,0.1)=26.28$, $u(\frac12,0.2)=41.16$, approaching the steady value 50. Only odd n contribute at $x=\frac12$ and for $t\ge 0.1$ the single term $50-\frac{200}{\pi}e^{-\pi^2 t}$ is accurate to better than 0.1: at $t=0.2$ it gives $50-63.66\times 0.1389=41.16$. ✓

Infinite and semi-infinite domains

When the rod is so long that its ends never "feel" the disturbance during the time of interest (a thick substrate under a hot spot, a semiconductor wafer seen from a surface a few micrometres deep), we replace the interval by the whole line or half-line. Fourier *series* become Fourier *integrals* (Ch. 16); the result can be written in closed form.

Heat kernel and solution on the whole line

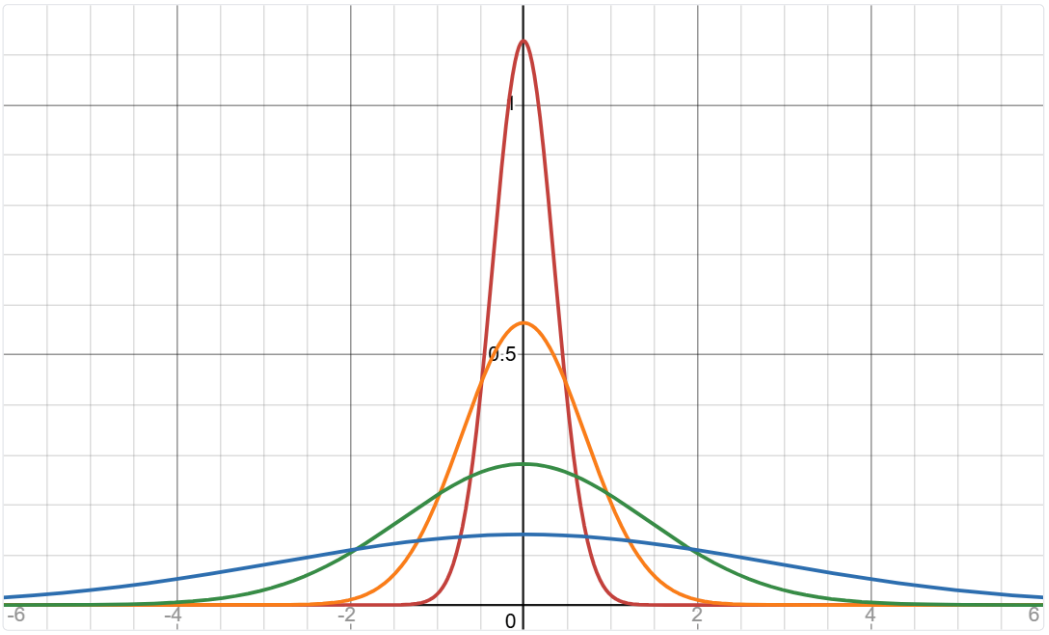
The function

$$\Phi(x,t)=\frac{1}{\sqrt{4\pi\alpha t}}\,e^{-x^2/(4\alpha t)},\qquad t>0,$$

solves $u_t=\alpha u_{xx}$, has $\int_{-\infty}^{\infty}\Phi\,dx=1$ for every $t>0$, and tends to $\delta(x)$ as $t\to 0^+$. For bounded continuous f, the solution of $u_t=\alpha u_{xx}$ on $-\infty<x<\infty$ with $u(x,0)=f(x)$ is the convolution

$$u(x,t)=\int_{-\infty}^{\infty}\Phi(x-s,t)\,f(s)\,ds.$$

Derivation sketch. The equation is unchanged by the scaling $x\to\kappa x$, $t\to\kappa^2 t$, which suggests looking for a solution of the form $t^{-1/2}F(\eta)$ with **similarity variable** $\eta=x/\sqrt{4\alpha t}$. Substituting gives the ODE $F''+2\eta F'+2F=0$, i.e. $(F'+2\eta F)'=0$, whose decaying solution is $F=Ce^{-\eta^2}$; C is fixed by unit area. Alternatively, Fourier-transform in x: $\hat u_t=-\alpha\omega^2\hat u$, so $\hat u=\hat f\,e^{-\alpha\omega^2 t}$, and the inverse transform of the Gaussian $e^{-\alpha\omega^2 t}$ is Φ (Ch. 16). In signal terms, the heat equation is a linear time-varying *Gaussian filter* whose impulse response has standard deviation $\sigma=\sqrt{2\alpha t}$.



The heat kernel ($\alpha = 1$) at $t = 1/16,\ 1/4,\ 1,\ 4$: each quadrupling of time doubles the width and halves the peak, keeping unit area.

For a semi-infinite body $x > 0$ initially at 0 whose surface is suddenly raised to T_s at $t = 0$, the similarity solution is built from the **error function** $\operatorname{erf} z = \frac{2}{\sqrt{\pi}} \int_0^z e^{-s^2}\,ds$ and its complement $\operatorname{erfc} z = 1 - \operatorname{erf} z$:

$$u(x,t) = T_s \operatorname{erfc} \frac{x}{2\sqrt{\alpha t}}.$$

Check: $\operatorname{erfc}(0) = 1$ gives $u(0,t) = T_s$; as $t \to 0^+$ for fixed $x > 0$ the argument $\to \infty$ and $u \to 0$; and u is a function of the similarity variable, so it solves the PDE by the derivation above (with F replaced by its integral). The surface heat flux $-k u_x(0,t) = k T_s / \sqrt{\pi \alpha t}$ is infinite at $t = 0^+$ and decays like $t^{-1/2}$.

Example 13.16 — Step response of a long RC interconnect

A long on-chip line with $RC = 4 \times 10^{-5}$ s/m^2 (Example 13.4) is initially discharged, and at $t = 0$ its input is stepped to V_0. Treat it as semi-infinite. When does the voltage at $x = 1$ mm reach $V_0/2$?

The RC-line equation $v_t = v_{xx}/(RC)$ is the heat equation with $\alpha = 1/(RC)$, so

$$v(x,t) = V_0 \operatorname{erfc}\left(\frac{x}{2}\sqrt{\frac{RC}{t}}\right).$$

Set $\operatorname{erfc}(z) = 0.5$: $z = 0.4769$. Then $t_{50} = RC\,x^2/(4z^2) = 1.099\,RC\,x^2$. With $x = 10^{-3}$ m: $t_{50} = 1.099 \times 4 \times 10^{-5} \times 10^{-6} = 4.4 \times 10^{-11}$ s $= 44$ ps.

The delay grows as x^2: repeaters (buffers) are inserted along long on-chip wires precisely because breaking a line of length ℓ into k segments cuts the diffusive delay from $\propto \ell^2$ to $\propto k(\ell/k)^2 = \ell^2/k$. For a *finite* open-ended line of length ℓ, the series solution (Section 13.7) gives the classic $t_{50} \approx 0.38\,RC\ell^2$; the semi-infinite estimate is pessimistic because there is no reflection from the open end to speed up charging.

Common pitfall — one-term approximations at early times

The dominant-mode approximation $b_1 e^{-t/\tau_1}\sin(\pi x/L)$ is excellent once $t \gtrsim 0.2\tau_1$ to τ_1 but grossly wrong at early times (Example 13.12 shows it exceeding the initial temperature). At early times use the semi-infinite erfc solution near each boundary instead: the two approximations are complementary, short-time and long-time.

Engineering note — thermal RC networks

Device datasheets give a transient thermal impedance $Z_{th}(t)$ as a sum of exponentials, the "Foster network" $Z_{th}(t) = \sum_i R_i(1 - e^{-t/\tau_i})$. That form is exactly a truncated eigenfunction expansion of the heat equation in the package: each τ_i is a modal time constant of the kind $L^2/(\mu_i^2\alpha)$, and the R_i are the modal weights. The $t^{1/2}$ behaviour of Z_{th} at very short times is the semi-infinite erfc regime.

13.5 Wave equation

Derivations

Lossless transmission line. With $R = G = 0$ the telegrapher's equations are $v_x = -L\,i_t$ and $i_x = -C\,v_t$, and eliminating i gives

$$v_{tt} = c^2 v_{xx}, \qquad c = \frac{1}{\sqrt{LC}}.$$

For a coaxial line with dielectric permittivity ε and permeability μ, $LC = \mu\varepsilon$, so $c = 1/\sqrt{\mu\varepsilon}$ — the speed of light in the dielectric, independent of the geometry.

Taut string. A string under tension T_s (N) with mass per unit length ρ_ℓ (kg/m), displaced by a small amount $u(x,t)$, feels a net transverse force $T_s[u_x(x+\Delta x)-u_x(x)]$ on a piece of length Δx (to first order in the slope). Newton's law $\rho_\ell \Delta x\, u_{tt} = T_s \Delta x\, u_{xx}$ gives $u_{tt} = c^2 u_{xx}$ with $c = \sqrt{T_s/\rho_\ell}$.

Electromagnetic plane waves. In a source-free, lossless medium Maxwell's equations give $\nabla^2 \mathbf{E} = \mu\varepsilon\, \mathbf{E}_{tt}$; for a field $E_y(x,t)$ that varies only with x, this is again the one-dimensional wave equation.

Wave equation

$$\frac{\partial^2 u}{\partial t^2} = c^2 \frac{\partial^2 u}{\partial x^2} \quad \text{(1-D)}, \qquad u_{tt} = c^2 \nabla^2 u \quad \text{(2-D, 3-D)},$$

where $c > 0$ is the **wave speed**. It is hyperbolic with characteristics $x \pm ct = \text{const}$.

d'Alembert's solution on the whole line

General solution of the 1-D wave equation

Every twice-differentiable solution of $u_{tt} = c^2 u_{xx}$ on $-\infty < x < \infty$ has the form

$$u(x,t) = F(x - ct) + G(x + ct)$$

for some functions F and G: the sum of a wave moving right at speed c and a wave moving left at speed c, each keeping its shape.

Proof. Change to characteristic variables $\xi = x - ct$, $\eta = x + ct$. Then $\partial_x = \partial_\xi + \partial_\eta$ and $\partial_t = c(\partial_\eta - \partial_\xi)$, so

$$u_{tt} - c^2 u_{xx} = c^2\big[(\partial_\eta - \partial_\xi)^2 - (\partial_\xi + \partial_\eta)^2\big]u = -4c^2\, u_{\xi\eta}.$$

The PDE becomes $u_{\xi\eta} = 0$, whose general solution (Example 13.1) is $F(\xi) + G(\eta)$. $\square$

A profile $F(x-ct)$ is constant along each line $x - ct = x_0$: the value that sat at x_0 at time 0 sits at $x_0 + ct$ at time t. Now impose the initial conditions $u(x,0) = f(x)$, $u_t(x,0) = g(x)$:

$$F(x) + G(x) = f(x), \qquad -cF'(x) + cG'(x) = g(x).$$

Integrate the second: $-F(x) + G(x) = \frac{1}{c}\int_0^x g(s)\,ds + K$. Adding and subtracting,

$$G(x) = \frac{1}{2}f(x) + \frac{1}{2c}\int_0^x g\,ds + \frac{K}{2}, \qquad F(x) = \frac{1}{2}f(x) - \frac{1}{2c}\int_0^x g\,ds - \frac{K}{2}.$$

Evaluate F at $x - ct$ and G at $x + ct$ and add; the constant K cancels:

d'Alembert's formula

The solution of $u_{tt} = c^2 u_{xx}$, $-\infty < x < \infty$, $u(x,0) = f(x)$, $u_t(x,0) = g(x)$ is

$$u(x,t) = \frac{f(x-ct) + f(x+ct)}{2} + \frac{1}{2c}\int_{x-ct}^{x+ct} g(s)\,ds.$$

If $f \in C^2$ and $g \in C^1$ this is a classical solution, and the problem is well posed: $|u_1 - u_2| \le \max|f_1 - f_2| + t\max|g_1 - g_2|$.

Three consequences follow from the formula.

- **Domain of dependence.** $u(x_0,t_0)$ depends only on the data on the interval $[x_0 - ct_0,\ x_0 + ct_0]$, the base of the backward characteristic triangle. Nothing outside can influence it.
- **Range of influence.** Data at a point x_0 influence only the forward wedge $|x - x_0| \le ct$. Signals travel at exactly speed c — in contrast to the heat equation, whose kernel is non-zero everywhere for every $t > 0$.
- **No smoothing.** A kink or jump in f is carried unchanged along the characteristics. The wave equation transmits information; it does not forget it.

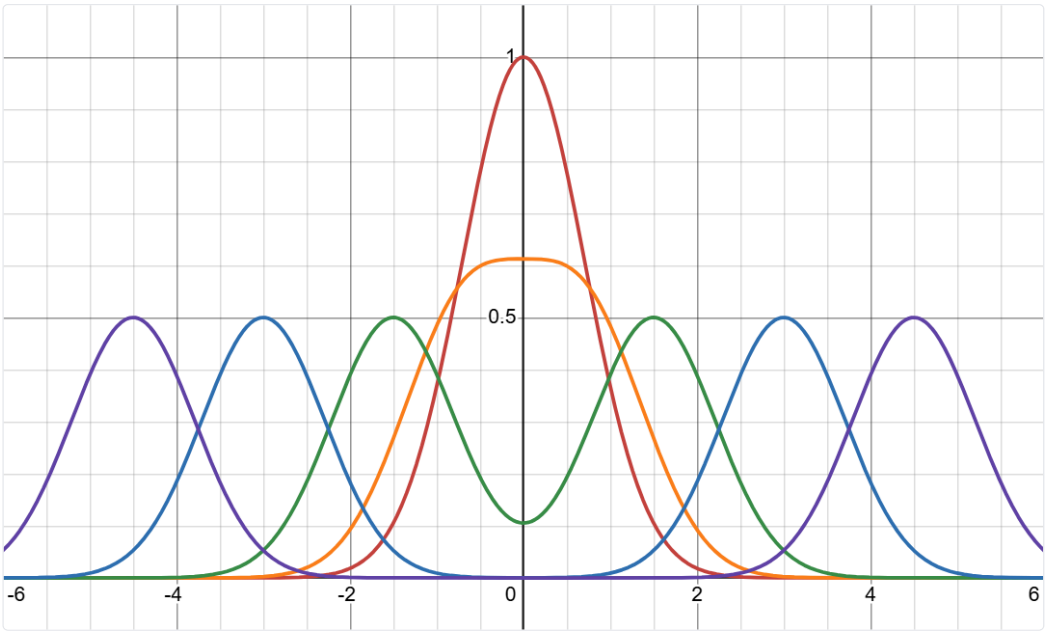
Example 13.17 — A Gaussian pulse splits in two

A string (or line) with $c = 1$ starts at rest with $f(x) = e^{-x^2}$, $g = 0$. By d'Alembert,

$$u(x,t) = \tfrac{1}{2}\big[e^{-(x-t)^2} + e^{-(x+t)^2}\big].$$

At $t = 0$ the peak is 1 at $x = 0$. By $t = 3$ the two halves are centred at $x = \pm 3$, each of height $\frac{1}{2}(1 + e^{-36}) \approx 0.5$; the overlap is negligible once $t \gtrsim 2$. At $x = 0$: $u(0,t) = e^{-t^2}$, e.g. $u(0,1) = 0.368$.

On a transmission line, the same statement reads: a voltage pulse with no accompanying current ($i(x,0) = 0$, so $v_t(x,0) = 0$) splits into equal forward and backward pulses of half the amplitude.



Snapshots of Example 13.17 at $t = 0,\ 0.7,\ 1.5,\ 3,\ 4.5$: the initial pulse separates into two half-height copies travelling in opposite directions without change of shape.

Example 13.18 — Response to an initial velocity

A string with $c = 2$ is initially straight, $f = 0$, and is struck so that $g(x) = \dfrac{1}{1+x^2}$. Find $u(x,t)$ and $u(0,t)$.

$$u(x,t) = \frac{1}{2c}\int_{x-ct}^{x+ct} \frac{ds}{1+s^2} = \frac{1}{4}\big[\arctan(x+2t) - \arctan(x-2t)\big].$$

At $x = 0$: $u(0,t) = \tfrac{1}{4}[\arctan 2t + \arctan 2t] = \tfrac{1}{2}\arctan(2t)$. So $u(0,0.5) = \tfrac{1}{2}\arctan 1 = 0.3927$, $u(0,1) = \tfrac{1}{2}\arctan 2 = 0.5536$, and $u(0,t) \to \pi/4 = 0.785$ as $t \to \infty$.

The string does **not** return to zero: an initial impulse of total momentum $\rho_\ell \int g\,dx$ produces a permanent displacement in the region the waves have passed. The total area $\int g\,dx = \pi$ is spread over a plateau of width $2ct$ and height $\frac{1}{2c}\int g = \pi/4$. On a line, the analogue is an initial current distribution leaving a residual voltage step.

Travelling waves on a transmission line

For the lossless line, d'Alembert's form applies to v, and the first telegrapher equation then determines i. Let $v = F(x-ct) + G(x+ct)$. From $i_x = -Cv_t = -C\big[-cF'(x-ct) + cG'(x+ct)\big]$, integrating in x:

$$i(x,t) = Cc\big[F(x-ct) - G(x+ct)\big] = \frac{1}{Z_0}\big[F(x-ct) - G(x+ct)\big], \qquad Z_0 = \frac{1}{Cc} = \sqrt{\frac{L}{C}}.$$

Forward and backward waves on a lossless line

Write $v^+ = F(x-ct)$ and $v^- = G(x+ct)$. Then

$$v = v^+ + v^-, \qquad i = \frac{v^+ - v^-}{Z_0},$$

where $Z_0 = \sqrt{L/C}$ is the **characteristic impedance**. A single travelling wave has $v/i = +Z_0$ (forward) or $-Z_0$ (backward); a line of finite length looks resistive, of value Z_0, to a signal until the first reflection returns.

Reflection at a resistive load. At $x = \ell$ put a resistor R_L, so $v(\ell,t) = R_L i(\ell,t)$:

$$v^+ + v^- = \frac{R_L}{Z_0}(v^+ - v^-) \quad\Longrightarrow\quad v^- = \Gamma\, v^+, \qquad \Gamma = \frac{R_L - Z_0}{R_L + Z_0}.$$

This is the solution of the dynamic boundary condition found in Example 13.7. Special cases: matched load $R_L = Z_0$, $\Gamma = 0$ (no reflection — the line looks infinite); open circuit $\Gamma = +1$; short circuit $\Gamma = -1$.

Example 13.19 — Step on a mismatched line

A $Z_0 = 50\ \Omega$ line of length $\ell = 2$ m with $c = 2 \times 10^8$ m/s is driven by a matched source (internal resistance $50\ \Omega$) whose open-circuit voltage steps from 0 to 10 V at $t = 0$, and is terminated in $R_L = 150\ \Omega$. Describe $v(x,t)$.

1. **Launch.** Initially the line looks like Z_0, so the source sees a $50\ \Omega$ divider: $v^+ = 10 \times \frac{50}{50+50} = 5$ V, and a 5 V step travels toward the load, arriving at $t_1 = \ell/c = 10$ ns.
2. **Reflection.** $\Gamma_L = (150-50)/(150+50) = 0.5$, so $v^- = 2.5$ V travels back. The load voltage jumps to $5 + 2.5 = 7.5$ V at $t = 10$ ns.
3. **Back at the source** at $t = 20$ ns: the source is matched, $\Gamma_S = 0$, so nothing more is reflected and the line voltage is 7.5 V everywhere.

Check against DC. The final state is a 10 V source driving $50\ \Omega + 150\ \Omega$: $v = 10 \times 150/200 = 7.5$ V. ✓ Current check at the load: $i = (5 - 2.5)/50 = 0.05$ A and $7.5/150 = 0.05$ A. ✓

With a mismatched source as well, the waves bounce repeatedly, multiplying by $\Gamma_L\Gamma_S$ on each round trip, and the line voltage approaches the DC value as a geometric series — the "bounce diagram" of signal-integrity analysis.

Finite string: the method of images

On a semi-infinite string $x > 0$ with a fixed end, $u(0,t) = 0$, extend the data to $x < 0$ **oddly**: $f(-x) = -f(x)$, $g(-x) = -g(x)$. The d'Alembert solution of the extended problem is odd in x for all t, so it vanishes at $x = 0$ automatically. A pulse approaching the fixed end meets its inverted mirror image coming the other way; they cancel at the end, and the image emerges as an **inverted reflected pulse** ($\Gamma = -1$, the short circuit). For a free end, $u_x(0,t) = 0$, extend **evenly**; the reflection is upright ($\Gamma = +1$, the open circuit). On $0 < x < L$ with both ends fixed, extend oddly about both ends, i.e. to an odd $2L$-periodic function, and apply d'Alembert to the extension.

Finite interval by separation of variables

For $u_{tt} = c^2 u_{xx}$ on $0 < x < L$ with $u(0,t) = u(L,t) = 0$, $u(x,0) = f(x)$, $u_t(x,0) = g(x)$, separation gives $X'' + \lambda X = 0$ (Dirichlet: $\lambda_n = (n\pi/L)^2$) and $T'' + c^2\lambda_n T = 0$, so $T_n = A_n \cos\omega_n t + B_n \sin\omega_n t$ with

$$\omega_n = \frac{n\pi c}{L}, \qquad f_n = \frac{\omega_n}{2\pi} = \frac{nc}{2L}.$$

Vibrating string / shorted line on $(0, L)$

$$u(x,t) = \sum_{n=1}^{\infty} \left(A_n \cos\frac{n\pi c t}{L} + B_n \sin\frac{n\pi c t}{L} \right) \sin\frac{n\pi x}{L},$$

$$A_n = \frac{2}{L}\int_0^L f(x)\sin\frac{n\pi x}{L}\,dx, \qquad B_n = \frac{2}{n\pi c}\int_0^L g(x)\sin\frac{n\pi x}{L}\,dx.$$

The nth term is the nth **normal mode** (standing wave), with natural frequency $f_n = nc/(2L)$, an integer multiple of the **fundamental** $f_1 = c/(2L)$. The motion is periodic with period $2L/c$.

The B_n formula comes from differentiating in t at $t = 0$: $g = \sum B_n\omega_n \sin(n\pi x/L)$, so $B_n\omega_n$ is the sine coefficient of g. Using $\sin a \cos b = \tfrac{1}{2}[\sin(a-b) + \sin(a+b)]$, each standing wave is the sum of two travelling waves, and the series reproduces d'Alembert's formula applied to the odd periodic extension.

Example 13.20 — The plucked string

A string of length $L = 1$ with $c = 1$ is pulled up at its midpoint to height h and released from rest: $f(x) = 2hx$ for $0 \le x \le \tfrac{1}{2}$, $f(x) = 2h(1-x)$ for $\tfrac{1}{2} \le x \le 1$; $g = 0$.

Coefficients. $B_n = 0$. By symmetry about $x = \tfrac{1}{2}$, $A_n = 0$ for even n. For any n, integrating by parts twice (or using the formula for the sine coefficients of a triangle),

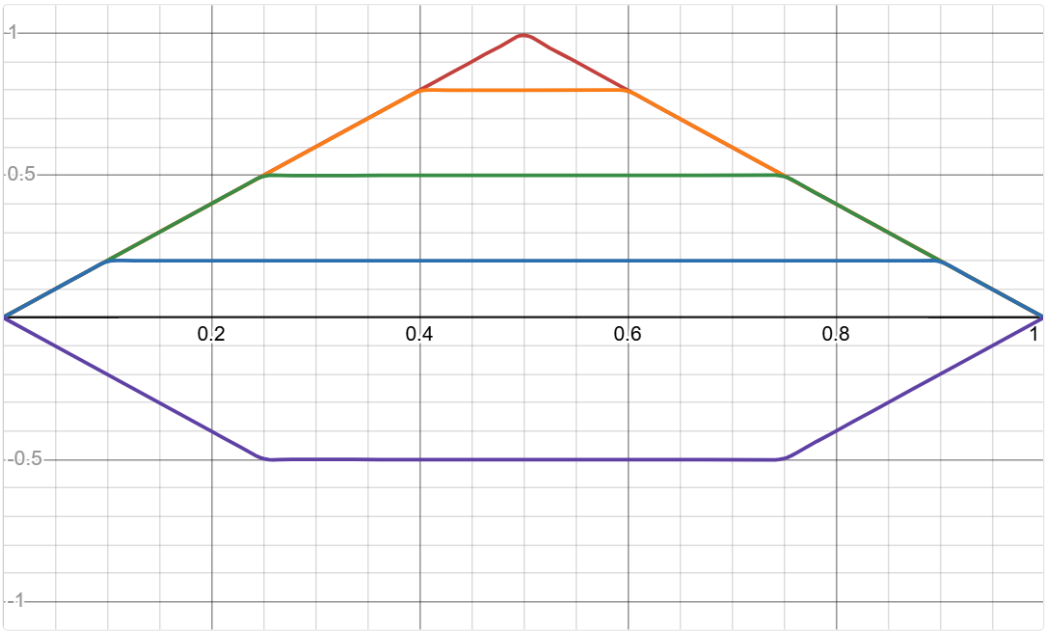
$$A_n = 2\int_0^1 f(x)\sin n\pi x\,dx = \frac{8h}{n^2\pi^2}\sin\frac{n\pi}{2}.$$

So $A_1 = 0.8106h$, $A_3 = -0.0901h$, $A_5 = 0.0324h$:

$$u(x,t) = \frac{8h}{\pi^2}\Big[\sin\pi x\cos\pi t - \frac{1}{9}\sin 3\pi x\cos 3\pi t + \frac{1}{25}\sin 5\pi x\cos 5\pi t - \cdots\Big].$$

Energy per mode. The energy of mode n is proportional to $\omega_n^2 A_n^2 \propto n^2 \cdot n^{-4} = n^{-2}$. The fraction in the fundamental is $1\big/\sum_{n\ \text{odd}} n^{-2} = 8/\pi^2 = 81.1\%$. Plucking at the centre suppresses all even harmonics; plucking nearer an end strengthens the higher harmonics, which is why a guitar sounds brighter near the bridge.

Shape. Summing 400 terms, at $t = \tfrac{1}{4}$ the profile is a trapezoid with a flat top at $h/2$ between $x = 0.25$ and 0.75; at $t = \tfrac{1}{2}$ the string is momentarily straight ($u \equiv 0$); at $t = 1$ it is the inverted triangle. The corners (kinks) travel at speed c and reflect from the ends — d'Alembert's picture.



The plucked string of Example 13.20 ($h = 1$) at $t = 0,\ 0.1,\ 0.25,\ 0.4,\ 0.75$: the initial triangle splits into two kinks that run outward, leaving a flat plateau that sinks through zero at $t = 0.5$ and reappears inverted.

Example 13.21 — Resonances of a shorted coaxial stub

A coaxial line of length $\ell = 0.75$ m with $c = 2 \times 10^8$ m/s is shorted at both ends (a closed resonator). Its voltage modes are $\sin(n\pi x/\ell)$ with

$$f_n = \frac{nc}{2\ell} = n \times \frac{2 \times 10^8}{1.5}\ \text{Hz} = 133.3\,n\ \text{MHz}.$$

If instead one end is open (D–N problem, Section 13.3), the eigenfunctions are $\sin\big((2n-1)\pi x/(2\ell)\big)$ and $f_n = (2n-1)c/(4\ell) = 66.7,\ 200,\ 333$ MHz, … — only odd multiples of the quarter-wave frequency. Only the odd multiples of the quarter-wave frequency resonate — the characteristic signature of a quarter-wave resonator, used in stub filters and in clock-distribution problems.

Energy conservation

Energy of the wave equation

For $u_{tt} = c^2 u_{xx}$ on $0 < x < L$ with fixed or free ends, the energy

$$E(t) = \frac{1}{2}\int_0^L \left(u_t^2 + c^2 u_x^2\right) dx$$

is constant in time.

Proof. $E'(t) = \int_0^L (u_t u_{tt} + c^2 u_x u_{xt})\,dx = \int_0^L u_t\,(u_{tt} - c^2 u_{xx})\,dx + c^2\big[u_x u_t\big]_0^L = 0$, because the PDE kills the integral and $u_t = 0$ (fixed end) or $u_x = 0$ (free end) kills the boundary term. □

For a transmission line the corresponding quantity is $\int_0^\ell \left(\tfrac{1}{2}Cv^2 + \tfrac{1}{2}Li^2\right)dx$, the electric plus magnetic stored energy; a resistive load makes the boundary term $-R_L i^2 \le 0$, the power it absorbs. Energy conservation gives uniqueness (as in Section 13.2) and, with Parseval's theorem (Ch. 15), the energy-per-mode decomposition used in Example 13.20.

The lossy line: distortion and the Heaviside condition

With losses, a sinusoidal wave $e^{j(\omega t - \beta x)}$ on the telegrapher's equation has a complex propagation constant $\gamma = \sqrt{(R + j\omega L)(G + j\omega C)}$, and in general both its attenuation and its phase velocity depend on frequency: a pulse spreads (disperses) as well as shrinks. There is one exception.

Distortionless line (Heaviside)

Put $v = e^{-at}w$ with $a = \tfrac{1}{2}(R/L + G/C)$. Then w satisfies

$$LC\,w_{tt} - w_{xx} = \tfrac{LC}{4}\left(\frac{R}{L} - \frac{G}{C}\right)^2 w.$$

If $R/L = G/C$ the right side vanishes, w obeys the lossless wave equation, and

$$v(x,t) = e^{-(R/L)t}\big[F(x - ct) + G(x + ct)\big], \qquad c = 1/\sqrt{LC}\,:$$

pulses travel at speed c without change of shape, merely attenuated.

Derivation. With $v = e^{-at}w$: $v_t = e^{-at}(w_t - aw)$, $v_{tt} = e^{-at}(w_{tt} - 2aw_t + a^2 w)$. Substituting into $v_{xx} = LCv_{tt} + (RC + GL)v_t + RGv$ and dividing by e^{-at}:

$$w_{xx} = LC\,w_{tt} + \big(RC + GL - 2aLC\big)w_t + \big(LCa^2 - (RC+GL)a + RG\big)w.$$

The choice $a = (RC+GL)/(2LC) = \tfrac{1}{2}(R/L + G/C)$ removes the w_t term, and the w coefficient becomes $RG - LCa^2 = -\tfrac{LC}{4}(R/L - G/C)^2$. $\square$

For a forward wave at position x the amplitude factor $e^{-(R/L)t}$, evaluated at the arrival time $t = x/c$, is $e^{-(R/L)\sqrt{LC}\,x} = e^{-(R/Z_0)x}$: the attenuation constant is $R/Z_0 = \sqrt{RG}$ nepers per metre.

Example 13.22 — Loading a line to make it distortionless

A telephone pair has $L = 0.6$ mH/km, $C = 50$ nF/km, $R = 50\ \Omega$/km, $G = 1\ \mu$S/km. Is it distortionless, and what series inductance would make it so?

$R/L = 50/(0.6\times10^{-3}) = 8.3\times10^{4}$ s^{-1}; $G/C = 10^{-6}/(50\times10^{-9}) = 20$ s^{-1}. Far from equal: $R/L \gg G/C$, the typical situation. Since adding G wastes power, Heaviside's remedy was to *increase* L: $L_{\text{new}} = RC/G = 50\times50\times10^{-9}/10^{-6} = 2.5$ H/km — impractically large, but even partial loading (Pupin coils of tens of mH every couple of km) dramatically reduced distortion on early long-distance telephone lines.

With full loading, $Z_0 = \sqrt{L/C} = \sqrt{2.5/(50\times10^{-9})} = 7071\ \Omega$ and the attenuation is $\sqrt{RG} = \sqrt{50\times10^{-6}} = 7.07\times10^{-3}$ Np/km (0.061 dB/km).

Common pitfall — applying d'Alembert directly on a finite interval

d'Alembert's formula needs f and g on the whole interval $[x-ct, x+ct]$. On a bounded interval, once ct exceeds the distance to an end, that interval sticks out of the domain: you must first extend f and g (oddly for fixed ends, evenly for free ends, periodically with period $2L$) and only then apply the formula. Forgetting this ignores the reflections.

Engineering note — time-domain reflectometry

A TDR instrument launches a fast step into a cable and watches the reflected wave. By d'Alembert, a reflection seen at time t comes from a discontinuity at distance $ct/2$, and its height and sign give the local Γ and hence the impedance there. Faults (opens, shorts, crushed sections, bad connectors) on cables and PCB traces are located this way to centimetre precision. The method relies on exactly the two properties proved above: finite propagation speed and shape preservation.

13.6 Laplace equation

Where it comes from

In electrostatics $\mathbf{E} = -\nabla V$ and Gauss's law $\nabla\cdot(\varepsilon\mathbf{E}) = \rho_v$ give, for uniform ε,

$$\nabla^2 V = -\frac{\rho_v}{\varepsilon} \quad \text{(Poisson)}, \qquad \nabla^2 V = 0 \quad \text{in charge-free regions (Laplace)}.$$

The same equation describes steady-state temperature ($u_t = 0$ in the heat equation), steady current flow in a resistive sheet or volume ($\nabla\cdot\mathbf{J} = 0$, $\mathbf{J} = -\sigma\nabla V$), magnetostatic scalar potential in current-free regions, and the steady state of any diffusion process. Laplace's equation is the **equilibrium** equation: it is what the heat and wave equations settle to once all transients have died.

Laplace's equation and harmonic functions

$$\nabla^2 u = 0, \qquad \text{in 2-D Cartesian } u_{xx} + u_{yy} = 0, \qquad \text{in polar } u_{rr} + \frac{1}{r}u_r + \frac{1}{r^2}u_{\phi\phi} = 0.$$

A twice continuously differentiable solution on a region Ω is called **harmonic** in Ω.

Examples of harmonic functions: x, xy, $x^2 - y^2$, $e^{kx}\sin ky$, $\ln r$, $r^n\cos n\phi$, $r^{-n}\sin n\phi$. In two dimensions, the real and imaginary parts of any analytic function of $z = x + jy$ are harmonic (Ch. 18); e.g. $z^2 = (x^2 - y^2) + j\,2xy$.

Properties of harmonic functions

Mean-value property

If u is harmonic in a region containing the closed disk of radius ρ centred at $\mathbf{x}_0$, then $u(\mathbf{x}_0)$ equals the average of u over the circle of radius ρ:

$$u(\mathbf{x}_0) = \frac{1}{2\pi}\int_0^{2\pi} u(\mathbf{x}_0 + \rho\,\hat{\mathbf{r}}(\phi))\,d\phi.$$

(In 3-D, the average over a sphere.)

Proof sketch. Let $M(\rho)$ be the circle average. Differentiating under the integral, $M'(\rho) = \frac{1}{2\pi}\int_0^{2\pi}\partial u/\partial r\,d\phi = \frac{1}{2\pi\rho}\oint \partial u/\partial n\,ds$, which by the divergence theorem equals $\frac{1}{2\pi\rho}\iint \nabla^2 u\,dA = 0$. So M is constant, and $M(0^+) = u(\mathbf{x}_0)$. $\square$

Maximum principle and uniqueness

A non-constant harmonic function on a bounded connected region attains its maximum and minimum only on the boundary. Consequently the Dirichlet problem $\nabla^2 u = 0$ in Ω, $u = h$ on $\partial\Omega$, has at most one solution, and if $|h_1 - h_2| \le \varepsilon$ on the boundary then $|u_1 - u_2| \le \varepsilon$ throughout.

The maximum principle follows from the mean-value property: a value cannot be an average of its neighbours and strictly larger than all of them. Physically, **there is no electrostatic potential maximum in free space**, so a charge cannot be held in stable equilibrium by electrostatic forces alone (Earnshaw's theorem), and the hottest point of an unheated plate is on its edge.

Rectangular domains

Consider the rectangle $0 < x < a$, $0 < y < b$ with Dirichlet data. By superposition, split a problem with data on all four sides into four problems, each with data on one side and zero on the other three. Take the case of data on the top side:

$$u_{xx} + u_{yy} = 0, \qquad u(0,y) = u(a,y) = 0, \quad u(x,0) = 0, \quad u(x,b) = h(x).$$

Separate, $u = X(x)Y(y)$: $X''/X = -Y''/Y = -\lambda$. The homogeneous conditions at $x = 0, a$ give the Dirichlet eigenproblem, $\lambda_n = (n\pi/a)^2$, $X_n = \sin(n\pi x/a)$. Then $Y'' - (n\pi/a)^2 Y = 0$ with $Y(0) = 0$, so $Y_n = \sinh(n\pi y/a)$. (In the direction that carries the non-homogeneous data the solutions are exponential, not oscillatory — the hallmark of Laplace's equation.) Superposing,

$$u(x,y) = \sum_{n=1}^{\infty} c_n \sinh\frac{n\pi y}{a}\sin\frac{n\pi x}{a},$$

and the top condition $u(x,b) = h(x)$ makes $c_n \sinh(n\pi b/a)$ the sine coefficients of h.

Dirichlet problem on a rectangle, data on one side

$$u(x,y) = \sum_{n=1}^{\infty} h_n \frac{\sinh(n\pi y/a)}{\sinh(n\pi b/a)}\sin\frac{n\pi x}{a}, \qquad h_n = \frac{2}{a}\int_0^a h(x)\sin\frac{n\pi x}{a}\,dx.$$

The ratio $\sinh(n\pi y/a)/\sinh(n\pi b/a) \approx e^{-n\pi(b-y)/a}$ for large n: the nth harmonic of the boundary data decays exponentially with distance from the boundary, over a length $a/(n\pi)$.

That last remark is fundamental. Fine detail in the boundary potential (period $2a/n$) is invisible a short distance away; only the smoothest components penetrate. This is why the field far from a periodic electrode array (an interdigitated capacitor, a grating) is nearly uniform, and why a grounded shield with small holes still shields well.

Example 13.23 — A single-harmonic boundary

On the square $0 < x, y < 1$, $u = 0$ on three sides and $u(x,1) = V_0 \sin \pi x$. Find u at the centre.

Only $h_1 = V_0$ is non-zero, so the series has one term:

$$u(x,y) = V_0 \frac{\sinh \pi y}{\sinh \pi}\sin \pi x.$$

At the centre: $u(\tfrac12,\tfrac12) = V_0 \sinh(\pi/2)/\sinh\pi = V_0 \times 2.3013/11.5487 = 0.1993\,V_0$.

Check harmonicity directly: $u_{xx} = -\pi^2 u$, $u_{yy} = +\pi^2 u$, sum 0. ✓ Check the maximum principle: the maximum V_0 is on the boundary at $(\tfrac12, 1)$. ✓

Example 13.24 — Trough with a raised lid

A long rectangular conducting trough of width a and height b has its three sides grounded and is closed by a lid, insulated from the sides, at potential V_0. Find $V(x,y)$ and evaluate it for a square trough.

With $h = V_0$: $h_n = \frac{2V_0}{a}\int_0^a \sin\frac{n\pi x}{a}dx = \frac{2V_0}{n\pi}(1 - \cos n\pi)$, i.e. $4V_0/(n\pi)$ for odd n, 0 for even n:

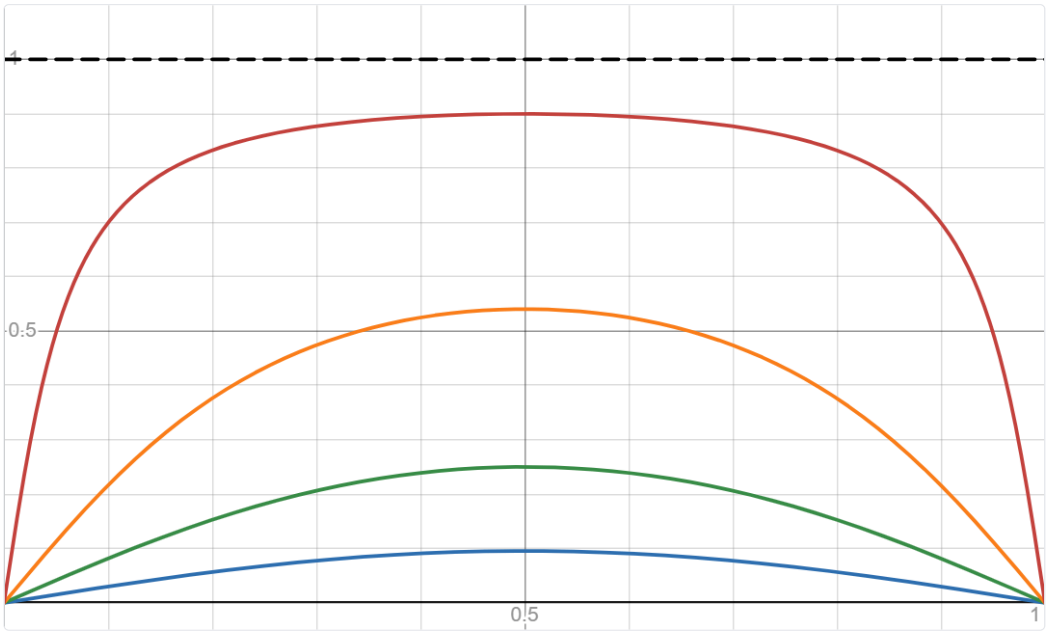
$$V(x,y) = \frac{4V_0}{\pi}\sum_{n\ \text{odd}} \frac{1}{n}\frac{\sinh(n\pi y/a)}{\sinh(n\pi b/a)}\sin\frac{n\pi x}{a}.$$

Square trough ($a = b = 1$), numerical values:

Point (x,y)	V/V_0
$(0.5,\ 0.25)$	0.0954
$(0.25,\ 0.5)$	0.1820
$(0.5,\ 0.5)$	0.2500
$(0.5,\ 0.75)$	0.5405

Exact check at the centre. Rotate the square by 90° four times: each rotation gives a problem with the lid on a different side. Their sum has V_0 on all four sides, whose solution is the constant V_0. By symmetry all four contribute equally at the centre, so $V(\tfrac12,\tfrac12) = V_0/4$ exactly. The series gives 0.25000; its first term alone gives 0.2537, already within 1.5%, because $\sinh(n\pi/2)/\sinh(n\pi) \approx e^{-n\pi/2}$ decays fast.

Near the top corners the series converges slowly, because the boundary data jump from V_0 to 0 there (the Gibbs phenomenon of Ch. 15 is present on the line $y = b$ itself, but disappears for $y < b$).



Potential profiles $V(x,y_0)/V_0$ across the square trough of Example 13.24 at heights $y_0 = 0.25,\ 0.5,\ 0.75,\ 0.95$ (blue to red). Close to the lid the profile approaches the flat boundary value with sharp edges; deeper down only the smooth fundamental survives.

Example 13.25 — Data on two sides; a semi-infinite strip

(a) A square plate $0 < x, y < 1$ has $u(x,1) = 100$ and $u(1,y) = 100$, the other two sides at 0. By superposition this is the sum of Example 13.24 (lid on top) and its reflection in the diagonal $y = x$ (lid on the right). At the centre, $u = 25 + 25 = 50$; at $(0.5, 0.25)$, $u = 100(0.0954) + 100\,V_{\text{lid}}(0.25, 0.5) = 9.54 + 18.20 = 27.74$, using the table (the reflection maps $(0.5, 0.25)$ to $(0.25, 0.5)$).

(b) **Semi-infinite strip.** $0 < x < a$, $y > 0$, sides $x = 0, a$ grounded, bottom $u(x,0) = h(x)$, u bounded as $y \to \infty$. Now $Y'' = (n\pi/a)^2 Y$ must stay bounded, so $Y_n = e^{-n\pi y/a}$ and

$$u(x,y) = \sum_{n=1}^{\infty} h_n\, e^{-n\pi y/a} \sin\frac{n\pi x}{a}.$$

With $h = V_0$ and $a = 1$, at $y = 1$ the first term is $\frac{4V_0}{\pi}e^{-\pi} = 0.055\,V_0$ and the next is $\frac{4V_0}{3\pi}e^{-3\pi} = 3.4 \times 10^{-5} V_0$: one width above the electrode only the fundamental is left. This is the basis of the rule of thumb that a grounded slot or waveguide below cut-off attenuates fields by about 27 dB ($e^{-\pi}$) per width of length.

Polar domains: disks, exteriors and annuli

From Example 13.11, the product solutions of Laplace's equation in polar coordinates are

$$1, \quad \ln r, \quad r^n\cos n\phi, \quad r^n \sin n\phi, \quad r^{-n}\cos n\phi, \quad r^{-n}\sin n\phi \qquad (n = 1, 2, \dots).$$

Which ones are allowed depends on the region:

Region	Allowed terms	Reason
Interior of disk $r < a$	$1,\ r^n\cos n\phi,\ r^n\sin n\phi$	$\ln r$ and r^{-n} blow up at $r = 0$
Exterior $r > a$, bounded at ∞	$1,\ r^{-n}\cos n\phi,\ r^{-n}\sin n\phi$	r^n and $\ln r$ grow without bound
Annulus $a < r < b$	all	$r = 0$ and ∞ excluded

Dirichlet problem for a disk

The solution of $\nabla^2 u = 0$ in $r < a$ with $u(a,\phi) = h(\phi)$ is

$$u(r,\phi) = \frac{a_0}{2} + \sum_{n=1}^{\infty} \left(\frac{r}{a}\right)^n \big(a_n\cos n\phi + b_n \sin n\phi\big),$$

where a_n, b_n are the ordinary Fourier coefficients of h on $(-\pi, \pi)$: $a_n = \frac{1}{\pi}\int_{-\pi}^{\pi} h\cos n\phi\, d\phi$, $b_n = \frac{1}{\pi}\int_{-\pi}^{\pi} h \sin n\phi\, d\phi$. Summing the series in closed form gives **Poisson's integral formula**

$$u(r,\phi) = \frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{a^2 - r^2}{a^2 - 2ar\cos(\phi - \psi) + r^2}\, h(\psi)\, d\psi.$$

Derivation of Poisson's formula. Substitute the coefficient integrals into the series and exchange sum and integral (legitimate for $r < a$ because of the geometric factor $(r/a)^n$):

$$u = \frac{1}{2\pi}\int_{-\pi}^{\pi} h(\psi)\Big[1 + 2\sum_{n=1}^{\infty}\Big(\frac{r}{a}\Big)^n \cos n(\phi-\psi)\Big]\,d\psi.$$

With $\rho = r/a$ and $\theta = \phi - \psi$, the bracket is $\operatorname{Re}\{1 + 2\sum_{n\ge1}(\rho e^{j\theta})^n\} = \operatorname{Re}\frac{1+\rho e^{j\theta}}{1-\rho e^{j\theta}} = \frac{1-\rho^2}{1-2\rho\cos\theta+\rho^2}$, a geometric series. □

At $r = 0$ Poisson's formula gives $u(0) = \frac{1}{2\pi}\int h\,d\psi$ — the mean-value property again. The **Poisson kernel** is positive, has unit integral and concentrates at $\psi = \phi$ as $r \to a$: it plays for the disk the role the heat kernel plays for the line.

Example 13.26 — A split cylinder

A long conducting cylinder of radius a is split lengthwise into two halves separated by thin insulating gaps; the upper half ($0 < \phi < \pi$) is held at V_0, the lower half at 0. Find the potential inside.

Coefficients. $a_0 = \frac{1}{\pi}\int_0^{\pi} V_0\,d\phi = V_0$; $a_n = \frac{V_0}{\pi}\int_0^{\pi}\cos n\phi\,d\phi = 0$; $b_n = \frac{V_0}{\pi}\int_0^{\pi}\sin n\phi\,d\phi = \frac{V_0}{n\pi}(1-\cos n\pi)$, i.e. $2V_0/(n\pi)$ for odd n:

$$V(r,\phi) = \frac{V_0}{2} + \frac{2V_0}{\pi}\sum_{n\ \text{odd}}\frac{1}{n}\Big(\frac{r}{a}\Big)^n \sin n\phi.$$

Closed form. Using $\sum_{n\ \text{odd}}\frac{z^n}{n} = \frac{1}{2}\ln\frac{1+z}{1-z}$ with $z = (r/a)e^{j\phi}$ and taking imaginary parts,

$$V(r,\phi) = \frac{V_0}{2} + \frac{V_0}{\pi}\arctan\frac{2ar\sin\phi}{a^2 - r^2}.$$

Numbers. At $r = a/2$, $\phi = \pi/2$: the arctan argument is $1/(3/4) = 4/3$, so $V = V_0[0.5 + \arctan(4/3)/\pi] = V_0(0.5 + 0.2952) = 0.7952\,V_0$; the series (200 terms) gives the same value. At the centre $V = V_0/2$, the average of the boundary, as the mean-value property demands. The equipotentials are arcs of circles through the two gaps.

Example 13.27 — Coaxial line: the annulus

Find the potential between the conductors of a coaxial line, inner radius a at V_0 and outer radius b grounded, and its capacitance per unit length.

The data do not depend on ϕ, so only the $n = 0$ terms survive: $V = A + B\ln r$. $V(b) = 0$ and $V(a) = V_0$ give

$$V(r) = V_0\frac{\ln(b/r)}{\ln(b/a)}, \qquad E_r = -\frac{dV}{dr} = \frac{V_0}{r\ln(b/a)}.$$

The surface charge on the inner conductor is $\varepsilon E_r(a)$; per unit length the charge is $Q' = 2\pi a\,\varepsilon E_r(a) = 2\pi\varepsilon V_0/\ln(b/a)$, so

$$C' = \frac{Q'}{V_0} = \frac{2\pi\varepsilon}{\ln(b/a)}.$$

Numbers (RG-58-like): $a = 0.45$ mm, $b = 1.47$ mm, $\varepsilon_r = 2.25$. $\ln(b/a) = 1.1838$, $C' = 2\pi \times 8.854\times10^{-12}\times 2.25/1.1838 = 105.7$ pF/m. With $L' = \frac{\mu_0}{2\pi}\ln(b/a) = 236.8$ nH/m, the characteristic impedance is $Z_0 = \sqrt{L'/C'} = 47.3\ \Omega$ and $c = 1/\sqrt{L'C'} = 2.0\times10^8$ m/s, closing the loop with the transmission-line equations of Section 13.5. At $V_0 = 100$ V the peak field (at $r = a$) is 1.88×10^5 V/m.

Example 13.28 — Conducting cylinder in a uniform field (exterior problem)

A grounded conducting cylinder of radius a is placed in a uniform applied field $\mathbf{E}_0 = E_0\hat{\mathbf{x}}$, whose potential is $-E_0x = -E_0r\cos\phi$. Find the potential outside.

We need $V(a,\phi) = 0$ and $V \to -E_0 r\cos\phi$ as $r\to\infty$. The applied potential is the $n = 1$ cosine term $r\cos\phi$; add the decaying partner $r^{-1}\cos\phi$:

$$V = -E_0\Big(r - \frac{a^2}{r}\Big)\cos\phi.$$

It is harmonic (sum of two product solutions), vanishes at $r = a$, and approaches the applied potential far away. The surface field is $E_r(a,\phi) = -\partial V/\partial r\big|_a = 2E_0\cos\phi$: the cylinder **doubles** the field at the points facing the applied field. (For a sphere the factor is 3.) Field enhancement at curved conductors is why high-voltage hardware uses large radii and why sharp points emit corona.

Common pitfall — forgetting the $\ln r$ and r^{-n} terms in an annulus

In an annulus or an exterior region with non-zero net charge, the term $\ln r$ (and for the annulus also r^{-n}) is essential; dropping it makes the coax problem unsolvable. Conversely, in a full disk including the origin those terms must be dropped. The rule is not "always use r^n"; it is "keep exactly those terms that are finite everywhere in the region".

Engineering note — capacitance and resistance extraction

Every capacitance or resistance calculation for an arbitrary geometry is a Laplace problem: solve $\nabla^2 V = 0$ with the electrodes at fixed potentials, compute the charge (or current) by integrating the normal field over an electrode, and divide by the voltage. Closed forms exist for coax, parallel plates, the split cylinder, and a few conformally mappable shapes; everything else (PCB traces, IC interconnect, connector pins) is done by field solvers that discretise exactly this equation.

13.7 Fourier-series solutions

Sections 13.4–13.6 all ended with the same step: expand a given function (initial temperature, initial displacement, boundary potential) in the eigenfunctions of a Sturm–Liouville problem. This section collects the general framework, explains what convergence results we can rely on, and extends the method to non-homogeneous equations (sources and forcing) and to two space dimensions. The theory of Fourier series itself — coefficient formulas, even and odd extensions, Dirichlet conditions, the Gibbs phenomenon, Parseval's theorem — is developed in Ch. 15; here we use its results.

The general recipe

For a linear evolution problem $u_t = \mathcal{A}u$ (or $u_{tt} = \mathcal{A}u$) with $\mathcal{A} = \alpha\,\partial_x^2$ (or $c^2\partial_x^2$) and homogeneous boundary conditions, let $\{X_n\}$ be the eigenfunctions of $-\partial_x^2$ with those boundary conditions, $X_n'' = -\lambda_n X_n$. Expand the unknown at every instant:

$$u(x,t) = \sum_n T_n(t)\,X_n(x), \qquad T_n(t) = \frac{\langle u(\cdot,t), X_n\rangle}{\langle X_n, X_n\rangle}.$$

Because ∂_x^2 acting on X_n just multiplies by $-\lambda_n$, the PDE becomes an *uncoupled* set of ODEs, one per mode:

PDE	Modal ODE	Modal solution
$u_t = \alpha u_{xx}$	$T_n' = -\alpha\lambda_n T_n$	$T_n(0)\,e^{-\alpha\lambda_n t}$
$u_{tt} = c^2 u_{xx}$	$T_n'' = -c^2\lambda_n T_n$	$T_n(0)\cos\omega_n t + \dfrac{T_n'(0)}{\omega_n}\sin\omega_n t$, $\omega_n = c\sqrt{\lambda_n}$
$u_{xx} + u_{yy} = 0$ (y plays "time")	$Y_n'' = \lambda_n Y_n$	$A_n\cosh\sqrt{\lambda_n}y + B_n\sinh\sqrt{\lambda_n}y$

The initial data supply $T_n(0)$, $T_n'(0)$ through the **Fourier coefficients** of f and g. In matrix language, the eigenfunctions diagonalise the spatial operator, exactly as eigenvectors diagonalise $\mathbf{A}$ in $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$.

Which Fourier series?

The boundary conditions decide which expansion is natural on $(0, L)$:

Boundary conditions	Expansion of f on $(0,L)$	Equivalent periodic extension
D–D	sine series $\sum b_n \sin(n\pi x/L)$	odd, period $2L$
N–N	cosine series $\frac{a_0}{2} + \sum a_n\cos(n\pi x/L)$	even, period $2L$
D–N	quarter-wave sine series $\sum b_n \sin\frac{(2n-1)\pi x}{2L}$	odd about 0, even about L, period $4L$
periodic on $(-\pi,\pi)$	full series $\frac{a_0}{2} + \sum(a_n\cos n\phi + b_n\sin n\phi)$	2π-periodic
Robin	$\sum c_n X_n$ with $c_n = \int f X_n / \int X_n^2$	none simple; use Sturm–Liouville orthogonality

The middle column is what you compute; the right-hand column tells you, via Ch. 15, how fast the coefficients decay and where Gibbs overshoot will appear. For example, a constant initial temperature $f = 100$ with Dirichlet ends has an odd extension that is a square wave: coefficients $\propto 1/n$, Gibbs ringing at the ends at $t = 0$. With Neumann ends the even extension of the same constant is constant: the expansion has a single term.

Convergence: what we may rely on

Convergence of series solutions

Let f be piecewise smooth on $[0, L]$.

1. **At $t = 0$** the series equals the Fourier series of the appropriate extension of f; it converges to $f(x)$ where the extension is continuous and to the average of the one-sided limits at jumps (Ch. 15). Convergence is uniform if and only if the extension is continuous (no jumps, including at the ends).
2. **Heat equation, $t > 0$:** the series and all its term-by-term derivatives converge uniformly; u is C^∞ and satisfies the PDE classically. Moreover $u(\cdot,t) \to f$ in mean square as $t \to 0^+$.
3. **Wave equation:** no smoothing. The series is a classical solution if the odd extensions of f and g are C^2 and C^1 respectively (equivalently $\sum n^2|A_n|$ and $\sum n|B_n|$ converge); otherwise it is a **weak solution** whose kinks or jumps travel along characteristics.
4. **Laplace equation:** inside the region, at positive distance from the boundary that carries the data, the factors $e^{-n\pi d/a}$ (rectangle) or $(r/a)^n$ (disk) make the series converge uniformly with all derivatives, and u is C^∞ — even real-analytic — however rough the data.

The smoothness of f controls the decay of its coefficients: jumps give $1/n$, kinks (continuous f, jump in f') give $1/n^2$, and so on, each extra derivative of continuity buying one more power of n (Ch. 15). For the heat equation this matters only at small t; for the wave equation it matters for all time.

How many terms?

Because the modal factors decay like $e^{-\alpha\lambda_n t}$, the number of terms needed for a given accuracy is set by t.

Example 13.29 — Truncation error of the cooling-rod series

In Example 13.12 ($u = \frac{400}{\pi}\sum_{n\text{ odd}} \frac{1}{n} e^{-n^2\pi^2 t}\sin n\pi x$), how many terms are needed for an error below 0.01 at $t = 0.01$ and at $t = 0.001$?

Bound. $|\sin| \le 1$, so the error after keeping all odd $n < N$ is at most the tail $\varepsilon_N(t) = \dfrac{400}{\pi}\displaystyle\sum_{n \ge N,\ \text{odd}} \frac{1}{n} e^{-n^2\pi^2 t}$. Since the terms decrease faster than geometrically, the first omitted term is a good estimate.

t	$N = 5$	$N = 11$	$N = 21$	$N = 41$
0.01	2.31	7.6×10^{-5}	$\approx 10^{-18}$	—
0.001	44.5	7.02	0.124	2.4×10^{-7}

At $t = 0.01$ the odd terms $n = 1, \dots, 9$ (five terms) suffice; at $t = 0.001$ about $n \le 29$ is needed (between $N = 21$ and $N = 41$). A rule of thumb: keep terms until $n^2\pi^2 \alpha t / L^2 \gtrsim 10$, i.e. $n \gtrsim \frac{L}{\pi}\sqrt{10/(\alpha t)}$. For very small t, switch to the erfc approximation of Section 13.4.

Non-homogeneous equations: eigenfunction expansion

Sources and forcing are handled by the same expansion. Consider

$$u_t = \alpha u_{xx} + s(x,t), \qquad u(0,t) = u(L,t) = 0, \qquad u(x,0) = f(x).$$

Expand $u = \sum T_n(t)\sin(n\pi x/L)$ and $s = \sum s_n(t)\sin(n\pi x/L)$ with $s_n(t) = \frac{2}{L}\int_0^L s(x,t)\sin(n\pi x/L)\,dx$. Substituting and matching coefficients (orthogonality),

$$T_n' + \alpha\lambda_n T_n = s_n(t), \qquad T_n(0) = b_n,$$

a first-order linear ODE for each mode (Ch. 11) with solution

$$T_n(t) = b_n e^{-\alpha\lambda_n t} + \int_0^t e^{-\alpha\lambda_n (t-\tau)} s_n(\tau)\,d\tau.$$

The second term is a **convolution** of the modal source with the modal impulse response $e^{-\alpha\lambda_n t}$ — **Duhamel's principle**. Each mode is a first-order low-pass filter with cut-off $\alpha\lambda_n$, driven by the projection of the source onto that mode. The same idea for the wave equation gives a bank of undamped resonators $T_n'' + \omega_n^2 T_n = s_n(t)$, and a source whose time dependence contains ω_n excites mode n resonantly.

Example 13.30 — Joule heating of a wire with cold ends

A wire of length $L = 1$ (nondimensional, $\alpha = 1$) starts at $u = 0$, its ends are held at 0, and a uniform current switched on at $t = 0$ produces a constant source $s = 1$. Find $u(x,t)$ and the midpoint temperature.

Modal source. $s_n = 2\int_0^1 \sin n\pi x\,dx = 4/(n\pi)$ for odd n, 0 for even n. With $b_n = 0$ and constant s_n:

$$T_n(t) = \frac{s_n}{\lambda_n}\bigl(1 - e^{-\lambda_n t}\bigr) = \frac{4}{n^3\pi^3}\bigl(1 - e^{-n^2\pi^2 t}\bigr), \qquad n \text{ odd}.$$

$$u(x,t) = \frac{4}{\pi^3}\sum_{n\text{ odd}} \frac{1 - e^{-n^2\pi^2 t}}{n^3}\sin n\pi x.$$

Steady state check. As $t \to \infty$, $u \to u_s$ with $u_s'' = -1$, $u_s(0) = u_s(1) = 0$, i.e. $u_s = x(1-x)/2$, maximum 0.125 at the centre. The series gives $\frac{4}{\pi^3}\sum_{\text{odd}} \frac{(-1)^{(n-1)/2}}{n^3} = \frac{4}{\pi^3}\cdot\frac{\pi^3}{32} = 0.125$. ✓ (The one-term value is $4/\pi^3 = 0.1290$: the $1/n^3$ decay makes even the steady-state series converge fast.)

Transient. $u(\tfrac12, 0.05) = 0.0463$, $u(\tfrac12, 0.1) = 0.0769$, $u(\tfrac12, 1) = 0.12499$. The approach to steady state is governed by the slowest mode, time constant $1/\pi^2$.

In dimensional form with $s = g/(\rho c_p)$, $g = J^2/\sigma$, the steady centre temperature rise is $gL^2/(8k)$: halving the length of a fuse element quarters its temperature rise, a key design relation for fuses and thin-film resistors.

Example 13.31 — Finite open-ended RC line (the 0.38 $RC\ell^2$ rule)

An RC line of length ℓ, open at $x=\ell$, initially discharged, has its input stepped to V_0 at $t=0$. Find $v(\ell,t)$ and the 50% delay.

Set-up. $v_t = v_{xx}/(RC)$, $v(0,t)=V_0$ (Dirichlet), $v_x(\ell,t)=0$ (open circuit, Section 13.2), $v(x,0)=0$. Steady state $v_s=V_0$; transient $w=v-V_0$ with D–N eigenfunctions $\sin\mu_n x$, $\mu_n=(2n-1)\pi/(2\ell)$, and $w(x,0)=-V_0$:

$$b_n=\frac{2}{\ell}\int_0^{\ell}(-V_0)\sin\mu_n x\,dx=-\frac{2V_0}{\ell\mu_n}=-\frac{4V_0}{(2n-1)\pi}.$$

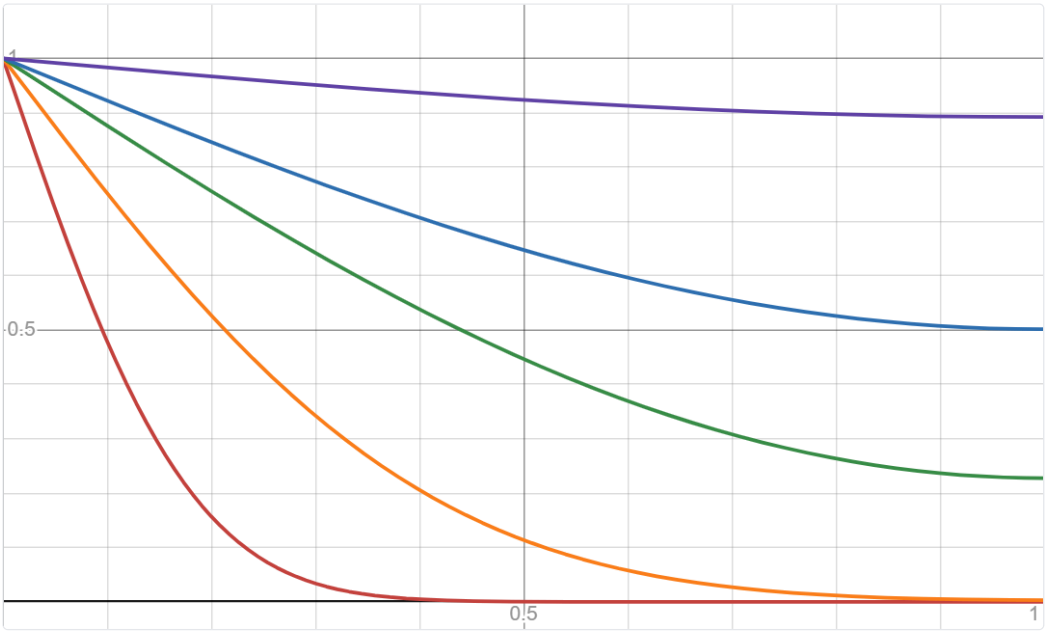
$$v(x,t)=V_0\Big[1-\frac{4}{\pi}\sum_{n=1}^{\infty}\frac{\sin\mu_n x}{2n-1}\,e^{-\mu_n^2 t/(RC)}\Big].$$

At the open end, $\sin\mu_n\ell=(-1)^{n-1}$. In terms of $\tau=t/(RC\ell^2)$:

$$\frac{v(\ell,t)}{V_0}=1-\frac{4}{\pi}\Big[e^{-\pi^2\tau/4}-\frac{1}{3}e^{-9\pi^2\tau/4}+\frac{1}{5}e^{-25\pi^2\tau/4}-\cdots\Big].$$

Solving $v(\ell,t)=V_0/2$ numerically gives $\tau_{50}=0.3787$, so $t_{50}=0.38\,RC\ell^2$ — the standard figure used in interconnect timing. The one-term formula $\tau_{50}=\frac{4}{\pi^2}\ln\frac{8}{\pi}=0.3788$ is already accurate to four figures. The 90% point is at $\tau=1.03$.

Comparison. The semi-infinite estimate of Example 13.16 gave $1.10\,RC\ell^2$; the finite open line is about three times faster because charge stops flowing out at the open end and piles up there.



Voltage $v(x,t)/V_0$ along the open-ended RC line of Example 13.31 (x in units of ℓ) at $\tau=t/(RC\ell^2)=0.01,\ 0.05,\ 0.2,\ 0.38,\ 1$. The profile has zero slope at the open end; at $\tau=0.38$ the far end reaches one half.

Two space dimensions: double Fourier series

On a rectangle $0<x<a$, $0<y<b$ with all edges at zero, the heat equation $u_t=\alpha(u_{xx}+u_{yy})$ separates as $X(x)Y(y)T(t)$ with two separation constants. The eigenfunctions are products,

$$\psi_{mn}(x,y)=\sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b},\qquad \lambda_{mn}=\Big(\frac{m\pi}{a}\Big)^2+\Big(\frac{n\pi}{b}\Big)^2,$$

and the solution is a **double Fourier sine series**

$$u=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}B_{mn}\,e^{-\alpha\lambda_{mn}t}\,\psi_{mn},\qquad B_{mn}=\frac{4}{ab}\int_0^a\int_0^b f(x,y)\,\psi_{mn}\,dy\,dx.$$

For the wave equation (a rectangular membrane; the same eigenvalues give the cut-off frequencies of the TM modes of a rectangular waveguide) the frequencies are $\omega_{mn}=c\sqrt{\lambda_{mn}}$.

Example 13.32 — Cooling of a square plate; degenerate modes

A square plate of side $a = 1$ ($\alpha = 1$) with edges at zero starts at $u = 1$.

$B_{mn} = 4\left(\int_0^1 \sin m\pi x\,dx\right)\left(\int_0^1 \sin n\pi y\,dy\right) = \dfrac{16}{mn\pi^2}$ for m, n both odd, zero otherwise. The slowest mode $(1,1)$ has $\lambda_{11} = 2\pi^2$, time constant $1/(2\pi^2) = 0.0507$ — half that of a rod of the same length, because heat now escapes in two directions.

Centre temperature for large t: $u(\tfrac12, \tfrac12, t) \approx \tfrac{16}{\pi^2} e^{-2\pi^2 t}$. Note this is exactly the *square* of the 1-D one-term result $\tfrac{4}{\pi}e^{-\pi^2 t}$: for product initial data on a product domain, the 2-D solution is the product of 1-D solutions, $u(x,y,t) = u_1(x,t)\,u_1(y,t)$.

Degeneracy. $\lambda_{13} = \lambda_{31} = 10\pi^2$: distinct eigenfunctions share an eigenvalue. In a square drum or a square waveguide this means two modes with the same frequency; any combination $\alpha\psi_{13} + \beta\psi_{31}$ is also a mode, and small asymmetries split the pair. Circular regions lead to Bessel functions in r (a singular Sturm–Liouville problem; see the Further reading), with the same structure.

Common pitfall — differentiating a Fourier series term by term

Term-by-term differentiation is safe for the heat-equation series at $t > 0$ and for Laplace series away from the data boundary, but **not** at $t = 0$, and not for wave-equation series with non-smooth data. Differentiating the sine series of a square wave produces a divergent series. If you need u_x at a boundary (to compute a heat flux or a surface charge), either use $t > 0$ or interior points and take a limit, or differentiate the closed form.

Engineering note — spectral solvers

Computing the coefficients numerically with the FFT, multiplying each by its modal factor $e^{-\alpha\lambda_n t}$ or $\cos\omega_n t$, and transforming back is a **spectral method**. For simple geometries it is far more accurate per unknown than finite differences, because the error falls faster than any power of the number of modes when the solution is smooth. Spectral methods are used in thermal modelling of layered IC stacks and in optical beam propagation, which solves a heat-like (paraxial) equation.

13.8 Applications to fields, diffusion, and heat transfer

This final section applies the methods of the chapter to three problems that every electrical engineer meets. In each case the mathematics is already in hand; the work is in setting up the PDE, its domain and its auxiliary conditions, and in reading the answer. (Deeper treatment of the physics belongs to courses on electromagnetics, device physics and thermal design.)

Fields: the skin effect as a diffusion problem

Inside a good conductor ($\sigma \gg \omega\varepsilon$) the displacement current is negligible, so Ampère's and Faraday's laws read $\nabla \times \mathbf{H} = \sigma\mathbf{E}$ and $\nabla \times \mathbf{E} = -\mu\,\partial\mathbf{H}/\partial t$. Taking the curl of the first and using $\nabla \times \nabla \times \mathbf{H} = \nabla(\nabla\cdot\mathbf{H}) - \nabla^2\mathbf{H}$ with $\nabla\cdot\mathbf{H} = 0$ (Ch. 7):

$$\nabla^2 \mathbf{H} = \mu\sigma\,\frac{\partial \mathbf{H}}{\partial t}.$$

This is a **diffusion equation** with diffusivity $1/(\mu\sigma)$ — the magnetic field (and with it the current density $\mathbf{J} = \nabla \times \mathbf{H}$) *diffuses* into a conductor rather than propagating as a wave.

Sinusoidal steady state. For a conductor filling $x > 0$ with a tangential surface field $H_y(0,t) = H_0\cos\omega t$, use phasors (Ch. 2): $H_y(x,t) = \mathrm{Re}\{\tilde{H}(x)e^{j\omega t}\}$. The PDE becomes the ODE

$$\tilde{H}'' = j\omega\mu\sigma\,\tilde{H}, \qquad \tilde{H}(0) = H_0, \qquad \tilde{H} \text{ bounded as } x \to \infty.$$

Its characteristic roots are $\pm\sqrt{j\omega\mu\sigma} = \pm(1+j)/\delta$ with

$$\delta = \sqrt{\frac{2}{\omega\mu\sigma}},$$

since $\left((1+j)/\delta\right)^2 = 2j/\delta^2 = j\omega\mu\sigma$. Boundedness rejects the growing root:

Skin-effect field in a conducting half-space

$$H_y(x,t) = H_0\,e^{-x/\delta}\cos\left(\omega t - \frac{x}{\delta}\right), \qquad \delta = \sqrt{\frac{2}{\omega\mu\sigma}}\ \text{(skin depth)}.$$

The amplitude falls by e^{-1} per skin depth, and the phase lags by one radian per skin depth. The current density has the same profile, and the conductor's AC resistance per square is the **surface resistance** $R_s = 1/(\sigma\delta)$ — as if the current flowed uniformly in a layer of thickness δ.

The solution is a "critically damped" wave: a travelling wave $\cos(\omega t - x/\delta)$ whose wavelength $2\pi\delta$ equals its decay length times 2π, so it is attenuated by $e^{-2\pi} \approx 0.002$ within one wavelength. Exactly the same mathematics describes the daily or annual temperature wave penetrating into the ground, or into a heat sink under a pulsed load, with $\mu\sigma$ replaced by $1/\alpha$: the "thermal skin depth" is $\sqrt{2\alpha/\omega}$.

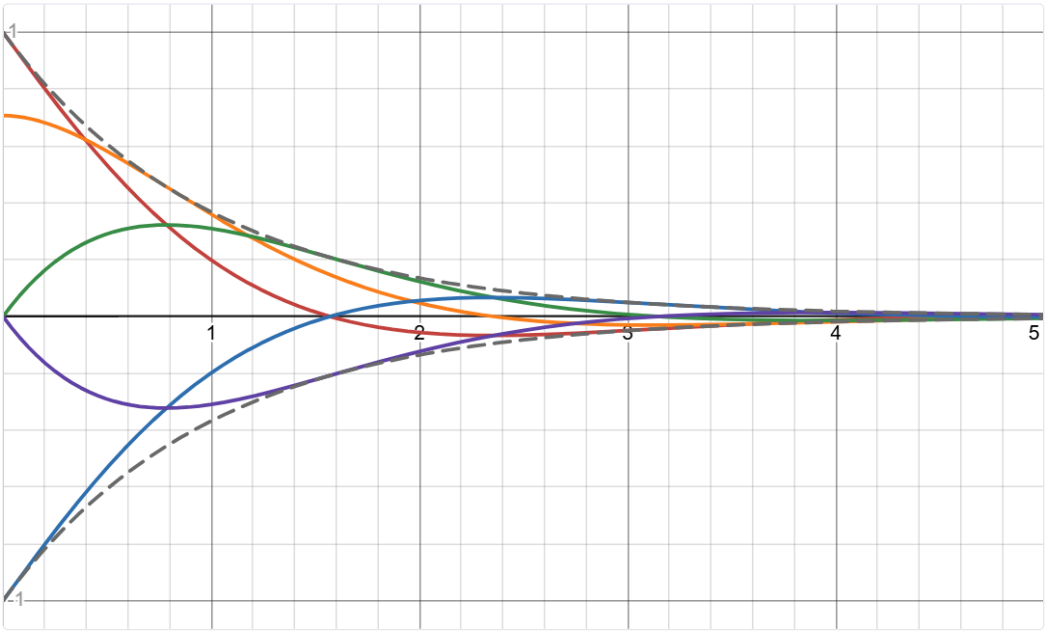
Example 13.33 — Skin depth in copper

Copper: $\sigma = 5.8 \times 10^{7}\ \mathrm{S/m}$, $\mu = \mu_0 = 4\pi \times 10^{-7}\ \mathrm{H/m}$.

f	$\delta = \sqrt{2/(2\pi f \mu_0 \sigma)}$	$R_s = 1/(\sigma\delta)$
60 Hz	8.53 mm	2.0 $\mu\Omega$
1 MHz	66.1 μm	0.26 mΩ
1 GHz	2.09 μm	8.25 mΩ

Check of units: $\omega\mu\sigma$ has units $\mathrm{s^{-1}} \cdot \mathrm{H\,m^{-1}} \cdot \mathrm{S\,m^{-1}} = \mathrm{m^{-2}}$ (since $\mathrm{H} \cdot \mathrm{S} = \mathrm{s}$), so δ is in metres. ✓

Consequences. At 60 Hz conductors thicker than about $2\delta \approx 17$ mm waste copper, which is why large bus bars are hollow or laminated. A round wire of radius $a = 1$ mm at 1 MHz ($a \gg \delta$) carries current essentially in an annulus of thickness δ, giving $R_{ac}/R_{dc} \approx a/(2\delta) = 7.6$; this motivates Litz wire in switch-mode power-supply transformers. At 1 GHz the current flows within a few micrometres of the surface, so surface roughness of PCB copper (comparable to δ) noticeably increases loss.



Skin-effect field H_y/H_0 versus depth x/δ at phases $\omega t = 0,\ \pi/4,\ \pi/2,\ \pi,\ 3\pi/2$ (red to purple), inside the envelope $\pm e^{-x/\delta}$ (dashed). Beyond about 3δ the field is negligible at every instant.

Diffusion: dopant profiles in semiconductors

Impurity atoms are introduced into silicon by diffusion at high temperature. With a constant diffusion coefficient D, the concentration $N(x,t)$ below a planar surface obeys Fick's second law,

$$\frac{\partial N}{\partial t} = D\,\frac{\partial^2 N}{\partial x^2}, \qquad x > 0,$$

on what is effectively a semi-infinite domain (diffusion lengths are micrometres, wafers are hundreds of micrometres thick). Two boundary conditions model the two standard process steps.

Standard diffusion profiles

1. **Constant-source (predeposition):** the surface is held at the solid-solubility limit, $N(0,t) = C_s$, and $N(x,0) = 0$. Then (Section 13.4)

$$N(x,t) = C_s\ \mathrm{erfc}\,\frac{x}{2\sqrt{Dt}}, \qquad Q(t) = \int_0^\infty N\,dx = \frac{2C_s\sqrt{Dt}}{\sqrt{\pi}}.$$

2. **Limited-source (drive-in):** a fixed dose Q (atoms per unit area) starts at the surface and the surface is sealed, $N_x(0,t) = 0$ (Neumann). By the method of images (even extension) the whole-line heat kernel gives

$$N(x,t) = \frac{Q}{\sqrt{\pi Dt}}\,e^{-x^2/(4Dt)},$$

a half-Gaussian whose surface concentration $Q/\sqrt{\pi Dt}$ falls as the dose spreads.

The **junction depth** x_j is where the diffused concentration equals the opposite-type background doping N_B.

Example 13.34 — Junction depths

Boron diffuses into an n-type wafer with background $N_B = 10^{16}\ \text{cm}^{-3}$ at a temperature where $D = 10^{-12}\ \text{cm}^2/\text{s}$, for $t = 1\ \text{h} = 3600\ \text{s}$. Then $\sqrt{Dt} = \sqrt{3.6\times10^{-9}} = 6.0\times10^{-5}\ \text{cm} = 0.60\ \mu\text{m}$.

(a) Predeposition with $C_s = 10^{20}\ \text{cm}^{-3}$. Solve $\operatorname{erfc}\left(x_j/(2\sqrt{Dt})\right) = N_B/C_s = 10^{-4}$: $\operatorname{erfc}^{-1}(10^{-4}) = 2.751$, so

$$x_j = 2\times 0.60\ \mu\text{m}\times 2.751 = 3.30\ \mu\text{m}.$$

The dose introduced is $Q = 2C_s\sqrt{Dt/\pi} = 2\times10^{20}\times6.0\times10^{-5}/1.7725 = 6.8\times10^{15}\ \text{cm}^{-2}$.

(b) Drive-in of an implanted dose $Q = 10^{14}\ \text{cm}^{-2}$ under the same D and t. Surface concentration $N(0) = Q/\sqrt{\pi Dt} = 10^{14}/(1.7725\times6.0\times10^{-5}) = 9.40\times10^{17}\ \text{cm}^{-3}$. Junction: $N(0)e^{-x_j^2/(4Dt)} = N_B$ gives

$$x_j = \sqrt{4Dt\,\ln\frac{N(0)}{N_B}} = \sqrt{4\times3.6\times10^{-9}\times\ln 94.0}\ \text{cm} = 2.56\ \mu\text{m}.$$

Scaling check. Both depths scale as $\sqrt{Dt}$: doubling the diffusion time deepens the junction by $\sqrt{2}$ (only approximately for (b), since the log factor also changes). This is the thermal-budget constraint of IC processing: every later high-temperature step adds to Dt and moves all earlier junctions.

Engineering note — the same erfc in carrier transport

Minority carriers injected into a long neutral region obey $\partial\Delta n/\partial t = D_n\Delta n_{xx} - \Delta n/\tau_n$, a diffusion equation with a decay term. In steady state it becomes the ODE $\Delta n'' = \Delta n/L_n^2$, $L_n = \sqrt{D_n\tau_n}$ (the diffusion length), whose decaying exponential solution underlies the ideal-diode equation. The transient (switching) behaviour of a diode is the full PDE, solved with the methods of this chapter after the substitution $\Delta n = e^{-t/\tau_n}w$, which removes the decay term exactly as in the distortionless-line trick of Section 13.5.

Heat transfer: transient cooling with convection

A plate of thickness $2L_h$ (a ceramic substrate, a heat-spreader, a slab of potting compound) is initially at uniform excess temperature θ_i above the coolant, and at $t = 0$ both faces are exposed to a fluid with heat-transfer coefficient h_c. Measure x from the mid-plane and let $\theta = u - u_\infty$. By symmetry we solve on $0 < x < L_h$:

$$\theta_t = \alpha\,\theta_{xx}, \qquad \theta_x(0,t) = 0\ \text{(symmetry)}, \qquad -k\,\theta_x(L_h,t) = h_c\,\theta(L_h,t)\ \text{(Robin)}, \qquad \theta(x,0) = \theta_i.$$

Nondimensionalise: $\xi = x/L_h$, **Fourier number** $\text{Fo} = \alpha t/L_h^2$, **Biot number** $\text{Bi} = h_cL_h/k$. The Biot number compares internal conduction resistance L_h/k with surface convection resistance $1/h_c$.

Separation (Section 13.3) with $X'(0) = 0$ gives $X = \cos\mu\xi$, and the Robin condition $X'(1) + \text{Bi}\,X(1) = 0$ gives the eigenvalue equation

$$\mu\tan\mu = \text{Bi},$$

with one root μ_n in each interval $\left((n-1)\pi,\ (n-\tfrac12)\pi\right)$. The generalised Fourier coefficients of the constant initial value (Sturm–Liouville theorem, with $\int_0^1\cos^2\mu_n\xi\,d\xi = \tfrac12 + \frac{\sin 2\mu_n}{4\mu_n}$) are

$$C_n = \frac{\int_0^1\cos\mu_n\xi\,d\xi}{\int_0^1\cos^2\mu_n\xi\,d\xi} = \frac{4\sin\mu_n}{2\mu_n + \sin 2\mu_n},$$

so

$$\frac{\theta(\xi,\text{Fo})}{\theta_i} = \sum_{n=1}^{\infty} C_n\,e^{-\mu_n^2\text{Fo}}\cos\mu_n\xi.$$

Example 13.35 — Biot number and the lumped-capacitance limit

Compute μ_1, C_1 and the centre temperature at $\mathrm{Fo} = 1$ for $\mathrm{Bi} = 0.1,\ 1,\ 10$.

Solving $\mu \tan\mu = \mathrm{Bi}$ by bisection on $(0, \pi/2)$:

Bi	μ_1	μ_1^2	C_1	μ_2	$\theta(0,1)/\theta_i$ **(one term)**
0.1	0.3111	0.0968	1.016	3.173	0.922
1	0.8603	0.7402	1.119	3.426	0.534
10	1.4289	2.042	1.262	4.306	0.164

For $\mathrm{Bi} = 1$ the full series (50 terms) gives $\theta(0,1)/\theta_i = 0.53386$ identical to five figures with the one-term value. At $\mathrm{Fo} = 0.2$ the series gives 0.9506 and one term gives 0.9651, still within 1.5%; the second mode has $\mu_2^2 = 11.7$, so it is negligible once $\mathrm{Fo} \gtrsim 0.2$.

Interpretation.

- $\mathrm{Bi} \ll 1$: $\mu_1^2 \approx \mathrm{Bi}$ (here $0.0968 \approx 0.1$) and $C_1 \approx 1$. The solution reduces to $\theta \approx \theta_i e^{-\mathrm{Bi}\,\mathrm{Fo}} = \theta_i e^{-h_c t/(\rho c_p L_h)}$: the **lumped-capacitance** (single RC) model, with thermal time constant $\rho c_p L_h / h_c$ = (heat capacity per unit area)×(surface resistance). The temperature is nearly uniform across the plate. The usual criterion for using a lumped model is $\mathrm{Bi} < 0.1$.
- $\mathrm{Bi} \gg 1$: $\mu_1 \to \pi/2$, the surface is effectively clamped at the coolant temperature (Dirichlet), and internal conduction limits the cooling.

Dimensional numbers. An alumina substrate ($k = 30\ \mathrm{W\,m^{-1}K^{-1}}$, $\rho c_p = 3.43 \times 10^6\ \mathrm{J\,m^{-3}K^{-1}}$, so $\alpha = 8.74 \times 10^{-6}\ \mathrm{m^2/s}$) of half-thickness $L_h = 5$ mm in forced water cooling with $h_c = 6000\ \mathrm{W\,m^{-2}K^{-1}}$ has $\mathrm{Bi} = 1$. Its dominant time constant is $L_h^2/(\mu_1^2\alpha) = 2.5 \times 10^{-5}/(0.7402 \times 8.74 \times 10^{-6}) = 3.86$ s; a lumped model would wrongly predict $\rho c_p L_h / h_c = 2.86$ s and a uniform temperature.

Common pitfall — lumping when Bi is not small

The single-time-constant "thermal RC" model is a one-mode truncation that is valid only when $\mathrm{Bi} \lesssim 0.1$ *and* Fo is not small. For a power device on a thick, poorly conducting substrate, Bi can exceed 1, and the lumped model underestimates both the time constant and the peak junction temperature at short times. Use the distributed solution (or a multi-mode Foster/Cauer network).

Choosing the method: a summary of the chapter's toolkit

Situation	Method	Section
Finite interval/rectangle/disk, homogeneous BCs on all but one side	separation of variables + Fourier series	13.3, 13.7
Constant non-homogeneous BCs	subtract steady state, then separate	13.2, 13.4
Sources or time-dependent BCs	eigenfunction expansion + Duhamel (modal ODEs)	13.7
Infinite line, wave equation	d'Alembert, characteristics	13.5
Semi-infinite line, wave equation with fixed/free end	method of images (odd/even extension)	13.5
Infinite/semi-infinite domain, diffusion	heat kernel, erfc similarity solution	13.4, 13.8
Sinusoidal steady state	phasors turn the PDE into an ODE in space	13.8
Short-time heat transfer	erfc near each boundary; long time: one-mode series	13.4
Lossy line with $R/L = G/C$	exponential substitution → lossless wave	13.5
Irregular geometry	numerical methods (Ch. 22), conformal maps (Ch. 18)	—

Summary

Topic	Key formula / fact
Telegrapher's equations	$v_x = -Ri - Li_t,\ i_x = -Gv - Cv_t$
Transmission-line equation	$v_{xx} = LC\,v_{tt} + (RC + GL)\,v_t + RG\,v$
Limits	lossless: $v_{tt} = c^2 v_{xx}$, $c = 1/\sqrt{LC}$; RC: $v_t = v_{xx}/(RC)$
Classification	$a_{11}u_{xx} + 2a_{12}u_{xy} + a_{22}u_{yy}$: $\Delta = a_{12}^2 - a_{11}a_{22}$; >0 hyperbolic, $=0$ parabolic, <0 elliptic
Characteristics	$dy/dx = (a_{12} \pm \sqrt{\Delta})/a_{11}$
Boundary conditions	Dirichlet $u = h$; Neumann $\partial u/\partial n = h$; Robin $\beta u + \partial u/\partial n = h$
Steady-state subtraction	$u = u_s(x) + w$, $u_s = T_1 + (T_2 - T_1)x/L$
Dirichlet eigenpairs	$\lambda_n = (n\pi/L)^2$, $X_n = \sin(n\pi x/L)$
D–N eigenpairs	$\lambda_n = ((2n-1)\pi/2L)^2$, $X_n = \sin((2n-1)\pi x/2L)$
Robin (D–R)	$\tan\mu = -\mu/h$; slab cooling $\mu\tan\mu = \mathrm{Bi}$
Sturm–Liouville coefficients	$c_n = \int f X_n w\,dx \big/ \int X_n^2 w\,dx$
Heat equation, D–D	$u = \sum b_n e^{-\alpha n^2\pi^2 t/L^2}\sin(n\pi x/L)$, $b_n = \frac{2}{L}\int_0^L f \sin\frac{n\pi x}{L}dx$

Topic	Key formula / fact
Thermal time constant	$\tau_1 = L^2/(\pi^2\alpha)$; diffusion length $\sim \sqrt{\alpha t}$
Heat kernel	$\Phi = (4\pi\alpha t)^{-1/2} e^{-x^2/(4\alpha t)}$, $u = \Phi * f$
Semi-infinite step	$u = T_s \operatorname{erfc}\left(x/(2\sqrt{\alpha t})\right)$
d'Alembert	$u = \frac{1}{2}[f(x-ct) + f(x+ct)] + \frac{1}{2c}\int_{x-ct}^{x+ct} g\,ds$
Line waves	$v = v^+ + v^-$, $i = (v^+ - v^-)/Z_0$, $Z_0 = \sqrt{L/C}$
Reflection coefficient	$\Gamma = (R_L - Z_0)/(R_L + Z_0)$
String / shorted line modes	$f_n = nc/(2L)$; $B_n = \frac{2}{n\pi c}\int_0^L g \sin\frac{n\pi x}{L} dx$
Wave energy	$E = \frac{1}{2}\int (u_t^2 + c^2 u_x^2)\,dx$ conserved
Distortionless line	$R/L = G/C$: $v = e^{-(R/L)t}[F(x-ct) + G(x+ct)]$, attenuation $\sqrt{RG}$ Np/m
Laplace, rectangle	$u = \sum h_n \frac{\sinh(n\pi y/a)}{\sinh(n\pi b/a)} \sin\frac{n\pi x}{a}$
Laplace, polar products	$1,\ \ln r,\ r^{\pm n}\cos n\phi,\ r^{\pm n}\sin n\phi$
Disk / Poisson integral	$u = \frac{a_0}{2} + \sum (r/a)^n (a_n \cos n\phi + b_n \sin n\phi)$; kernel $\frac{a^2 - r^2}{a^2 - 2ar\cos(\phi-\psi) + r^2}$
Coax	$V = V_0 \ln(b/r)/\ln(b/a)$, $C' = 2\pi\varepsilon/\ln(b/a)$
Mean value / max principle	$u(\mathbf{x}_0)$ = circle average; extrema on the boundary
Duhamel (modal)	$T_n' + \alpha\lambda_n T_n = s_n(t)$, $T_n = b_n e^{-\alpha\lambda_n t} + \int_0^t e^{-\alpha\lambda_n(t-\tau)} s_n\,d\tau$
Open RC line delay	$t_{50} = 0.38\,RC\ell^2$
Skin depth	$\delta = \sqrt{2/(\omega\mu\sigma)}$, $H = H_0 e^{-x/\delta}\cos(\omega t - x/\delta)$, $R_s = 1/(\sigma\delta)$
Dopant profiles	$C_s \operatorname{erfc}\left(x/2\sqrt{Dt}\right)$; $\frac{Q}{\sqrt{\pi Dt}} e^{-x^2/4Dt}$

Part V — Transforms and Mathematical Analysis

Chapter 14 — Laplace Transforms

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 5 (integral calculus, improper integrals), Ch. 11 and Ch. 12 (ordinary and linear differential equations)
> **Learning outcomes:** After this chapter you can
>
> - define the unilateral Laplace transform with lower limit 0^-, decide whether it exists, and find its region of convergence;
> - use the transform properties (shifts, scaling, differentiation, integration, multiplication by t, periodicity) to build transforms without integrating;
> - invert rational transforms by partial fractions, including repeated and complex-conjugate poles and delayed terms e^{-sT};
> - apply the convolution theorem and the initial- and final-value theorems, and know exactly when the latter is valid;
> - solve linear constant-coefficient differential, integro-differential and simultaneous equations as initial-value problems in one pass;
> - model circuits directly in the s-domain, form transfer functions, read poles and zeros, and judge stability from pole locations.

A linear circuit with capacitors and inductors obeys a linear differential equation. In Ch. 12 such equations were solved by finding a complementary function, guessing a particular integral, and then fitting constants to the initial conditions — three separate steps, each with its own traps. The Laplace transform turns the whole initial-value problem into **algebra**: differentiation becomes multiplication by s, the initial conditions enter automatically, and the solution is recovered from a table after a partial-fraction expansion. Beyond solving equations, the transform gives the language in which engineers *think* about linear systems: impedances sL and $1/(sC)$, transfer functions, poles and zeros, and stability. The Fourier transform of Ch. 16 is the special case $s = j\omega$, and the Z-transform of Ch. 17 is its discrete-time sibling. The complex-variable theory behind the inversion integral is developed in Ch. 18.

14.1 Definition and existence

Motivation: from differentiation to multiplication

The exponential e^{st} is the one function that differentiation leaves essentially unchanged: $\frac{d}{dt}e^{st} = s\,e^{st}$. If a signal could be written as a superposition of exponentials e^{st} with weights $X(s)$, then differentiating the signal would simply multiply each weight by s. The Laplace transform is the recipe for computing those weights. Unlike the Fourier transform, which uses only the undamped exponentials $e^{j\omega t}$, it allows a real part σ in $s = \sigma + j\omega$. The factor $e^{-\sigma t}$ tames signals that grow — ramps, unstable responses, e^{3t} — so that many signals with no ordinary Fourier transform still have a Laplace transform.

The unilateral transform

Unilateral Laplace transform

Let $x(t)$ be defined for $t \geq 0$ (its values for $t < 0$ are ignored). Its **Laplace transform** is

$$X(s) = \mathcal{L}\{x(t)\} = \int_{0^-}^{\infty} x(t)\,e^{-st}\,dt = \lim_{\varepsilon \to 0^+,\; T \to \infty} \int_{-\varepsilon}^{T} x(t)\,e^{-st}\,dt,$$

where $s = \sigma + j\omega$ is a complex variable. The set of s for which the integral converges is the **region of convergence (ROC)**. We write $x(t) \leftrightarrow X(s)$ and call t the *time domain* and s the *s-domain* or *complex-frequency domain*.

Three points of convention deserve attention from the start.

1. **Lower limit 0^-.** The integral starts just *before* $t = 0$. An impulse $\delta(t)$ or a jump located at the origin is therefore fully inside the range of integration, so $\mathcal{L}\{\delta(t)\} = 1$, and the initial conditions that appear in the derivative rule are the values $x(0^-)$ *before* any switching event. These are exactly the values an engineer knows: the capacitor voltage and inductor current just before the switch closes. With a 0^+ lower limit, one needs instead the values just after switching, which are usually what one is trying to find. This book uses 0^- throughout.
2. **Causality.** Because only $t \geq 0$ matters, $x(t)$ and $x(t)u(t)$ have the same transform. It is good practice to write time functions with an explicit $u(t)$, for example $e^{-2t}u(t)$, whenever the distinction could matter (shifts, convolution). Tables often omit the $u(t)$; it is always understood.
3. **Units.** Since dt carries seconds, $X(s)$ has the units of x times seconds, and s has units s^{-1} (it is a complex frequency). A voltage step $V_0u(t)$ in volts has transform V_0/s in V·s. Checking that every term of an s-domain expression has the same units is as useful here as in the time domain.

The **bilateral** transform $\int_{-\infty}^{\infty} x(t)e^{-st}dt$ is used for non-causal signals in signal theory; it requires the ROC to be stated to make the inverse unique (two different signals, $e^{-at}u(t)$ and $-e^{-at}u(-t)$, both have bilateral transform $1/(s+a)$, with ROCs $\sigma > -a$ and $\sigma < -a$). For initial-value problems and circuits the unilateral transform is the right tool and all statements below refer to it.

First transforms from the definition

Worked Example 14.1 — the step and the exponential

Find $\mathcal{L}\{u(t)\}$ and $\mathcal{L}\{e^{at}\}$ for real or complex constant a, with their ROCs.

Step. For $t > 0$, $u(t) = 1$:

$$\int_{0^-}^{\infty} e^{-st}\,dt = \lim_{T\to\infty}\left[\frac{-e^{-st}}{s}\right]_0^{T} = \frac{1}{s} - \lim_{T\to\infty}\frac{e^{-\sigma T}e^{-j\omega T}}{s}.$$

The factor $e^{-j\omega T}$ has modulus 1, so the limit is zero exactly when $\sigma > 0$. Hence $\mathcal{L}\{u(t)\} = 1/s$ with ROC $\operatorname{Re}\{s\} > 0$.

Exponential. $\int_0^{\infty} e^{at}e^{-st}\,dt = \int_0^{\infty} e^{-(s-a)t}\,dt$ is the same integral with s replaced by $s - a$:

$$\mathcal{L}\{e^{at}\} = \frac{1}{s-a}, \qquad \operatorname{Re}\{s\} > \operatorname{Re}\{a\}.$$

Check. With $a = -2$: $\int_0^{\infty} e^{-2t}e^{-st}\,dt$ at $s = 1$ is $\int_0^{\infty} e^{-3t}\,dt = 1/3 = 1/(1+2)$. ✓

Worked Example 14.2 — the ramp, by parts

Find $\mathcal{L}\{t\}$.

Integrate by parts with $f = t$, $dg = e^{-st}\,dt$, valid for $\sigma > 0$:

$$\int_0^{\infty} t\,e^{-st}\,dt = \left[-\frac{t\,e^{-st}}{s}\right]_0^{\infty} + \frac{1}{s}\int_0^{\infty} e^{-st}\,dt = 0 + \frac{1}{s}\cdot\frac{1}{s} = \frac{1}{s^2}.$$

The boundary term vanishes at infinity because $te^{-\sigma t} \to 0$ for $\sigma > 0$ (exponential decay beats polynomial growth). Repeating the argument n times gives $\mathcal{L}\{t^n\} = n!/s^{n+1}$ (Section 14.3).

Check. At $s = 2$: $\int_0^{\infty} te^{-2t}\,dt = 1/4$, and $1/s^2 = 1/4$. ✓

Worked Example 14.3 — the impulse and a sifting check

Find $\mathcal{L}\{\delta(t)\}$ and $\mathcal{L}\{\delta(t-T)\}$ for $T > 0$.

By the sifting property $\int g(t)\delta(t-t_0)\,dt = g(t_0)$ for any t_0 inside the range of integration,

$$\mathcal{L}\{\delta(t)\} = \int_{0^-}^{\infty}\delta(t)e^{-st}\,dt = e^{0} = 1, \qquad \mathcal{L}\{\delta(t-T)\} = e^{-sT},$$

both for every s (ROC: the whole plane). With a 0^+ lower limit, the impulse at the origin would be *excluded* and the transform would be 0 — a clear sign that 0^- is the right choice for systems driven by impulses.

Existence: exponential order

Not every function has a Laplace transform. The integral can fail at the lower end (a non-integrable singularity) or at infinity (growth faster than any exponential). A simple sufficient condition rules out both.

Piecewise continuity and exponential order

A function $x(t)$ is **piecewise continuous** on $[0,\infty)$ if on every finite interval it has at most finitely many discontinuities, each a finite jump. It is of **exponential order** α if there are constants $M > 0$, $T_0 \ge 0$ such that

$$|x(t)| \le Me^{\alpha t} \quad \text{for all } t \ge T_0.$$

Polynomials, e^{at}, $\sin\omega t$, $\cosh t$ and all their products are of exponential order. The function e^{t^2} is not: for any α, $e^{t^2}/e^{\alpha t} = e^{t(t-\alpha)} \to \infty$.

Existence theorem

If $x(t)$ is piecewise continuous on $[0,\infty)$ and of exponential order α, then $\mathcal{L}\{x\}$ exists for all $\operatorname{Re}\{s\} > \alpha$, the integral converging absolutely. Moreover $X(s) \to 0$ as $\operatorname{Re}\{s\} \to \infty$.

Proof sketch. Split $\int_0^{\infty} = \int_0^{T_0} + \int_{T_0}^{\infty}$. The first part is the integral of a bounded piecewise continuous function over a finite interval, hence finite. For the second, with $\sigma = \operatorname{Re}\{s\} > \alpha$,

$$\int_{T_0}^{\infty}|x(t)e^{-st}|\,dt \le M\int_{T_0}^{\infty}e^{-(\sigma-\alpha)t}\,dt = \frac{Me^{-(\sigma-\alpha)T_0}}{\sigma-\alpha} < \infty.$$

Absolute convergence implies convergence. For the decay, bound $|x| \le M'e^{\alpha t}$ on all of $[0,\infty)$ (possible after enlarging M, since x is bounded on $[0,T_0]$); then $|X(s)| \le M'/(\sigma-\alpha) \to 0$. □

The infimum of all α that work is the **abscissa of convergence** σ_c; the ROC is the open half-plane $\operatorname{Re}\{s\} > \sigma_c$ (a unilateral transform always has a right half-plane as ROC). For a rational $X(s)$ the ROC begins at the right-most pole: $\sigma_c = \max \operatorname{Re}\{p_k\}$.

The conditions are **sufficient, not necessary**. The function $t^{-1/2}$ is unbounded at $t = 0$, so it is not piecewise continuous there, yet $\int_0^\infty t^{-1/2} e^{-st}\,dt = \sqrt{\pi/s}$ converges because the singularity is integrable. Impulses are not functions at all but are handled by the sifting property. In practice, every signal met in circuit analysis has a transform.

Worked Example 14.4 — deciding existence and the ROC

For each signal, decide whether the unilateral transform exists and, if so, give the ROC.

(a) $x(t) = 3e^{-t} + 2e^{4t}$. Both terms are of exponential order; the larger exponent is 4, so $|x| \le 5e^{4t}$ and the transform $\frac{3}{s+1} + \frac{2}{s-4}$ exists for $\mathrm{Re}\{s\} > 4$. The ROC of a sum is (at least) the intersection of the individual ROCs — here governed by the fastest-growing term, i.e. the right-most pole.

(b) $x(t) = e^{t^2}$. Not of exponential order. For any real s, the integrand $e^{t^2 - st}$ grows without bound once $t > s$, so the integral diverges for every s: **no transform**.

(c) $x(t) = 1/t$. Of exponential order for large t, but near the origin $\int_0^1 t^{-1} e^{-st}\,dt \ge e^{-\sigma}\int_0^1 t^{-1}\,dt = \infty$ for real $s = \sigma$. The singularity is not integrable: **no transform**. Contrast $t^{-1/2}$, whose singularity is integrable and whose transform $\sqrt{\pi/s}$ exists.

(d) $x(t) = \sin(e^{t^2})$. This oscillates ever faster, but $|x| \le 1 = e^{0\cdot t}$, so it is of exponential order 0 and the transform exists for $\mathrm{Re}\{s\} > 0$. Rapid oscillation is harmless; only growth and non-integrable singularities matter.

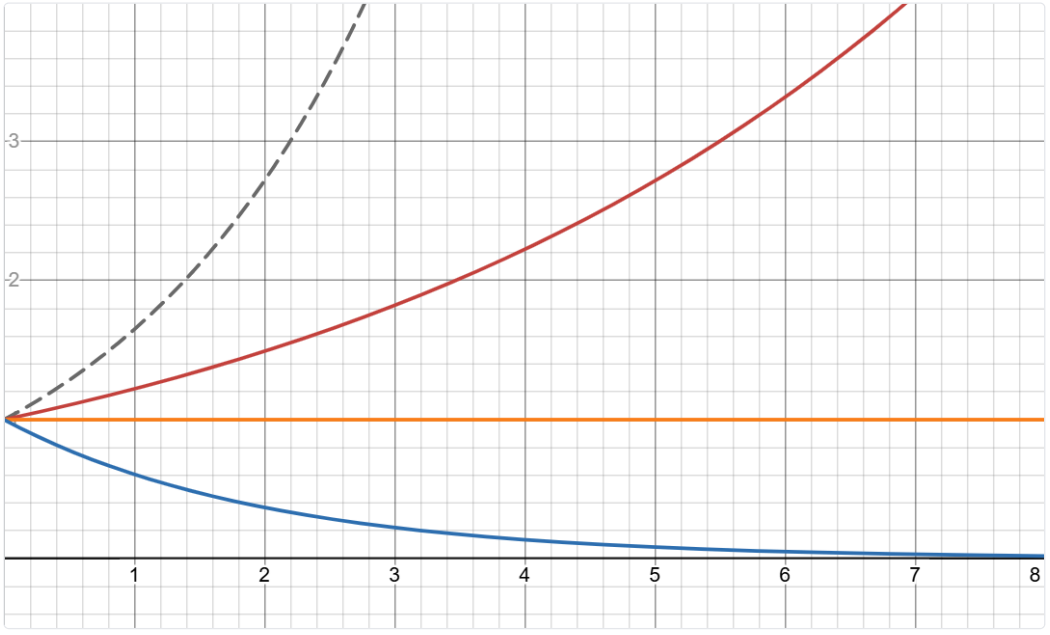
(e) $x(t) = \cosh(2t)\, e^{-3t}$. Since $\cosh 2t\, e^{-3t} = \tfrac{1}{2}(e^{-t} + e^{-5t})$, the transform $\tfrac{1}{2}\left(\frac{1}{s+1} + \frac{1}{s+5}\right)$ exists for $\mathrm{Re}\{s\} > -1$. Here the ROC includes the $j\omega$-axis, so this signal also has a Fourier transform.

Uniqueness (Lerch)

If two piecewise continuous functions of exponential order have the same Laplace transform on some half-plane $\mathrm{Re}\{s\} > \sigma_0$, they are equal at every $t > 0$ where both are continuous.

Uniqueness is what makes table look-up legitimate: if we recognise $X(s)$ as the transform of $x(t)$, then $x(t)$ is *the* answer (up to values at isolated points, which no physical measurement can detect).

The behaviour of the integrand explains the ROC graphically. For $x(t) = e^{0.5t}$, the weighted integrand $x(t)e^{-\sigma t}$ decays only when $\sigma > 0.5$:



The signal $e^{0.5t}$ (grey) multiplied by $e^{-\sigma t}$ for $\sigma = 0.3$ (red, still growing), $\sigma = 0.5$ (orange, constant — integral diverges) and $\sigma = 1$ (blue, decaying — integral converges). The ROC is $\sigma > 0.5$.

Common Pitfall — evaluating outside the ROC

The formula $1/(s-a)$ is defined for all $s \ne a$, but the *integral* converges only for $\mathrm{Re}\{s\} > \mathrm{Re}\{a\}$. For the unilateral transform this rarely causes errors, because the ROC is always a right half-plane determined by the right-most singularity. It matters when passing to the Fourier transform: $X(j\omega)$ is the Fourier transform only if the $j\omega$-axis lies in the ROC. For $e^{2t}u(t)$, $X(s) = 1/(s-2)$, but $1/(j\omega - 2)$ is **not** its Fourier transform — it has none (Ch. 16).

Engineering Note — why engineers accept a complex frequency

A pole at $s = \sigma + j\omega$ corresponds to a time behaviour $e^{\sigma t}e^{j\omega t}$: ω is the oscillation frequency in rad/s and σ is the growth rate (decay if negative) in nepers per second. Every natural response of a lumped linear circuit is a combination of such terms, so the s-plane is a map of every possible "mode" of a circuit, with stability determined by which half of the map the modes lie in (Section 14.9).

14.2 Properties

Computing every transform from the integral would be tedious. A handful of properties, each a one-line consequence of the definition, lets us build almost any transform needed in practice from a few basic pairs, and — more importantly — tells us how operations on signals (delay, differentiation, damping) appear in the s-domain. Throughout, $x(t) \leftrightarrow X(s)$ with ROC $\mathrm{Re}\{s\} > \sigma_x$, and similarly for y.

Linearity

Linearity

For constants a, b:

$$\mathcal{L}\{a\,x(t) + b\,y(t)\} = a\,X(s) + b\,Y(s),$$

valid at least on the intersection of the two ROCs.

This is inherited directly from linearity of the integral. Combined with Euler's formula it already yields the trigonometric transforms: $\cos\omega t = \tfrac{1}{2}(e^{j\omega t} + e^{-j\omega t})$ gives

$$\mathcal{L}\{\cos\omega t\} = \frac{1}{2}\left(\frac{1}{s-j\omega} + \frac{1}{s+j\omega}\right) = \frac{s}{s^2+\omega^2}, \qquad \mathcal{L}\{\sin\omega t\} = \frac{1}{2j}\left(\frac{1}{s-j\omega} - \frac{1}{s+j\omega}\right) = \frac{\omega}{s^2+\omega^2},$$

both with ROC $\mathrm{Re}\{s\} > 0$.

Frequency shift (multiplication by an exponential)

First shifting theorem (s-shift)

$$\mathcal{L}\{e^{at}x(t)\} = X(s-a), \qquad \mathrm{Re}\{s\} > \sigma_x + \mathrm{Re}\{a\}.$$

Proof. $\int_{0^-}^{\infty} e^{at}x(t)e^{-st}dt = \int_{0^-}^{\infty} x(t)e^{-(s-a)t}dt = X(s-a)$. □

Damping a signal by $e^{-\alpha t}$ slides its transform — and all its poles — a distance α to the left in the s-plane. Thus

$$e^{-\alpha t}\cos\omega t \leftrightarrow \frac{s+\alpha}{(s+\alpha)^2+\omega^2}, \qquad e^{-\alpha t}\sin\omega t \leftrightarrow \frac{\omega}{(s+\alpha)^2+\omega^2}, \qquad t^n e^{-\alpha t} \leftrightarrow \frac{n!}{(s+\alpha)^{n+1}}.$$

Time shift (delay)

Second shifting theorem (t-shift)

For $T \geq 0$,

$$\mathcal{L}\{x(t-T)\,u(t-T)\} = e^{-sT}X(s).$$

Proof. The integrand vanishes for $t < T$; substitute $\tau = t - T$:

$$\int_T^{\infty} x(t-T)e^{-st}dt = \int_0^{\infty} x(\tau)e^{-s(\tau+T)}d\tau = e^{-sT}X(s). \qquad \square$$

The factor e^{-sT} is the s-domain signature of a pure delay. The theorem applies to the *whole function* shifted, $x(t-T)u(t-T)$; it does not apply to $x(t)u(t-T)$ until that is rewritten. The safe procedure for $\mathcal{L}\{g(t)u(t-T)\}$ is

$$\mathcal{L}\{g(t)\,u(t-T)\} = e^{-sT}\,\mathcal{L}\{g(t+T)\},$$

which follows from the same substitution.

Worked Example 14.5 — piecewise signals with steps

A voltage rises linearly from 0 to 1 V during the first second and then stays at 1 V: $x(t) = t$ for $0 \leq t < 1$, $x(t) = 1$ for $t \geq 1$. Find $X(s)$.

Write with steps. A ramp that starts at $t = 0$, minus a ramp that starts at $t = 1$, levels the signal off:

$$x(t) = t\,u(t) - (t-1)\,u(t-1).$$

(Check: for $t \geq 1$, $t - (t-1) = 1$. ✓)

Transform. Each term is a ramp, one of them delayed:

$$X(s) = \frac{1}{s^2} - \frac{e^{-s}}{s^2} = \frac{1-e^{-s}}{s^2}.$$

Check by integration. $\int_0^1 te^{-st}dt + \int_1^{\infty} e^{-st}dt$ at $s = 1$: the first integral is $1 - 2e^{-1} = 0.26424$, the second $e^{-1} = 0.36788$; the sum is 0.63212. The formula gives $1 - e^{-1} = 0.63212$. ✓

Worked Example 14.6 — a shifted sinusoid

Find $\mathcal{L}\{\sin(t)\,u(t-\pi/2)\}$.

The sine is not written as a function of $t-\pi/2$. Use $g(t)u(t-T)\leftrightarrow e^{-sT}\mathcal{L}\{g(t+T)\}$ with $g=\sin$, $T=\pi/2$: $g(t+\pi/2)=\sin(t+\pi/2)=\cos t$, so

$$\mathcal{L}\{\sin t\,u(t-\pi/2)\}=e^{-\pi s/2}\,\frac{s}{s^2+1}.$$

The tempting but wrong answer $e^{-\pi s/2}/(s^2+1)$ would be the transform of $\sin(t-\pi/2)u(t-\pi/2)=-\cos t\,u(t-\pi/2)$, a signal of opposite sign.

Time scaling

Scaling

For $a>0$,

$$\mathcal{L}\{x(at)\}=\frac{1}{a}\,X\!\left(\frac{s}{a}\right).$$

Proof. Substitute $\tau=at$: $\int_0^\infty x(at)e^{-st}dt=\frac{1}{a}\int_0^\infty x(\tau)e^{-(s/a)\tau}d\tau$. $\square$

Compressing in time ($a>1$) expands in s: poles move outward by the factor a. This is the basis of *frequency scaling* of filter designs: a prototype with cut-off 1 rad/s becomes one with cut-off ω_c by replacing s with s/ω_c.

Differentiation in time

This is the property that makes the transform useful for differential equations.

Derivative rule

If x is continuous on $(0^-,\infty)$ with piecewise continuous derivative, both of exponential order, then

$$\mathcal{L}\{\dot{x}(t)\}=sX(s)-x(0^-),$$

and, applying the rule repeatedly,

$$\mathcal{L}\{x^{(n)}(t)\}=s^nX(s)-s^{n-1}x(0^-)-s^{n-2}\dot{x}(0^-)-\cdots-x^{(n-1)}(0^-).$$

Derivation. Integrate by parts:

$$\int_{0^-}^{\infty}\dot{x}(t)e^{-st}dt=\Big[x(t)e^{-st}\Big]_{0^-}^{\infty}+s\int_{0^-}^{\infty}x(t)e^{-st}dt=-x(0^-)+sX(s),$$

the upper boundary term vanishing in the ROC because x is of exponential order. For the second derivative apply the rule to $\dot{x}$: $\mathcal{L}\{\ddot{x}\}=s\mathcal{L}\{\dot{x}\}-\dot{x}(0^-)=s^2X-sx(0^-)-\dot{x}(0^-)$. Induction gives the general formula. $\square$

Jumps at the origin. With the 0^- convention, the rule remains true even when x jumps at $t=0$, provided $\dot{x}$ is understood in the generalized sense (a jump of size J contributes $J\,\delta(t)$ to $\dot{x}$). For instance $x(t)=e^{-t}u(t)$ has $x(0^-)=0$ and $\dot{x}=\delta(t)-e^{-t}u(t)$, whose transform is $1-\frac{1}{s+1}=\frac{s}{s+1}=sX(s)-0$. ✓ A version of the rule using $x(0^+)=1$ reads $sX-x(0^+)=-\frac{1}{s+1}$; it describes only the derivative for $t>0$ and silently drops the impulse. Both are self-consistent, but mixing them is a classic source of error; the 0^- form never needs to know what happens *at* the switching instant.

A jump at a later time $t_1>0$ of size J is handled the same way: $\mathcal{L}\{\dot{x}\}=sX-x(0^-)$ still holds if $\dot{x}$ includes the impulse $J\delta(t-t_1)$, while the ordinary (pointwise) derivative satisfies $\mathcal{L}\{\dot{x}_{\text{ord}}\}=sX-x(0^-)-Je^{-st_1}$.

Integration in time

Integral rule

$$\mathcal{L}\left\{\int_{0^-}^{t}x(\tau)\,d\tau\right\}=\frac{X(s)}{s}.$$

Proof. Let $g(t)=\int_{0^-}^{t}x\,d\tau$. Then $\dot{g}=x$ and $g(0^-)=0$, so the derivative rule gives $X=sG-0$. $\square$

Integration divides by s; differentiation multiplies by s. The integrator $1/s$ and the differentiator s are the two elementary dynamic operators, and $u(t)\leftrightarrow 1/s$ is the integral of $\delta(t)\leftrightarrow 1$. If the integral starts from an earlier time with a stored value, as for a capacitor voltage $v_C(t)=v_C(0^-)+\frac{1}{C}\int_{0^-}^{t}i\,d\tau$, the transform is $V_C=v_C(0^-)/s+I/(sC)$ — the form used for circuit models in Section 14.9.

Multiplication by t and division by t

Differentiation in s

$$\mathcal{L}\{t\,x(t)\}=-\frac{dX}{ds},\qquad \mathcal{L}\{t^n x(t)\}=(-1)^n\frac{d^nX}{ds^n}.$$

Proof. In the ROC the integral converges uniformly on closed sub-half-planes, so we may differentiate under the integral sign: $\frac{d}{ds}\int x(t)e^{-st}dt = \int(-t)x(t)e^{-st}dt$. $\square$

A by-product: inside its ROC, $X(s)$ is differentiable as a function of the complex variable s, i.e. **analytic** (Ch. 18). Singularities (poles) can only occur on or to the left of the boundary of the ROC.

Integration in s

If $x(t)/t$ has a finite limit as $t \to 0^+$,

$$\mathcal{L}\left\{\frac{x(t)}{t}\right\} = \int_s^\infty X(p)\,dp.$$

Proof sketch. $\int_s^\infty X(p)dp = \int_s^\infty \int_0^\infty x(t)e^{-pt}dt\,dp$; exchanging the order, $\int_s^\infty e^{-pt}dp = e^{-st}/t$, which leaves $\int_0^\infty \frac{x(t)}{t}e^{-st}dt$. $\square$

Worked Example 14.7 — combining t-multiplication and s-shift

Find $\mathcal{L}\{t\,e^{-2t}\sin 3t\}$.

Step 1 (basic pair). $\sin 3t \leftrightarrow \dfrac{3}{s^2+9}$.

Step 2 (multiply by t).

$$t\sin 3t \leftrightarrow -\frac{d}{ds}\frac{3}{s^2+9} = \frac{6s}{(s^2+9)^2}.$$

Step 3 (damp by e^{-2t}: replace s by $s+2$).

$$t\,e^{-2t}\sin 3t \leftrightarrow \frac{6(s+2)}{\big((s+2)^2+9\big)^2} = \frac{6(s+2)}{(s^2+4s+13)^2}.$$

Check. At $s=0$ the formula gives $12/169 = 0.071006$. Direct numerical integration of $\int_0^\infty te^{-2t}\sin 3t\,dt$ gives 0.071006. ✓ The order of steps 2 and 3 does not matter, but doing the s-shift last keeps the algebra simplest.

Worked Example 14.8 — the sine integral by division by t

Find $\mathcal{L}\{\sin t/t\}$ and deduce $\int_0^\infty \frac{\sin t}{t}dt$.

Since $\sin t/t \to 1$ as $t \to 0$, the rule applies:

$$\mathcal{L}\left\{\frac{\sin t}{t}\right\} = \int_s^\infty \frac{dp}{p^2+1} = \frac{\pi}{2} - \arctan s = \arctan\frac{1}{s}.$$

Letting $s \to 0^+$ (justified by Abel's theorem for Laplace integrals, since $\int_0^\infty \sin t/t\,dt$ converges) gives

$$\int_0^\infty \frac{\sin t}{t}dt = \lim_{s\to 0^+}\arctan\frac{1}{s} = \frac{\pi}{2} \approx 1.5708.$$

This integral (the area under the unnormalized sinc) is awkward by elementary methods; here it costs two lines. It reappears in Gibbs' phenomenon in Ch. 15.

Periodic functions

Transform of a periodic function

If $x(t+T) = x(t)$ for $t \geq 0$, and $x_1(t)$ denotes one period (x on $[0,T)$, zero elsewhere) with transform $X_1(s)$, then

$$X(s) = \frac{X_1(s)}{1-e^{-sT}} = \frac{1}{1-e^{-sT}}\int_0^T x(t)e^{-st}dt, \qquad \mathrm{Re}\{s\} > 0.$$

Proof. $x(t) = \sum_{k=0}^\infty x_1(t-kT)$, so by the time-shift rule $X = X_1\sum_{k=0}^\infty e^{-ksT}$, a geometric series with ratio $|e^{-sT}| = e^{-\sigma T} < 1$. $\square$

Worked Example 14.9 — square wave and full-wave rectified sine

(a) A unipolar square wave equals 1 on $[0, T/2)$ and 0 on $[T/2, T)$, repeating with period T. One period is $u(t) - u(t - T/2)$, so $X_1 = (1 - e^{-sT/2})/s$ and

$$X(s) = \frac{1 - e^{-sT/2}}{s(1 - e^{-sT})} = \frac{1}{s\,(1 + e^{-sT/2})},$$

using $1 - e^{-sT} = (1 - e^{-sT/2})(1 + e^{-sT/2})$.

(b) The full-wave rectified sine $|\sin t|$ has period π. One period:

$$\int_0^{\pi} \sin t\, e^{-st}\,dt = \frac{1 + e^{-\pi s}}{s^2 + 1} \quad\Longrightarrow\quad X(s) = \frac{1 + e^{-\pi s}}{(s^2+1)(1 - e^{-\pi s})} = \frac{1}{s^2+1}\coth\frac{\pi s}{2}.$$

Check. At $s = 1$, $\coth(\pi/2)/2 = 0.54517$; numerical integration of $\int_0^\infty |\sin t| e^{-t}dt$ gives 0.54517. ✓ As $s \to 0$, $sX(s) \to 2/\pi \approx 0.6366$, the average value of $|\sin t|$ — a preview of the final-value idea in Section 14.7.

Common Pitfall — shifting in the wrong domain

Multiplication by e^{at} in time shifts in s ($s \to s - a$); multiplication by e^{-sT} in s delays in time. The signs are easy to swap. A quick check: damping ($a < 0$) must move poles to the **left**, and a delay must leave X unchanged in magnitude on the $j\omega$-axis ($|e^{-j\omega T}| = 1$).

Engineering Note — properties as building blocks

The properties map one-to-one onto block-diagram components: $1/s$ is an integrator (an op-amp integrator stage), s a differentiator, e^{-sT} a transport delay (a cable, a sampling latency), and $s \to s/\omega_c$ a frequency scaling of a filter prototype. Circuit simulators that work in the s-domain (small-signal AC analysis) are built on exactly these rules.

14.3 Standard transforms

A working engineer inverts transforms by recognising patterns, so a reliable table is part of the toolkit. This section collects the standard pairs, derives the less obvious ones, and shows how the table is extended with the properties of Section 14.2. All time functions are understood to be multiplied by $u(t)$; a, α, ω, b are real constants unless stated otherwise, n is a non-negative integer, and $\nu > -1$ is real.

Powers of t and the Gamma function

For integer powers, repeated use of the t-multiplication rule on $1 \leftrightarrow 1/s$ gives

$$t^n = t \cdot t^{n-1} \leftrightarrow -\frac{d}{ds}\frac{(n-1)!}{s^n} = \frac{n!}{s^{n+1}}.$$

For non-integer powers, substitute $\tau = st$ (first for real $s > 0$, then extend by analytic continuation):

$$\int_0^\infty t^\nu e^{-st}dt = \frac{1}{s^{\nu+1}}\int_0^\infty \tau^\nu e^{-\tau}d\tau = \frac{\Gamma(\nu+1)}{s^{\nu+1}}, \qquad \nu > -1,$$

where $\Gamma(z) = \int_0^\infty \tau^{z-1}e^{-\tau}d\tau$ is the **Gamma function**. It satisfies $\Gamma(z+1) = z\Gamma(z)$ (integrate by parts), $\Gamma(n+1) = n!$, and $\Gamma(\tfrac12) = \sqrt{\pi}$ (from the Gaussian integral of Ch. 6).

Worked Example 14.10 — half-integer powers

Find $\mathcal{L}\{t^{-1/2}\}$, $\mathcal{L}\{t^{1/2}\}$ and $\mathcal{L}\{t^{3/2}\}$.

$$t^{-1/2} \leftrightarrow \frac{\Gamma(\frac12)}{s^{1/2}} = \sqrt{\frac{\pi}{s}}, \qquad t^{1/2} \leftrightarrow \frac{\Gamma(\frac32)}{s^{3/2}} = \frac{\frac12\sqrt{\pi}}{s^{3/2}}, \qquad t^{3/2} \leftrightarrow \frac{\Gamma(\frac52)}{s^{5/2}} = \frac{\frac34\sqrt{\pi}}{s^{5/2}}.$$

Check. At $s = 1$, $\int_0^\infty t^{3/2}e^{-t}dt = \Gamma(2.5) = 1.32934$, and $\frac34\sqrt{\pi} = 1.32934$. ✓

Transforms with $\sqrt{s}$ arise from distributed systems — diffusion in a semiconductor, heat flow, the RC transmission line — where the "impedance" of an infinitely long line is proportional to $1/\sqrt{s}$, so step responses contain $\sqrt{t}$ and $1/\sqrt{t}$ rather than exponentials.

Exponentials, sinusoids and their products

Everything in this family follows from $e^{at} \leftrightarrow 1/(s-a)$ with complex a, plus linearity and the s-shift. Two further derivations illustrate the technique.

Hyperbolic functions. $\cosh at = \frac12(e^{at} + e^{-at}) \leftrightarrow \frac12\left(\frac{1}{s-a} + \frac{1}{s+a}\right) = \frac{s}{s^2-a^2}$, and similarly $\sinh at \leftrightarrow \frac{a}{s^2-a^2}$ (ROC $\mathrm{Re}\{s\} > |a|$). Compare with cos and sin: only the sign in the denominator changes, mirroring $\cos(jat) = \cosh at$.

$t\sin$ and $t\cos$ (resonance terms). By the t-multiplication rule,

$$t\sin\omega t \leftrightarrow -\frac{d}{ds}\frac{\omega}{s^2+\omega^2} = \frac{2\omega s}{(s^2+\omega^2)^2}, \qquad t\cos\omega t \leftrightarrow -\frac{d}{ds}\frac{s}{s^2+\omega^2} = \frac{s^2-\omega^2}{(s^2+\omega^2)^2}.$$

Combining, $\sin\omega t - \omega t\cos\omega t \leftrightarrow \frac{\omega(s^2+\omega^2) - \omega(s^2-\omega^2)}{(s^2+\omega^2)^2} = \frac{2\omega^3}{(s^2+\omega^2)^2}$. A *repeated* pair of imaginary poles therefore produces an oscillation whose amplitude grows linearly in t — the signature of a lossless system driven at resonance.

Worked Example 14.11 — a general damped sinusoid

Find the transform of $x(t) = A e^{-\alpha t}\cos(\omega t + \phi)$.

Expand the cosine: $\cos(\omega t+\phi) = \cos\phi\cos\omega t - \sin\phi\sin\omega t$. Then, by the s-shift,

$$X(s) = A\,\frac{(s+\alpha)\cos\phi - \omega\sin\phi}{(s+\alpha)^2 + \omega^2}.$$

Numerical case. $A=2$, $\alpha=1$, $\omega=2$, $\phi=\pi/3$: $\cos\phi = 0.5$, $\sin\phi = 0.8660$, so

$$X(s) = \frac{(s+1) - 3.4641}{s^2+2s+5} = \frac{s - 2.4641}{s^2+2s+5}.$$

Check. $x(0) = 2\cos(\pi/3) = 1$; the initial-value theorem (Section 14.7) gives $\lim_{s\to\infty} sX = 1$. ✓ This pair, read backwards, is how complex-conjugate poles are converted to a single real cosine with amplitude and phase (Section 14.5).

Pulses, staircases and other non-smooth signals

Rectangular pulses, staircases and sawtooth waves are written with steps and handled by the time-shift rule. A rectangular pulse of height 1 from $t=a$ to $t=b$ is $u(t-a) - u(t-b) \leftrightarrow \frac{e^{-as}-e^{-bs}}{s}$. A **staircase** $\sum_{k=0}^{\infty} u(t-kT)$ (value $k+1$ on $[kT,(k+1)T)$) has transform $\frac{1}{s}\sum_{k} e^{-ksT} = \frac{1}{s(1-e^{-sT})}$. A sawtooth of slope $1/T$ resetting every T is a ramp minus a staircase: $\frac{t}{T} - \sum_{k\ge 1} u(t-kT) \leftrightarrow \frac{1}{Ts^2} - \frac{e^{-sT}}{s(1-e^{-sT})}$.

Worked Example 14.12 — a finite pulse train

A gate signal consists of three unit pulses of width 1 ms starting at $t = 0$, 3 ms and 6 ms. Find its transform (work in milliseconds, so s is in ms^{-1}).

Each pulse is $u(t-t_k) - u(t-t_k-1) \leftrightarrow e^{-st_k}(1-e^{-s})/s$. Summing over $t_k = 0, 3, 6$:

$$X(s) = \frac{1-e^{-s}}{s}\left(1 + e^{-3s} + e^{-6s}\right) = \frac{(1-e^{-s})(1-e^{-9s})}{s(1-e^{-3s})},$$

the last form using the finite geometric sum $1 + r + r^2 = (1-r^3)/(1-r)$ with $r = e^{-3s}$.

Check. As $s\to 0$, $X(s) \to$ total area: $\frac{(s)(9s)}{s\cdot 3s} = 3$ ms. Three pulses of 1 ms each. ✓

The standard transform table

Table of unilateral Laplace transforms

(All $x(t)$ are for $t \ge 0$, i.e. implicitly multiplied by $u(t)$.)

#	$x(t)$	$X(s)$	ROC
1	$\delta(t)$	1	all s
2	$\delta(t-T),\ T\ge 0$	e^{-sT}	all s
3	$\delta^{(n)}(t)$	s^n	all s
4	$u(t)$	$\dfrac{1}{s}$	$\sigma > 0$
5	$u(t-T)$	$\dfrac{e^{-sT}}{s}$	$\sigma > 0$
6	$u(t-a)-u(t-b),\ 0\le a<b$	$\dfrac{e^{-as}-e^{-bs}}{s}$	all s
7	t	$\dfrac{1}{s^2}$	$\sigma > 0$
8	t^n	$\dfrac{n!}{s^{n+1}}$	$\sigma > 0$

Worked Example 14.13 — extending the table: a logarithmic pair

Verify entry 36, $\dfrac{e^{-bt}-e^{-at}}{t} \leftrightarrow \ln\dfrac{s+a}{s+b}$.

The numerator $x(t)=e^{-bt}-e^{-at}$ has $X(p)=\frac{1}{p+b}-\frac{1}{p+a}$, and $x(t)/t \to a-b$ (finite) as $t\to 0$. Dividing by t:

$$\int_s^\infty \left(\frac{1}{p+b}-\frac{1}{p+a}\right)dp = \left[\ln\frac{p+b}{p+a}\right]_s^\infty = 0-\ln\frac{s+b}{s+a}=\ln\frac{s+a}{s+b}.$$

Corollary (Frullani integral). Letting $s\to 0$: $\int_0^\infty \frac{e^{-bt}-e^{-at}}{t}dt=\ln\frac{a}{b}$. For $a=2, b=1$ this is $\ln 2 = 0.693147$; numerical quadrature gives 0.693147. ✓

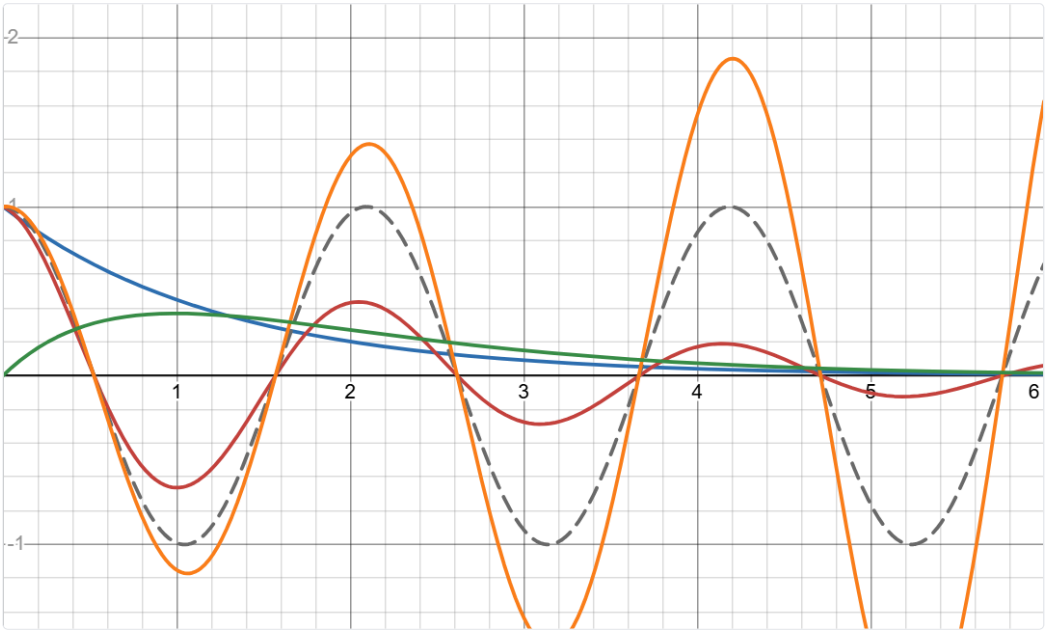
Worked Example 14.14 — $\sin^2\omega t$ two ways

Identity. $\sin^2\omega t=\frac{1}{2}(1-\cos 2\omega t)\leftrightarrow \frac{1}{2}\left(\frac{1}{s}-\frac{s}{s^2+4\omega^2}\right)=\frac{2\omega^2}{s(s^2+4\omega^2)}$.

Derivative rule. Let $x=\sin^2\omega t$: $x(0^-)=0$, $\dot{x}=2\omega\sin\omega t\cos\omega t=\omega\sin 2\omega t\leftrightarrow\frac{2\omega^2}{s^2+4\omega^2}$. Since $\mathcal{L}\{\dot{x}\}=sX$, dividing by s gives the same result. ✓

The second route is often faster when the derivative is simpler than the function.

The table shows a pattern worth internalising: **the denominator of $X(s)$ encodes the modes, the numerator encodes how much of each mode is present.** The roots of the denominator — the poles — determine the *shape* of the signal: a real pole $-a$ gives e^{-at}, a pair $-\alpha\pm j\omega$ gives $e^{-\alpha t}\cos(\omega t+\phi)$, a repeated pole multiplies by powers of t.



Pole location and time shape: real pole at -0.8 (blue); poles $-0.4\pm j3$ (red, decaying oscillation); poles $\pm j3$ (grey dashed, sustained); poles $0.15\pm j3$ (orange, growing); double pole at -1 giving te^{-t} (green).

Common Pitfall — misreading ω in the denominator

In $\dfrac{1}{s^2+9}$ the frequency is $\omega=3$, not 9, and the numerator needed for a pure sine is $\omega=3$: $\dfrac{1}{s^2+9}=\dfrac{1}{3}\cdot\dfrac{3}{s^2+9}\leftrightarrow\dfrac{1}{3}\sin 3t$. Forgetting the $\frac{1}{3}$ is one of the most frequent errors in inversion. Always check the value at $t=0^+$ or the DC gain as a sanity test.

Engineering Note — where the exotic entries appear

Entries 9–11 and 39–40 (fractional powers, $\sqrt{s}$, erfc) describe diffusion: carrier diffusion in a diode, heat spreading into a heatsink, and the step response of a long RC line (on-chip interconnect, the original transatlantic telegraph cable). Entry 38 (J_0) appears in cylindrical problems such as skin effect in round wires. Entries 41–44 describe clock and switching waveforms in power electronics.

14.4 Inverse Laplace transforms

Solving a problem in the s-domain is only half the job; the answer must be returned to the time domain, where voltages and currents are measured. The inverse transform does this. In practice we almost never evaluate an inversion integral: we rearrange $X(s)$ into a sum of table entries and read off the time function, using uniqueness (Lerch's theorem, Section 14.1) to guarantee the answer is the only one.

Definition and the inversion integral

Inverse Laplace transform

If $X(s) = \mathcal{L}\{x(t)\}$, then $x(t) = \mathcal{L}^{-1}\{X(s)\}$ is the **inverse Laplace transform** of X. By Lerch's theorem it is unique for $t > 0$ apart from values at isolated points. The inverse is linear: $\mathcal{L}^{-1}\{aX + bY\} = a\,x + b\,y$.

There is an explicit formula. Writing $s = \sigma + j\omega$ with fixed σ in the ROC, the Laplace transform of $x(t)$ is the Fourier transform of $x(t)e^{-\sigma t}u(t)$. Applying the inverse Fourier transform of Ch. 16 and multiplying by $e^{\sigma t}$ gives the following.

Bromwich inversion integral

If $X(s)$ is the transform of $x(t)$ with abscissa of convergence σ_c, then for any $\gamma > \sigma_c$,

$$x(t) = \frac{1}{2\pi j}\int_{\gamma - j\infty}^{\gamma + j\infty} X(s)\,e^{st}\,ds, \qquad t > 0,$$

where the integral is along the vertical line $\operatorname{Re}\{s\} = \gamma$ (to the right of all singularities). At a jump discontinuity the integral returns the midpoint $\tfrac{1}{2}[x(t^-) + x(t^+)]$; for $t < 0$ it returns 0.

Derivation sketch. $X(\gamma + j\omega) = \int_0^\infty \left[x(t)e^{-\gamma t}\right]e^{-j\omega t}dt$ is the Fourier transform of $g(t) = x(t)e^{-\gamma t}u(t)$, which is absolutely integrable because $\gamma > \sigma_c$. Fourier inversion gives $g(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\gamma + j\omega)e^{j\omega t}d\omega$. Multiply both sides by $e^{\gamma t}$ and change variable to $s = \gamma + j\omega$, $ds = j\,d\omega$. $\square$

This is a contour integral in the complex plane. For $t > 0$ the line can be closed by a large semicircle to the left; when $X(s)$ is rational the semicircle contributes nothing, and the **residue theorem** turns the integral into a finite sum:

$$x(t) = \sum_{\text{poles } p_k \text{ of } X} \operatorname{Res}_{s = p_k}\left[X(s)e^{st}\right], \qquad t > 0.$$

Closing the contour, Jordan's lemma, and the computation of residues are the subject of Ch. 18. The partial-fraction method of Section 14.5 is exactly this residue sum carried out with algebra, so for rational functions nothing is lost by using tables.

Inversion by table and properties

The working method is:

1. **Separate delays.** Collect terms by their factor e^{-sT}; invert each coefficient and then apply the delay $t \to t - T$ with $u(t - T)$.
2. **Reduce to proper rational form.** If the degree of the numerator is not less than that of the denominator, divide (polynomial long division); the polynomial part inverts to impulses and their derivatives.
3. **Expand in partial fractions** (Section 14.5) or, for a single quadratic factor, **complete the square**.
4. **Read the table**, using the s-shift to absorb $s + \alpha$ and adjusting constants so each term matches a table entry exactly.
5. **Check** at least one value: $x(0^+) = \lim_{s\to\infty} sX(s)$, or the final value, or X at a convenient real s.

Worked Example 14.15 — completing the square

Find $\mathcal{L}^{-1}\left\{\dfrac{2s + 12}{s^2 + 2s + 5}\right\}$.

Complete the square. $s^2 + 2s + 5 = (s + 1)^2 + 4$: the poles are $-1 \pm j2$, so expect e^{-t} times sinusoids of frequency 2 rad/s.

Rewrite the numerator in terms of $s + 1$. $2s + 12 = 2(s + 1) + 10$:

$$X(s) = 2\,\frac{s + 1}{(s + 1)^2 + 2^2} + 5 \cdot \frac{2}{(s + 1)^2 + 2^2}.$$

Table entries 23 and 24.

$$x(t) = e^{-t}\,(2\cos 2t + 5\sin 2t) = \sqrt{29}\,e^{-t}\cos(2t - 1.1903),$$

using $A\cos\theta + B\sin\theta = \sqrt{A^2 + B^2}\cos(\theta - \arctan(B/A))$ with $\arctan(5/2) = 1.1903$ rad.

Check. $x(0^+) = 2$, and $\lim_{s\to\infty} sX = \lim \frac{2s^2 + 12s}{s^2 + 2s + 5} = 2$. ✓ Also $X(0) = 12/5 = 2.4$; numerically $\int_0^\infty e^{-t}(2\cos 2t + 5\sin 2t)dt = 2 \cdot \frac{1}{5} + 5 \cdot \frac{2}{5} = 2.4$. ✓

Worked Example 14.16 — a delayed response

Find $\mathcal{L}^{-1}\left\{\dfrac{3e^{-2s}}{s(s + 3)}\right\}$.

Invert the coefficient. By entry 15 with $a = 3$: $\dfrac{3}{s(s + 3)} \leftrightarrow 1 - e^{-3t}$.

Apply the delay ($T = 2$): replace t by $t - 2$ and multiply by $u(t - 2)$:

$$x(t) = \left(1 - e^{-3(t-2)}\right)u(t - 2).$$

This is the response of a first-order system with time constant $\frac{1}{3}$ s to a step applied at $t = 2$ s. A common slip is to write $(1 - e^{-3t})u(t - 2)$, which jumps discontinuously at $t = 2$ to $1 - e^{-6}$ instead of starting smoothly from 0.

Worked Example 14.17 — repeated quadratic factor via the table

Find $\mathcal{L}^{-1}\left\{\dfrac{s}{(s^2+4)^2}\right\}$ and $\mathcal{L}^{-1}\left\{\dfrac{1}{(s^2+4)^2}\right\}$.

First. Entry 27 with $\omega = 2$: $\dfrac{4s}{(s^2+4)^2} \leftrightarrow t\sin 2t$, hence $\dfrac{s}{(s^2+4)^2} \leftrightarrow \dfrac{t\sin 2t}{4}$.

Second. Entry 29 with $\omega = 2$: $\dfrac{16}{(s^2+4)^2} \leftrightarrow \sin 2t - 2t\cos 2t$, hence

$$\frac{1}{(s^2+4)^2} \leftrightarrow \frac{\sin 2t - 2t\cos 2t}{16}.$$

Cross-check with the integral rule. $\frac{1}{(s^2+4)^2} = \frac{1}{s}\cdot\frac{s}{(s^2+4)^2}$, so the answer must equal $\int_0^t \frac{\tau\sin 2\tau}{4}\,d\tau = \frac{1}{4}\left[\frac{\sin 2\tau}{4} - \frac{\tau\cos 2\tau}{2}\right]_0^t = \frac{\sin 2t - 2t\cos 2t}{16}$. ✓

Worked Example 14.18 — several delays: a triangular pulse

Find and sketch $\mathcal{L}^{-1}\left\{\dfrac{1-2e^{-s}+e^{-2s}}{s^2}\right\}$, and identify the waveform.

Separate by delay. The coefficient of each exponential is $1/s^2 \leftrightarrow t$, so

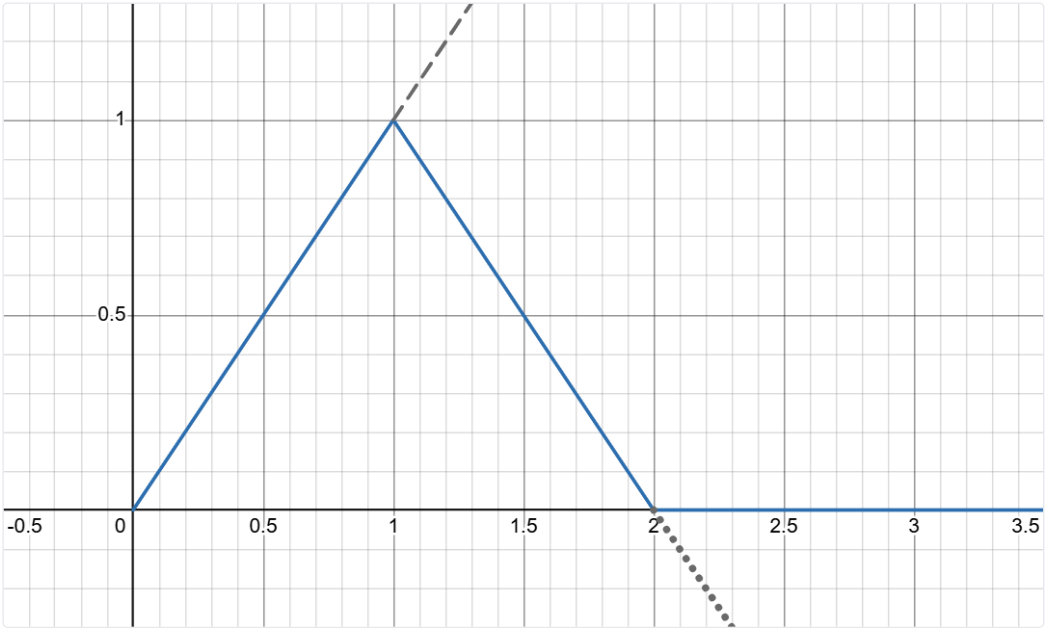
$$x(t) = t\,u(t) - 2(t-1)\,u(t-1) + (t-2)\,u(t-2).$$

Evaluate piece by piece.

- $0 \le t < 1$: $x = t$ (rising ramp).
- $1 \le t < 2$: $x = t - 2(t-1) = 2 - t$ (falling ramp).
- $t \ge 2$: $x = t - 2t + 2 + t - 2 = 0$.

The signal is a **triangular pulse** of height 1 at $t = 1$ and base 2. Note also that $\frac{(1-e^{-s})^2}{s^2} = \left(\frac{1-e^{-s}}{s}\right)^2$: the triangle is the convolution of a unit rectangular pulse with itself (Section 14.6).

Check. Area: $X(0) = \lim_{s\to 0}\frac{(1-e^{-s})^2}{s^2} = 1$, and the triangle's area is $\frac{1}{2}\cdot 2\cdot 1 = 1$ ✓.



Example 14.18: the ramp t (grey dashed beyond $t = 1$) is bent down by $-2(t-1)u(t-1)$ (grey dotted beyond $t = 2$) and levelled by $(t-2)u(t-2)$, producing the triangular pulse (blue).

Non-rational transforms

Transforms involving logarithms, inverse tangents or square roots cannot be split into partial fractions. Two tricks often work.

- **Differentiate in s.** If $X'(s)$ is rational, invert it and use $\mathcal{L}^{-1}\{X'\} = -t\,x(t)$, so $x(t) = -\frac{1}{t}\mathcal{L}^{-1}\{X'(s)\}$.
- **Recognise a scaled or shifted table entry**, e.g. $1/\sqrt{s+a} \leftrightarrow e^{-at}/\sqrt{\pi t}$ by the s-shift of entry 10.

Worked Example 14.19 — inverting an arctangent

Find $\mathcal{L}^{-1}\left\{\arctan\dfrac{2}{s}\right\}$.

Differentiate. $\dfrac{d}{ds}\arctan\dfrac{2}{s} = \dfrac{1}{1+4/s^2}\cdot\left(-\dfrac{2}{s^2}\right) = -\dfrac{2}{s^2+4} \leftrightarrow -\sin 2t$.

Undo the t-multiplication. Since $-t\,x(t) = -\sin 2t$,

$$x(t) = \frac{\sin 2t}{t},$$

agreeing with entry 35. **Check.** $x(0^+) = 2$; and $\lim_{s\to\infty} s\arctan(2/s) = \lim s\cdot\frac{2}{s} = 2$. ✓

Common Pitfall — not every function of s is a transform

By the existence theorem, a genuine transform of an ordinary function satisfies $X(s)\to 0$ as $\mathrm{Re}\{s\}\to\infty$. Functions such as s, $s^2/(s+1)$ or e^{+sT} do not; the first two contain impulses or their derivatives (handled after long division), and e^{sT} would be an *advance*, which no causal signal has. If an analysis produces e^{+sT}, a sign error has been made.

Engineering Note — numerical inversion

When $X(s)$ is known only numerically (e.g. from a measured impedance or a transmission-line model with $\sqrt{s}$), engineers use numerical Laplace inversion: the Talbot method deforms the Bromwich line into a contour where e^{st} decays rapidly, and the Stehfest algorithm uses only real values of $X(s)$. Both are standard in circuit-simulation and geophysics codes (Ch. 22).

14.5 Partial fractions

Almost every transform produced by a lumped circuit or a constant-coefficient ODE is a **rational function** — a ratio of polynomials in s:

$$X(s) = \frac{N(s)}{D(s)} = \frac{b_m s^m + \cdots + b_1 s + b_0}{a_n s^n + \cdots + a_1 s + a_0}.$$

Partial-fraction expansion rewrites it as a sum of simple terms, each of which is a table entry. Because each term corresponds to one *mode* (pole) of the system, the expansion is also a modal decomposition: it tells us how strongly each natural frequency is excited.

Proper and improper rational functions

$X(s)$ is **strictly proper** if $m < n$. Only strictly proper functions are transforms of ordinary functions (Section 14.4). If $m \ge n$, long division gives

$$X(s) = Q(s) + \frac{R(s)}{D(s)}, \qquad \deg R < \deg D,$$

and the polynomial quotient $Q(s) = c_0 + c_1 s + \cdots$ inverts to $c_0\delta(t) + c_1\dot\delta(t) + \cdots$. Physically, an improper transfer function is a differentiator: such terms appear for idealised elements (the current through an ideal capacitor driven by a voltage step), and they are a warning that the model has no high-frequency roll-off.

The expansion theorem

Factor the denominator over $\mathbb{C}$: $D(s) = a_n\prod_k (s-p_k)^{r_k}$, where the p_k are the distinct **poles** with multiplicities r_k, $\sum r_k = n$.

Partial-fraction expansion

A strictly proper rational function can be written uniquely as

$$\frac{N(s)}{D(s)} = \sum_{k}\sum_{i=1}^{r_k}\frac{K_{k,i}}{(s-p_k)^i},$$

with the coefficients of the highest power at each pole and the others given by

$$K_{k,r_k} = \Big[(s-p_k)^{r_k}X(s)\Big]_{s=p_k}, \qquad K_{k,r_k-j} = \frac{1}{j!}\frac{d^j}{ds^j}\Big[(s-p_k)^{r_k}X(s)\Big]_{s=p_k}, \quad j=1,\dots,r_k-1.$$

The inverse transform is then

$$x(t) = \sum_k e^{p_k t}\sum_{i=1}^{r_k} K_{k,i}\,\frac{t^{\,i-1}}{(i-1)!}, \qquad t>0.$$

Why the formulas work. Multiply the expansion by $(s-p_k)^{r_k}$. Every term belonging to another pole acquires a factor $(s-p_k)^{r_k}$ and vanishes at $s=p_k$, while the terms belonging to p_k become the polynomial $K_{k,r_k} + K_{k,r_k-1}(s-p_k) + \cdots + K_{k,1}(s-p_k)^{r_k-1}$. Evaluating it and its derivatives at $s=p_k$ isolates the coefficients one at a time — this is just Taylor's theorem. Existence and uniqueness follow from the fact that the n functions $(s-p_k)^{-i}$ are linearly independent and n coefficients match n degrees of freedom of N. The inverse formula uses entry 14 with the s-shift. □

For a **simple pole** ($r_k = 1$), the coefficient K_k is the **residue** of X at p_k. Since $D(p_k)=0$, L'Hôpital's rule gives a useful alternative.

Heaviside expansion formula (simple poles)

If all poles p_k of N/D are simple,

$$K_k = \left.\frac{N(s)}{D'(s)}\right|_{s=p_k}, \qquad x(t) = \sum_k \frac{N(p_k)}{D'(p_k)}\, e^{p_k t}.$$

This avoids factoring D symbolically: only its roots are needed, which a computer finds numerically.

Case 1 — distinct real poles: the cover-up rule

For a simple real pole, $K_k = [(s-p_k)X(s)]_{s=p_k}$: "cover up" the factor $(s-p_k)$ in the denominator and substitute $s=p_k$ in what remains.

Worked Example 14.20 — three real poles

Invert $X(s) = \dfrac{3s+7}{(s+1)(s+2)(s+3)}$.

Form. $X = \dfrac{K_1}{s+1} + \dfrac{K_2}{s+2} + \dfrac{K_3}{s+3}$.

Cover-up.

$$K_1 = \left.\frac{3s+7}{(s+2)(s+3)}\right|_{s=-1} = \frac{4}{(1)(2)} = 2, \quad K_2 = \left.\frac{3s+7}{(s+1)(s+3)}\right|_{s=-2} = \frac{1}{(-1)(1)} = -1, \quad K_3 = \left.\frac{3s+7}{(s+1)(s+2)}\right|_{s=-3} = \frac{-2}{(-2)(-1)} = -1.$$

Heaviside check. $D = s^3+6s^2+11s+6$, $D' = 3s^2+12s+11$: $D'(-1)=2$, $D'(-2)=-1$, $D'(-3)=2$, so $K_1 = 4/2 = 2$, $K_2 = 1/(-1) = -1$, $K_3 = -2/2 = -1$. ✓

Inverse.

$$x(t) = 2e^{-t} - e^{-2t} - e^{-3t}, \qquad t \geq 0.$$

Check. $x(0^+) = 2-1-1 = 0$, consistent with $\lim sX = \lim \frac{3s^2}{s^3} = 0$. Also $X(0) = 7/6$ and $\int_0^\infty x\,dt = 2 - \frac{1}{2} - \frac{1}{3} = \frac{7}{6}$. ✓

Case 2 — repeated poles

A pole of multiplicity r needs r terms. The top coefficient comes from the cover-up rule; the lower ones need derivatives (or, often more simply, comparison of coefficients or substitution of convenient values of s).

Worked Example 14.21 — a triple pole

Invert $X(s) = \dfrac{s^2+2s+5}{(s+1)^3(s+2)}$.

Form. $X = \dfrac{A_3}{(s+1)^3} + \dfrac{A_2}{(s+1)^2} + \dfrac{A_1}{s+1} + \dfrac{B}{s+2}$.

Simple pole. $B = \left.\dfrac{s^2+2s+5}{(s+1)^3}\right|_{s=-2} = \dfrac{5}{-1} = -5$.

Triple pole. Let $g(s) = (s+1)^3 X(s) = \dfrac{s^2+2s+5}{s+2}$. Division gives $g(s) = s + \dfrac{5}{s+2}$, which is easy to differentiate:

$$g(-1) = -1+5 = 4, \qquad g'(s) = 1 - \frac{5}{(s+2)^2} \Rightarrow g'(-1) = -4, \qquad g''(s) = \frac{10}{(s+2)^3} \Rightarrow \tfrac{1}{2}g''(-1) = 5.$$

So $A_3 = 4$, $A_2 = -4$, $A_1 = 5$.

Sanity check of coefficients. For large s, $X \approx 1/s^2$, so the $1/s$ terms must cancel: $A_1 + B = 5 - 5 = 0$. ✓

Inverse (entry 14):

$$x(t) = \left(2t^2 - 4t + 5\right) e^{-t} - 5e^{-2t}.$$

Check. $x(0^+) = 0$ ✓ (matches $\lim sX = 0$). At $s=0$: $X(0) = 5/2$; from the expansion $4 - 4 + 5 - \frac{5}{2} = \frac{5}{2}$. ✓

Case 3 — complex-conjugate poles

If D has real coefficients, complex poles occur in conjugate pairs $p, \bar{p} = -\alpha \pm j\beta$, and their coefficients are conjugates, K and $\bar{K}$. Their combined contribution is real:

$$Ke^{pt} + \bar{K}e^{\bar{p}t} = 2\,\mathrm{Re}\{Ke^{pt}\} = 2|K|e^{-\alpha t}\cos\left(\beta t + \angle K\right).$$

Complex-pole pair

If $X(s)$ has simple poles at $-\alpha \pm j\beta$ with residue $K = [(s+\alpha-j\beta)X(s)]_{s=-\alpha+j\beta}$ at the upper pole, their contribution to $x(t)$ is

$$2|K|\, e^{-\alpha t}\cos(\beta t + \angle K).$$

Two equivalent working methods exist:

- **Complex residues** (above): compute one complex number per pair and write amplitude and phase directly. Efficient, and natural for numerical work.
- **Real quadratic factor:** keep $(s+\alpha)^2+\beta^2$ intact with numerator $Bs+C$, find B, C by comparing coefficients, then complete the square as in Example 14.15. Avoids complex arithmetic and is often quicker by hand.

Worked Example 14.22 — one real pole and a complex pair, both methods

Invert $X(s) = \dfrac{s+3}{(s+1)(s^2+4s+13)}$.

The quadratic has roots $-2 \pm j3$.

Real pole (cover-up). $A = \left.\dfrac{s+3}{s^2+4s+13}\right|_{s=-1} = \dfrac{2}{10} = \dfrac{1}{5}$.

Method 1 — real quadratic. Write $X = \dfrac{1/5}{s+1} + \dfrac{Bs+C}{s^2+4s+13}$ and clear denominators:

$$s+3 = \tfrac{1}{5}(s^2+4s+13) + (Bs+C)(s+1).$$

s^2: $0 = \frac{1}{5} + B \Rightarrow B = -\frac{1}{5}$. Constant: $3 = \frac{13}{5} + C \Rightarrow C = \frac{2}{5}$. Then

$$\frac{-\frac{1}{5}s + \frac{2}{5}}{(s+2)^2+9} = -\frac{1}{5}\,\frac{(s+2)-4}{(s+2)^2+9} = -\frac{1}{5}\,\frac{s+2}{(s+2)^2+9} + \frac{4}{15}\,\frac{3}{(s+2)^2+9},$$

so

$$x(t) = \tfrac{1}{5}e^{-t} + e^{-2t}\left(-\tfrac{1}{5}\cos 3t + \tfrac{4}{15}\sin 3t\right).$$

Method 2 — complex residue. At $p = -2+j3$:

$$K = \left.\frac{s+3}{(s+1)(s+2+j3)}\right|_{s=-2+j3} = \frac{1+j3}{(-1+j3)(j6)} = \frac{1+j3}{-18-j6} = -0.1 - j0.1333.$$

$|K| = \frac{1}{6}$, $\angle K = -2.2143$ rad ($-126.87°$). The pair contributes $\frac{1}{3}e^{-2t}\cos(3t - 2.2143)$. Expanding, $\frac{1}{3}[\cos(2.2143)\cos 3t + \sin(2.2143)\sin 3t] = \frac{1}{3}[-0.6\cos 3t + 0.8\sin 3t] = -\frac{1}{5}\cos 3t + \frac{4}{15}\sin 3t$. ✓ Both methods agree.

Check. $x(0^+) = \frac{1}{5} - \frac{1}{5} = 0$ ✓; at $t = 0.7$ both forms give 0.18098.

Case 4 — improper functions

Worked Example 14.23 — long division first

Invert $X(s) = \dfrac{s^3+2s^2+3s+1}{s^2+s+1}$.

Divide. $s^3+2s^2+3s+1 = (s+1)(s^2+s+1) + s$, so

$$X(s) = s + 1 + \frac{s}{s^2+s+1}.$$

Proper part. $s^2+s+1 = (s+\frac{1}{2})^2 + \frac{3}{4}$, and $s = (s+\frac{1}{2}) - \frac{1}{2}$:

$$\frac{s}{s^2+s+1} = \frac{s+\frac{1}{2}}{(s+\frac{1}{2})^2+\frac{3}{4}} - \frac{1}{\sqrt{3}}\cdot\frac{\frac{\sqrt{3}}{2}}{(s+\frac{1}{2})^2+\frac{3}{4}}.$$

Inverse.

$$x(t) = \dot{\delta}(t) + \delta(t) + e^{-t/2}\left(\cos\frac{\sqrt{3}}{2}t - \frac{1}{\sqrt{3}}\sin\frac{\sqrt{3}}{2}t\right)u(t).$$

The impulse terms are a genuine part of the answer. If X were a transfer function, the system would differentiate its input — physically unrealisable at high frequencies, which is why practical transfer functions are proper.

Choosing a method, and checking

Situation	Fastest method
Distinct real poles	Cover-up (or N/D')
Repeated pole, low multiplicity	Cover-up for top term, then compare coefficients or substitute a value of s
Repeated pole, high multiplicity	Derivative formula, after simplifying $g(s) = (s-p)^r X$
One complex pair, hand work	Real quadratic + completing the square
Several complex pairs, numerical	Complex residues, amplitude–phase form
$\deg N \geq \deg D$	Long division first

Common Pitfall — too few terms for a repeated pole

Writing $\dfrac{1}{(s+1)^2(s+2)} = \dfrac{A}{(s+1)^2} + \dfrac{B}{s+2}$ is wrong: there are three unknowns' worth of freedom ($\deg D = 3$) and the term $\dfrac{C}{s+1}$ is missing. The correct expansion is $\dfrac{1}{(s+1)^2} - \dfrac{1}{s+1} + \dfrac{1}{s+2}$. A quick count — the number of coefficients must equal $\deg D$ — catches this every time.

Engineering Note — residues as modal amplitudes

In a circuit response, each coefficient K_k is the initial amplitude of mode $e^{p_k t}$. A pole with a tiny residue is barely excited and can often be dropped (*dominant-pole approximation*); a pole and zero that nearly coincide (a "doublet") produce a small residue and a slow, low-amplitude tail that can still matter for settling time in precision amplifiers. Computer tools (`residue` in MATLAB, `scipy.signal.residue` in Python) implement the Heaviside formula with numerical root-finding.

14.6 Convolution theorem

Partial fractions invert *sums*; the convolution theorem inverts *products*. It answers the question "if I know the time functions for $F(s)$ and $G(s)$, what time function has transform $F(s)G(s)$?" The answer — their convolution — is also the central formula of linear system theory: the output of a linear time-invariant system is the convolution of its input with its impulse response.

Definition

Convolution of causal signals

For functions f, g defined on $t \geq 0$ (zero for $t < 0$), the **convolution** is

$$(f * g)(t) = \int_{0^-}^{t} f(\tau)\, g(t-\tau)\, d\tau, \qquad t \geq 0.$$

For general (two-sided) signals the integral runs over $(-\infty, \infty)$; for causal signals the integrand vanishes outside $0 \leq \tau \leq t$, giving the finite limits above. The operation "flip g, slide it by t, multiply by f, integrate" is linear in each argument and

- commutative: $f * g = g * f$ (substitute $\tau' = t - \tau$);
- associative: $(f * g) * h = f * (g * h)$;
- distributive: $f * (g + h) = f * g + f * h$;
- has identity δ: $f * \delta = f$, and $f * \delta(t - T) = f(t - T)u(t - T)$;
- $f * u$ is the running integral: $(f * u)(t) = \int_0^t f(\tau) d\tau$.

The theorem

Convolution theorem

If $f \leftrightarrow F(s)$ and $g \leftrightarrow G(s)$, both of exponential order, then

$$\mathcal{L}\{(f * g)(t)\} = F(s)\, G(s),$$

on the intersection of the ROCs. Equivalently, $\mathcal{L}^{-1}\{F(s)G(s)\} = \int_0^t f(\tau) g(t-\tau) d\tau$.

Proof. Write the convolution with a step so that the upper limit becomes infinite:

$$\mathcal{L}\{f * g\} = \int_0^\infty e^{-st} \int_0^\infty f(\tau)\, g(t-\tau)\, u(t-\tau)\, d\tau\, dt.$$

For s in both ROCs the double integral converges absolutely, so the order of integration can be exchanged (Fubini's theorem, Ch. 6):

$$= \int_0^\infty f(\tau) \left[\int_\tau^\infty g(t-\tau) e^{-st} dt \right] d\tau = \int_0^\infty f(\tau)\, e^{-s\tau} G(s)\, d\tau = F(s)G(s),$$

where the inner integral was evaluated with $t' = t - \tau$ exactly as in the time-shift theorem. $\square$

The region of integration is the wedge $0 \leq \tau \leq t$ in the (τ, t) plane; swapping the order means integrating first over t from τ to ∞ — a picture worth drawing once.

Impulse response and the system equation

Consider an LTI system initially at rest. If the input $x(t) = \delta(t)$ produces the output $h(t)$ — the **impulse response** — then by linearity and time invariance the input $x(\tau)\delta(t-\tau)\, d\tau$ produces $x(\tau)h(t-\tau)\, d\tau$, and summing over all τ:

$$y(t) = \int_{0^-}^{t} x(\tau)\, h(t-\tau)\, d\tau = (x * h)(t) \quad \Longleftrightarrow \quad Y(s) = H(s)X(s).$$

The function $H(s) = \mathcal{L}\{h(t)\}$ is the **transfer function** (Section 14.9). Convolution in time — an integral over the whole past of the input — becomes multiplication in s. This is the deepest reason the Laplace transform simplifies linear-system analysis.

A related form, **Duhamel's integral**, uses the step response $a(t) = \int_0^t h\,d\tau$ instead: since $HX = (sA)X = A\,(sX)$, the response is $y(t) = x(0^-)a(t) + \int_0^t \dot{x}(\tau)a(t-\tau)d\tau$. It is useful when the step response has been measured experimentally.

Worked Example 14.24 — inverting a product by convolution

Find $\mathcal{L}^{-1}\left\{\dfrac{1}{s^2(s+1)}\right\}$ by convolution and confirm by partial fractions.

Factor. $F = 1/s^2 \leftrightarrow t$, $G = 1/(s+1) \leftrightarrow e^{-t}$.

Convolve (choose the order that makes the integral easiest; here put the exponential in the shifted slot):

$$\int_0^t \tau\, e^{-(t-\tau)}d\tau = e^{-t}\int_0^t \tau e^{\tau}d\tau = e^{-t}\Big[(\tau-1)e^{\tau}\Big]_0^t = e^{-t}\big[(t-1)e^t + 1\big] = t - 1 + e^{-t}.$$

Partial fractions. $\dfrac{1}{s^2(s+1)} = \dfrac{1}{s^2} - \dfrac{1}{s} + \dfrac{1}{s+1} \leftrightarrow t - 1 + e^{-t}$. ✓ (Table entry 18 with $a = 1$.)

Worked Example 14.25 — a repeated quadratic by convolution

Find $\mathcal{L}^{-1}\left\{\dfrac{1}{(s^2+1)^2}\right\}$.

$\dfrac{1}{(s^2+1)^2} = \dfrac{1}{s^2+1}\cdot\dfrac{1}{s^2+1} \leftrightarrow \sin t * \sin t$. Using $\sin A \sin B = \tfrac{1}{2}[\cos(A-B) - \cos(A+B)]$:

$$\int_0^t \sin\tau\,\sin(t-\tau)\,d\tau = \frac{1}{2}\int_0^t \big[\cos(2\tau - t) - \cos t\big]d\tau = \frac{1}{2}\left[\frac{\sin(2\tau - t)}{2}\right]_0^t - \frac{t\cos t}{2} = \frac{\sin t}{2} - \frac{t\cos t}{2}.$$

So $\mathcal{L}^{-1}\{(s^2+1)^{-2}\} = \tfrac{1}{2}(\sin t - t\cos t)$, entry 29 with $\omega = 1$. ✓ Partial fractions cannot simplify $(s^2+1)^{-2}$ further over the reals, so convolution (or the table) is the natural route.

Worked Example 14.26 — pulse response of an RC low-pass filter

An RC low-pass filter with $RC = 1$ ms has impulse response $h(t) = \frac{1}{RC}e^{-t/RC}u(t)$. Find the output for a 1 V input pulse lasting 1 ms. Work in milliseconds so $h(t) = e^{-t}$.

Time domain. The input is $x(t) = u(t) - u(t-1)$. For $0 \le t < 1$ the pulse overlaps $[0, t]$:

$$y(t) = \int_0^t 1\cdot e^{-(t-\tau)}d\tau = 1 - e^{-t}.$$

For $t \ge 1$ only $[0, 1]$ contributes:

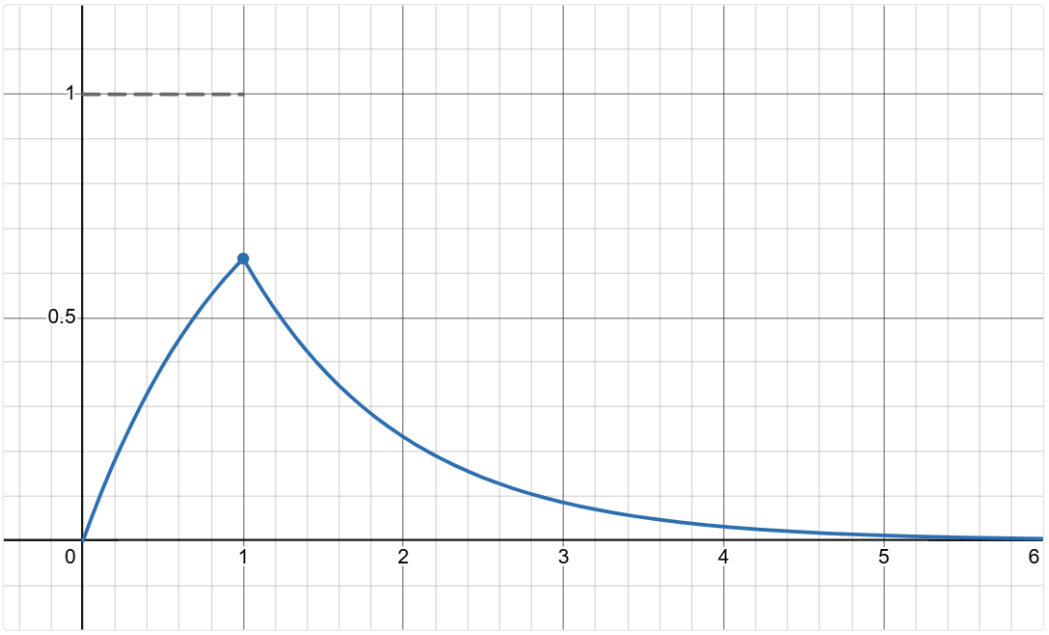
$$y(t) = \int_0^1 e^{-(t-\tau)}d\tau = e^{-t}(e-1).$$

s-domain. $Y = HX = \dfrac{1}{s+1}\cdot\dfrac{1-e^{-s}}{s} = (1-e^{-s})\left(\dfrac{1}{s} - \dfrac{1}{s+1}\right)$, so

$$y(t) = (1 - e^{-t})u(t) - \big(1 - e^{-(t-1)}\big)u(t-1).$$

For $t \ge 1$: $1 - e^{-t} - 1 + e^{-t+1} = e^{-t}(e-1)$. ✓ Both routes agree; the s-domain route needed no case analysis.

Numbers. Peak at $t = 1$ ms: $y = 1 - e^{-1} = 0.632$ V; at $t = 3$ ms: $y = (e-1)e^{-3} = 0.0855$ V.



Response of an RC low-pass filter ($RC = 1$ ms) to a 1 V, 1 ms pulse (grey): the capacitor charges toward 1 V while the pulse lasts, then discharges exponentially (Example 14.26; time in ms).

Worked Example 14.27 — a Volterra integral equation

Solve $y(t) = t + \int_0^t \sin(t-\tau)\, y(\tau)\, d\tau$.

The integral is $\sin * y$. Transforming, with $\mathcal{L}\{\sin t\} = 1/(s^2+1)$:

$$Y = \frac{1}{s^2} + \frac{Y}{s^2+1} \quad\Longrightarrow\quad Y\,\frac{s^2}{s^2+1} = \frac{1}{s^2} \quad\Longrightarrow\quad Y = \frac{s^2+1}{s^4} = \frac{1}{s^2} + \frac{1}{s^4}.$$

$$y(t) = t + \frac{t^3}{6}.$$

Check by substitution. $\int_0^t \sin(t-\tau)\left(\tau + \frac{\tau^3}{6}\right) d\tau$: using $\sin * \tau = t - \sin t$ and $\sin * \frac{\tau^3}{6} = \frac{t^3}{6} - t + \sin t$ (from $\frac{1}{s^4(s^2+1)} = \frac{1}{s^4} - \frac{1}{s^2} + \frac{1}{s^2+1}$), the sum is $t^3/6$, and $t + t^3/6 = y$. ✓

Integral equations of this convolution type arise in models with memory: hereditary (viscoelastic) materials, and circuits described by their impulse response rather than by an ODE.

Common Pitfall — the product of transforms is not the transform of the product

$\mathcal{L}\{f(t)g(t)\} \neq F(s)G(s)$. Multiplication in time corresponds to a *complex convolution* in s (a contour integral), which is rarely used in circuit work. For example $\mathcal{L}\{t \cdot t\} = 2/s^3$, while $\frac{1}{s^2}\cdot\frac{1}{s^2} = \frac{1}{s^4} \leftrightarrow t^3/6$.

Engineering Note — convolution in practice

Measuring $h(t)$ directly with an impulse is difficult, but its integral, the step response, is easy to record on an oscilloscope. Duhamel's integral then predicts the response to any input. In digital signal processing the same idea, in discrete form, is the FIR filter: the output is a weighted sum of past inputs with the impulse response as weights (Ch. 17).

14.7 Initial- and final-value theorems

Often an engineer does not need the whole response — only where it starts and where it ends. Does the output voltage jump when the switch closes? What is the steady-state error of a control loop? What is the DC gain? The initial- and final-value theorems read these numbers directly from $X(s)$, with no inversion. They are also the quickest way to check a partial-fraction result.

Statements

Initial-value theorem (IVT)

If $x(t)$ and $\dot{x}(t)$ (excluding any impulse at the origin) are transformable and $X(s)$ is strictly proper, then

$$x(0^+) = \lim_{s\to\infty} sX(s),$$

the limit taken along the positive real axis (or any path with $\operatorname{Re}\{s\} \to \infty$).

Final-value theorem (FVT)

If $x(t)$ and $\dot{x}(t)$ are transformable and **all poles of $sX(s)$ lie in the open left half-plane** $\mathrm{Re}\{s\} < 0$, then $x(\infty) = \lim_{t\to\infty} x(t)$ exists and

$$\lim_{t\to\infty} x(t) = \lim_{s\to 0} sX(s).$$

The condition on the poles of $sX(s)$ means: $X(s)$ may have at most a *simple* pole at the origin (cancelled by the factor s), and every other pole must have negative real part. Without it, the right-hand side still produces a number, but that number is meaningless.

Proofs

Both theorems come from the derivative rule. Split the derivative integral at the origin:

$$\int_{0^-}^{\infty} \dot{x}(t)e^{-st}dt = sX(s) - x(0^-).$$

The part from 0^- to 0^+ picks up the jump $x(0^+) - x(0^-)$ (the impulse in $\dot{x}$), so

$$sX(s) - x(0^+) = \int_{0^+}^{\infty} \dot{x}(t)e^{-st}dt.$$

IVT. As $s \to \infty$ along the real axis, $e^{-st} \to 0$ for every $t > 0$, and (dominated convergence, using exponential order) the right side tends to 0. Hence $sX(s) \to x(0^+)$. If X were not strictly proper, x would contain an impulse at the origin, $x(0^+)$ would not describe it, and $sX \to \infty$.

FVT. As $s \to 0$, $e^{-st} \to 1$ and the right side tends to $\int_{0^+}^{\infty} \dot{x}\,dt = x(\infty) - x(0^+)$ — *provided* this integral converges, which the pole condition guarantees (every mode of $\dot{x}$ then decays exponentially). Adding $x(0^+)$ to both sides gives $\lim_{s\to 0} sX = x(\infty)$. □

In terms of partial fractions the FVT is transparent: with all poles of X except a simple one at $s = 0$ in the left half-plane, every exponential term dies out and only the constant K_0 from the term K_0/s survives. That constant is $\lim_{s\to 0} sX(s)$ by the cover-up rule.

Higher initial derivatives

Applying the IVT to $\dot{x}$ (whose transform, for $t > 0$, is $sX - x(0^+)$) gives

$$\dot{x}(0^+) = \lim_{s\to\infty} s\big[sX(s) - x(0^+)\big], \qquad \ddot{x}(0^+) = \lim_{s\to\infty} s\big[s^2X(s) - sx(0^+) - \dot{x}(0^+)\big],$$

and so on. For a rational $X = N/D$ with $\deg D - \deg N = r$ (the **relative degree**), x and its first $r - 2$ derivatives start at zero, and $x^{(r-1)}(0^+) = b_m/a_n$, the ratio of leading coefficients. A high relative degree means a response that leaves zero gently — a smooth start.

Worked Example 14.28 — start, slope and end without inversion

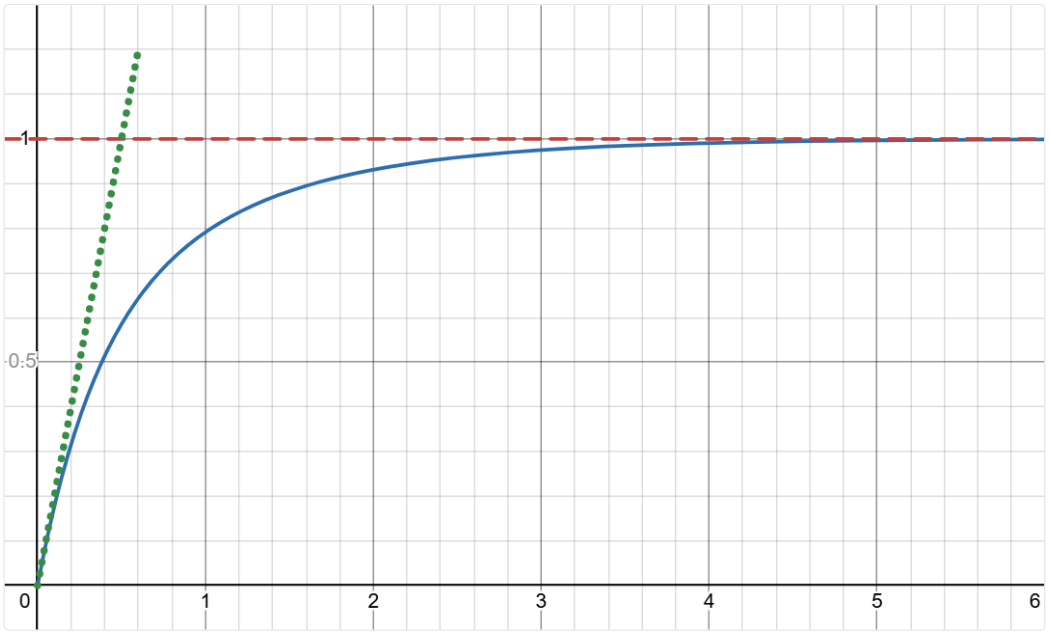
For $X(s) = \dfrac{2s+3}{s(s+1)(s+3)}$ find $x(0^+)$, $\dot{x}(0^+)$ and $x(\infty)$; then check against the inverse.

Initial value. $sX = \dfrac{2s+3}{(s+1)(s+3)} \to \dfrac{2s}{s^2} \to 0$. So $x(0^+) = 0$.

Initial slope. $\dot{x}(0^+) = \lim s \cdot sX = \lim \dfrac{s(2s+3)}{(s+1)(s+3)} = 2$. (Relative degree 2, leading-coefficient ratio $2/1$.)

Final value. Poles of sX are $-1, -3$: both in the left half-plane, so the FVT applies: $x(\infty) = \dfrac{3}{(1)(3)} = 1$.

Check. Partial fractions give $X = \dfrac{1}{s} - \dfrac{1/2}{s+1} - \dfrac{1/2}{s+3}$, so $x(t) = 1 - \tfrac{1}{2}e^{-t} - \tfrac{1}{2}e^{-3t}$: $x(0) = 0$ ✓, $\dot{x}(0) = \tfrac{1}{2} + \tfrac{3}{2} = 2$ ✓, $x(\infty) = 1$ ✓.



$x(t) = 1 - \frac{1}{2}e^{-t} - \frac{1}{2}e^{-3t}$ (blue) starts at $x(0^+) = 0$ with slope 2 (green dotted tangent) and settles to $x(\infty) = 1$ (red dashed) — all three read from $X(s)$ in Example 14.28.

Worked Example 14.29 — when the FVT lies

Apply $\lim_{s\to 0} sX(s)$ blindly to each transform, and compare with the truth.

$X(s)$	$\lim_{s\to 0} sX$	**true** $x(t)$	**verdict**
$\frac{1}{s-2}$	0	$e^{2t} \to \infty$	pole at $+2$ in RHP: FVT invalid
$\frac{\omega}{s^2+\omega^2}$	0	$\sin \omega t$, no limit	poles $\pm j\omega$ on axis: FVT invalid
$\frac{1}{s(s^2+1)}$	1	$1 - \cos t$, no limit	sX has poles $\pm j$: FVT invalid
$\frac{1}{s^2}$	∞	$t \to \infty$	double pole at 0: FVT invalid (but correctly signals unboundedness)
$\frac{4}{s(s+2)}$	2	$2 - 2e^{-2t} \to 2$	valid ✓

The third row is the dangerous one: the theorem returns a finite, plausible number (the *average* of $1 - \cos t$) for a signal that never settles. Always check the pole condition first.

Worked Example 14.30 — an impulse at the origin

$X(s) = \dfrac{s+2}{s+1}$. Find $x(0^+)$.

X is not strictly proper; $sX \to \infty$. Divide first: $X = 1 + \dfrac{1}{s+1}$, so $x(t) = \delta(t) + e^{-t}u(t)$. The IVT applies to the strictly proper part: $x(0^+) = \lim_{s\to\infty} \dfrac{s}{s+1} = 1$. The impulse lives at $t = 0$ itself, not at 0^+, and must be reported separately.

Worked Example 14.31 — DC gain and initial slope of a step response

An amplifier has transfer function $H(s) = \dfrac{10(s+5)}{s^2+3s+50}$. For a unit-step input, find the initial value, initial slope and final value of the output.

The output is $Y(s) = H(s)/s$, so $sY = H(s)$.

- $y(0^+) = \lim_{s\to\infty} H(s) = 0$ (relative degree 1 of H, so the step response is continuous).
- $\dot{y}(0^+) = \lim_{s\to\infty} sH(s) = 10$ V/s per volt of input (ratio of leading coefficients).
- Poles of H: $s^2 + 3s + 50 = 0 \Rightarrow s = -1.5 \pm j6.91$, in the LHP, so $y(\infty) = H(0) = \dfrac{50}{50} = 1$.

General rule: for a stable system, the final value of the step response is the **DC gain** $H(0)$. The step response here overshoots substantially (damping ratio $\zeta = 1.5/\sqrt{50} = 0.21$), something the FVT says nothing about — it describes only where the response ends, not how it gets there.

Common Pitfall — using the theorems on X instead of sX

Both theorems involve $sX(s)$, not $X(s)$. Forgetting the factor s gives $\lim_{s\to 0} X(s)$, which for a step response is infinite and for an impulse response equals the *area* $\int_0^\infty x\,dt$ — a different (and sometimes useful) quantity.

Engineering Note — steady-state error in control loops

In a unity-feedback loop with open-loop transfer function $G(s)$, the error for a reference $R(s)$ is $E(s) = R(s)/(1+G(s))$. The FVT gives the steady-state error $e_{ss} = \lim_{s\to 0} sR/(1+G)$. For a unit step this is $1/(1+G(0))$, which is zero exactly when G has a pole at $s=0$ (an integrator in the loop). This one-line calculation is the basis of the "system type" classification in control engineering (Section 14.9).

14.8 Solving differential equations

This is the application that justifies the whole apparatus. A linear constant-coefficient ODE with initial conditions — an **initial-value problem (IVP)** — becomes an algebraic equation for $Y(s)$. Solving it produces, in a single expression, both the natural response (fixed by the initial conditions) and the forced response (fixed by the input). Discontinuous and impulsive inputs, which are awkward for the classical method of Ch. 12, cause no extra difficulty.

The general procedure

Consider the nth-order equation

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 \dot{y} + a_0 y = x(t), \qquad y(0^-),\ \dot{y}(0^-),\ \ldots,\ y^{(n-1)}(0^-) \text{ given.}$$

1. **Transform** both sides, using the derivative rule for each $y^{(k)}$ and the table for $x(t)$.
2. **Collect** the terms in $Y(s)$ on the left. The coefficient of Y is the **characteristic polynomial** $P(s) = a_n s^n + \cdots + a_0$ — the same polynomial whose roots gave the exponents in the classical method.
3. **Solve** algebraically for $Y(s)$, which always takes the form shown below.
4. **Invert** by partial fractions (Section 14.5) and the table.
5. **Check** the initial conditions (IVT) and, if applicable, the final value (FVT) — or substitute back.

$$Y(s) = \underbrace{\frac{C(s)}{P(s)}}_{\text{zero-input}} + \underbrace{\frac{X(s)}{P(s)}}_{\text{zero-state}},$$

where $C(s)$ is a polynomial of degree $< n$ built from the initial conditions.

The **zero-input response** is what the system does from its initial state with no input; the **zero-state response** is what the input does to a system initially at rest. Their sum is the complete response. The ratio $H(s) = 1/P(s)$ that multiplies $X(s)$ is the transfer function of the equation.

Structure of the solution

The poles of $Y(s)$ are the roots of $P(s)$ (the **natural frequencies** or characteristic roots) together with the poles of $X(s)$ (the **forced frequencies**). The terms belonging to the roots of P form the natural (transient) response; those belonging to the poles of X form the forced (particular) response. If a pole of X coincides with a root of P, the pole of Y is repeated and terms $t^k e^{pt}$ appear — the resonance case that the classical method treats by "multiplying the trial solution by t".

Worked Example 14.32 — first-order RC charging

A capacitor voltage obeys $\dot{y} + 2y = 4$, $y(0^-) = 1$ (time in ms, voltage in V). Find $y(t)$.

Transform. $sY - 1 + 2Y = \dfrac{4}{s}$.

Solve. $Y = \dfrac{1}{s+2} + \dfrac{4}{s(s+2)} = \dfrac{s+4}{s(s+2)}$.

Partial fractions (cover-up): at $s=0$: $4/2 = 2$; at $s=-2$: $2/(-2) = -1$.

$$Y = \frac{2}{s} - \frac{1}{s+2} \quad\Longrightarrow\quad y(t) = 2 - e^{-2t}\ \text{V}.$$

Check. $y(0^+) = 1$ ✓ (no jump, as expected for a capacitor voltage); $\dot{y} + 2y = 2e^{-2t} + 4 - 2e^{-2t} = 4$ ✓; final value 2 V = forcing/coefficient ✓.

Worked Example 14.33 — second order, zero-input and zero-state parts

Solve $\ddot{y} + 3\dot{y} + 2y = e^{-3t}$ with $y(0^-) = 1$, $\dot{y}(0^-) = 0$.

Transform.

$$\big[s^2Y - s\cdot 1 - 0\big] + 3\big[sY - 1\big] + 2Y = \frac{1}{s+3}.$$

Collect. $(s^2+3s+2)Y = (s+3) + \dfrac{1}{s+3}$, with $P(s) = (s+1)(s+2)$:

$$Y = \underbrace{\frac{s+3}{(s+1)(s+2)}}_{Y_{zi}} + \underbrace{\frac{1}{(s+1)(s+2)(s+3)}}_{Y_{zs}}.$$

Zero-input. Cover-up: $\dfrac{2}{s+1} - \dfrac{1}{s+2} \leftrightarrow 2e^{-t} - e^{-2t}$.

Zero-state. Cover-up: at -1: $\frac{1}{(1)(2)} = \frac{1}{2}$; at -2: $\frac{1}{(-1)(1)} = -1$; at -3: $\frac{1}{(-2)(-1)} = \frac{1}{2}$. So $\frac{1}{2}e^{-t} - e^{-2t} + \frac{1}{2}e^{-3t}$.

Complete response.

$$y(t) = \tfrac{5}{2}e^{-t} - 2e^{-2t} + \tfrac{1}{2}e^{-3t}.$$

Check. $y(0) = \frac{5}{2} - 2 + \frac{1}{2} = 1$ ✓; $\dot{y}(0) = -\frac{5}{2} + 4 - \frac{3}{2} = 0$ ✓. Substituting into the ODE: the e^{-t} and e^{-2t} terms are annihilated by P (since $P(-1) = P(-2) = 0$), and the e^{-3t} term gives $\frac{1}{2}P(-3)e^{-3t} = \frac{1}{2}\cdot 2\,e^{-3t} = e^{-3t}$ ✓.

Note how the classical method's three steps (complementary function, particular integral, fitting constants) collapsed into one partial-fraction expansion.

Discontinuous and impulsive inputs

Worked Example 14.34 — a rectangular pulse into an undamped oscillator

An undamped LC tank, initially at rest, obeys $\ddot{y} + 4y = x(t)$ where $x(t) = 1$ for $0 \le t < \pi$ and 0 afterwards. Find $y(t)$.

Input. $x = u(t) - u(t-\pi) \leftrightarrow \dfrac{1 - e^{-\pi s}}{s}$.

Transform. $(s^2+4)Y = \dfrac{1-e^{-\pi s}}{s}$, so $Y = (1 - e^{-\pi s})\,G(s)$ with

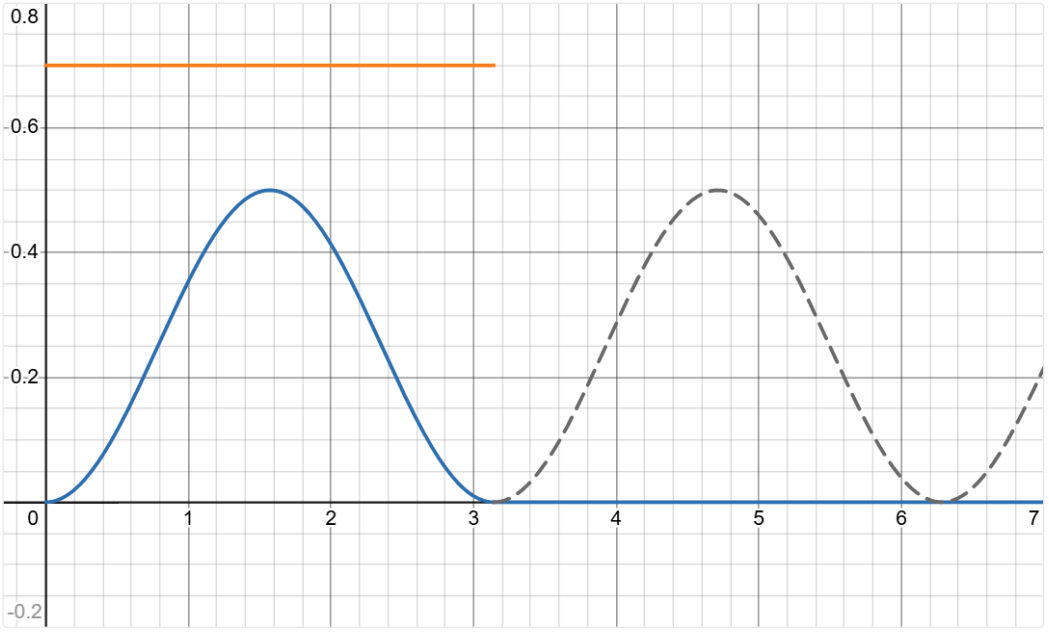
$$G(s) = \frac{1}{s(s^2+4)} = \frac{1}{4}\left(\frac{1}{s} - \frac{s}{s^2+4}\right) \leftrightarrow g(t) = \frac{1-\cos 2t}{4}.$$

Invert with the delay.

$$y(t) = \frac{1-\cos 2t}{4} - \frac{1-\cos 2(t-\pi)}{4}\,u(t-\pi).$$

For $t \ge \pi$, $\cos 2(t-\pi) = \cos 2t$, so the two terms cancel exactly: $y(t) = 0$ **for** $t \ge \pi$**.**

Interpretation. The pulse lasts exactly one natural period ($2\pi/2 = \pi$). The energy it pumps in during the first half-period is withdrawn in the second, leaving the oscillator at rest: $y(\pi) = 0$ and $\dot{y}(\pi) = \frac{1}{2}\sin 2\pi = 0$. A pulse of any other length would leave a residual oscillation. This "input shaping" idea is used to move resonant mechanical loads (disk-drive heads, cranes) without exciting vibration.



Example 14.34: during the pulse (orange, scaled) the oscillator swings once (blue) and is left exactly at rest at $t=\pi$; without the pulse ending, it would continue oscillating (grey dashed).

Worked Example 14.35 — resonance

Solve $\ddot{y}+\omega^2 y=\sin\omega t$, $y(0^-)=\dot{y}(0^-)=0$.

$$Y=\frac{\omega}{(s^2+\omega^2)^2}=\frac{1}{2\omega^2}\cdot\frac{2\omega^3}{(s^2+\omega^2)^2}\quad\Longrightarrow\quad y(t)=\frac{\sin\omega t-\omega t\cos\omega t}{2\omega^2}$$

by table entry 29. The forcing frequency coincides with the natural frequency, the poles $\pm j\omega$ are doubled, and the amplitude grows linearly as $t/(2\omega)$ without bound. In a real circuit the resistance limits the growth; the ideal model warns that a lightly damped resonator driven at resonance develops very large voltages (a factor Q above the drive).

Check ($\omega=2$, $t=1$): $y=\frac{\sin 2-2\cos 2}{8}=\frac{0.9093+0.8323}{8}=0.2177$. Numerical integration of the ODE gives 0.2177. ✓

Integro-differential equations

Equations containing both derivatives and running integrals of the unknown — typical of loop equations with capacitors — are handled just as easily, because the integral rule turns $\int_0^t y\,d\tau$ into Y/s.

Worked Example 14.36 — an integro-differential equation

Solve $\dot{y}+3y+2\displaystyle\int_0^t y(\tau)\,d\tau=u(t)$, $y(0^-)=0$.

Transform. $sY+3Y+\dfrac{2Y}{s}=\dfrac{1}{s}$. Multiply by s: $(s^2+3s+2)Y=1$.

$$Y=\frac{1}{(s+1)(s+2)}=\frac{1}{s+1}-\frac{1}{s+2}\quad\Longrightarrow\quad y(t)=e^{-t}-e^{-2t}.$$

This is the loop current of a series RLC circuit ($L=1$, $R=3$, $1/C=2$) connected to a unit step: it rises from zero, peaks at $t=\ln 2=0.693$ (value 0.25), and decays because the charged capacitor eventually blocks DC.

Simultaneous equations

Coupled circuits (mutual inductance, multi-loop networks) and state-space models give systems of ODEs. Each equation transforms to a linear algebraic equation, and the resulting linear system in $X(s), Y(s), \dots$ is solved by elimination or Cramer's rule (Ch. 8).

In matrix form, $\dot{\mathbf{x}}=\mathbf{A}\mathbf{x}+\mathbf{b}\,v(t)$ transforms to $s\mathbf{X}-\mathbf{x}(0^-)=\mathbf{A}\mathbf{X}+\mathbf{b}V$, so

$$\mathbf{X}(s)=(s\mathbf{I}-\mathbf{A})^{-1}\big[\mathbf{x}(0^-)+\mathbf{b}V(s)\big].$$

Since $(s\mathbf{I}-\mathbf{A})^{-1}=\operatorname{adj}(s\mathbf{I}-\mathbf{A})/\det(s\mathbf{I}-\mathbf{A})$, the poles of every solution component are the **eigenvalues of $\mathbf{A}$** (Ch. 10), and the matrix exponential is $e^{\mathbf{A}t}=\mathcal{L}^{-1}\{(s\mathbf{I}-\mathbf{A})^{-1}\}$.

Worked Example 14.37 — a coupled pair

Solve $\dot{x}=-2x+y$, $\dot{y}=x-2y+2$ for $t\ge 0$, with $x(0^-)=1$, $y(0^-)=0$.

Transform.

$$\begin{aligned}(s+2)X-Y&=1,\\ -X+(s+2)Y&=\frac{2}{s}.\end{aligned}$$

Cramer's rule. $\Delta=(s+2)^2-1=(s+1)(s+3)$ — the eigenvalues of $\mathbf{A}=\begin{bmatrix}-2&1\\1&-2\end{bmatrix}$ are -1 and -3.

$$X=\frac{(s+2)+\frac{2}{s}}{(s+1)(s+3)}=\frac{s^2+2s+2}{s(s+1)(s+3)},\qquad Y=\frac{(s+2)\frac{2}{s}+1}{(s+1)(s+3)}=\frac{3s+4}{s(s+1)(s+3)}.$$

Partial fractions (cover-up).

$$X=\frac{2/3}{s}-\frac{1/2}{s+1}+\frac{5/6}{s+3},\qquad Y=\frac{4/3}{s}-\frac{1/2}{s+1}-\frac{5/6}{s+3}.$$

$$x(t)=\tfrac{2}{3}-\tfrac{1}{2}e^{-t}+\tfrac{5}{6}e^{-3t},\qquad y(t)=\tfrac{4}{3}-\tfrac{1}{2}e^{-t}-\tfrac{5}{6}e^{-3t}.$$

Check. $x(0)=\frac{2}{3}-\frac{1}{2}+\frac{5}{6}=1$ ✓, $y(0)=\frac{4}{3}-\frac{1}{2}-\frac{5}{6}=0$ ✓. Steady state: setting derivatives to zero, $-2x+y=0$ and $x-2y+2=0$ give $x=\frac{2}{3}$, $y=\frac{4}{3}$ ✓.

Equations with polynomial coefficients

The transform is designed for constant coefficients, but the rule $\mathcal{L}\{t\,y\}=-dY/ds$ converts a coefficient t into a derivative in s. An ODE in t with linear coefficients becomes a *first-order* ODE in s, which is sometimes easier.

Worked Example 14.38 — Bessel's equation of order zero

Solve $t\ddot{y} + \dot{y} + ty = 0$ with $y(0) = 1$ (bounded solution).

Transform each term. $\mathcal{L}\{t\ddot{y}\} = -\frac{d}{ds}\left[s^2Y - s\,y(0) - \dot{y}(0)\right] = -2sY - s^2Y' + 1$; $\mathcal{L}\{\dot{y}\} = sY - 1$; $\mathcal{L}\{ty\} = -Y'$.

Sum. $-(s^2+1)Y' - sY = 0$, a separable first-order ODE in s:

$$\frac{Y'}{Y} = -\frac{s}{s^2+1} \quad\Longrightarrow\quad Y = \frac{C}{\sqrt{s^2+1}}.$$

Constant. IVT: $y(0^+) = \lim sY = C = 1$. So $Y = 1/\sqrt{s^2+1}$, i.e. $y(t) = J_0(t)$ (table entry 38), the Bessel function that describes, among other things, the current distribution in a round conductor at high frequency.

Common Pitfall — initial conditions at the wrong instant

If a problem states "the switch closes at $t = 0$ and $v_C(0^+) = \ldots$", the 0^- derivative rule cannot use that value directly. Either compute $v_C(0^-)$ from the circuit before switching (the usual case — capacitor voltages and inductor currents are continuous unless impulses act), or switch consistently to the 0^+ convention and exclude impulses at the origin from the input. Mixing the two produces answers that are wrong by an impulse or a step.

Engineering Note — why simulation tools think in s

SPICE's ".ac" analysis evaluates the zero-state transfer function on the $j\omega$-axis, and its ".tran" analysis integrates the ODE numerically. Laplace-domain hand analysis sits between the two: it gives the transient in closed form, exposes which poles cause ringing or slow settling, and provides the reference solution against which a numerical integrator is checked (Ch. 22).

14.9 Applications to circuits and control

The previous section transformed a differential equation that had already been written down. For circuits there is a shortcut: transform the **element laws** once and for all, draw an s-domain circuit, and apply Kirchhoff's laws and ordinary resistive-circuit techniques (series/parallel combination, voltage dividers, nodal and mesh analysis, Thévenin equivalents) directly to it. No differential equation is ever written. This section develops that method, and then the language it leads to: transfer functions, poles and zeros, stability and feedback. As elsewhere in this book, the circuits are there to motivate the mathematics; circuit theory proper belongs to its own course.

Kirchhoff's laws in the s-domain

KCL ($\sum i_k(t) = 0$ at a node) and KVL ($\sum v_k(t) = 0$ around a loop) are linear relations with constant coefficients, so by linearity of the transform they hold for the transforms too: $\sum I_k(s) = 0$ and $\sum V_k(s) = 0$. Only the element laws need translating.

s-domain element models

Resistor. $v = Ri$ transforms to $V(s) = R\,I(s)$.

Inductor. $v = L\,\dfrac{di}{dt}$ transforms, by the derivative rule, to

$$V(s) = sL\,I(s) - L\,i(0^-).$$

This is the law of an impedance sL **in series** with a voltage source $L\,i(0^-)$ (polarity opposing the stored current, as the minus sign shows). Solving instead for I:

$$I(s) = \frac{V(s)}{sL} + \frac{i(0^-)}{s},$$

an impedance sL **in parallel** with a current source $i(0^-)/s$ — the transform of a constant current $i(0^-)$.

Capacitor. $i = C\,\dfrac{dv}{dt}$ transforms to

$$I(s) = sC\,V(s) - C\,v(0^-) \qquad\Longleftrightarrow\qquad V(s) = \frac{I(s)}{sC} + \frac{v(0^-)}{s}.$$

The first form is an admittance sC in parallel with a current source $C\,v(0^-)$ (the transform of the impulse $Cv(0^-)\delta(t)$, i.e. the stored charge); the second is an impedance $1/(sC)$ in series with a voltage source $v(0^-)/s$ (a step of the stored voltage).

Impedance and admittance

For an element or two-terminal network initially at rest, the **impedance** is $Z(s) = V(s)/I(s)$ and the **admittance** $Y(s) = 1/Z(s)$:

$$Z_R = R, \qquad Z_L = sL, \qquad Z_C = \frac{1}{sC}.$$

Impedances combine like resistances: in series they add, in parallel their admittances add.

On the $j\omega$-axis these become the phasor impedances $j\omega L$ and $1/(j\omega C)$ of AC circuit analysis. The s-domain impedance is their generalisation to arbitrary (including transient and growing) signals, and it carries the initial energy through the extra sources.

Units check. sL has units $\mathrm{s}^{-1}\cdot\mathrm{H} = \Omega$ ✓; $1/(sC)$ has $1/(\mathrm{s}^{-1}\cdot\mathrm{F}) = \Omega$ ✓; $L\,i(0^-)$ has $\mathrm{H}\cdot\mathrm{A} = \mathrm{V}\cdot\mathrm{s}$, the units of a transformed voltage ✓.

Element	Time law	s-domain, series form	s-domain, parallel form
R	$v = Ri$	$V = RI$	$I = V/R$
L	$v = L\,di/dt$	$V = sLI - Li(0^-)$	$I = \dfrac{V}{sL} + \dfrac{i(0^-)}{s}$
C	$i = C\,dv/dt$	$V = \dfrac{I}{sC} + \dfrac{v(0^-)}{s}$	$I = sCV - Cv(0^-)$

Worked Example 14.39 — an inductor with stored current

A series circuit contains a source $v_s(t) = 20u(t)$ V, a resistor $R = 5\ \Omega$ and an inductor $L = 0.5$ H carrying $i(0^-) = 2$ A (from an earlier source configuration). Find $i(t)$.

s-domain circuit. Source $20/s$; impedances 5 and $0.5s$; the inductor's series source $L\,i(0^-) = 1$ V·s, aiding the existing current direction.

KVL. $\dfrac{20}{s} + 1 = (5 + 0.5s)\,I(s)$, so

$$I(s) = \frac{20/s + 1}{0.5(s + 10)} = \frac{40 + 2s}{s(s + 10)} = \frac{4}{s} - \frac{2}{s + 10}.$$

(Cover-up: at 0, $40/10 = 4$; at -10, $(40 - 20)/(-10) = -2$.)

$$i(t) = 4 - 2e^{-10t}\ \text{A}, \qquad t \geq 0.$$

Check. $i(0^+) = 2$ A — continuous, as an inductor current must be ✓. $i(\infty) = 20/5 = 4$ A, the DC value with the inductor a short circuit ✓. Time constant $L/R = 0.1$ s, matching the pole at $-10\ \text{s}^{-1}$ ✓.

Worked Example 14.40 — series RLC with a charged capacitor

A series RLC circuit has $R = 12\ \Omega$, $L = 10$ mH, $C = 100\ \mu$F. The capacitor holds $v_C(0^-) = 2$ V and $i(0^-) = 0$. At $t = 0$ a 10 V DC source is switched in. Find $i(t)$ and $v_C(t)$.

s-domain circuit. Source $10/s$; impedances R, sL, $1/(sC)$; the capacitor's series source $v_C(0^-)/s = 2/s$ opposes the drive (it is charged with the same polarity as the source would charge it).

KVL.

$$\frac{10}{s} - \frac{2}{s} = \left(R + sL + \frac{1}{sC}\right) I(s) \quad \Longrightarrow \quad I(s) = \frac{8/s}{R + sL + \frac{1}{sC}} = \frac{8}{L\left(s^2 + \frac{R}{L}s + \frac{1}{LC}\right)}.$$

With $R/L = 1200\ \text{s}^{-1}$, $1/(LC) = 10^6\ \text{s}^{-2}$, $1/L = 100\ \text{H}^{-1}$:

$$I(s) = \frac{800}{s^2 + 1200s + 10^6} = \frac{800}{(s + 600)^2 + 800^2}.$$

Inverse (entry 23):

$$i(t) = e^{-600t}\sin(800t)\ \text{A}.$$

Capacitor voltage. $V_C = \dfrac{I}{sC} + \dfrac{2}{s} = \dfrac{8 \times 10^6}{s(s^2 + 1200s + 10^6)} + \dfrac{2}{s}$. Partial fractions on the first term give $\dfrac{8}{s} - \dfrac{8(s + 600) + 6 \cdot 800}{(s + 600)^2 + 800^2}$, so

$$v_C(t) = 10 - e^{-600t}\left(8\cos 800t + 6\sin 800t\right)\ \text{V}.$$

Checks. $v_C(0^+) = 10 - 8 = 2$ V ✓ (continuous). $v_C(\infty) = 10$ V ✓ (FVT). $i(0^+) = 0$ ✓. Also $C\,dv_C/dt = 10^{-4} \cdot e^{-600t}\big[600(8\cos + 6\sin) - 800(-8\sin + 6\cos)\big] = 10^{-4}e^{-600t}(10000\sin 800t) = i$ ✓.

Transfer functions

Transfer function

For a linear time-invariant system **initially at rest**, with input $x(t)$ and output $y(t)$, the **transfer function** is

$$H(s) = \frac{Y(s)}{X(s)} = \mathcal{L}\{h(t)\},$$

where $h(t)$ is the impulse response. For a lumped system, $H(s)$ is a real rational function

$$H(s) = \frac{N(s)}{D(s)} = K\,\frac{(s - z_1)(s - z_2)\cdots(s - z_m)}{(s - p_1)(s - p_2)\cdots(s - p_n)}.$$

The roots z_i of N are the **zeros**, the roots p_k of D the **poles**, and K the gain constant. H is **proper** if $m \leq n$.

For the ODE $a_n y^{(n)} + \cdots + a_0 y = b_m x^{(m)} + \cdots + b_0 x$, transforming with zero initial conditions gives $H(s) = \dfrac{b_m s^m + \cdots + b_0}{a_n s^n + \cdots + a_0}$: the transfer function can be written down by inspection, and conversely. For a circuit it is found from the s-domain circuit with all initial-condition sources removed, using dividers and impedance combinations.

The **pole–zero plot** marks poles with × and zeros with ○ in the s-plane. Together with K, it determines H completely. Its interpretation:

- **Poles** are the natural frequencies. Each contributes a mode $e^{p_k t}$ (or $t^j e^{p_k t}$ if repeated) to the impulse response and to every transient.
- **Zeros** are frequencies at which the system blocks transmission: an input $e^{z_i t}$ produces no forced output. They do not create modes; they set the *amplitudes* (residues) of the modes and shape the frequency response.
- **Frequency response.** For a stable system, the steady-state response to $\cos \omega t$ is $|H(j\omega)| \cos(\omega t + \angle H(j\omega))$. Geometrically, $|H(j\omega)| = |K| \frac{\prod |j\omega - z_i|}{\prod |j\omega - p_k|}$: the product of distances from the point $j\omega$ to the zeros divided by that to the poles. A pole close to the $j\omega$-axis produces a sharp resonant peak; a zero on the axis produces a notch. Bode plots and the Fourier view of $H(j\omega)$ are developed in Ch. 16.

Worked Example 14.41 — zeros on the $j\omega$-axis: a notch filter

A notch filter for removing 50 Hz mains interference has

$$H(s) = \frac{s^2 + \omega_0^2}{s^2 + \frac{\omega_0}{Q} s + \omega_0^2}, \qquad \omega_0 = 2\pi \cdot 50 = 314.16 \text{ rad/s}, \quad Q = 5.$$

Find the poles and zeros, and $|H(j\omega)|$ at $\omega = 0$, ω_0, $1.1\omega_0$ and ∞.

Zeros. $s^2 + \omega_0^2 = 0 \Rightarrow s = \pm j\omega_0 = \pm j314.16$: on the $j\omega$-axis.

Poles. $s = -\frac{\omega_0}{2Q} \pm j\omega_0 \sqrt{1 - \frac{1}{4Q^2}} = -31.42 \pm j312.58$: in the LHP, so the filter is stable, and close to the zeros.

Frequency response. On the axis, $H(j\omega) = \dfrac{\omega_0^2 - \omega^2}{\omega_0^2 - \omega^2 + j\omega\omega_0/Q}$.

- $\omega = 0$: $|H| = 1$ (DC passes).
- $\omega = \omega_0$: numerator zero, $|H| = 0$ — the 50 Hz component is removed completely.
- $\omega = 1.1\omega_0$: $\omega_0^2 - \omega^2 = -0.21\omega_0^2$, $\omega\omega_0/Q = 0.22\omega_0^2$, so $|H| = \frac{0.21}{\sqrt{0.21^2 + 0.22^2}} = 0.690$.
- $\omega \to \infty$: $|H| \to 1$.

Geometric reading. At $s = j\omega$ near $j\omega_0$, the distance to the zero is tiny while the distance to the nearby pole is about $\omega_0/(2Q)$, so the ratio — and $|H|$ — dips sharply. Raising Q moves the poles closer to the axis and narrows the notch: the -3 dB width is $\omega_0/Q = 62.8$ rad/s, i.e. 10 Hz.

First- and second-order standard forms

Most systems are understood through their dominant first- and second-order factors.

First order. $H(s) = \dfrac{K}{1 + s\tau}$: one real pole at $-1/\tau$. The unit-step response is $K(1 - e^{-t/\tau})$: it reaches 63.2% of its final value at $t = \tau$ and 98.2% at 4τ. The RC low-pass filter has $\tau = RC$, $K = 1$.

Second order.

$$H(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2},$$

with **natural frequency** $\omega_n > 0$ and **damping ratio** $\zeta \geq 0$. The poles are

$$p_{1,2} = -\zeta\omega_n \pm \omega_n \sqrt{\zeta^2 - 1}.$$

Damping	Poles	Step response
$\zeta > 1$ overdamped	two distinct real, negative	sum of two decaying exponentials, no overshoot
$\zeta = 1$ critically damped	double real at $-\omega_n$	$1 - (1 + \omega_n t)e^{-\omega_n t}$, fastest without overshoot
$0 < \zeta < 1$ underdamped	$-\zeta\omega_n \pm j\omega_d$, $\omega_d = \omega_n\sqrt{1 - \zeta^2}$	decaying oscillation with overshoot
$\zeta = 0$ undamped	$\pm j\omega_n$	$1 - \cos \omega_n t$, sustained oscillation

For $0 < \zeta < 1$ the poles lie on a circle of radius ω_n, at angle $\theta = \arccos \zeta$ from the negative real axis. Partial fractions on $H(s)/s$ give the underdamped step response

$$y(t) = 1 - e^{-\zeta\omega_n t}\left(\cos \omega_d t + \frac{\zeta}{\sqrt{1 - \zeta^2}} \sin \omega_d t\right) = 1 - \frac{e^{-\zeta\omega_n t}}{\sqrt{1 - \zeta^2}} \sin(\omega_d t + \arccos \zeta)\,.$$

Setting $\dot{y} = 0$ (equivalently, the impulse response $h(t) = \frac{\omega_n}{\sqrt{1-\zeta^2}} e^{-\zeta\omega_n t} \sin \omega_d t = 0$) locates the first peak at $t_p = \pi/\omega_d$, where

$$\text{overshoot} = y(t_p) - 1 = e^{-\pi\zeta/\sqrt{1-\zeta^2}}.$$

The envelope $e^{-\zeta\omega_n t}$ gives the 2% **settling time** $t_s \approx 4/(\zeta\omega_n)$: the real part of the poles sets the decay rate, the imaginary part the ringing frequency.

Worked Example 14.42 — the RLC low-pass filter

Take the series RLC circuit of Example 14.40 ($R = 12\ \Omega$, $L = 10$ mH, $C = 100\ \mu$F) with output across the capacitor. Find $H(s)$, its poles and zeros, ω_n, ζ, and the step-response overshoot and peak time.

Voltage divider (zero initial conditions):

$$H(s) = \frac{V_C}{V_s} = \frac{1/(sC)}{R + sL + 1/(sC)} = \frac{1}{LCs^2 + RCs + 1} = \frac{1/(LC)}{s^2 + \frac{R}{L}s + \frac{1}{LC}} = \frac{10^6}{s^2 + 1200s + 10^6}.$$

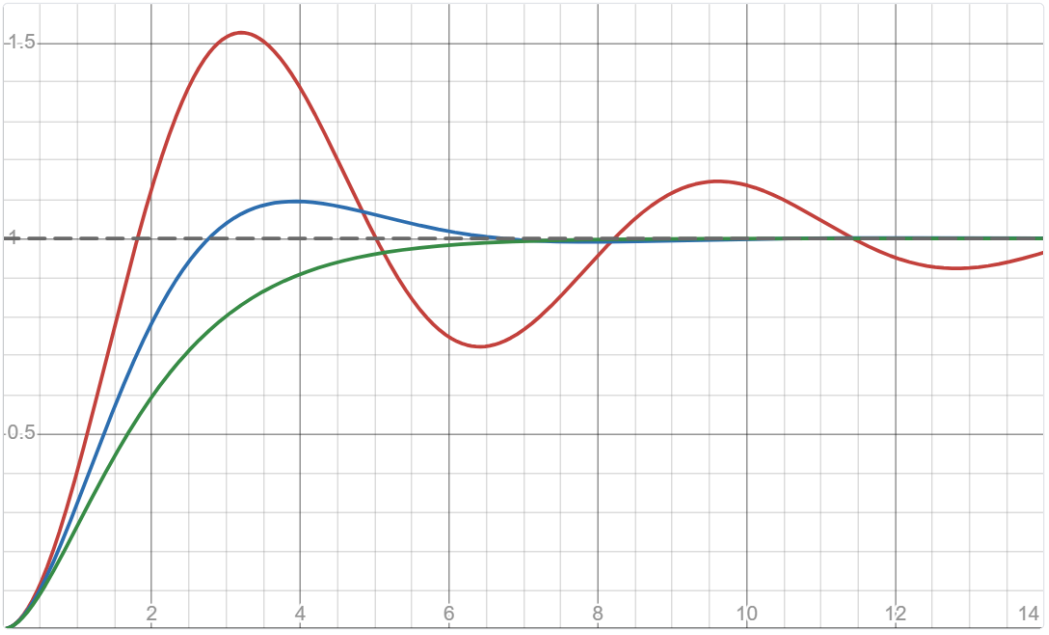
Poles and zeros. No finite zeros; poles $-600 \pm j800$ (as in Example 14.40 — the same circuit has the same natural frequencies whatever the output).

Parameters. $\omega_n = \sqrt{10^6} = 1000$ rad/s; $2\zeta\omega_n = 1200 \Rightarrow \zeta = 0.6$; $\omega_d = 800$ rad/s. In circuit terms $\zeta = \frac{R}{2}\sqrt{C/L} = 6\sqrt{0.01} = 0.6$ ✓.

Step response. $y(t) = 1 - e^{-600t}\left(\cos 800t + 0.75 \sin 800t\right)$.

- Peak time $t_p = \pi/800 = 3.93$ ms.
- Overshoot $e^{-\pi(0.6)/0.8} = e^{-2.356} = 0.0948$, i.e. 9.5%: the peak is 1.095.
- Settling time $t_s \approx 4/600 = 6.7$ ms.

Check. Evaluating $y(t)$ on a fine grid gives maximum 1.0948 at $t = 3.927$ ms ✓. DC gain $H(0) = 1$ ✓ (at DC the capacitor is open, so the full input appears across it).



Unit-step responses of the standard second-order system with $\omega_n = 1$ (time in units of $1/\omega_n$): $\zeta = 0.2$ (red, 53% overshoot), $\zeta = 0.6$ (blue, 9.5% overshoot — the RLC filter of Example 14.42 with time in ms), $\zeta = 1$ (green, critically damped).

Stability

BIBO stability

A system is **bounded-input, bounded-output (BIBO) stable** if every bounded input $|x(t)| \le M$ produces a bounded output. For an LTI system this holds if and only if the impulse response is absolutely integrable: $\int_0^\infty |h(t)|\,dt < \infty$.

Why. If $\int |h| = A < \infty$ then $|y(t)| \le \int_0^t |h(\tau)||x(t-\tau)|d\tau \le MA$. Conversely, if $\int |h| = \infty$, the bounded input $x(t-\tau) = \operatorname{sgn} h(\tau)$ makes $y(t) = \int_0^t |h|d\tau$ grow without bound.

Pole criterion for stability

A system with proper rational transfer function $H(s)$ (in lowest terms) is BIBO stable **if and only if every pole has negative real part** — all poles lie in the open left half-plane.

- Any pole with $\mathrm{Re}\{p\} > 0$, or a repeated pole on the $j\omega$-axis, gives an unbounded impulse response: **unstable**.
- Simple poles on the $j\omega$-axis (and none in the RHP) give a bounded but non-decaying impulse response: **marginally stable**, which is *not* BIBO stable (a bounded input at the pole frequency produces resonant growth, Example 14.35).

Proof sketch. By partial fractions, $h(t) = K_0\delta(t) + \sum_k \sum_i K_{k,i} \frac{t^{i-1}}{(i-1)!} e^{p_k t}$. Each term with $\mathrm{Re}\{p_k\} < 0$ is absolutely integrable (exponential decay beats any polynomial). A term with $\mathrm{Re}\{p_k\} \ge 0$ and $K \neq 0$ is not. Since the fraction is in lowest terms, no pole has zero residue at its highest power. □

Finding all roots of a high-order $D(s)$ is unnecessary to decide stability. The **Routh–Hurwitz criterion** answers it from the coefficients alone. Two consequences are easy to remember:

- **Necessary condition:** if all roots of $a_n s^n + \cdots + a_0$ (with $a_n > 0$) have negative real parts, then every coefficient is **positive**. A missing or negative coefficient means instability (or a $j\omega$-axis root).
- For **second order** positivity of all coefficients is also sufficient. For **third order**, $a_3 s^3 + a_2 s^2 + a_1 s + a_0$ with all $a_i > 0$ is stable if and only if $a_2 a_1 > a_3 a_0$.

Worked Example 14.43 — a stability range

For which gains K is the system with characteristic polynomial $D(s) = s^3 + 2s^2 + 3s + K$ stable? What happens at the boundary?

Positivity. Need $K > 0$.

Third-order condition. $a_2 a_1 > a_3 a_0$: $2 \cdot 3 > 1 \cdot K$, so $K < 6$. Stable for $0 < K < 6$.

Boundary. At $K = 6$: $D(s) = s^3 + 2s^2 + 3s + 6 = (s + 2)(s^2 + 3)$, poles -2 and $\pm j\sqrt{3} = \pm j1.732$. The system oscillates at $\sqrt{3}$ rad/s with constant amplitude — marginal stability. For $K > 6$ the complex pair crosses into the right half-plane. This is precisely how an oscillator is designed: raise the loop gain until a pole pair reaches the $j\omega$-axis.

Feedback and control

In a feedback loop with forward path $G(s)$ and feedback path $F(s)$, the error signal is $E = R - FY$ and $Y = GE$. Eliminating E:

$$T(s) = \frac{Y(s)}{R(s)} = \frac{G(s)}{1 + G(s)F(s)}.$$

The closed-loop poles are the roots of the **characteristic equation** $1 + G(s)F(s) = 0$ — they are not the poles of G. Feedback therefore *moves poles*, which is both its power (stabilising, speeding up, desensitising) and its danger (it can destabilise a stable plant, as in Example 14.43). For **unity feedback** ($F = 1$) the error is $E = R/(1 + G)$, and the final-value theorem gives the steady-state errors:

Reference	e_{ss}	Error constant
Step $1/s$	$\dfrac{1}{1 + K_p}$	$K_p = \lim_{s\to 0} G(s)$
Ramp $1/s^2$	$\dfrac{1}{K_v}$	$K_v = \lim_{s\to 0} sG(s)$
Parabola $1/s^3$	$\dfrac{1}{K_a}$	$K_a = \lim_{s\to 0} s^2 G(s)$

The number of pure integrators ($1/s$ factors) in G is the **system type**: a type-1 loop tracks a step with zero error, a type-2 loop tracks a ramp with zero error.

Worked Example 14.44 — a position servo

A motor-driven positioning system has open-loop transfer function $G(s) = \dfrac{K}{s(s + 4)}$ in a unity-feedback loop. Choose K for a damping ratio $\zeta = 0.5$; then find the overshoot, peak time, and steady-state errors for step and ramp references.

Closed loop.

$$T(s) = \frac{K/(s(s+4))}{1 + K/(s(s+4))} = \frac{K}{s^2 + 4s + K}.$$

Compare with the standard form: $\omega_n^2 = K$, $2\zeta\omega_n = 4$. With $\zeta = 0.5$: $\omega_n = 4$ rad/s, so $K = 16$.

Poles. $s^2 + 4s + 16 = 0 \Rightarrow s = -2 \pm j2\sqrt{3} = -2 \pm j3.464$.

Transient. Overshoot $e^{-\pi(0.5)/\sqrt{0.75}} = e^{-1.814} = 0.163$ (16.3%); peak time $t_p = \pi/\omega_d = \pi/3.464 = 0.907$ s; settling time $\approx 4/2 = 2$ s. Partial fractions give

$$y(t) = 1 - \frac{2}{\sqrt{3}} e^{-2t} \sin\!\left(2\sqrt{3}\,t + \frac{\pi}{3}\right).$$

A fine-grid evaluation gives a maximum of 1.1630 at $t = 0.907$ s ✓.

Steady-state errors. G has one integrator: type 1. Step: $K_p = \infty$, $e_{ss} = 0$. Ramp: $K_v = \lim sG = K/4 = 4\ \text{s}^{-1}$, so $e_{ss} = 1/4$ — the output lags a unit-slope ramp by 0.25 units.

Trade-off. Raising K reduces the ramp error ($e_{ss} = 4/K$) but lowers $\zeta = 2/\sqrt{K}$ and increases overshoot: the basic compromise of control design, visible entirely through pole locations.

Common Pitfall — pole–zero cancellation hides instability

Mathematically $\dfrac{s - 1}{(s - 1)(s + 2)} = \dfrac{1}{s + 2}$, which looks stable. Physically, if the factor $(s - 1)$ belongs to the plant and is "cancelled" by a controller zero, the unstable mode e^{t} is still present inside the system; any mismatch or initial condition excites it and an internal signal grows without bound. Stability must be judged on the internal (uncancelled) characteristic polynomial, never only on the simplified input–output transfer function.

Engineering Note — reading a system from its pole–zero plot

Experienced designers read pole–zero plots the way others read schematics. Poles far to the left are fast and usually negligible; the **dominant poles** nearest the $j\omega$-axis set the response time. The angle of a complex pair from the negative real axis fixes the damping ($\zeta = \cos\theta$, so poles at $\pm 45^\circ$ give $\zeta = 0.707$, the Butterworth value). A right-half-plane zero (common in boost converters and in amplifiers with feed-forward capacitance) produces an initial undershoot and limits the achievable bandwidth. Root-locus, Bode and Nyquist methods — the standard tools of control design — are graphical ways of tracking these pole positions as a gain varies; the Nyquist criterion itself is an application of the argument principle of Ch. 18.

Summary

Concept	Formula / statement
Unilateral transform	$X(s) = \int_{0^-}^{\infty} x(t)e^{-st}dt$, $s = \sigma + j\omega$, ROC $\mathrm{Re}\{s\} > \sigma_c$
Existence	piecewise continuous and $\lvert x\rvert \le Me^{\alpha t} \Rightarrow X$ exists for $\mathrm{Re}\{s\} > \alpha$, $X \to 0$
Uniqueness (Lerch)	equal transforms $\Rightarrow$ equal functions (at points of continuity)
Basic pairs	$\delta \leftrightarrow 1$, $u \leftrightarrow \frac{1}{s}$, $t^n \leftrightarrow \frac{n!}{s^{n+1}}$, $e^{-at} \leftrightarrow \frac{1}{s+a}$
Sinusoids	$\sin\omega t \leftrightarrow \frac{\omega}{s^2+\omega^2}$, $\cos\omega t \leftrightarrow \frac{s}{s^2+\omega^2}$
Damped sinusoids	$e^{-\alpha t}\sin\omega t \leftrightarrow \frac{\omega}{(s+\alpha)^2+\omega^2}$, $e^{-\alpha t}\cos\omega t \leftrightarrow \frac{s+\alpha}{(s+\alpha)^2+\omega^2}$
s-shift	$e^{at}x(t) \leftrightarrow X(s-a)$
Delay	$x(t-T)u(t-T) \leftrightarrow e^{-sT}X(s)$; $g(t)u(t-T) \leftrightarrow e^{-sT}\mathcal{L}\{g(t+T)\}$
Scaling	$x(at) \leftrightarrow \frac{1}{a}X(s/a)$
Derivatives	$\dot{x} \leftrightarrow sX - x(0^-)$; $\ddot{x} \leftrightarrow s^2X - sx(0^-) - \dot{x}(0^-)$
Integral	$\int_{0^-}^{t} x\,d\tau \leftrightarrow X/s$
t-multiplication / division	$tx \leftrightarrow -X'(s)$; $x/t \leftrightarrow \int_s^{\infty} X\,dp$
Periodic	$X = \frac{1}{1-e^{-sT}}\int_0^T xe^{-st}dt$
Bromwich inversion	$x(t) = \frac{1}{2\pi j}\int_{\gamma-j\infty}^{\gamma+j\infty} X(s)e^{st}ds = \sum \mathrm{Res}[Xe^{st}]$ (Ch. 18)
Simple-pole coefficient	$K_k = [(s-p_k)X]_{s=p_k} = N(p_k)/D'(p_k)$
Repeated pole	$K_{k,r-j} = \frac{1}{j!}\frac{d^j}{ds^j}[(s-p_k)^r X]_{p_k}$; $\frac{1}{(s-p)^i} \leftrightarrow \frac{t^{i-1}}{(i-1)!}e^{pt}$
Complex pair $-\alpha \pm j\beta$	$2\lvert K\rvert e^{-\alpha t}\cos(\beta t + \angle K)$
Convolution	$(f*g)(t) = \int_0^t f(\tau)g(t-\tau)d\tau \leftrightarrow F(s)G(s)$
Initial value	$x(0^+) = \lim_{s\to\infty} sX(s)$ (X strictly proper)
Final value	$x(\infty) = \lim_{s\to 0} sX(s)$ (all poles of sX in open LHP)
ODE solution	$Y = \frac{C(s)}{P(s)} + \frac{X(s)}{P(s)}$: zero-input + zero-state
State equations	$\mathbf{X} = (s\mathbf{I}-\mathbf{A})^{-1}[\mathbf{x}(0^-) + \mathbf{b}V]$, $e^{\mathbf{A}t} = \mathcal{L}^{-1}\{(s\mathbf{I}-\mathbf{A})^{-1}\}$
Element models	$Z_R = R$; $V_L = sLI - Li(0^-)$; $V_C = \frac{I}{sC} + \frac{v(0^-)}{s}$
Transfer function	$H(s) = Y/X$ (zero state) $= \mathcal{L}\{h\}$; $y = h*x$
Second-order form	$\frac{\omega_n^2}{s^2+2\zeta\omega_n s+\omega_n^2}$; poles $-\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2}$
Step overshoot, peak, settling	$e^{-\pi\zeta/\sqrt{1-\zeta^2}}$; $t_p = \pi/\omega_d$; $t_s \approx 4/(\zeta\omega_n)$
BIBO stability	all poles in open LHP $\Leftrightarrow \int_0^{\infty}\lvert h\rvert dt < \infty$
Cubic Routh condition	$a_3s^3 + a_2s^2 + a_1s + a_0$, all $a_i > 0$, stable iff $a_2a_1 > a_3a_0$
Feedback	$T = \frac{G}{1+GF}$; unity-feedback step error $\frac{1}{1+G(0)}$, ramp error $\frac{1}{\lim sG}$

Chapter 15 — Fourier Series and Fourier Analysis

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 3 (trigonometry and periodic functions), Ch. 5 (integral calculus), Ch. 9 (vector spaces and inner products), Ch. 12 (linear differential equations) **Learning outcomes:** After this chapter you can
>
> - compute trigonometric and complex (exponential) Fourier series of periodic waveforms of any period, and convert between the coefficient forms (a_n, b_n), (A_n, ϕ_n) and c_n;
> - use even, odd, half-wave and quarter-wave symmetry to predict which harmonics are present before integrating, and build half-range expansions;
> - state the Dirichlet conditions and the pointwise, uniform and mean-square convergence theorems, and explain and quantify the Gibbs phenomenon;
> - obtain coefficients quickly with the shift, differentiation, integration and jump methods, and predict how fast they decay from the smoothness of the waveform;
> - apply Parseval's theorem to compute RMS values, harmonic powers, power factor and total harmonic distortion, and to sum numerical series;
> - find the steady-state response of a linear time-invariant system to any periodic input, harmonic by harmonic.

A periodic waveform that is not a sinusoid — a clock square wave, the triangular ripple current of a buck converter, the humps of a rectified sine, the stepped output of an inverter — is still, in a precise sense, *made of* sinusoids. Chapter 3 introduced this idea informally: it established the orthogonality of harmonics (§3.7), the power of a finite sum of harmonics, the notion of total harmonic distortion, and the shapes and symmetries of the standard waveforms (§3.8). This chapter turns those observations into a complete theory. We ask, and answer, four questions:

1. **Representation.** Given a periodic function, which sinusoids does it contain, and with what amplitudes and phases? (The Fourier coefficients, §15.2–15.3, §15.7.)
2. **Structure.** How do properties of the waveform — symmetry, smoothness, discontinuities — show up in its coefficients? (§15.4, §15.5, §15.7.)
3. **Validity.** In what sense does the infinite sum of sinusoids actually equal the function, and what happens at jumps? (§15.6.)
4. **Use.** How do power, RMS values and distortion follow from the coefficients, and how does a linear system respond to a periodic input? (§15.8, §15.9.)

The next chapter lets the period tend to infinity and turns the discrete set of harmonics into the continuous Fourier transform. Everything here — orthogonality, Parseval, convolution, the trade-off between smoothness and spectral spread — carries over almost word for word.

Notation. A periodic function $x(t)$ has fundamental period T_0, fundamental frequency $f_0 = 1/T_0$ and fundamental angular frequency $\omega_0 = 2\pi/T_0$ (Ch. 3, §3.4). The harmonic index is n, so the nth harmonic has angular frequency $n\omega_0$. (Chapter 16 uses k for the same index when the discrete-time index n is also in play; the formulas are identical.) Many examples use the normalised period $T_0 = 2\pi$, $\omega_0 = 1$, in which case the time variable is written t and harmonics are $\cos nt$, $\sin nt$. The notation $\int_{T_0}$ means an integral over *any* interval of length T_0.

15.1 Periodic function decomposition

Motivation: why sinusoids, and why decompose at all?

There are infinitely many ways to write a function as a sum of simpler functions — powers of t (Taylor series, Ch. 4), polynomials, piecewise constants, wavelets. Engineers single out sums of sinusoids for one overriding reason:

> **A complex exponential $e^{j\omega t}$ is an eigenfunction of every linear time-invariant (LTI) system.**

If an LTI system with impulse response $h(t)$ is driven by $x(t) = e^{j\omega t}$, its output is

$$y(t) = \int_{-\infty}^{\infty} h(\tau)\, e^{j\omega(t-\tau)}\, d\tau = \Big[\int_{-\infty}^{\infty} h(\tau) e^{-j\omega\tau}\, d\tau\Big] e^{j\omega t} = H(j\omega)\, e^{j\omega t},$$

provided the integral converges. The input passes through *unchanged in shape*, multiplied by a single complex number $H(j\omega)$ — the frequency response, which for a circuit is the phasor transfer function of Ch. 2 and the Laplace transfer function $H(s)$ of Ch. 14 evaluated at $s = j\omega$. No other family of signals has this property for *all* LTI systems at once.

Now suppose a periodic input can be written as a sum of exponentials at the harmonic frequencies,

$$x(t) = \sum_{n=-\infty}^{\infty} c_n\, e^{jn\omega_0 t}.$$

By linearity (and, for an infinite sum, a convergence argument we postpone to §15.9) the steady-state output is

$$y(t) = \sum_{n=-\infty}^{\infty} c_n\, H(jn\omega_0)\, e^{jn\omega_0 t}.$$

A problem that in the time domain requires solving a differential equation with a discontinuous forcing function becomes, in the harmonic domain, a list of multiplications. That is the whole engineering case for Fourier series: **decompose, multiply harmonic by harmonic, recombine**. Section 15.9 carries this programme out in detail; the intervening sections build the mathematics that makes it trustworthy.

A second, independent motivation is *measurement*. Power-quality standards, audio distortion specifications, EMC emission limits and spectrum-analyser displays are all stated harmonic by harmonic. To read or write such a specification you must be able to move fluently between a waveform and its list of harmonics.

Periodic functions and their building blocks

Periodic function

A function $x:\mathbb{R}\to\mathbb{C}$ is **periodic with period** $T>0$ if $x(t+T)=x(t)$ for all t. The smallest such T, if it exists, is the **fundamental period** T_0. A function defined only on an interval of length T_0 is extended to all of $\mathbb{R}$ by **periodic extension**, $x(t+kT_0)=x(t)$, $k\in\mathbb{Z}$.

Every function in the set

$$\mathcal{B}=\{\,1,\ \cos\omega_0 t,\ \sin\omega_0 t,\ \cos 2\omega_0 t,\ \sin 2\omega_0 t,\ \dots\,\}$$

has period T_0 (the nth harmonic has period T_0/n, hence also period T_0). So does every finite linear combination of them, a **trigonometric polynomial of degree** N:

$$S_N(t)=\frac{a_0}{2}+\sum_{n=1}^{N}\bigl(a_n\cos n\omega_0 t+b_n\sin n\omega_0 t\bigr).$$

The decomposition problem is: *given a T_0-periodic $x(t)$, choose the coefficients so that S_N is as close as possible to x, and decide whether $S_N\to x$ as $N\to\infty$.*

The inner-product viewpoint

Chapter 9 treated vectors abstractly as elements of a space with an inner product. Functions of period T_0 form such a space. For real or complex functions that are square-integrable over a period, define

$$\langle x,y\rangle=\frac{1}{T_0}\int_{T_0}x(t)\,y^{*}(t)\,dt,\qquad \|x\|=\sqrt{\langle x,x\rangle}=\sqrt{\frac{1}{T_0}\int_{T_0}|x(t)|^2dt}.$$

The normalisation $1/T_0$ is the engineer's choice: it makes $\|x\|$ the **RMS value** of x and $\|x\|^2$ its **mean-square value**, the average power it would dissipate in a $1\ \Omega$ resistor. (Mathematics texts often omit $1/T_0$, which changes constants but nothing else.) The space of all such functions is denoted $L^2(T_0)$.

Orthogonality of the harmonic basis

With $\omega_0=2\pi/T_0$ and integers m,n:

$$\langle e^{jm\omega_0 t},e^{jn\omega_0 t}\rangle=\frac{1}{T_0}\int_{T_0}e^{j(m-n)\omega_0 t}\,dt=\begin{cases}1, & m=n,\\ 0, & m\neq n.\end{cases}$$

Equivalently, for the real functions with $m,n\geq 0$:

$$\frac{2}{T_0}\int_{T_0}\cos m\omega_0 t\,\cos n\omega_0 t\,dt=\delta_{mn}\quad(m,n\geq 1),\qquad \frac{2}{T_0}\int_{T_0}\sin m\omega_0 t\,\sin n\omega_0 t\,dt=\delta_{mn},$$
$$\int_{T_0}\sin m\omega_0 t\,\cos n\omega_0 t\,dt=0,\qquad \frac{1}{T_0}\int_{T_0}1\cdot 1\,dt=1,$$

where δ_{mn} is the Kronecker delta.

Proof (complex form). For $m=n$ the integrand is 1. For $m\neq n$, let $k=m-n\neq 0$; then $\int_{t_1}^{t_1+T_0}e^{jk\omega_0 t}dt=\bigl[e^{jk\omega_0 t}/(jk\omega_0)\bigr]_{t_1}^{t_1+T_0}=e^{jk\omega_0 t_1}(e^{j2\pi k}-1)/(jk\omega_0)=0$. The real relations follow by writing cos and sin as combinations of $e^{\pm j\theta}$, or directly by product-to-sum as in Ch. 3, §3.7. $\square$

So the set $\{e^{jn\omega_0 t}\}_{n\in\mathbb{Z}}$ is **orthonormal**, and the real set $\{1,\sqrt{2}\cos n\omega_0 t,\sqrt{2}\sin n\omega_0 t\}$ is orthonormal too. Each harmonic is a unit vector at "right angles" to every other.

Coefficients as projections

In $\mathbb{R}^3$ the component of a vector $\mathbf{v}$ along a unit vector $\hat{\mathbf{e}}$ is the projection $\langle\mathbf{v},\hat{\mathbf{e}}\rangle$, and the closest point to $\mathbf{v}$ in a plane spanned by orthonormal $\hat{\mathbf{e}}_1,\hat{\mathbf{e}}_2$ is $\langle\mathbf{v},\hat{\mathbf{e}}_1\rangle\hat{\mathbf{e}}_1+\langle\mathbf{v},\hat{\mathbf{e}}_2\rangle\hat{\mathbf{e}}_2$. Exactly the same holds in the function space.

Best approximation (least squares)

Let $x\in L^2(T_0)$ and let $\{\varphi_n\}_{n=-N}^{N}$ with $\varphi_n(t)=e^{jn\omega_0 t}$. Among all trigonometric polynomials $p(t)=\sum_{n=-N}^{N}d_n\varphi_n(t)$, the mean-square error $\|x-p\|^2$ is minimised uniquely by

$$d_n=c_n=\langle x,\varphi_n\rangle=\frac{1}{T_0}\int_{T_0}x(t)\,e^{-jn\omega_0 t}\,dt,$$

and the minimum error is

$$\|x-S_N\|^2=\|x\|^2-\sum_{n=-N}^{N}|c_n|^2.$$

Proof. Expand, using orthonormality:

$$\begin{aligned}\|x-p\|^2&=\|x\|^2-\sum_{n}\bigl(d_n^{*}\langle x,\varphi_n\rangle+d_n\langle x,\varphi_n\rangle^{*}\bigr)+\sum_{n}|d_n|^2\\&=\|x\|^2-\sum_{n}|c_n|^2+\sum_{n}|d_n-c_n|^2.\end{aligned}$$

(The second line follows by completing the square: $|d_n - c_n|^2 = |d_n|^2 - d_n^* c_n - d_n c_n^* + |c_n|^2$.) The last sum is non-negative and vanishes only when every $d_n = c_n$. $\square$

Three consequences are worth stating separately, because they recur throughout the chapter.

1. **Coefficients do not change when N grows.** Because the basis is orthogonal, the best coefficient for $\cos 3\omega_0 t$ is the same whether we approximate with 3 harmonics or 300. Contrast this with fitting a polynomial by least squares in the monomials $1, t, t^2, \ldots$, where adding a term changes all the earlier coefficients. This *finality of coefficients* is why a spectrum analyser can report "the 3rd harmonic" without reference to how many others it measures.
2. **Bessel's inequality.** Since the error is non-negative, $\sum_{n=-N}^{N} |c_n|^2 \le \|x\|^2$ for every N, hence $\sum_{n=-\infty}^{\infty} |c_n|^2 \le \|x\|^2 < \infty$. In particular $c_n \to 0$ as $|n| \to \infty$.
3. **Completeness and Parseval.** If the error tends to zero as $N \to \infty$, Bessel's inequality becomes an equality — Parseval's theorem (§15.8). That it does tend to zero for *every* square-integrable x is a deep theorem (the completeness of the trigonometric system) whose proof sketch appears in §15.6.

Fourier series

The **Fourier series** of a T_0-periodic function x is the formal series whose coefficients are the projections of x on the harmonics:

$$x(t) \sim \sum_{n=-\infty}^{\infty} c_n \, e^{jn\omega_0 t} = \frac{a_0}{2} + \sum_{n=1}^{\infty} \big(a_n \cos n\omega_0 t + b_n \sin n\omega_0 t\big).$$

The symbol $\sim$ means "has the Fourier series"; replacing it by $=$ requires the convergence theorems of §15.6.

Worked Example 15.1 — Least-squares approximation of a sawtooth

Let $x(t) = t$ on $(-\pi, \pi)$, extended with period 2π (a sawtooth). Find the best mean-square approximation by (a) a single term $b_1 \sin t$ and (b) $\sum_{n=1}^{3} b_n \sin nt$, and the residual mean-square error in each case. (Cosine terms and the constant are zero because x is odd; see §15.4.)

Solution. Mean-square value: $\|x\|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} t^2 dt = \frac{\pi^2}{3} = 3.2899$.

The projection on $\sin nt$ in real form is $b_n = \frac{2}{2\pi}\int_{-\pi}^{\pi} t \sin nt \, dt$. Integrating by parts,

$$\int_{-\pi}^{\pi} t \sin nt \, dt = \Big[-\frac{t\cos nt}{n}\Big]_{-\pi}^{\pi} + \frac{1}{n}\int_{-\pi}^{\pi} \cos nt \, dt = -\frac{2\pi\cos n\pi}{n} = \frac{2\pi(-1)^{n+1}}{n},$$

so $b_n = 2(-1)^{n+1}/n$: $b_1 = 2$, $b_2 = -1$, $b_3 = 2/3$.

Each term $b_n \sin nt$ has mean-square value $b_n^2/2$, and by orthogonality the error is $\|x\|^2$ minus the sum of these.

(a) Error $= 3.2899 - \frac{4}{2} = 1.2899$: the single sine captures $2/3.2899 = 60.8\%$ of the mean-square value.

(b) Error $= 3.2899 - 2 - 0.5 - 0.2222 = 0.5676$: three terms capture 82.7%.

Check. Numerically integrating $(t - \sum_{n\le 3} b_n \sin nt)^2$ over a period and dividing by 2π gives 0.56765. ✓ Note that $b_1 = 2$ is the best coefficient in both (a) and (b) — finality of coefficients. The slow capture (still 17% error with three terms) reflects the jump of the sawtooth at $t = \pm\pi$; §15.7 explains why jumps force $|b_n| \propto 1/n$.

Worked Example 15.2 — Why a non-orthogonal basis is awkward

Approximate $x(t) = |t|$ on $(-\pi, \pi)$ in mean square by (a) a constant d_0, and (b) $d_0 + d_1 \cos t$. Compare with what happens if we instead used the non-orthogonal pair $\{1, \cos^2(t/2)\}$.

Solution. (a) The best constant is the projection on 1: $d_0 = \frac{1}{2\pi}\int_{-\pi}^{\pi} |t| dt = \frac{\pi}{2} = 1.5708$, the mean value.

(b) Because 1 and $\cos t$ are orthogonal, d_0 is unchanged and $d_1 = \frac{2}{2\pi}\int_{-\pi}^{\pi} |t| \cos t \, dt = \frac{2}{\pi}\int_0^{\pi} t\cos t \, dt = \frac{2}{\pi}[t\sin t + \cos t]_0^{\pi} = \frac{2}{\pi}(-2) = -\frac{4}{\pi} = -1.2732$.

Now note $\cos^2(t/2) = \frac{1}{2} + \frac{1}{2}\cos t$ spans the same two-dimensional space as $\{1, \cos t\}$, so the best approximation is the same function $1.5708 - 1.2732\cos t = e_0 + e_1 \cos^2(t/2)$ with $e_1 = -2.5465$ and $e_0 = 1.5708 + 1.2732 = 2.8440$. The best constant *by itself* was 1.5708, but in the combination it must change to 2.8440: with a non-orthogonal basis, adding a function alters the coefficients already found, and each coefficient is no longer a single integral but the solution of a linear system (the normal equations of Ch. 8). Orthogonality makes each coefficient an independent, final, one-line integral.

Engineering note — a spectrum analyser computes projections

A swept or FFT spectrum analyser estimates $|c_n|$ by correlating the input with $e^{-jn\omega_0 t}$ over a finite window: exactly the projection integral above. A lock-in amplifier does the same for one chosen harmonic, multiplying by a reference $\cos n\omega_0 t$ and $\sin n\omega_0 t$ and low-pass filtering (averaging) the products. The orthogonality relations are why the other harmonics average out of the measurement.

Pitfall — the decomposition needs exact periodicity

Orthogonality holds only over an *exact* period, or a whole number of periods. Integrating over a window that is not a whole number of periods (a common situation when analysing measured data) leaks energy from each harmonic into its neighbours. The Fourier series is a statement about an exactly periodic idealisation; finite-record effects belong to the Fourier transform and the DFT (Ch. 16, Ch. 24).

15.2 Trigonometric Fourier series

Motivation

The trigonometric form uses only real functions — cosines and sines — and so is the natural form when the waveform is real, when we want to see its symmetry directly, and when we want amplitudes and phases that can be read on an oscilloscope or written into a phasor calculation. It is also the form that arises from separation of variables in the heat, wave and Laplace equations (Ch. 13), where sines and cosines appear as eigenfunctions of d^2/dx^2 with boundary conditions.

The Euler (Euler–Fourier) formulas

Suppose a T_0-periodic function can be written as

$$x(t) = \frac{a_0}{2} + \sum_{n=1}^{\infty} \left(a_n \cos n\omega_0 t + b_n \sin n\omega_0 t \right),$$

and that the series may be integrated term by term after multiplication by a bounded function (true, for example, when it converges uniformly; §15.6 shows the formulas below are correct in far greater generality). Multiply both sides by $\cos m\omega_0 t$, $m \geq 1$, and integrate over a period. By orthogonality every term vanishes except $a_m \int_{T_0} \cos^2 m\omega_0 t \, dt = a_m T_0/2$. Similarly with $\sin m\omega_0 t$. Integrating without a multiplier kills every harmonic and leaves $\frac{a_0}{2} T_0$.

Euler formulas for the trigonometric Fourier coefficients

For a T_0-periodic function integrable over a period, with $\omega_0 = 2\pi/T_0$,

$$a_n = \frac{2}{T_0} \int_{T_0} x(t) \cos n\omega_0 t \, dt \quad (n \geq 0), \qquad b_n = \frac{2}{T_0} \int_{T_0} x(t) \sin n\omega_0 t \, dt \quad (n \geq 1).$$

The constant term is $\dfrac{a_0}{2} = \dfrac{1}{T_0} \displaystyle\int_{T_0} x(t)\, dt$, the **mean (DC) value** of x.

The convention of writing the constant as $a_0/2$ is purely so that the formula for a_n also gives a_0; some books write a_0 for the mean value instead and adjust the formula. Always check which convention a table uses.

For the normalised period $T_0 = 2\pi$ ($\omega_0 = 1$) the formulas read

$$a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} x(t) \cos nt \, dt, \qquad b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} x(t) \sin nt \, dt.$$

For a function given on $(-L, L)$, so $T_0 = 2L$ and $\omega_0 = \pi/L$ — the usual form for spatial problems in Ch. 13:

$$x(s) \sim \frac{a_0}{2} + \sum_{n=1}^{\infty} \left(a_n \cos \frac{n\pi s}{L} + b_n \sin \frac{n\pi s}{L} \right), \qquad a_n = \frac{1}{L} \int_{-L}^{L} x(s) \cos \frac{n\pi s}{L} \, ds, \quad b_n = \frac{1}{L} \int_{-L}^{L} x(s) \sin \frac{n\pi s}{L} \, ds.$$

Choice of interval. The integrand $x(t)\cos n\omega_0 t$ is itself T_0-periodic, and the integral of a periodic function over one period does not depend on where the period starts:

$$\int_{\alpha}^{\alpha + T_0} g(t)\, dt = \int_{0}^{T_0} g(t)\, dt \qquad \text{for every } \alpha,$$

because the piece cut from one end is exactly the piece added at the other. Choose the interval that makes the integration easiest — usually the one in which x has the fewest pieces or a symmetric form.

Dimensions. a_n and b_n carry the units of x (the factor $2/T_0$ cancels the seconds from dt), and $n\omega_0 t$ is dimensionless. A coefficient in volt-seconds signals a forgotten $1/T_0$.

Amplitude–phase (harmonic) form

Grouping each cosine–sine pair into one sinusoid (Ch. 3, §3.2):

$$a_n \cos n\omega_0 t + b_n \sin n\omega_0 t = A_n \cos(n\omega_0 t + \phi_n), \qquad A_n = \sqrt{a_n^2 + b_n^2}, \quad \phi_n = \operatorname{atan2}(-b_n,\, a_n).$$

So

$$x(t) \sim A_0 + \sum_{n=1}^{\infty} A_n \cos(n\omega_0 t + \phi_n), \qquad A_0 = \frac{a_0}{2}.$$

The pair (A_n, ϕ_n) is the **amplitude** and **phase** of the nth harmonic; plotted against $n\omega_0$ they form the one-sided amplitude and phase spectra (§15.5). Note the sign in ϕ_n: with the cosine reference, a pure $+\sin$ term has phase $-90°$. A sine-reference form $A_n \sin(n\omega_0 t + \psi_n)$ with $\psi_n = \phi_n + 90°$ is common in power-systems literature; state the reference whenever phases are quoted.

A first full example: the square wave

Worked Example 15.3 — Square wave

Find the Fourier series of the square wave $x(t) = A$ for $0 < t < T_0/2$, $x(t) = -A$ for $T_0/2 < t < T_0$, period T_0.

Solution. Mean value: the two halves cancel, so $a_0 = 0$.

Cosine coefficients:

$$a_n = \frac{2}{T_0}\Big[\int_0^{T_0/2} A\cos n\omega_0 t\,dt - \int_{T_0/2}^{T_0} A\cos n\omega_0 t\,dt\Big] = \frac{2A}{T_0 n\omega_0}\Big[\sin n\omega_0 t\Big|_0^{T_0/2} - \sin n\omega_0 t\Big|_{T_0/2}^{T_0}\Big] = 0,$$

since $\sin(n\pi) = \sin(2n\pi) = 0$.

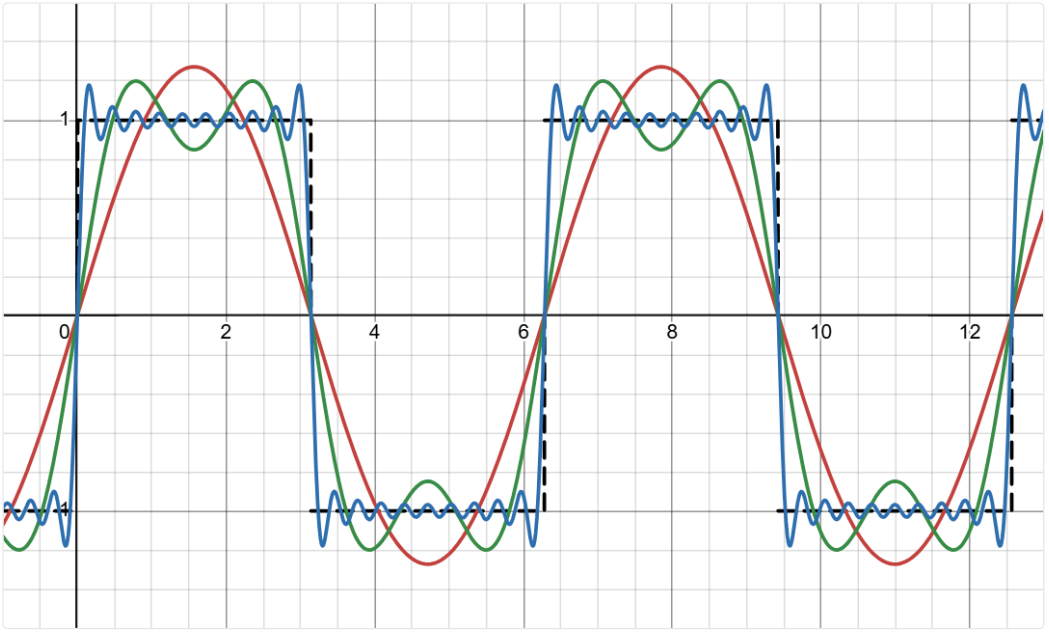
Sine coefficients, with $n\omega_0 T_0/2 = n\pi$ and $T_0\omega_0 = 2\pi$:

$$b_n = \frac{2A}{T_0 n\omega_0}\Big[-\cos n\omega_0 t\Big|_0^{T_0/2} + \cos n\omega_0 t\Big|_{T_0/2}^{T_0}\Big] = \frac{A}{n\pi}\big[(1-\cos n\pi) + (1-\cos n\pi)\big] = \frac{2A}{n\pi}\big(1-(-1)^n\big).$$

So $b_n = 4A/(n\pi)$ for odd n and 0 for even n:

$$x(t) = \frac{4A}{\pi}\Big(\sin\omega_0 t + \frac{1}{3}\sin 3\omega_0 t + \frac{1}{5}\sin 5\omega_0 t + \cdots\Big) = \frac{4A}{\pi}\sum_{k=1}^{\infty}\frac{\sin(2k-1)\omega_0 t}{2k-1}.$$

Checks. (i) Only odd harmonics — predicted by half-wave symmetry (§15.4). (ii) Only sines — predicted by odd symmetry. (iii) At $t = T_0/4$: $\frac{4A}{\pi}(1 - \frac{1}{3} + \frac{1}{5} - \cdots) = \frac{4A}{\pi}\cdot\frac{\pi}{4} = A$ by the Leibniz series. ✓ (iv) The fundamental amplitude $4A/\pi = 1.273A$ *exceeds* the square wave's peak — a reminder that harmonics can add destructively.



Partial sums of the square-wave series with $\omega_0 = 1$, $A = 1$: fundamental only (red), harmonics 1 and 3 (green), harmonics up to 19 (blue). The sum approaches the square wave (dashed) everywhere except near the jumps, where an overshoot persists (§15.6).

More standard waveforms

Worked Example 15.4 — Ramp on a non-symmetric interval

A sawtooth generator produces $x(t) = t$ volts for $0 < t < 2$ s, repeating with period $T_0 = 2$ s. Find its trigonometric Fourier series.

Solution. $\omega_0 = 2\pi/2 = \pi$ rad/s. The interval $(0, 2)$ is the natural one here.

Mean value: $\frac{a_0}{2} = \frac{1}{2}\int_0^2 t\,dt = 1$ V.

For $n \geq 1$ integrate by parts, using $\sin 2n\pi = 0$, $\cos 2n\pi = 1$:

$$a_n = \frac{2}{2}\int_0^2 t\cos n\pi t\,dt = \Big[\frac{t\sin n\pi t}{n\pi}\Big]_0^2 - \frac{1}{n\pi}\int_0^2 \sin n\pi t\,dt = 0 + \frac{1}{n^2\pi^2}\Big[\cos n\pi t\Big]_0^2 = 0,$$

$$b_n = \int_0^2 t\sin n\pi t\,dt = \Big[-\frac{t\cos n\pi t}{n\pi}\Big]_0^2 + \frac{1}{n\pi}\int_0^2 \cos n\pi t\,dt = -\frac{2}{n\pi}.$$

Hence

$$x(t) = 1 - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{\sin n\pi t}{n}\ \text{V}.$$

Interpretation. After removing the mean, the periodic function $x(t) - 1$ is odd: $x(-t) - 1 = -(x(t) - 1)$ (check: for $0 < t < 2$, $x(-t) = x(2 - t) = 2 - t$, so $x(-t) - 1 = 1 - t$). That is why only sines survive. Every harmonic, odd and even, is present, with amplitude $2/(n\pi)$: 0.637 V, 0.318 V, 0.212 V, … — falling only as $1/n$ because of the jump at $t = 0$.

Check. Numerical quadrature gives $a_1 = 0.0000$, $b_1 = -0.6366$, $b_2 = -0.3183$, $b_3 = -0.2122$. ✓

Worked Example 15.5 — Half-wave rectified sine

A half-wave rectifier fed by $V_m \sin\omega_0 t$ produces $x(t) = V_m \sin\omega_0 t$ for $0 \leq \omega_0 t \leq \pi$ and $x(t) = 0$ for $\pi < \omega_0 t < 2\pi$. Find the Fourier series.

Solution. Work in $\theta = \omega_0 t$, period 2π, and set $V_m = 1$ (multiply by V_m at the end).

Mean: $\frac{a_0}{2} = \frac{1}{2\pi}\int_0^{\pi}\sin\theta\,d\theta = \frac{1}{\pi}$.

Cosine coefficients. Use $\sin\theta\cos n\theta = \frac{1}{2}[\sin(1+n)\theta + \sin(1-n)\theta]$. For $n \neq 1$,

$$a_n = \frac{1}{\pi}\int_0^{\pi}\sin\theta\cos n\theta\,d\theta = \frac{1}{2\pi}\Big[\frac{1-\cos(1+n)\pi}{1+n} + \frac{1-\cos(1-n)\pi}{1-n}\Big].$$

For odd $n \neq 1$, $1 \pm n$ is even, both cosines equal 1 and $a_n = 0$. For even n, $\cos(1 \pm n)\pi = -1$ and

$$a_n = \frac{1}{2\pi}\Big[\frac{2}{1+n} + \frac{2}{1-n}\Big] = \frac{1}{\pi}\cdot\frac{2}{1-n^2} = -\frac{2}{\pi(n^2-1)}.$$

For $n = 1$: $a_1 = \frac{1}{\pi}\int_0^{\pi}\sin\theta\cos\theta\,d\theta = 0$.

Sine coefficients. $b_1 = \frac{1}{\pi}\int_0^{\pi}\sin^2\theta\,d\theta = \frac{1}{2}$. For $n \geq 2$, $\sin\theta\sin n\theta = \frac{1}{2}[\cos(n-1)\theta - \cos(n+1)\theta]$ integrates over $(0, \pi)$ to $\frac{1}{2}\big[\frac{\sin(n-1)\pi}{n-1} - \frac{\sin(n+1)\pi}{n+1}\big] = 0$. So $b_n = 0$ for $n \geq 2$.

Result (writing $n = 2k$):

$$x(t) = V_m\Big[\frac{1}{\pi} + \frac{1}{2}\sin\omega_0 t - \frac{2}{\pi}\sum_{k=1}^{\infty}\frac{\cos 2k\omega_0 t}{4k^2-1}\Big] = V_m\Big[0.3183 + 0.5\sin\omega_0 t - 0.2122\cos 2\omega_0 t - 0.0424\cos 4\omega_0 t - \cdots\Big].$$

Interpretation. The waveform contains DC (the useful output of a rectifier), *half* of the original fundamental, and even harmonics only. The structure is explained in §15.4: $x(t) = \frac{V_m}{2}\big(\sin\omega_0 t + |\sin\omega_0 t|\big)$, the sum of half the input sinusoid and half of a full-wave rectified sine, which contains only DC and even harmonics.

Check. Numerical quadrature: $a_0 = 0.63662$, $b_1 = 0.5$, $a_2 = -0.212207$, $a_4 = -0.042441$, $a_3 = b_3 = 0$. ✓

Worked Example 15.6 — Rectangular pulse train (trigonometric form)

A pulse train has height A, width τ and period T_0, centred on $t = 0$: $x(t) = A$ for $|t| < \tau/2$ and 0 elsewhere in $(-T_0/2, T_0/2)$. Let $D = \tau/T_0$ be the duty cycle. Find a_n, b_n.

Solution. The function is even about $t = 0$, so every $b_n = \frac{2}{T_0}\int x(t)\sin n\omega_0 t\,dt = 0$ (odd integrand on a symmetric interval). Mean value $a_0/2 = A\tau/T_0 = AD$. For $n \geq 1$,

$$a_n = \frac{2}{T_0}\int_{-\tau/2}^{\tau/2} A\cos n\omega_0 t\,dt = \frac{4A}{T_0 n\omega_0}\sin\frac{n\omega_0\tau}{2} = \frac{2A}{n\pi}\sin(n\pi D) = 2AD\,\mathrm{sinc}(nD),$$

with the normalised $\mathrm{sinc}(u) = \sin(\pi u)/(\pi u)$ used in Ch. 16. So

$$x(t) = AD + 2AD\sum_{n=1}^{\infty}\mathrm{sinc}(nD)\cos n\omega_0 t.$$

Special cases. $D = \frac{1}{2}$ gives $a_n = \frac{2A}{n\pi}\sin\frac{n\pi}{2}$: $\frac{2A}{\pi}, 0, -\frac{2A}{3\pi}, 0, \frac{2A}{5\pi}, \ldots$ — a square wave of levels 0 and A, i.e. $\frac{A}{2}$ plus half of Worked Example 15.3 shifted by a quarter period (the sign alternation is that shift; §15.7). $D = \frac{1}{4}$ gives harmonics 4, 8, 12, … missing, because $\sin(n\pi/4) = 0$ at those n. In general, whenever $1/D$ is an integer, the harmonics at multiples of $1/D$ vanish.

The envelope of a_n is $2AD\,\mathrm{sinc}(fD/f_0)$ with first null at $f = 1/\tau$: **narrower pulses spread their power over more harmonics.** This is the discrete version of the pulse-width/bandwidth reciprocity of Ch. 16.

Engineering note — table conventions

Tables of Fourier series differ in (i) whether the constant is a_0 or $a_0/2$, (ii) the time origin of the waveform (a shift changes the sine/cosine mix but not the amplitudes A_n), (iii) whether amplitudes are peak or RMS values, and (iv) whether frequency is in rad/s or Hz. When a datasheet says "3rd harmonic 4%" it almost always means the ratio A_3/A_1, which is the same for peak and RMS values.

Pitfall — special values and the forgotten $n = 1$

Two errors account for most wrong coefficients. (1) Writing $\cos n\pi = 1$ instead of $(-1)^n$, or $\sin(n\pi/2) = 1$ for all n. Keep a table: $\sin n\pi = 0$, $\cos n\pi = (-1)^n$, $\sin\frac{n\pi}{2} = 0, 1, 0, -1, \ldots$ for $n = 0, 1, 2, 3$, $\cos\frac{n\pi}{2} = 1, 0, -1, 0, \ldots$. (2) Dividing by $n - 1$ or $n^2 - 1$ and forgetting to treat $n = 1$ separately, as in Worked Example 15.5. Whenever a formula has a factor that vanishes for a particular n, compute that coefficient directly.

15.3 Complex Fourier series

Motivation

The trigonometric form needs two families of coefficients and two families of formulas, and its algebra — shifting, differentiating, multiplying by a frequency response — keeps generating products of sines and cosines that must be untangled with identities. The complex exponential form packs each harmonic into a *single* complex number, turns differentiation into multiplication by $jn\omega_0$, turns a time shift into multiplication by a phase factor, and makes the LTI response $c_n H(jn\omega_0)$ a one-line statement. It is also the form that generalises directly to the Fourier transform (Ch. 16), the Z-transform (Ch. 17) and the DFT. In signals and systems work it is the default.

From real to complex form

Euler's formula gives $\cos\theta = \frac{1}{2}(e^{j\theta} + e^{-j\theta})$ and $\sin\theta = \frac{1}{2j}(e^{j\theta} - e^{-j\theta})$. Substituting into the trigonometric series,

$$a_n\cos n\omega_0 t + b_n\sin n\omega_0 t = \frac{a_n - jb_n}{2}e^{jn\omega_0 t} + \frac{a_n + jb_n}{2}e^{-jn\omega_0 t}.$$

Defining

$$c_0 = \frac{a_0}{2}, \qquad c_n = \frac{a_n - jb_n}{2}, \qquad c_{-n} = \frac{a_n + jb_n}{2} \qquad (n \geq 1),$$

the series becomes a single two-sided sum.

Complex (exponential) Fourier series

The complex Fourier series of a T_0-periodic function x is

$$x(t) \sim \sum_{n=-\infty}^{\infty} c_n\, e^{jn\omega_0 t}, \qquad c_n = \frac{1}{T_0}\int_{T_0} x(t)\, e^{-jn\omega_0 t}\,dt, \quad n \in \mathbb{Z}.$$

The partial sums are taken symmetrically, $S_N(t) = \sum_{n=-N}^{N} c_n e^{jn\omega_0 t}$, so that S_N is the same function as the trigonometric partial sum of degree N.

The coefficient formula can be derived directly — it is the projection $\langle x, e^{jn\omega_0 t}\rangle$ of §15.1 — or checked by combining the Euler formulas: $\frac{a_n - jb_n}{2} = \frac{1}{T_0}\int x(t)(\cos n\omega_0 t - j\sin n\omega_0 t)\,dt$. Note the single prefactor $1/T_0$, not $2/T_0$: each real harmonic of amplitude A_n is split equally between two lines of magnitude $A_n/2$ at $\pm n\omega_0$.

Conversions between coefficient forms

For $n \geq 1$:

$$a_n = c_n + c_{-n}, \qquad b_n = j(c_n - c_{-n}),$$
$$A_n = 2|c_n| \text{ (if } x \text{ real)}, \quad \phi_n = \angle c_n \text{ (if } x \text{ real)},$$

and $c_0 = a_0/2 = A_0$. For a real x, $a_n = 2\,\mathrm{Re}\{c_n\}$ and $b_n = -2\,\mathrm{Im}\{c_n\}$.

The phase relation follows because $c_n = \frac{a_n - jb_n}{2} = \frac{A_n}{2}e^{j\phi_n}$ with $\phi_n = \operatorname{atan2}(-b_n, a_n)$, exactly the phase of the amplitude–phase form in §15.2. Then $c_n e^{jn\omega_0 t} + c_{-n}e^{-jn\omega_0 t} = 2\,\mathrm{Re}\{c_n e^{jn\omega_0 t}\} = A_n\cos(n\omega_0 t + \phi_n)$: c_n **is half the phasor of the nth harmonic.** This is the bridge to Ch. 2 phasor analysis.

Real signals: conjugate symmetry

Conjugate symmetry

$x(t)$ is real if and only if $c_{-n} = c_n^*$ for all n. Then $|c_{-n}| = |c_n|$ (even magnitude spectrum) and $\angle c_{-n} = -\angle c_n$ (odd phase spectrum).

Proof. $c_{-n} = \frac{1}{T_0}\int x(t)e^{jn\omega_0 t}dt$ and $c_n^* = \frac{1}{T_0}\int x^*(t)e^{jn\omega_0 t}dt$; these agree for all n iff $x = x^*$ (by uniqueness of coefficients, §15.6). □

The negative-frequency coefficients of a real signal therefore carry no new information; they are the "clockwise-rotating" partners of Ch. 3, §3.5, needed so that the imaginary parts cancel. For a *complex* signal — the analytic signal or the baseband I/Q signal of a radio receiver, $x = I + jQ$ — the positive- and negative-frequency coefficients are independent, and a one-sided description loses information.

Line spectra, two-sided

Plotting $|c_n|$ and $\angle c_n$ against $\omega = n\omega_0$ (or $f = nf_0$) for $n \in \mathbb{Z}$ gives the **two-sided line spectrum**: a set of vertical lines at the harmonic frequencies. Because the frequencies are discrete, a periodic signal has a *line* (discrete) spectrum, while an aperiodic signal has a continuous spectrum (Ch. 16). Section 15.5 compares one- and two-sided spectra and their conventions.

Computing c_n directly

The complex formula usually needs fewer integrations than the real pair, because $\int e^{at}dt = e^{at}/a$ handles exponential, sinusoidal and constant pieces at once.

Worked Example 15.7 — Pulse train in complex form, with numbers

A clock signal is a rectangular pulse train of height $A = 5$ V, width $\tau = 1$ μs and period $T_0 = 4$ μs, with a pulse centred on $t = 0$. Find c_n, and list $c_0, \dots, c_4$ and the frequencies at which they occur.

Solution. $\omega_0 = 2\pi/T_0$, $D = \tau/T_0 = 1/4$. For $n \neq 0$,

$$c_n = \frac{1}{T_0}\int_{-\tau/2}^{\tau/2} Ae^{-jn\omega_0 t}\,dt = \frac{A}{T_0}\cdot\frac{e^{-jn\omega_0\tau/2} - e^{jn\omega_0\tau/2}}{-jn\omega_0} = \frac{A}{T_0}\cdot\frac{2\sin(n\omega_0\tau/2)}{n\omega_0} = AD\,\mathrm{sinc}(nD),$$

using $n\omega_0\tau/2 = n\pi D$. For $n = 0$ the mean is AD, consistent with $\mathrm{sinc}\,0 = 1$. The coefficients are real (because x is real and even; §15.4).

n	$f = n/T_0$	$c_n = 1.25\,\mathrm{sinc}(n/4)$ **(V)**
0	0	1.2500
±1	250 kHz	1.1254
±2	500 kHz	0.7958
±3	750 kHz	0.3751
±4	1 MHz	0

The first null is at $f = 1/\tau = 1$ MHz. Compare with Worked Example 15.6: $a_n = 2c_n$, e.g. the 250 kHz harmonic has peak amplitude $2(1.1254) = 2.251$ V.

Check. $c_1 = 1.25 \cdot \sin(\pi/4)/(\pi/4) = 1.25 \times 0.9003 = 1.1254$. ✓

Worked Example 15.8 — Periodic exponential decay

The waveform $x(t) = e^{-at}$ for $0 \le t < T_0$, repeated with period T_0, models a periodically recharged and discharged RC node. Find c_n, and evaluate for $a = 1\ \text{s}^{-1}$, $T_0 = 2\pi$ s.

Solution.

$$c_n = \frac{1}{T_0}\int_0^{T_0} e^{-at}e^{-jn\omega_0 t}\,dt = \frac{1}{T_0}\Big[\frac{e^{-(a+jn\omega_0)t}}{-(a+jn\omega_0)}\Big]_0^{T_0} = \frac{1-e^{-aT_0}e^{-jn2\pi}}{T_0(a+jn\omega_0)} = \frac{1-e^{-aT_0}}{T_0\,(a+jn\omega_0)}.$$

With $a=1$, $T_0=2\pi$, $\omega_0=1$: $\frac{1-e^{-2\pi}}{2\pi} = 0.158858$, so $c_n = 0.158858/(1+jn)$: $c_0 = 0.1589$, $c_1 = 0.0794 - 0.0794j = 0.1123\angle -45^\circ$, $c_2 = 0.0318 - 0.0635j = 0.0710\angle -63.4^\circ$.

Interpretation. $|c_n| \approx 0.159/n$ for large n: a $1/n$ decay, because the waveform jumps from e^{-aT_0} back to 1 at each period boundary. The factor $1/(a+jn\omega_0)$ is the Laplace transform $1/(s+a)$ at $s = jn\omega_0$ — a connection made general next.

Check. Numerical quadrature of the defining integral reproduces $c_1 = 0.079429 - 0.079429j$ and $c_2 = 0.031772 - 0.063543j$. ✓

Coefficients from the Laplace transform of one period

Let $x_1(t)$ be one period of x, i.e. $x_1(t) = x(t)$ on $[0, T_0)$ and 0 elsewhere, and let $X_1(s) = \mathcal{L}\{x_1\} = \int_0^{T_0} x(t)e^{-st}dt$, an entire function of s because the integral is over a finite interval. Comparing with the definition of c_n:

Coefficients via the one-period transform

$$c_n = \frac{1}{T_0}\,X_1(jn\omega_0), \qquad X_1(s) = \int_0^{T_0} x(t)\,e^{-st}\,dt.$$

Chapter 14 showed that the Laplace transform of the periodic extension (starting at $t=0$) is $X(s) = X_1(s)/(1-e^{-sT_0})$. Its poles are at the zeros of $1-e^{-sT_0}$, i.e. at $s = jn\omega_0$, and the residue there is $X_1(jn\omega_0)/T_0 = c_n$. So the Fourier coefficients are exactly the residues of the Laplace transform at its imaginary-axis poles — the steady-state part of the inverse Laplace transform. Chapter 16 obtains the same relation as $c_n = X(n\omega_0)/T_0$ from the Fourier transform of one period.

Worked Example 15.9 — Half-wave rectifier via the one-period transform

Recompute the coefficients of Worked Example 15.5 ($V_m = 1$, $\omega_0 = 1$) using $X_1(s)$.

Solution. One period is $\sin t$ on $[0,\pi]$ and 0 on $(\pi, 2\pi)$. Writing $\sin t\,[u(t) - u(t-\pi)] = \sin t\,u(t) + \sin(t-\pi)u(t-\pi)$ and using the shift theorem of Ch. 14,

$$X_1(s) = \frac{1+e^{-\pi s}}{s^2+1}.$$

For $n \neq \pm 1$: $c_n = \frac{1}{2\pi}\cdot\frac{1+(-1)^n}{1-n^2}$, which is 0 for odd n and $\frac{1}{\pi(1-n^2)}$ for even n. Then $a_n = 2\,\mathrm{Re}\,c_n = -\frac{2}{\pi(n^2-1)}$ — as before. For $n=0$, $c_0 = 1/\pi$. ✓

For $n = 1$, $X_1(s)$ has a removable $0/0$ at $s = j$: write $X_1(s) = \frac{1+e^{-\pi s}}{(s-j)(s+j)}$ and apply l'Hôpital to the numerator over $(s-j)$: $\lim_{s\to j}\frac{-\pi e^{-\pi s}}{1}\cdot\frac{1}{s+j} = \frac{-\pi e^{-j\pi}}{2j} = \frac{\pi}{2j}$. So $c_1 = \frac{1}{2\pi}\cdot\frac{\pi}{2j} = -\frac{j}{4}$ and $b_1 = -2\,\mathrm{Im}\,c_1 = \frac{1}{2}$. ✓

Lesson. The one-period transform is often the quickest route when x_1 is built from standard Laplace pairs and shifts; the special harmonics where the denominator vanishes need a limit.

Worked Example 15.10 — Reading coefficients off without integration

Find the complex Fourier coefficients of $x(t) = \cos^3\omega_0 t + 2\sin 2\omega_0 t$, and of the sawtooth $x(t) = t$ on $(-\pi, \pi)$ from its known sine series.

Solution. (a) By the power-reduction formula of Ch. 3, $\cos^3\theta = \frac{3}{4}\cos\theta + \frac{1}{4}\cos 3\theta$. So

$$x(t) = \tfrac{3}{8}\big(e^{j\omega_0 t} + e^{-j\omega_0 t}\big) + \tfrac{1}{8}\big(e^{j3\omega_0 t} + e^{-j3\omega_0 t}\big) + \tfrac{1}{j}\big(e^{j2\omega_0 t} - e^{-j2\omega_0 t}\big).$$

Hence $c_{\pm 1} = \frac{3}{8}$, $c_{\pm 3} = \frac{1}{8}$, $c_2 = -j$, $c_{-2} = j$, all others zero. Uniqueness of coefficients (§15.6) guarantees that *any* way of writing x as a finite sum of harmonics gives its Fourier series.

(b) From Worked Example 15.1, $a_n = 0$, $b_n = 2(-1)^{n+1}/n$. Then $c_n = \frac{a_n - jb_n}{2} = -j\frac{(-1)^{n+1}}{n} = j\frac{(-1)^n}{n}$ for $n \neq 0$, $c_0 = 0$. Check conjugate symmetry: $c_{-n} = j\frac{(-1)^n}{-n} = -j\frac{(-1)^n}{n} = c_n^*$. ✓

Pitfall — factor-of-two errors between the forms

The most frequent mistake in this whole subject is mixing the $1/T_0$ of c_n with the $2/T_0$ of a_n, b_n, or reading $|c_n|$ as the amplitude of the nth harmonic. For a real signal the amplitude of the harmonic at $n\omega_0$ is $A_n = 2|c_n|$; only the DC term has $A_0 = c_0$ with no factor 2. A quick sanity test: $\cos\omega_0 t$ has $c_{\pm 1} = \frac{1}{2}$ and $a_1 = 1$.

Engineering note — phasors are positive-frequency coefficients

In AC circuit analysis a voltage $V_m\cos(\omega t+\phi)$ is represented by the phasor $\mathbf{V}=V_m e^{j\phi}$ (peak) or $\frac{V_m}{\sqrt{2}}e^{j\phi}$ (RMS). In Fourier language $\mathbf{V}_{\text{peak}}=2c_1$. A multi-harmonic waveform is then a *list* of phasors $\mathbf{V}_n=2c_n$, one per harmonic, each analysed with the impedances $Z(jn\omega_0)$ at its own frequency — the method of §15.9.

15.4 Even and odd functions

Motivation

Most of the integrals in §15.2 turned out to be zero, and in every case the zero could have been predicted from a symmetry of the waveform. Recognising symmetry before integrating halves (or quarters) the work, provides an independent check on the answer, and — more importantly for engineers — links the *shape* of a waveform to its *harmonic content*: a symmetrical inverter output has no even harmonics, a balanced push–pull amplifier cancels even-order distortion, and an asymmetrical clipping characteristic generates a second harmonic and a DC shift. This section collects the symmetry rules and the half-range expansions that follow from them.

Even and odd functions

Even and odd functions

A function is **even** if $x(-t)=x(t)$ for all t (graph symmetric about the vertical axis) and **odd** if $x(-t)=-x(t)$ (graph symmetric under a 180° rotation about the origin). An odd function defined at 0 has $x(0)=0$.

The rules for products follow the rules for signs: even × even and odd × odd are even; even × odd is odd. For integrals over a symmetric interval,

$$\int_{-a}^{a} x_{\text{even}}(t)\,dt = 2\int_{0}^{a} x_{\text{even}}(t)\,dt, \qquad \int_{-a}^{a} x_{\text{odd}}(t)\,dt = 0.$$

Since $\cos n\omega_0 t$ is even and $\sin n\omega_0 t$ is odd, applying these rules to the Euler formulas over $(-T_0/2, T_0/2)$ gives:

Fourier series of even and odd functions

If x is even, $b_n=0$ for all n and x has a **Fourier cosine series**

$$x(t)\sim \frac{a_0}{2}+\sum_{n=1}^{\infty} a_n\cos n\omega_0 t, \qquad a_n=\frac{4}{T_0}\int_0^{T_0/2} x(t)\cos n\omega_0 t\,dt.$$

If x is odd, $a_n=0$ for all n (including a_0) and x has a **Fourier sine series**

$$x(t)\sim \sum_{n=1}^{\infty} b_n\sin n\omega_0 t, \qquad b_n=\frac{4}{T_0}\int_0^{T_0/2} x(t)\sin n\omega_0 t\,dt.$$

In complex form: x real and even $\iff$ c_n real and even in n; x real and odd $\iff$ c_n purely imaginary and odd in n.

Even/odd decomposition. Every function splits uniquely into even and odd parts,

$$x(t)=x_e(t)+x_o(t), \qquad x_e(t)=\frac{x(t)+x(-t)}{2}, \qquad x_o(t)=\frac{x(t)-x(-t)}{2}.$$

The cosine terms of the Fourier series of x are exactly the Fourier series of x_e, and the sine terms are the series of x_o. For real x: $x_e \leftrightarrow \operatorname{Re}\{c_n\}$ and $x_o \leftrightarrow j\operatorname{Im}\{c_n\}$.

Symmetry is a property of the waveform *and the chosen time origin*. The square wave of Worked Example 15.3 is odd about $t=0$; shifting the origin by $T_0/4$ makes it even, and its series becomes a cosine series with the same amplitudes (§15.7). Many waveforms have **hidden symmetry**: they become even or odd after subtracting their mean value (Worked Example 15.4) or after a shift of origin. Look for both before integrating.

Half-wave symmetry

Half-wave (odd-harmonic) symmetry

A T_0-periodic function has **half-wave symmetry** if

$$x\!\left(t+\frac{T_0}{2}\right)=-x(t) \qquad \text{for all } t.$$

Graphically, the second half-cycle is the first half-cycle shifted by $T_0/2$ and turned upside down. The mean value is necessarily zero.

Half-wave symmetry ⇔ odd harmonics only

x has half-wave symmetry if and only if $c_n=0$ (equivalently $a_n=b_n=0$) for every even n, including $n=0$. In that case, for odd n,

$$a_n=\frac{4}{T_0}\int_0^{T_0/2} x(t)\cos n\omega_0 t\,dt, \qquad b_n=\frac{4}{T_0}\int_0^{T_0/2} x(t)\sin n\omega_0 t\,dt.$$

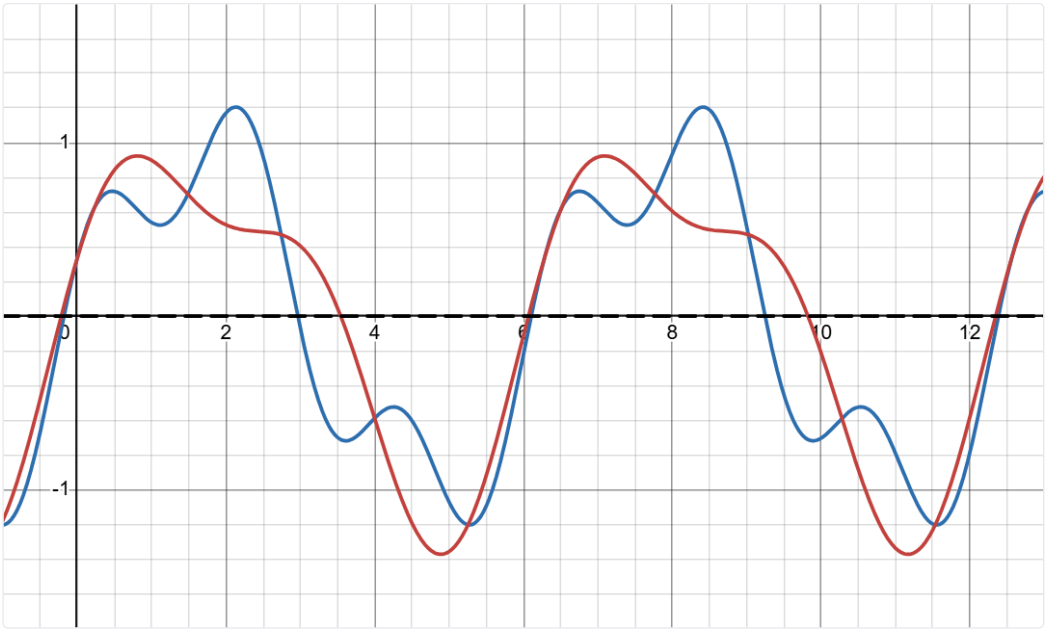
Proof. Split the coefficient integral into two half-periods and substitute $t = t' + T_0/2$ in the second:

$$c_n = \frac{1}{T_0}\int_0^{T_0/2} x(t)e^{-jn\omega_0 t}dt + \frac{1}{T_0}\int_0^{T_0/2} x\Big(t' + \frac{T_0}{2}\Big)e^{-jn\omega_0 t'}e^{-jn\pi}\,dt'.$$

With half-wave symmetry the second integrand is $-x(t')e^{-jn\omega_0 t'}(-1)^n$, so $c_n = \big(1-(-1)^n\big)\frac{1}{T_0}\int_0^{T_0/2} x(t)e^{-jn\omega_0 t}dt$: zero for even n and twice the half-period integral for odd n. Conversely, if only odd harmonics are present then each term satisfies $e^{jn\omega_0(t+T_0/2)} = (-1)^n e^{jn\omega_0 t} = -e^{jn\omega_0 t}$, so the sum does too. □

The physical reading is powerful: **any system that treats positive and negative half-cycles identically (apart from sign) produces only odd harmonics.** A symmetric clipper, a push–pull output stage, a transformer core with a symmetric B–H loop and a full-bridge inverter switched symmetrically all have half-wave-symmetric outputs when driven by a sinusoid. Even harmonics are the signature of *asymmetry*: a half-wave rectifier, a single-ended amplifier stage with a square-law term, or DC magnetisation of a transformer core.

The opposite condition $x(t + T_0/2) = +x(t)$ simply means that $T_0/2$ is a period; then only even harmonics of ω_0 appear — they are all the harmonics of the true fundamental $2\omega_0$. The full-wave rectified sine $|\sin \omega_0 t|$ is the standard example.



Blue: fundamental plus a third harmonic — each negative half-cycle is the inverted copy of the preceding positive one (half-wave symmetry). Red: fundamental plus a second harmonic — the positive and negative half-cycles have different shapes, and no shift-and-invert maps one onto the other.

Quarter-wave symmetry

Quarter-wave symmetry

A function has **quarter-wave symmetry** if it has half-wave symmetry *and* is either even or odd (about a suitable origin).

Then only odd harmonics are present and, in addition, only cosines (even case) or only sines (odd case). Combining the two reductions, one quarter-period suffices:

Quarter-wave formulas

If x is odd with half-wave symmetry, then $a_n = 0$ for all n, $b_n = 0$ for even n, and for odd n

$$b_n = \frac{8}{T_0}\int_0^{T_0/4} x(t)\sin n\omega_0 t\,dt.$$

If x is even with half-wave symmetry, then $b_n = 0$ for all n, $a_n = 0$ for even n, and for odd n

$$a_n = \frac{8}{T_0}\int_0^{T_0/4} x(t)\cos n\omega_0 t\,dt.$$

Proof sketch (odd case). Odd symmetry gives $b_n = \frac{4}{T_0}\int_0^{T_0/2} x\sin n\omega_0 t\,dt$. Odd plus half-wave implies $x(T_0/2 - t) = -x(t - T_0/2) = x(t)$: on $(0, T_0/2)$ the graph is symmetric about $t = T_0/4$. For odd n, $\sin n\omega_0(T_0/2 - t) = \sin(n\pi - n\omega_0 t) = \sin n\omega_0 t$, so the integrand is symmetric about $T_0/4$ too and the half-period integral is twice the quarter-period integral. □

Symmetry	Condition	Harmonics present	Coefficient integral
none	—	all, a_n and b_n	full period, $2/T_0$
even	$x(-t) = x(t)$	DC and cosines	half period, $4/T_0$
odd	$x(-t) = -x(t)$	sines only, no DC	half period, $4/T_0$
half-wave	$x(t + T_0/2) = -x(t)$	odd n only, no DC	half period, $4/T_0$

Symmetry	Condition	Harmonics present	Coefficient integral
even quarter-wave	even and half-wave	cosines, odd n	quarter period, $8/T_0$
odd quarter-wave	odd and half-wave	sines, odd n	quarter period, $8/T_0$

Worked Example 15.11 — Triangle wave by the quarter-wave formula

The triangle wave of peak A and period T_0 has $x(t) = A\big(1 - 4|t|/T_0\big)$ on $(-T_0/2, T_0/2)$. Find its Fourier series using symmetry.

Solution. Symmetry: x is even; and $x(t + T_0/2) = -x(t)$ (check at $t = 0$: $x(T_0/2) = A(1-2) = -A = -x(0)$; the graph is a straight line falling from A to $-A$ on $(0, T_0/2)$ and rising back on $(T_0/2, T_0)$). So it is even quarter-wave: only a_n with odd n.

Let $\theta = \omega_0 t$; on $(0, \pi/2)$, $x = A(1 - 2\theta/\pi)$. For odd n,

$$a_n = \frac{8}{T_0}\int_0^{T_0/4} x\cos n\omega_0 t\,dt = \frac{4}{\pi}\int_0^{\pi/2} A\Big(1-\frac{2\theta}{\pi}\Big)\cos n\theta\,d\theta.$$

By parts, $\int_0^{\pi/2}(1-\frac{2\theta}{\pi})\cos n\theta\,d\theta = \big[(1-\frac{2\theta}{\pi})\frac{\sin n\theta}{n}\big]_0^{\pi/2} + \frac{2}{\pi n}\int_0^{\pi/2}\sin n\theta\,d\theta = 0 + \frac{2}{\pi n^2}\Big(1-\cos\frac{n\pi}{2}\Big) = \frac{2}{\pi n^2}$ for odd n. Hence

$$a_n = \frac{8A}{\pi^2 n^2}\ (n \text{ odd}), \qquad x(t) = \frac{8A}{\pi^2}\Big(\cos\omega_0 t + \frac{1}{9}\cos 3\omega_0 t + \frac{1}{25}\cos 5\omega_0 t + \cdots\Big).$$

Checks. At $t = 0$: $\frac{8A}{\pi^2}\sum_{\text{odd}}\frac{1}{n^2} = \frac{8A}{\pi^2}\cdot\frac{\pi^2}{8} = A$. ✓ The coefficients fall as $1/n^2$ — the triangle is continuous with jumps only in its slope (§15.7). The fundamental, $0.811A$, is already very close to the waveform: the third harmonic is only $1/9$ of it.

Worked Example 15.12 — Quasi-square (120° conduction) waveform

A three-phase six-step inverter produces a line-to-line voltage that is $+V$ for $30^\circ < \theta < 150^\circ$, $-V$ for $210^\circ < \theta < 330^\circ$ and zero otherwise ($\theta = \omega_0 t$). Find its harmonic content.

Solution. With the origin as given, x is odd ($x(-\theta) = -x(\theta)$, since $-V$ occupies $(-150^\circ, -30^\circ) \equiv (210^\circ, 330^\circ)$) and half-wave symmetric. So only sine terms with odd n; use the quarter-wave formula with $T_0 = 2\pi$:

$$b_n = \frac{8}{2\pi}\int_0^{\pi/2} x\sin n\theta\,d\theta = \frac{4V}{\pi}\int_{\pi/6}^{\pi/2}\sin n\theta\,d\theta = \frac{4V}{n\pi}\Big[\cos\frac{n\pi}{6} - \cos\frac{n\pi}{2}\Big] = \frac{4V}{n\pi}\cos\frac{n\pi}{6} \quad (n \text{ odd}).$$

- $n = 3, 9, 15, \ldots$ (triplen): $\cos(n\pi/6) = \cos(k\pi/2)$ with odd k, which is 0. **No triplen harmonics** — the line-to-line voltage is the difference of two phase waveforms displaced by 120°, and triplens are in phase in all three phases (Ch. 3, §3.7), so they cancel.
- $n = 6k \pm 1$: $|\cos(n\pi/6)| = \sqrt{3}/2$, so $|b_n| = \frac{2\sqrt{3}V}{n\pi} = \frac{1.1027V}{n}$.

Numbers: $b_1 = 1.1027V$, $b_5 = -0.2205V$, $b_7 = -0.1575V$, $b_{11} = 0.1002V$, $b_{13} = 0.0848V$ — each exactly $1/n$ of the fundamental. **Check:** direct quadrature over a full period reproduces all five values to 10^{-12}. ✓ The distortion of this waveform is computed with Parseval's theorem in §15.8.

Half-range expansions

In boundary-value problems (Ch. 13) a function is given only on a half-interval $0 < x < L$ — the initial temperature along a rod, the initial displacement of a string, the voltage on one face of a box — and we are free to extend it to $(-L, 0)$ however suits the boundary conditions. Two extensions are standard.

Half-range expansions

Let f be given on $(0, L)$.

The **even extension** ($f(-x) = f(x)$, period $2L$) yields the **half-range cosine series**

$$f(x) \sim \frac{a_0}{2} + \sum_{n=1}^{\infty} a_n \cos\frac{n\pi x}{L}, \qquad a_n = \frac{2}{L}\int_0^L f(x)\cos\frac{n\pi x}{L}\,dx.$$

The **odd extension** ($f(-x) = -f(x)$, period $2L$) yields the **half-range sine series**

$$f(x) \sim \sum_{n=1}^{\infty} b_n \sin\frac{n\pi x}{L}, \qquad b_n = \frac{2}{L}\int_0^L f(x)\sin\frac{n\pi x}{L}\,dx.$$

Both series represent f on $(0, L)$; they differ outside it and at the endpoints. The sine series vanishes at $x = 0$ and $x = L$, suiting Dirichlet conditions $u = 0$ at the ends; the cosine series has zero slope there (each term does), suiting Neumann (insulated) conditions. Note the harmonics are π/L apart, half the spacing $2\pi/L$ of an ordinary series of period L — the extension doubles the period.

Worked Example 15.13 — Sine and cosine expansions of a ramp

Expand $f(x) = x$ on $(0, L)$ in (a) a half-range sine series and (b) a half-range cosine series, and compare them.

Solution. (a) Odd extension is the sawtooth x on $(-L, L)$. By parts,

$$b_n = \frac{2}{L}\int_0^L x \sin\frac{n\pi x}{L}\,dx = \frac{2}{L}\Big[-\frac{Lx}{n\pi}\cos\frac{n\pi x}{L}\Big]_0^L + \frac{2}{L}\cdot\frac{L}{n\pi}\int_0^L \cos\frac{n\pi x}{L}dx = \frac{2L(-1)^{n+1}}{n\pi}.$$

So $x = \frac{2L}{\pi}\big(\sin\frac{\pi x}{L} - \frac{1}{2}\sin\frac{2\pi x}{L} + \frac{1}{3}\sin\frac{3\pi x}{L} - \cdots\big)$ on $(0, L)$.

(b) Even extension is the triangle $|x|$ on $(-L, L)$. $a_0 = \frac{2}{L}\int_0^L x\,dx = L$, and for $n \geq 1$

$$a_n = \frac{2}{L}\int_0^L x\cos\frac{n\pi x}{L}\,dx = \frac{2}{L}\Big[\frac{L^2}{n^2\pi^2}\cos\frac{n\pi x}{L}\Big]_0^L = \frac{2L}{n^2\pi^2}\big((-1)^n - 1\big),$$

i.e. $-\frac{4L}{n^2\pi^2}$ for odd n, 0 for even n. So $x = \frac{L}{2} - \frac{4L}{\pi^2}\big(\cos\frac{\pi x}{L} + \frac{1}{9}\cos\frac{3\pi x}{L} + \cdots\big)$ on $(0, L)$.

Comparison. The odd extension jumps from L to $-L$ at $x = L$, so the sine series converges slowly ($1/n$), shows a Gibbs overshoot near $x = L$ (§15.6) and converges to 0 (the midpoint) at $x = L$. The even extension is continuous, so the cosine series converges uniformly with $1/n^2$ coefficients and gives the right value L at $x = L$. With $L = 1$ and three non-zero harmonics each (sine: $n = 1, 2, 3$; cosine: $n = 1, 3, 5$): at $x = 0.9$ the sine series gives 0.556 and the cosine series 0.912 (exact 0.9); at $x = 1$ the sine series gives 0, the cosine series 0.967 (exact 1). Choose the extension that is continuous whenever the boundary conditions leave you the choice.

Worked Example 15.14 — Even and odd parts from the coefficients

For the periodic exponential of Worked Example 15.8 (e^{-t} on $[0, 2\pi)$), find the Fourier series of its even part without further integration.

Solution. $c_n = \frac{0.158858}{1+jn} = 0.158858\frac{1-jn}{1+n^2}$. The even part has coefficients $\mathrm{Re}\{c_n\} = \frac{0.158858}{1+n^2}$, so

$$x_e(t) = 0.158858\Big(1 + 2\sum_{n=1}^{\infty}\frac{\cos nt}{1+n^2}\Big),$$

and the odd part is $x_o(t) = 0.317716\sum_{n\geq 1}\frac{n\sin nt}{1+n^2}$. Directly, $x_e(t) = \frac{1}{2}\big(e^{-t} + e^{-(2\pi - t)}\big)$ on $(0, 2\pi)$, which is $\frac{1}{2}(1 + e^{-2\pi}) = 0.500934$ at $t = 0^+$. **Check:** summing the cosine series at $t = 0$ to 200 000 terms gives $0.158858\,(1 + 2 \times 1.076674) = 0.50093$. ✓ (The continuous even part's series has $1/n^2$ coefficients; the odd part carries the jump and has $1/n$ coefficients.)

Pitfall — symmetry depends on the origin, and on the whole period

A waveform that "looks odd" over the half-period you sketched may not be odd as a periodic function; check $x(-t) = -x(t)$ using the periodic extension (for instance $x(-t) = x(T_0 - t)$). And half-wave symmetry is a statement about shifting by exactly $T_0/2$: a waveform whose negative half-cycle is a *mirror image in time* (rather than a shifted copy) of the positive one need not have half-wave symmetry.

Engineering note — even-order distortion and push–pull cancellation

If an amplifier's transfer characteristic is $y = a_1x + a_2x^2 + a_3x^3$, a push–pull pair of matched devices produces $y_1 - y_2$ with y_2 the same characteristic driven by $-x$: the even-order terms cancel, leaving $2a_1x + 2a_3x^3$, an odd function of x. An odd function of a half-wave-symmetric input is half-wave symmetric, so the output has no even harmonics. Measured second-harmonic distortion in such an amplifier is therefore a direct measure of device mismatch.

15.5 Harmonics

Motivation

Once a waveform has been decomposed, engineers stop thinking about the waveform and start thinking about its **harmonics**: "the 5th harmonic current exceeds the limit", "the third harmonic of the oscillator is 40 dB down", "the triplen harmonics overload the neutral". This section fixes the vocabulary, defines line spectra precisely in their one-sided and two-sided forms, and records how simple operations on a waveform — shifting it, compressing it in time, scaling it — move and reshape its spectrum.

Vocabulary

Harmonics

For a periodic signal with fundamental angular frequency ω_0:

- the **fundamental** (first harmonic) is the component at ω_0;
- the n**th harmonic** is the component $A_n\cos(n\omega_0 t + \phi_n)$ at $n\omega_0$, $n \geq 2$;
- the **DC component** is $A_0 = c_0$, sometimes called the zeroth harmonic;
- **odd** and **even** harmonics have odd and even n; harmonics with n a multiple of 3 are called **triplen** harmonics.

Three related terms are often confused:

- An **overtone** (acoustics) is any component above the fundamental; the first overtone is the *second* harmonic.

- An **interharmonic** is a component at a frequency that is *not* an integer multiple of the supply frequency, for instance a 175 Hz component in a 50 Hz system produced by a cycloconverter or an arc furnace. A signal containing interharmonics is periodic only with a longer period (if the frequency ratio is rational) or not at all (Ch. 3, §3.4), and its Fourier series with respect to 50 Hz does not exist.
- A **subharmonic** has a frequency ω_0/m below the fundamental. Its presence means the true period is mT_0; relative to that longer period, it is simply a low-order harmonic.

One-sided and two-sided line spectra

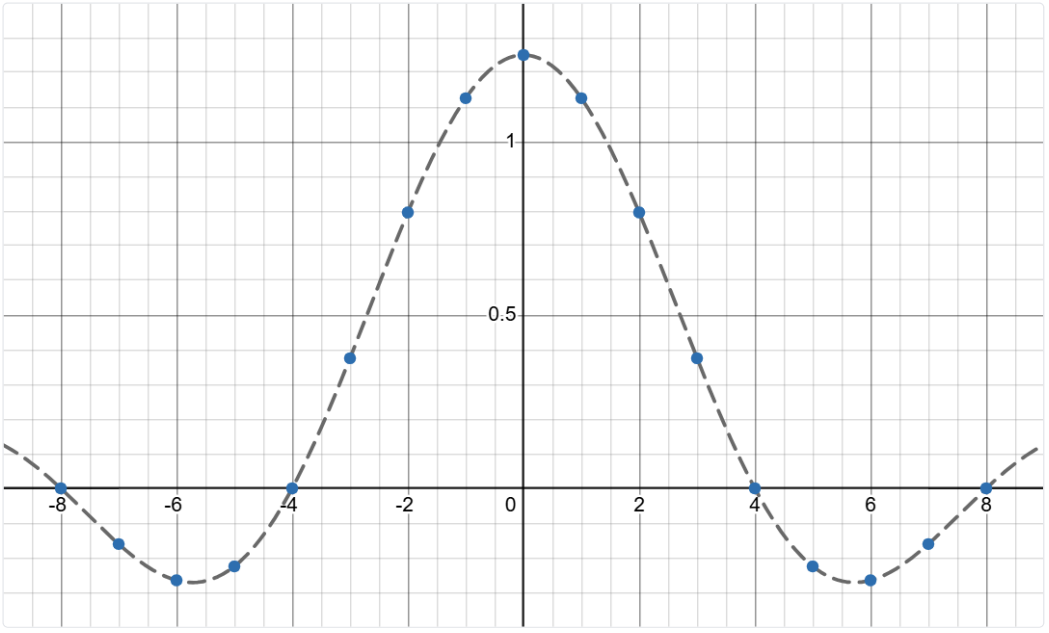
For a real signal there are two equivalent ways to draw the spectrum.

> **Line spectra**
>
> The **one-sided amplitude and phase spectra** are the sets of lines A_n and ϕ_n at frequencies $n\omega_0 \geq 0$, from the form $x(t) = A_0 + \sum_{n\geq 1} A_n \cos(n\omega_0 t + \phi_n)$.
>
> The **two-sided magnitude and phase spectra** are the lines $|c_n|$ and $\angle c_n$ at $n\omega_0$ for all $n \in \mathbb{Z}$, from $x(t) = \sum_n c_n e^{jn\omega_0 t}$.
>
> The **power spectrum** consists of lines $|c_n|^2$ (two-sided) or A_0^2, $A_n^2/2$ (one-sided), whose sum is the mean-square value (Parseval, §15.8).

The conversion is: one-sided line height $= 2\times$ two-sided height for $n \geq 1$; equal for DC. For phase, the one-sided spectrum is the right half of the two-sided one, and the left half is its negative. Lines with $A_n = 0$ have undefined phase and are omitted from phase plots.

Phase conventions matter when lines have negative real coefficients. A coefficient $a_n = -0.2$ can be plotted as amplitude -0.2 with phase 0, or (properly, since amplitudes are non-negative) as $A_n = 0.2$ with phase $\pm 180^\circ$. Both appear in textbooks; the non-negative-amplitude convention is the one used by instruments.

Amplitudes are frequently given in decibels relative to the fundamental, $20\log_{10}(A_n/A_1)$ dBc, or relative to a reference level such as 1 µV (dBµV, used in EMC). Because harmonics often span several orders of magnitude, a log scale is the only practical display.



Two-sided line spectrum $c_n = 1.25\,\mathrm{sinc}(n/4)$ of the 5 V, 25%-duty pulse train of Worked Example 15.7 (blue points, horizontal axis = harmonic number n), lying on the continuous sinc envelope (dashed). Every 4th harmonic is missing. Plotted as magnitudes, lines 5–7 would be drawn upwards with phase 180°.

How operations on the waveform change the spectrum

Let $x(t) \leftrightarrow c_n$ denote that x has coefficients c_n with fundamental ω_0. Each of the following follows in one line from the coefficient integral.

Amplitude scaling and adding a constant. $Kx(t) + B \leftrightarrow Kc_n + B\,\delta_{n0}$: scaling scales every line; adding a DC level changes only the $n = 0$ line.

Time shift. $x(t - t_0) \leftrightarrow c_n e^{-jn\omega_0 t_0}$. Substitute $t' = t - t_0$ in $\frac{1}{T_0}\int x(t - t_0)e^{-jn\omega_0 t}dt$. The magnitudes are unchanged; each phase shifts by $-n\omega_0 t_0$, **linearly in frequency**. A delay is invisible on an amplitude spectrum and is a straight line of slope $-t_0$ on a phase-versus-frequency plot.

Time scaling. $x(at)$, $a > 0$, has period T_0/a and fundamental $a\omega_0$, with the *same* coefficients c_n: compressing a waveform in time moves every line outward in frequency in proportion, without changing heights. A 1 kHz square wave and a 1 MHz square wave have identical coefficient lists.

Time reversal. $x(-t) \leftrightarrow c_{-n}$; for real x this is c_n^*, which negates every phase.

Harmonic content versus shape. The amplitude spectrum alone does not determine the waveform: phases matter. Ch. 3 showed a fundamental plus a third harmonic in phase and in anti-phase, with identical A_n, giving a flattened and a peaked waveform. Peak value, crest factor and the risk of clipping depend on phases; power and RMS do not (§15.8).

Worked Example 15.15 — One- and two-sided spectra of a rectified sine

Draw up the one-sided amplitude and phase spectrum and the two-sided spectrum of the half-wave rectified 230 V (RMS), 50 Hz mains, $V_m = 325.3$ V, up to the 6th harmonic, with amplitudes also in dBc.

Solution. From Worked Example 15.5, $x = V_m\left[\frac{1}{\pi} + \frac{1}{2}\sin\omega_0 t - \frac{2}{\pi}\sum_k \frac{\cos 2k\omega_0 t}{4k^2-1}\right]$. Convert to cosine-reference amplitude–phase form: $\frac{1}{2}\sin\omega_0 t = \frac{1}{2}\cos(\omega_0 t - 90^\circ)$, and $-\frac{2}{\pi(4k^2-1)}\cos 2k\omega_0 t = \frac{2}{\pi(4k^2-1)}\cos(2k\omega_0 t + 180^\circ)$.

n	f (Hz)	A_n/V_m	A_n (V)	ϕ_n	dBc	c_n (V)
0	0	0.3183	103.5	—	—	103.5
1	50	0.5000	162.6	-90°	0	$81.3\angle -90^\circ$
2	100	0.2122	69.0	180°	-7.4	$34.5\angle 180^\circ$
3, 5	150, 250	0	0	—	—	0
4	200	0.0424	13.8	180°	-21.4	$6.9\angle 180^\circ$
6	300	0.0182	5.9	180°	-28.8	$3.0\angle 180^\circ$

The two-sided spectrum has $c_{-n} = c_n^*$: lines of the same heights at $-50, -100, \ldots$ Hz, with phases $+90^\circ$ at -50 Hz and 180° (equivalently -180°) at the even negative harmonics.

Check. $A_2/A_1 = 0.2122/0.5 = 0.4244$, $20\log_{10} 0.4244 = -7.44$ dB. ✓ $A_6/V_m = 2/(35\pi) = 0.01819$. ✓

Worked Example 15.16 — Spectrum of a delayed pulse train

The pulse train of Worked Example 15.7 is delayed so that each pulse starts, rather than is centred, at $t = 0$: $x(t) = 5$ V for $0 < t < 1$ μs, period 4 μs. Find the new coefficients.

Solution. The new waveform is the old one delayed by $t_0 = \tau/2 = 0.5$ μs. By the shift rule,

$$c_n^{\text{new}} = 1.25\,\text{sinc}(n/4)\,e^{-jn\omega_0 t_0} = 1.25\,\text{sinc}(n/4)\,e^{-jn\pi/4},$$

since $\omega_0 t_0 = 2\pi \cdot 0.5/4 = \pi/4$. Magnitudes are unchanged; the phase of harmonic n is $-45^\circ n$ (plus 180° where sinc is negative). For example $c_1 = 1.1254\angle -45^\circ$, $c_2 = 0.7958\angle -90^\circ$, $c_3 = 0.3751\angle -135^\circ$.

Check by direct integration. $c_1 = \frac{5}{4\,\mu\text{s}}\int_0^{1\,\mu\text{s}} e^{-j\omega_0 t}dt = \frac{5}{4}\cdot\frac{1-e^{-j\pi/2}}{j\pi/2} = \frac{5}{4}\cdot\frac{1+j}{j\pi/2} = \frac{5}{2\pi}(1-j) = 0.7958 - 0.7958j = 1.1254\angle -45^\circ$. ✓

Harmonics in three-phase systems

In a balanced three-phase system the phase-b and phase-c waveforms are the phase-a waveform delayed by $T_0/3$ and $2T_0/3$. By the shift rule the nth harmonic of phase b is that of phase a shifted by $-n \cdot 120^\circ$. Hence:

- $n = 1, 4, 7, \ldots$ ($n = 3k+1$): shifts $-120^\circ, -240^\circ$ — **positive sequence** a-b-c, like the fundamental;
- $n = 2, 5, 8, \ldots$ ($n = 3k+2$): shifts $-240^\circ \equiv +120^\circ$ — **negative sequence** a-c-b, producing reverse torque in induction motors;
- $n = 3, 6, 9, \ldots$ (triplen): shifts that are multiples of 360° — **zero sequence**, in phase in all three lines.

Zero-sequence currents add in the neutral instead of cancelling, and cancel in any line-to-line quantity (Worked Example 15.12).

Worked Example 15.17 — Neutral current from triplen harmonics

Each phase of a balanced four-wire system supplies a nonlinear load drawing $I_1 = 10$ A (RMS) at 50 Hz and a third harmonic $I_3 = 3$ A (RMS), plus negligible higher harmonics. Find the RMS neutral current, and compare with the phase current.

Solution. The neutral current is $i_a + i_b + i_c$. Fundamental components are 120° apart and sum to zero; third-harmonic components are in phase and add: $i_N = 3 \times \sqrt{2}\,(3)\cos(3\omega_0 t + \phi_3)$. So $I_N = 9$ A RMS at 150 Hz.

The phase RMS current is $\sqrt{10^2 + 3^2} = 10.44$ A (orthogonality, §15.8). The neutral carries 86% of the phase current even though the load is perfectly balanced — the reason modern installations with many switch-mode loads size the neutral conductor at or above the phase conductors.

Pitfall — "the 3rd harmonic" of what?

Harmonic numbers refer to a stated fundamental. A 12-pulse rectifier's characteristic harmonics are $12k \pm 1$ of the *supply* frequency; the ripple of a full-wave rectifier is at the 2nd harmonic of the supply but the *fundamental* of the ripple waveform. When writing or reading a specification, say which fundamental the harmonic numbers refer to.

Engineering note — harmonic limits

Power-quality standards (e.g. IEC 61000-3-2 for equipment currents, IEEE 519 for system voltages and currents) specify limits harmonic by harmonic, typically up to the 40th or 50th, and in total via THD (§15.8). Measurement standards (IEC 61000-4-7) prescribe exactly the Fourier analysis of this chapter applied to a 10-cycle (50 Hz) or 12-cycle (60 Hz) window, which gives 5 Hz resolution and therefore also resolves interharmonics.

15.6 Convergence

Motivation

So far we have computed coefficients and written "$\sim$". An engineer is entitled to ask whether the sum really *is* the function. The question is not pedantic. The square-wave series converges to 0 at the jumps, where the square wave is $\pm A$ — so at some points the answer is "no". Its partial sums overshoot by 9% near every jump no matter how many terms are taken — so even "approximately equal" needs qualification. And the identities we want to use — Parseval's theorem, term-by-term differentiation, the LTI response formula — each require a particular kind of convergence. This section states the three standard modes of convergence (pointwise, uniform, mean-square), the conditions under which each holds, and the Gibbs phenomenon that marks the boundary between them.

Dirichlet conditions and pointwise convergence

Dirichlet conditions

A T_0-periodic function x satisfies the **Dirichlet conditions** if, over one period,

1. x is absolutely integrable: $\int_{T_0} |x(t)|\,dt < \infty$;
2. x has a finite number of maxima and minima;
3. x has a finite number of discontinuities, each of them finite (a jump).

Conditions 2 and 3 together say that x is of bounded variation on a period. A simpler sufficient set used in many texts is that x be **piecewise smooth**: the period splits into finitely many intervals on each of which x and x' are continuous and have finite one-sided limits at the ends.

Dirichlet's theorem (pointwise convergence)

If x satisfies the Dirichlet conditions, its Fourier series converges at every t, and

$$\lim_{N\to\infty} S_N(t) = \frac{x(t^+) + x(t^-)}{2},$$

where $x(t^\pm)$ are the one-sided limits. At points of continuity the series converges to $x(t)$; at a jump it converges to the **midpoint** of the jump.

All waveforms met in practice — square, triangle, sawtooth, rectified sines, pulse trains, PWM signals, exponential segments — satisfy the Dirichlet conditions. Functions that violate them are mathematical constructions such as $\sin(1/t)$ near $t = 0$ (infinitely many extrema) or $\tan t$ (not integrable).

Proof sketch. The argument has three steps and is worth knowing because the same kernel reappears in the DFT and in antenna-array theory.

Step 1 — the Dirichlet kernel. Use $T_0 = 2\pi$. Substituting the coefficient integral into the partial sum and exchanging the finite sum with the integral,

$$S_N(t) = \sum_{n=-N}^{N} \left[\frac{1}{2\pi}\int_{-\pi}^{\pi} x(s) e^{-jns} ds\right] e^{jnt} = \frac{1}{2\pi}\int_{-\pi}^{\pi} x(s)\, D_N(t-s)\, ds,$$

where, summing the geometric series as in Ch. 3, §3.6,

$$D_N(u) = \sum_{n=-N}^{N} e^{jnu} = \frac{\sin\left((N+\tfrac{1}{2})u\right)}{\sin(u/2)}.$$

D_N is even, 2π-periodic, has $\frac{1}{2\pi}\int_{-\pi}^{\pi} D_N(u)\,du = 1$ (only the $n=0$ term survives), and has a tall central peak of height $2N+1$ and width about $2\pi/(N+\tfrac{1}{2})$ flanked by oscillating side lobes. So $S_N(t)$ is a weighted local average of x near t, with weights that become more sharply concentrated as N grows — but that also oscillate in sign.

Step 2 — split at the point. Changing variable to $u = t - s$ and using evenness of D_N,

$$S_N(t) - \frac{x(t^+)+x(t^-)}{2} = \frac{1}{2\pi}\int_0^{\pi} \Big[x(t+u) - x(t^+) + x(t-u) - x(t^-)\Big] D_N(u)\,du,$$

because $\frac{1}{2\pi}\int_0^{\pi} D_N = \frac{1}{2}$.

Step 3 — Riemann–Lebesgue. Write $D_N(u) = \sin\left((N+\tfrac{1}{2})u\right)/\sin(u/2)$. The function $g(u) = \big[x(t+u) - x(t^+) + x(t-u) - x(t^-)\big]/\sin(u/2)$ is integrable on $(0,\pi)$: near $u=0$ the bracket is $O(u)$ when x is piecewise smooth (one-sided derivatives exist), cancelling the $u/2$ in the denominator. The **Riemann–Lebesgue lemma** states that $\int_a^b g(u)\sin(\lambda u)\,du \to 0$ as $\lambda\to\infty$ for every integrable g — rapid oscillation averages any fixed integrable function to zero (proof: true for step functions by direct integration; approximate g by step functions). With $\lambda = N + \tfrac{1}{2}$ the right-hand side tends to zero. $\square$

The Riemann–Lebesgue lemma applied to the coefficient integral itself gives the companion fact $c_n \to 0$ as $|n|\to\infty$ for every absolutely integrable x.

Uniqueness

If two piecewise-continuous T_0-periodic functions have the same Fourier coefficients, they are equal at every point where both are continuous. In particular, a function whose coefficients are all zero vanishes except at isolated points.

Uniqueness is what justifies reading off coefficients from any convenient expansion (Worked Example 15.10) and solving for unknown waveforms by matching harmonics.

Uniform convergence

Pointwise convergence can be very uneven: near a jump, the number of terms needed for a given accuracy grows without bound as t approaches the jump. **Uniform convergence** means $\max_t |S_N(t) - x(t)| \to 0$: a single N achieves a given accuracy everywhere.

Uniform convergence

(a) If $\sum_n |c_n| < \infty$, the Fourier series converges absolutely and uniformly to a continuous function (Weierstrass M-test), which equals x wherever x is continuous.

(b) If x is continuous everywhere (including across the period boundary, $x(t_1 + T_0) = x(t_1)$) and piecewise smooth, then $\sum |c_n| < \infty$ and the series converges uniformly to x.

(c) If x has a jump, the convergence cannot be uniform near that jump: a uniform limit of continuous functions is continuous.

Proof of (b). Let x' have coefficients d_n. Integrating by parts, with the boundary terms cancelling by continuity and periodicity, $d_n = jn\omega_0 c_n$ (§15.7). By Cauchy–Schwarz and Bessel's inequality applied to x',

$$\sum_{n\neq 0} |c_n| = \sum_{n\neq 0} \frac{|d_n|}{|n|\omega_0} \le \frac{1}{\omega_0}\Big(\sum_{n\neq 0}\frac{1}{n^2}\Big)^{1/2}\Big(\sum_{n}|d_n|^2\Big)^{1/2} \le \frac{1}{\omega_0}\sqrt{\frac{\pi^2}{3}}\,\|x'\| < \infty. \quad \square$$

So the triangle wave, the full-wave rectified sine and the trapezoid converge uniformly; the square wave, sawtooth, pulse trains and the periodic exponential of Worked Example 15.8 do not.

Mean-square convergence

The weakest but most useful mode is convergence in the RMS sense, $\|x - S_N\| \to 0$. It ignores what happens at individual points and measures only the power of the error — exactly the quantity that matters for energy, noise and distortion.

Mean-square convergence (completeness)

If $\frac{1}{T_0}\int_{T_0}|x|^2 dt < \infty$, then

$$\lim_{N\to\infty} \frac{1}{T_0}\int_{T_0} \big|x(t) - S_N(t)\big|^2 dt = 0.$$

Conversely (Riesz–Fischer), every sequence with $\sum |c_n|^2 < \infty$ is the coefficient sequence of some square-integrable x.

Proof sketch. By the best-approximation theorem of §15.1, $\|x - S_N\| \le \|x - p\|$ for every trigonometric polynomial p of degree N. So it suffices that trigonometric polynomials can approximate x arbitrarily well in RMS. First approximate x in RMS by a continuous periodic function g (possible for any square-integrable x). Then approximate g *uniformly* — hence also in RMS — by the **Fejér (Cesàro) means**

$$\sigma_N(t) = \frac{S_0(t) + S_1(t) + \cdots + S_N(t)}{N+1} = \frac{1}{2\pi}\int_{-\pi}^{\pi} g(t-u)F_N(u)\,du, \qquad F_N(u) = \frac{1}{N+1}\Big[\frac{\sin\big((N+1)u/2\big)}{\sin(u/2)}\Big]^2.$$

The **Fejér kernel** F_N is *non-negative*, has unit mean, and concentrates at $u = 0$; a positive averaging kernel of this kind converges uniformly for continuous g (Fejér's theorem). The triangle inequality completes the argument. $\square$

Mean-square convergence is what makes Parseval's theorem (§15.8) true for *every* finite-power periodic signal, square wave included, and it is the natural setting for the Fourier-series solutions of PDEs in Ch. 13.

Mode	Measure of error	Holds when	Square wave?
pointwise	$\lvert x(t) - S_N(t)\rvert$ at each t	Dirichlet conditions (limit = midpoint at jumps)	yes, with midpoint at jumps
uniform	$\max_t \lvert x - S_N\rvert$	x continuous and piecewise smooth, or $\sum\lvert c_n\rvert < \infty$	no
mean-square	$\|x - S_N\|$	x square-integrable	yes

Pitfall — continuity alone is not enough

There exist continuous periodic functions whose Fourier series diverge at a point (du Bois-Reymond, 1873). Continuity guarantees mean-square convergence and Fejér-mean convergence, but pointwise convergence of the ordinary partial sums needs something more — piecewise smoothness, bounded variation (Dirichlet), or a Hölder condition. For engineering waveforms this is never an issue, but it explains why theorems are stated with conditions that look fussier than "continuous".

Worked Example 15.18 — Using pointwise convergence to sum series

Use the convergence theorem to evaluate (a) $1 - \frac{1}{3} + \frac{1}{5} - \cdots$, (b) $\sum_{k\ge1} \frac{1}{(2k-1)^2}$, (c) the value of the sawtooth series $\sum_{n\ge1} \frac{2(-1)^{n+1}}{n} \sin nt$ at $t = \pi$.

Solution. (a) The square wave ($A = 1$, $\omega_0 = 1$) is continuous at $t = \pi/2$ with value 1: $\frac{4}{\pi}\left(\sin\frac{\pi}{2} + \frac{1}{3}\sin\frac{3\pi}{2} + \frac{1}{5}\sin\frac{5\pi}{2} + \cdots\right) = \frac{4}{\pi}\left(1 - \frac{1}{3} + \frac{1}{5} - \cdots\right) = 1$, so the sum is $\pi/4$.

(b) The triangle wave of Worked Example 15.11 is continuous at $t = 0$ with value A: $\frac{8A}{\pi^2}\sum_{\text{odd } n}\frac{1}{n^2} = A$, so $\sum \frac{1}{(2k-1)^2} = \frac{\pi^2}{8} = 1.2337$.

(c) Every term contains $\sin n\pi = 0$, so the series sums to 0. The sawtooth jumps from π (left limit) to $-\pi$ (right limit) at $t = \pi$; the midpoint is 0. ✓ This is not an approximation failure: the series *converges*, to the midpoint.

Check. $4\sum_{k=0}^{10^6-1}\frac{(-1)^k}{2k+1} = 3.1415917$ (error 10^{-6}, the slow $1/N$ convergence of an alternating series). The first three terms of (b) give $1 + \frac{1}{9} + \frac{1}{25} = 1.1511$; the exact $\pi^2/8 = 1.2337$. ✓

The Gibbs phenomenon

Near a jump, the partial sums of a Fourier series overshoot. As N grows, the overshoot moves closer to the jump and becomes narrower, but its height does **not** decrease. This is the **Gibbs phenomenon** (observed by Michelson's harmonic analyser in 1898, explained by Gibbs in 1899, and in fact found by Wilbraham in 1848).

Derivation for the square wave. Take $A = 1$, $\omega_0 = 1$ and let $S_M(t) = \frac{4}{\pi}\sum_{k=1}^{M}\frac{\sin(2k-1)t}{2k-1}$ contain the first M odd harmonics (highest harmonic $N = 2M - 1$). Differentiate and sum the cosines with the formula of Ch. 3, §3.6:

$$S_M'(t) = \frac{4}{\pi}\sum_{k=1}^{M}\cos(2k-1)t = \frac{2}{\pi}\cdot\frac{\sin 2Mt}{\sin t}.$$

The first zero of S_M' to the right of the jump at $t = 0$ is at $t^* = \pi/(2M)$, the location of the first and largest maximum. Since $S_M(0) = 0$,

$$S_M(t^*) = \frac{2}{\pi}\int_0^{\pi/(2M)}\frac{\sin 2Mt}{\sin t}\,dt.$$

Substitute $u = 2Mt$: $S_M(t^*) = \frac{2}{\pi}\int_0^{\pi}\frac{\sin u}{2M\sin(u/2M)}\,du$. As $M \to \infty$, $2M\sin(u/2M) \to u$, so

$$\lim_{M\to\infty} S_M(t^*) = \frac{2}{\pi}\int_0^{\pi}\frac{\sin u}{u}\,du = \frac{2}{\pi}\,\mathrm{Si}(\pi) = 1.178980,$$

where $\mathrm{Si}(z) = \int_0^z \frac{\sin u}{u}du$ is the sine integral, $\mathrm{Si}(\pi) = 1.851937$.

Gibbs phenomenon

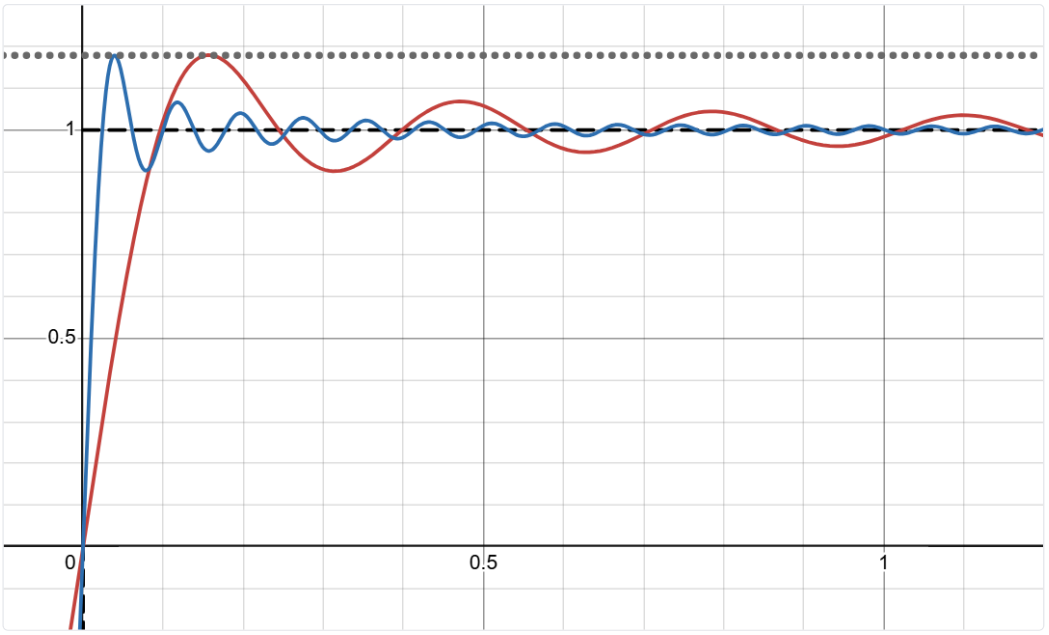
Let x be piecewise smooth with a jump of size $J = x(t_0^+) - x(t_0^-)$ at t_0. Then near t_0 the partial sums S_N overshoot $x(t_0^+)$ (and undershoot $x(t_0^-)$) by an amount tending to

$$J\left(\frac{1}{\pi}\,\mathrm{Si}(\pi) - \frac{1}{2}\right) = 0.08949\,J,$$

i.e. about **8.95% of the jump**, on each side. The overshoot occurs at a distance of order $T_0/(2N)$ from the jump, which tends to zero; its height does not.

The general case reduces to the square wave: subtract from x a multiple of a sawtooth or square wave with the same jump at t_0; the remainder is continuous near t_0 and its series converges uniformly there, so it contributes no overshoot.

Gibbs is fully consistent with the convergence theorems. At each *fixed* $t \neq t_0$ the overshoot eventually moves past t, so pointwise convergence holds; the overshoot region has width $O(1/N)$, so its contribution to the mean-square error tends to zero; but the *maximum* error never falls below about $0.09J$, so convergence is not uniform.



Zoom on the jump of the unit square wave at $t = 0$: partial sums with harmonics up to 19 (red) and up to 79 (blue). Increasing N squeezes the overshoot towards the jump but both peaks reach the same height, about 1.179 (dotted).

Worked Example 15.19 — Size and position of the Gibbs overshoot

A 1 kHz, ± 5 V square wave is passed through an ideal (brick-wall) low-pass filter that keeps harmonics up to 19 kHz and removes the rest. Find the peak output voltage and the time after each edge at which it occurs. Repeat for a 79 kHz cutoff.

Solution. The filter output is the partial sum with harmonics $1, 3, \dots, 19$, i.e. $M = 10$ odd harmonics. The peak is at $\theta^* = \pi/(2M) = \pi/20$ after the edge, i.e. $t^* = \frac{\theta^*}{\omega_0} = \frac{\pi/20}{2\pi \times 1000} = 25\ \mu$s. Its value for finite M: numerically $S_{10}(\pi/20) = 1.17981$, so the peak is $5 \times 1.1798 = 5.90$ V — an overshoot of 0.90 V, which is 9.0% of the 10 V jump.

With harmonics to 79 kHz ($M = 40$): $t^* = \frac{1}{4 \cdot 40 \cdot 1000} = 6.25\ \mu$s, and $S_{40}(t^*) = 1.17903$, peak 5.895 V. The overshoot has moved four times closer to the edge but is essentially the same size; the limit is $5 \times 1.17898 = 5.8949$ V.

Check. A brute-force search of S_M on a fine grid gives maxima 1.17981 at $t = 0.15708$ ($M = 10$) and 1.17903 at $t = 0.03927$ ($M = 40$), matching $\pi/20$ and $\pi/80$. ✓

Taming Gibbs: smoothing the partial sums

When a truncated series must be *used* — to synthesise a waveform, to design an FIR filter by truncating an ideal response, to display a reconstructed signal — the overshoot is usually unwanted. It comes from the abrupt truncation of the coefficients at $n = N$; tapering them removes it at the cost of a slower edge.

- **Fejér (Cesàro) means**: multiply c_n by $1 - \frac{|n|}{N+1}$. Since the Fejér kernel is non-negative, σ_N never leaves the range $[\min x, \max x]$: no overshoot at all, but a noticeably rounded edge.
- **Lanczos σ-factors**: multiply c_n by $\operatorname{sinc}\big(n/(N+1)\big)$. Equivalent to averaging S_N over a window one period of the highest harmonic wide; it reduces the overshoot to about 1% of the jump while keeping a reasonably sharp edge.

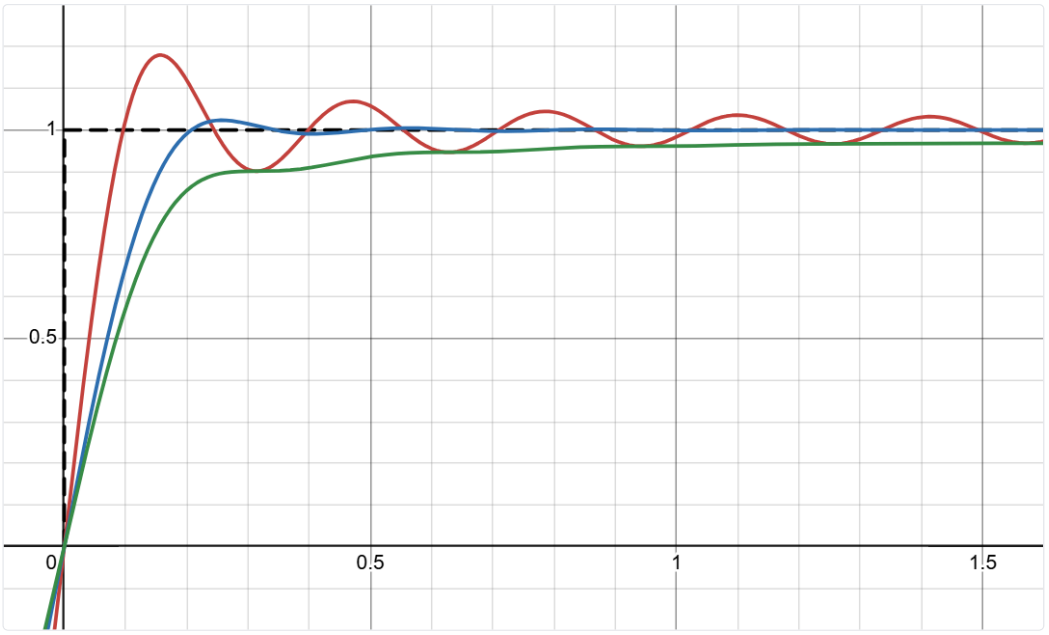
Worked Example 15.20 — Smoothed partial sums of a square wave

For the unit square wave with harmonics up to $N = 19$, compare the maximum of the raw partial sum with the Lanczos-smoothed and Fejér-smoothed sums.

Solution. The weights on harmonic n are 1, $\operatorname{sinc}(n/20)$ and $1 - n/20$ respectively; e.g. for $n = 19$ they are 1, 0.0524 and 0.05. Evaluating on a fine grid over a half-period, and measuring the 10%–90% rise time from the edge:

Partial sum	Maximum	Overshoot	10–90% rise (rad)
raw S_{19}	1.1798	18.0% of A (9.0% of jump)	0.074
Lanczos σ	1.0235	2.3% of A	0.143
Fejér	0.9682 (at $t = \pi/2$)	none	0.263

The Fejér sum stays below 1 everywhere, as the positivity of its kernel guarantees, but at the price of a rise time three and a half times that of the raw sum; the Lanczos sum is the usual compromise.



Harmonics up to 19 of the unit square wave: raw partial sum (red) with the Gibbs overshoot, Lanczos-smoothed (blue) with almost no overshoot, Fejér-smoothed (green) with none but a slower rise.

Engineering note — Gibbs in hardware

Any system with a sharp cutoff in frequency rings at sharp edges in time. The step response of an ideal low-pass filter overshoots by 8.95% for the same mathematical reason (Ch. 16); steep anti-aliasing filters and brick-wall digital filters show this ringing on square-wave tests; and FIR filters designed by truncating an ideal impulse response have ripples of about 9% (−21 dB) near the band edge whatever their length. Tapered windows (Hann, Hamming, Kaiser) are the filter-design version of the σ-factors above: they trade transition sharpness for suppressed ripple.

Pitfall — more terms do not remove the overshoot

It is tempting to blame a 9% overshoot in a reconstructed waveform on "too few harmonics". Adding harmonics only narrows it. If the overshoot matters, taper the coefficients (or, in hardware, use a filter with a gentler roll-off) — do not just raise N.

15.7 Fourier coefficients

Motivation

The Euler integrals of §15.2 always work, but integrating by parts over several pieces is slow and error-prone. Experienced analysts rarely do it. Instead they (i) build new series from known ones using the *properties* of the coefficient map — shifting, scaling, differentiating, integrating, multiplying; (ii) use the **jump method**, which reads the coefficients of any piecewise-polynomial waveform straight off the sizes and positions of its discontinuities; and (iii) compute coefficients numerically with the FFT when no formula is available, knowing exactly what error that introduces. This section develops all three, together with the result that ties them together: **the smoothness of a waveform determines how fast its coefficients decay**.

Properties of the coefficients

Write $x \leftrightarrow c_n$ and $y \leftrightarrow d_n$ for two signals with the same period T_0.

Fourier-coefficient properties

Operation	Signal	Coefficients
linearity	$\alpha x + \beta y$	$\alpha c_n + \beta d_n$
time shift	$x(t - t_0)$	$e^{-jn\omega_0 t_0} c_n$
frequency shift (modulation by a harmonic)	$e^{jm\omega_0 t} x(t)$	c_{n-m}
time reversal	$x(-t)$	c_{-n}
conjugation	$x^*(t)$	c^*_{-n}
time scaling ($a > 0$; period T_0/a)	$x(at)$	c_n (at frequencies $na\omega_0$)
differentiation	$x'(t)$	$jn\omega_0\, c_n$
integration (requires $c_0 = 0$)	$\int^t x(\tau)\, d\tau$	$\frac{c_n}{jn\omega_0}$ ($n \neq 0$), plus a constant
periodic convolution	$\frac{1}{T_0}\int_{T_0} x(\tau) y(t-\tau)\, d\tau$	$c_n d_n$
multiplication	$x(t)\, y(t)$	$\sum_{m=-\infty}^{\infty} c_m d_{n-m}$

Proofs. The shift, modulation, reversal and conjugation rules are substitutions in the coefficient integral. *Differentiation:* if x is continuous and periodic with piecewise-continuous x', integrate by parts:

$$\frac{1}{T_0}\int_{T_0} x'(t) e^{-jn\omega_0 t}\, dt = \frac{1}{T_0}\Big[x(t) e^{-jn\omega_0 t}\Big]_{t_1}^{t_1+T_0} + \frac{jn\omega_0}{T_0}\int_{T_0} x(t) e^{-jn\omega_0 t}\, dt = jn\omega_0 c_n,$$

the boundary term vanishing by periodicity. *Integration* is differentiation read backwards; the condition $c_0 = 0$ is needed because the integral of a signal with non-zero mean grows linearly and is not periodic. *Periodic convolution:* substitute the series of y and use orthogonality,

$$\frac{1}{T_0}\int_{T_0} x(\tau) \sum_m d_m e^{jm\omega_0(t-\tau)}\, d\tau = \sum_m d_m e^{jm\omega_0 t}\, \frac{1}{T_0}\int_{T_0} x(\tau) e^{-jm\omega_0 \tau}\, d\tau = \sum_m c_m d_m e^{jm\omega_0 t}.$$

Multiplication: the product of $\sum_m c_m e^{jm\omega_0 t}$ and $\sum_k d_k e^{jk\omega_0 t}$ collects, at frequency $n\omega_0$, all pairs with $m + k = n$. □

The last two rules are the duality at the heart of Fourier analysis: **convolution in time ↔ multiplication of coefficients; multiplication in time ↔ (discrete) convolution of coefficients.** Chapter 16 states the same pair for the transform. The multiplication rule explains why a nonlinearity spreads the spectrum: squaring a signal convolves its line spectrum with itself, producing lines at all sums and differences of the original frequencies (Ch. 3, §3.7).

Term-by-term differentiation and integration

(a) **Integration is always allowed.** If x is piecewise continuous, the Fourier series of x — whether or not it converges — may be integrated term by term between any limits, and the resulting series converges (uniformly) to the integral of x.

(b) **Differentiation needs care.** If x is continuous, periodic and piecewise smooth (in particular, no jumps, *including at the period boundary*), then the term-by-term derivative of its series is the Fourier series of x', converging to $\frac{1}{2}[x'(t^+) + x'(t^-)]$ wherever x' satisfies the Dirichlet conditions.

Integration improves convergence (coefficients gain a factor $1/n$); differentiation worsens it (coefficients gain a factor n). Differentiating the square-wave series term by term gives $\frac{4A\omega_0}{\pi}\sum_{\text{odd}} \cos n\omega_0 t$, which diverges at every t — the derivative of a function with jumps contains impulses, which no ordinary function represents. The jump method below makes this precise.

Worked Example 15.21 — Triangle wave from the square wave by integration

Obtain the series of the triangle wave of Worked Example 15.11 by integrating the square wave, and confirm the result.

Solution. Let $s(t)$ be the square wave of amplitude A (Worked Example 15.3), $s(t) = \frac{4A}{\pi}\sum_{\text{odd } n} \frac{\sin n\omega_0 t}{n}$. Its integral from 0 is a triangle: $\int_0^t s = At$ for $0 < t < T_0/2$, rising from 0 to $AT_0/2$, then falling back — a triangle of peak-to-peak $AT_0/2$ with mean $AT_0/4$. Integrating term by term:

$$\int_0^t s(\tau)\, d\tau = \frac{4A}{\pi\omega_0}\sum_{\text{odd } n}\frac{1-\cos n\omega_0 t}{n^2} = \frac{4A}{\pi\omega_0}\cdot\frac{\pi^2}{8} - \frac{4A}{\pi\omega_0}\sum_{\text{odd } n}\frac{\cos n\omega_0 t}{n^2},$$

using $\sum_{\text{odd}} 1/n^2 = \pi^2/8$ (Worked Example 15.18). The constant is $\frac{A\pi}{2\omega_0} = \frac{AT_0}{4}$, the mean. ✓ The triangle of Worked Example 15.11 has peak B at $t = 0$ and is $B - \frac{4B}{AT_0}\int_0^t s$ (scaled and inverted so that it falls from B to $-B$). Its cosine coefficients are therefore $\frac{4B}{AT_0}\cdot\frac{4A}{\pi\omega_0 n^2} = \frac{16B}{\pi T_0\omega_0 n^2} = \frac{8B}{\pi^2 n^2}$ for odd n. ✓

Smoothness and the rate of decay

Decay of Fourier coefficients

Let x be T_0-periodic and let $k \geq 0$ be an integer.

- If x has a jump discontinuity, then c_n decays like $1/n$ and no faster (as $|n| \to \infty$, typically $|c_n| \approx C/|n|$ along a subsequence).
- If $x, x', \ldots, x^{(k-1)}$ are continuous (as periodic functions) and $x^{(k)}$ is piecewise smooth with jumps, then $|c_n| = O\big(1/|n|^{k+1}\big)$, with the leading term set by the jumps of $x^{(k)}$.
- If x has continuous derivatives of every order, c_n decays faster than any power of $1/n$; if x is analytic (Ch. 18), c_n decays exponentially.

Proof. Apply the differentiation rule k times: $c_n = \frac{\text{coefficient of } x^{(k)}}{(jn\omega_0)^k}$, and the coefficients of the piecewise-smooth $x^{(k)}$ with jumps are $O(1/n)$ by one more integration by parts (the boundary terms at the jumps give exactly $1/n$; the remaining integral is $o(1/n)$ by Riemann–Lebesgue). □

Waveform	Smoothness	Decay of $\lvert c_n\rvert$	Coefficients
square, sawtooth, pulse train	jumps in x	$1/n$	square: $b_n = 4A/(n\pi)$
triangle, trapezoid, rectified sine	x continuous, jumps in x'	$1/n^2$	triangle: $a_n = 8A/(\pi^2 n^2)$
parabolic wave t^2 on $(-\pi,\pi)$	x continuous, jumps in x' at $\pm\pi$	$1/n^2$	$a_n = 4(-1)^n/n^2$
cubic wave $t(\pi^2 - t^2)$ on $(-\pi,\pi)$	x, x' continuous, jumps in x''	$1/n^3$	$b_n = 12(-1)^{n+1}/n^3$
$e^{\cos t}$	analytic	exponential	$c_n = I_n(1)$ (modified Bessel)

(The parabolic wave is continuous at $\pm\pi$ but its slope jumps from 2π to -2π there. The cubic wave vanishes at $\pm\pi$ and has slope $-2\pi^2$ at both ends, so it and its derivative are continuous; its second derivative $-6t$ jumps from -6π to 6π.)

This theorem has direct engineering consequences. **Edges cost bandwidth.** A clock with ideal vertical edges has harmonics falling at only 20 dB/decade, so its spectrum extends far beyond the clock frequency and causes interference; rounding the edges (finite rise time) turns the decay into 40 dB/decade above a corner frequency of about $1/(\pi t_r)$. Conversely, the number of harmonics needed to reproduce a waveform to a given accuracy can be estimated before computing anything.

The jump method

For piecewise-polynomial waveforms, the coefficients can be read off from the jumps. Suppose that over one period x is piecewise smooth with jumps $J_i = x(t_i^+) - x(t_i^-)$ at points t_i. Then, in the generalised sense of Ch. 14 and Ch. 16, x' is its ordinary (piecewise) derivative x'_{reg} plus impulses:

$$x'(t) = x'_{\text{reg}}(t) + \sum_i J_i\,\delta_{T_0}(t - t_i), \qquad \delta_{T_0}(t) = \sum_k \delta(t - kT_0),$$

and the periodic impulse train has coefficients $\frac{1}{T_0}\int_{T_0}\delta(t-t_i)e^{-jn\omega_0 t}dt = \frac{1}{T_0}e^{-jn\omega_0 t_i}$. Applying $c_n(x') = jn\omega_0 c_n(x)$:

Jump formula

For $n \neq 0$,

$$c_n = \frac{1}{jn\omega_0}\Big[\frac{1}{T_0}\sum_i J_i\,e^{-jn\omega_0 t_i} + c_n(x'_{\text{reg}})\Big] = \frac{1}{jn\omega_0 T_0}\sum_i J_i e^{-jn\omega_0 t_i} + \frac{1}{jn\omega_0}\,c_n(x'_{\text{reg}}).$$

Apply the same formula to x'_{reg}, using the jumps J_i' of the derivative, and so on. For a piecewise-polynomial waveform the process terminates, because some derivative is piecewise constant and its regular derivative is zero.

The same result follows without impulses by integrating by parts piece by piece; the impulses simply keep the bookkeeping clean.

Worked Example 15.22 — Square wave and sawtooth by the jump method

(a) The square wave of Worked Example 15.3 has jumps $+2A$ at $t = 0$ and $-2A$ at $t = T_0/2$, and is constant in between ($x'_{\text{reg}} = 0$). So

$$c_n = \frac{1}{jn\omega_0 T_0}\big(2A - 2Ae^{-jn\pi}\big) = \frac{2A\,(1-(-1)^n)}{j2\pi n} = \frac{2A}{j\pi n}\ (n \text{ odd}),\ 0\ (n \text{ even}),$$

and $b_n = -2\,\mathrm{Im}\,c_n = \frac{4A}{\pi n}$. ✓

(b) The sawtooth $x = t$ on $(-\pi,\pi)$ has one jump, -2π at $t = \pi$, and $x'_{\text{reg}} = 1$, whose coefficients vanish for $n \neq 0$. So $c_n = \frac{1}{jn\cdot 2\pi}(-2\pi)e^{-jn\pi} = \frac{-(-1)^n}{jn} = \frac{j(-1)^n}{n}$ — Worked Example 15.10(b) in one line. ✓

Worked Example 15.23 — Trapezoidal wave

A trapezoidal voltage (a square wave with finite rise time) rises linearly from 0 to A over $0 < \theta < \alpha$, stays at A until $\theta = \pi - \alpha$, falls linearly to 0 at $\theta = \pi$, and repeats with opposite sign on $(\pi, 2\pi)$ ($\theta = \omega_0 t$, $0 < \alpha \le \pi/2$). Find its coefficients by the jump method and evaluate them for $\alpha = \pi/6$ (30° ramps).

Solution. x is continuous, so it has no jumps. Its derivative (with respect to θ, so $\omega_0 = 1$, $T_0 = 2\pi$) is piecewise constant: $+A/\alpha$ on $(-\alpha, \alpha)$, $-A/\alpha$ on $(\pi - \alpha, \pi + \alpha)$, and 0 elsewhere. The jumps of x' are

position	$-\alpha$	α	$\pi - \alpha$	$\pi + \alpha$
jump J_i'	$+A/\alpha$	$-A/\alpha$	$-A/\alpha$	$+A/\alpha$

and $x''_{\text{reg}} = 0$. Applying the jump formula twice (x has no jumps, so only the second level contributes):

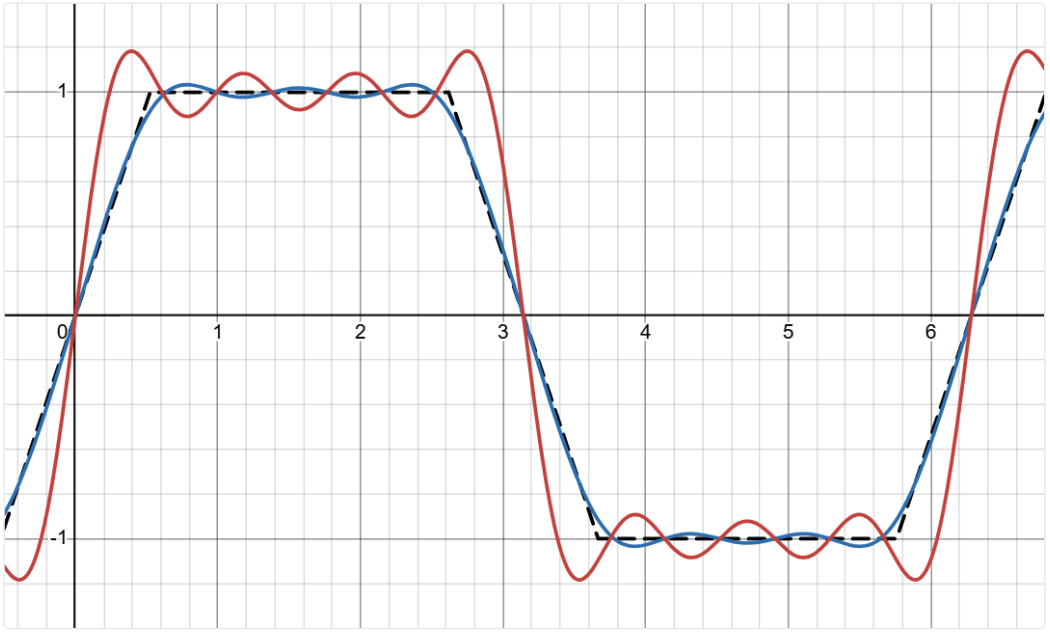
$$c_n = \frac{1}{jn} \cdot \frac{1}{jn\,2\pi} \sum_i J_i' e^{-jn\theta_i} = -\frac{A}{2\pi\alpha n^2}\left[e^{jn\alpha} - e^{-jn\alpha} - e^{-jn(\pi-\alpha)} + e^{-jn(\pi+\alpha)}\right].$$

The bracket is $2j\sin n\alpha - (-1)^n\left(e^{jn\alpha} - e^{-jn\alpha}\right) = 2j\sin n\alpha\,\left(1 - (-1)^n\right)$. So $c_n = 0$ for even n (half-wave symmetry ✓) and, for odd n, $c_n = -\frac{2jA\sin n\alpha}{\pi\alpha n^2}$, giving

$$b_n = -2\,\mathrm{Im}\,c_n = \frac{4A}{\pi\alpha} \cdot \frac{\sin n\alpha}{n^2} \quad (n \text{ odd}), \qquad a_n = 0.$$

With $\alpha = \pi/6$: $b_1 = 1.2159A$, $b_3 = 0.2702A$, $b_5 = 0.0486A$, $b_7 = -0.0248A$.

Checks. (i) Numerical quadrature reproduces all four values to 10^{-12}. ✓ (ii) As $\alpha \to 0$, $\frac{\sin n\alpha}{\alpha} \to n$ and $b_n \to \frac{4A}{\pi n}$ — the square wave. ✓ (iii) The ramps make the waveform continuous, so $b_n = O(1/n^2)$: compared with the square wave ($b_7 = 0.1819A$) the 7th harmonic is 7 times smaller. Writing $b_n = \frac{4A}{\pi n}\,\mathrm{sinc}\left(\frac{n\alpha}{\pi}\right)$ shows the trapezoid's spectrum as the square-wave spectrum multiplied by a sinc envelope whose first null is at $n = \pi/\alpha$: the frequency-domain picture of "finite rise time costs less bandwidth".



The trapezoidal wave with 30° ramps (dashed) and its partial sum through the 7th harmonic (blue), against the square-wave partial sum through the 7th harmonic (red). With the same four harmonics the trapezoid is reproduced closely because its coefficients fall as $1/n^2$.

Computing coefficients numerically: the DFT

When x is known only by samples — a measured current, a simulation output — the coefficient integral is approximated by a sum. Take N equally spaced samples $x_k = x(kT_0/N)$, $k = 0, \dots, N-1$, and apply the rectangle (equivalently, for periodic integrands, trapezoidal) rule:

$$\tilde{c}_n = \frac{1}{N}\sum_{k=0}^{N-1} x_k\, e^{-j2\pi nk/N}.$$

This is the **discrete Fourier transform** divided by N, computed by the FFT in $O(N \log N)$ operations (Ch. 24). Its error is described exactly by the following identity.

Aliasing of Fourier coefficients

If the Fourier series of x converges at the sample points (with the midpoint value used at any jump), then

$$\tilde{c}_n = \sum_{m=-\infty}^{\infty} c_{n+mN}.$$

In particular $\tilde{c}_n = c_n$ exactly for $|n| < N/2$ if x is band-limited with $c_n = 0$ for $|n| \ge N/2$.

Proof. Substitute $x_k = \sum_m c_m e^{j2\pi mk/N}$ and use $\frac{1}{N}\sum_{k=0}^{N-1} e^{j2\pi(m-n)k/N} = 1$ if $m \equiv n \pmod N$ and 0 otherwise (a finite geometric series). $\square$

Each computed coefficient is contaminated by every true coefficient whose index differs from it by a multiple of N — the coefficient-domain version of aliasing (Ch. 16, §16.8). The error therefore depends on how fast c_n decays: for a smooth periodic waveform it is tiny even for modest N (the trapezoidal rule is *spectrally accurate* for smooth periodic integrands), while for a waveform with jumps it is in general $O(1/N)$ (improving to $O(1/N^2)$ for a fixed harmonic when every jump falls on a sample instant and the midpoint value is used there).

Worked Example 15.24 — FFT estimate of sawtooth coefficients

Sample the sawtooth $x = t$ on $(-\pi, \pi)$ at $N = 16$ points $t_k = -\pi + 2\pi k/N$ (using the midpoint value 0 at the jump, $k = 0$), compute $\tilde{c}_1$ and $\tilde{c}_4$, and compare with the exact $c_n = j(-1)^n/n$. Repeat with $N = 64$.

Solution. Exact: $c_1 = -j$, $c_4 = 0.25j$. The FFT (with the phase factor $e^{jn\pi}$ that accounts for the samples starting at $-\pi$ instead of 0) gives

N	$\tilde{c}_1$	error	$\tilde{c}_4$	error
16	$-0.98712j$	1.3%	$0.19635j$	21%
64	$-0.99920j$	0.08%	$0.24678j$	1.3%

Explanation by the aliasing identity. For $N = 16$, $\tilde{c}_4 = \sum_m c_{4+16m} = j\sum_m \frac{1}{4+16m} = \frac{j}{16}\sum_m \frac{1}{m+\frac{1}{4}} = \frac{j}{16}\,\pi\cot\frac{\pi}{4} = \frac{j\pi}{16} = 0.19635j$, using the partial-fraction expansion $\pi\cot\pi z = \sum_m \frac{1}{z+m}$ (summed symmetrically; Ch. 18). ✓ For $N = 64$ the same formula gives $\frac{\pi}{64}\cot\frac{\pi}{16} = 0.24678$. ✓ The harmonic at a quarter of the sampling rate is badly aliased because the $1/n$ tail of the sawtooth is heavy, and the error of a fixed harmonic falls only like $1/N^2$ (here $21\% \to 1.3\%$ for a fourfold increase in N). A practical rule: to measure harmonics up to $n_{\max}$ to within a few per cent when the waveform has jumps, sample at many times $2n_{\max}$ per period, or low-pass filter before sampling.

Pitfall — coefficients of a waveform with jumps need an explicit midpoint

When sampling a waveform that has a jump exactly at a sample instant, use the midpoint value. Using either one-sided value adds a spurious constant $\pm J/(2N)$ to *every* $\tilde{c}_n$ — an error that does not decrease with n and that looks like a broadband noise floor.

Worked Example 15.25 — Full-wave rectified sine by the multiplication rule

Obtain the Fourier series of $|\sin t|$ from those of $\sin t$ and the square wave $s(t) = \operatorname{sgn}(\sin t)$, using $|\sin t| = \sin t \cdot s(t)$.

Solution. $\sin t$ has $d_1 = \frac{1}{2j}$, $d_{-1} = -\frac{1}{2j}$. The square wave ($A = 1$) has $c_m = \frac{2}{j\pi m}$ for odd m, zero for even m. By the multiplication rule the product has

$$e_n = \sum_m c_m d_{n-m} = c_{n-1}d_1 + c_{n+1}d_{-1} = \frac{1}{2j}\left(c_{n-1} - c_{n+1}\right).$$

For odd n, $n \pm 1$ is even, so $e_n = 0$. For even n, $e_n = \frac{1}{2j}\cdot\frac{2}{j\pi}\left(\frac{1}{n-1} - \frac{1}{n+1}\right) = -\frac{1}{\pi}\cdot\frac{2}{n^2-1}$. In particular $e_0 = \frac{2}{\pi}$. Then $a_n = 2e_n$:

$$|\sin t| = \frac{2}{\pi} - \frac{4}{\pi}\sum_{k=1}^{\infty}\frac{\cos 2kt}{4k^2-1}.$$

Check. This is twice the even-harmonic part of Worked Example 15.5, as $|\sin t| = 2\times$(half-wave rectified) $- \sin t$ requires. ✓ At $t = 0$: $\sum_k \frac{1}{4k^2-1} = \frac{1}{2}$ (telescoping), so the series gives $\frac{2}{\pi} - \frac{4}{\pi}\cdot\frac{1}{2} = 0 = |\sin 0|$. ✓

Engineering note — estimating EMI from edge rates

The jump formula applied to a trapezoidal clock of period T_0, duty 50% and rise time t_r gives the familiar EMC envelope: flat to f_0, -20 dB/decade from f_0 to about $1/(\pi\tau)$ (with τ the pulse width), and -40 dB/decade above $1/(\pi t_r)$. Slowing edges from 1 ns to 5 ns moves the second corner from 318 MHz to 64 MHz and reduces the harmonic amplitudes above 318 MHz by a factor 5 (14 dB), with a smaller reduction between the two corners — without changing the logic function.

15.8 Power and energy relationships

Motivation

The most frequently used result about Fourier series is not a formula for coefficients but a statement about *power*: the average power of a periodic signal equals the sum of the powers of its harmonics. It underlies every RMS meter calibrated for distorted waveforms, every harmonic-distortion specification, the definition of power factor in non-sinusoidal circuits, and the estimate of how much bandwidth a signal really needs. Chapter 3 (§3.7) proved it for a finite sum of harmonics; here we prove it for every finite-power periodic signal, extend it to products of two different signals (voltage and current), and use it to define and compute distortion measures.

Power signals

A periodic signal does not decay, so its total energy $\int_{-\infty}^{\infty}|x|^2dt$ is infinite. The meaningful quantities are the **energy per period** $E_{T_0} = \int_{T_0}|x|^2dt$ and the **average (normalised) power**

$$P_x = \frac{1}{T_0}\int_{T_0}|x(t)|^2dt = X_{\text{rms}}^2,$$

the power the signal would dissipate in a 1 Ω resistor if it were a voltage or a current. Periodic signals are **power signals**; the pulses and transients of Ch. 16, with finite total energy, are **energy signals**. For a voltage v across a resistance R the actual power is V_{rms}^2/R.

Parseval's theorem

Parseval's theorem for Fourier series

If x is T_0-periodic with $\int_{T_0}|x|^2dt<\infty$, then

$$\frac{1}{T_0}\int_{T_0}|x(t)|^2dt=\sum_{n=-\infty}^{\infty}|c_n|^2.$$

For real x in trigonometric and amplitude–phase form,

$$\frac{1}{T_0}\int_{T_0}x^2(t)\,dt=\left(\frac{a_0}{2}\right)^2+\frac{1}{2}\sum_{n=1}^{\infty}\left(a_n^2+b_n^2\right)=A_0^2+\sum_{n=1}^{\infty}\frac{A_n^2}{2}=A_0^2+\sum_{n=1}^{\infty}X_{n,\text{rms}}^2,$$

where $X_{n,\text{rms}}=A_n/\sqrt{2}$ is the RMS value of the nth harmonic.

Proof. By the best-approximation theorem (§15.1), $\|x-S_N\|^2=\|x\|^2-\sum_{|n|\le N}|c_n|^2$. By the mean-square convergence theorem (§15.6), the left side tends to 0 as $N\to\infty$. The trigonometric form follows from $|c_n|^2+|c_{-n}|^2=2|c_n|^2=\frac{A_n^2}{2}=\frac{a_n^2+b_n^2}{2}$ for real x. □

In words: **the mean-square value is the sum of the mean-square values of the harmonics, whatever their phases.** The harmonics are orthogonal "vectors" and Parseval's theorem is Pythagoras' theorem in the function space. It is a statement about power only: the peak value, the crest factor, and how hard an amplifier clips all depend on the phases.

The squared magnitudes $|c_n|^2$ form the **power spectrum**; the partial sums of Parseval give the **cumulative power**, and the error of a truncated series is

$$\|x-S_N\|^2=\sum_{|n|>N}|c_n|^2,$$

the power in the discarded harmonics. This is how one decides how many harmonics, or how much bandwidth, a waveform "needs".

Generalised Parseval (power of a product)

If $x\leftrightarrow c_n$ and $y\leftrightarrow d_n$ are T_0-periodic and square-integrable, then

$$\frac{1}{T_0}\int_{T_0}x(t)\,y^*(t)\,dt=\sum_{n=-\infty}^{\infty}c_n\,d_n^*.$$

For a real voltage $v=V_0+\sum_{n\ge1}V_n\cos(n\omega_0t+\alpha_n)$ and current $i=I_0+\sum_{n\ge1}I_n\cos(n\omega_0t+\beta_n)$ (peak amplitudes), the **average power** is

$$P=\frac{1}{T_0}\int_{T_0}v\,i\,dt=V_0I_0+\sum_{n=1}^{\infty}\frac{V_nI_n}{2}\cos(\alpha_n-\beta_n)=V_0I_0+\sum_{n=1}^{\infty}V_{n,\text{rms}}I_{n,\text{rms}}\cos\theta_n.$$

Proof. Apply Parseval to $x+y$ and $x+jy$ and use polarisation, or argue directly: the cross terms $c_md_n^*$ with $m\ne n$ average to zero by orthogonality. For the power formula take $c_n=\frac{V_n}{2}e^{j\alpha_n}$, $d_n=\frac{I_n}{2}e^{j\beta_n}$ and add the $\pm n$ terms: $2\,\text{Re}\{c_nd_n^*\}=\frac{V_nI_n}{2}\cos(\alpha_n-\beta_n)$. □

Only voltage and current harmonics of the same frequency transfer average power. A sinusoidal supply voltage delivers power only through the fundamental of the current; the current harmonics circulate without net energy transfer, yet they contribute to the RMS current and hence to losses in every conductor they pass through.

Distortion measures

Total harmonic distortion and related measures

For a periodic signal with zero mean, harmonic RMS values $X_1,X_2,\dots$ and total RMS value $X=\sqrt{\sum_{n\ge1}X_n^2}$:

- **THD (fundamental-referenced)**, the standard power-engineering definition (IEEE 519, IEC 61000):

$$\text{THD}_F=\frac{\sqrt{\sum_{n\ge2}X_n^2}}{X_1}=\sqrt{\frac{X^2}{X_1^2}-1};$$

- **THD (RMS-referenced)**, used by some audio analysers ("THD-R", or THD+N when noise is included):

$$\text{THD}_R=\frac{\sqrt{\sum_{n\ge2}X_n^2}}{X}=\frac{\text{THD}_F}{\sqrt{1+\text{THD}_F^2}};$$

- **distortion factor** (fundamental fraction) $X_1/X=1/\sqrt{1+\text{THD}_F^2}$;
- **crest factor** X_{peak}/X (equal to $\sqrt{2}$ for a sinusoid);
- **form factor** $X/\overline{|x|}$ (RMS over rectified mean; $\pi/(2\sqrt{2})=1.1107$ for a sinusoid).

THD_F can exceed 100%; THD_R cannot. For small distortion they agree. Parseval's theorem lets THD be computed from the total RMS value and the fundamental alone, without summing the infinite series of harmonics — the method used in all the examples below. A DC component, if present, is excluded from both numerator and denominator.

Power factor with a sinusoidal voltage. If v is a pure sinusoid at ω_0 and i is distorted, then $P = V I_1 \cos\theta_1$, with θ_1 the phase angle between v and the fundamental of i, while the apparent power is $S = VI$ (RMS values). Hence

$$\mathrm{PF} = \frac{P}{S} = \underbrace{\frac{I_1}{I}}_{\text{distortion factor}} \times \underbrace{\cos\theta_1}_{\text{displacement factor}} = \frac{\cos\theta_1}{\sqrt{1+\mathrm{THD}_i^2}}.$$

A load can have unity displacement factor and still a poor power factor.

Worked Example 15.26 — Summing series with Parseval

Use Parseval's theorem to evaluate $\sum_{n\ge1}\frac{1}{n^2}$, $\sum_{n\ge1}\frac{1}{n^4}$ and $\sum_{k\ge1}\frac{1}{(4k^2-1)^2}$.

Solution. (a) Sawtooth $x = t$ on $(-\pi,\pi)$: $b_n = \frac{2(-1)^{n+1}}{n}$, mean square $\frac{\pi^2}{3}$. Parseval: $\frac12\sum\frac{4}{n^2} = \frac{\pi^2}{3}$, so $\sum\frac{1}{n^2} = \frac{\pi^2}{6} = 1.644934$.

(b) Triangle of peak 1: $a_n = \frac{8}{\pi^2 n^2}$ (odd n), mean square $\frac13$ (a linear ramp from -1 to 1). Parseval: $\frac12\sum_{\text{odd}}\frac{64}{\pi^4 n^4} = \frac13$, so $\sum_{\text{odd}}\frac{1}{n^4} = \frac{\pi^4}{96}$. The even terms contribute $\sum\frac{1}{(2m)^4} = \frac{1}{16}\sum\frac{1}{m^4}$, so $\sum\frac{1}{n^4}\left(1-\frac{1}{16}\right) = \frac{\pi^4}{96}$ and $\sum\frac{1}{n^4} = \frac{\pi^4}{90} = 1.082323$.

(c) Full-wave rectified sine $|\sin t|$: mean square $\frac12$, DC $\frac{2}{\pi}$, $a_{2k} = -\frac{4}{\pi(4k^2-1)}$. Parseval: $\frac{4}{\pi^2} + \frac12\sum_k\frac{16}{\pi^2(4k^2-1)^2} = \frac12$, so $\sum_k\frac{1}{(4k^2-1)^2} = \frac{\pi^2}{16}\left(\frac12 - \frac{4}{\pi^2}\right) = \frac{\pi^2-8}{16} = 0.116850$.

Check. Direct summation to 10^6 terms: 1.644933, 1.082323, 0.116850. ✓

Worked Example 15.27 — THD of standard waveforms

Compute THD_F for the square wave, triangle, sawtooth, six-step (120° quasi-square) waveform of Worked Example 15.12 and the 30° trapezoid of Worked Example 15.23.

Solution. In each case compute the total mean square directly from the waveform and the fundamental's mean square $A_1^2/2$, then $\mathrm{THD}_F = \sqrt{X^2/X_1^2 - 1}$.

- *Square wave* ($\pm A$): $X^2 = A^2$; $X_1^2 = \frac12\left(\frac{4A}{\pi}\right)^2 = \frac{8A^2}{\pi^2}$. THD $= \sqrt{\frac{\pi^2}{8}-1} = 48.34\%$.
- *Triangle* (peak A): $X^2 = \frac{A^2}{3}$; $X_1^2 = \frac12\cdot\frac{64A^2}{\pi^4}$. THD $= \sqrt{\frac{\pi^4}{96}-1} = 12.12\%$.
- *Sawtooth* (t on $(-\pi,\pi)$): $X^2 = \frac{\pi^2}{3}$; $X_1^2 = \frac{2^2}{2} = 2$. THD $= \sqrt{\frac{\pi^2}{6}-1} = 80.31\%$.
- *Six-step*: the waveform is $\pm V$ for $\frac23$ of the period, so $X^2 = \frac23 V^2$; $b_1 = \frac{2\sqrt3}{\pi}V$, $X_1^2 = \frac{6}{\pi^2}V^2$. THD $= \sqrt{\frac{2\pi^2}{18}-1} = \sqrt{\frac{\pi^2}{9}-1} = 31.08\%$.
- *Trapezoid* ($\alpha = \pi/6$, peak A): each ramp of duration α contributes mean square $\frac13 A^2$, so over a half-period $X^2 = \frac{(\pi-2\alpha)A^2 + 2\alpha A^2/3}{\pi} = \left(1-\frac{4\alpha}{3\pi}\right)A^2 = 0.7778A^2$; $X_1^2 = \frac12(1.2159A)^2 = 0.7392A^2$. THD $= 22.86\%$.

Waveform	X/A	X_1/A	THD_F	THD_R	Crest factor
sine	0.7071	0.7071	0	0	1.414
triangle	0.5774	0.5732	12.1%	12.0%	1.732
trapezoid (30°)	0.8819	0.8597	22.9%	22.3%	1.134
six-step (120°)	0.8165	0.7797	31.1%	29.7%	1.225
square	1	0.9003	48.3%	43.5%	1
sawtooth ($A=\pi$)	0.5774	0.4502	80.3%	62.6%	1.732

Check. Summing $b_n^2/2$ numerically for the six-step wave over $n \le 20\,001$ and comparing with $\frac23 V^2$ reproduces 31.08%. ✓ Note how THD tracks smoothness (§15.7): jumps give large THD, kinks small THD.

Worked Example 15.28 — Power in a circuit with harmonics

A supply voltage $v(t) = 325\cos\omega_0 t + 30\cos 3\omega_0 t$ V drives a nonlinear load drawing $i(t) = 10\cos(\omega_0 t - 30^\circ) + 4\cos(3\omega_0 t - 60^\circ) + 2\cos(5\omega_0 t + 20^\circ)$ A. Find the RMS voltage and current, the average power, the apparent power, the power factor, and the voltage and current THD.

Solution. RMS values by Parseval: $V = \sqrt{\frac{325^2+30^2}{2}} = 230.79$ V, $\quad I = \sqrt{\frac{10^2+4^2+2^2}{2}} = \sqrt{60} = 7.746$ A.

Average power — only matching harmonics contribute; the 5th harmonic current has no 5th harmonic voltage to work against:

$$P = \frac{325\times10}{2}\cos 30^\circ + \frac{30\times4}{2}\cos 60^\circ + 0 = 1407.3 + 30.0 = 1437.3\ \text{W}.$$

Apparent power $S = VI = 1787.7$ VA; power factor $P/S = 0.804$.

$\mathrm{THD}_v = 30/325 = 9.23\%$; $\mathrm{THD}_i = \sqrt{4^2+2^2}/10 = 44.7\%$.

Interpretation. The fundamental displacement factor alone is $\cos 30^\circ = 0.866$; harmonics pull the true power factor down to 0.804. The third-harmonic product contributes a small amount of *real* power (30 W) because the supply itself is distorted.

Check. Averaging $v(t)\,i(t)$, v^2 and i^2 numerically over 10^6 points per period gives 1437.29 W, 230.787 V and 7.7460 A. ✓

Worked Example 15.29 — Power factor of a rectifier with a large DC inductor

A single-phase bridge rectifier with a large DC-side inductor draws a square-wave current of amplitude I_d in phase with the sinusoidal supply voltage $V\sqrt{2}\sin\omega_0 t$. Find the power factor.

Solution. The current is a square wave $\pm I_d$, so $I = I_d$ and $I_1 = \frac{4I_d}{\pi\sqrt{2}} = 0.9003 I_d$, in phase with the voltage ($\cos\theta_1 = 1$). Hence

$$\mathrm{PF} = \frac{I_1}{I}\cos\theta_1 = \frac{2\sqrt{2}}{\pi} = 0.9003, \qquad \mathrm{THD}_i = 48.3\%.$$

The load is "resistive" as far as the fundamental is concerned, yet about 10% of the conductor capacity is wasted on harmonic current. Active power-factor-correction front ends shape the current into a sinusoid to push PF above 0.99.

Worked Example 15.30 — How much bandwidth does a pulse train need?

For the 5 V, 25%-duty pulse train of Worked Example 15.7, what fraction of the total power lies in the harmonics inside the first spectral null ($|f| < 1/\tau$)? How much power lies in the DC term? For the $\pm A$ square wave, what fraction lies in the fundamental, in harmonics up to the 5th, and up to the 19th?

Solution. Total power of the pulse train: the signal is 5 V for a quarter of the time, so $P = 25 \times \frac{1}{4} = 6.25\ \mathrm{V}^2$. Inside the null, $|n| \le 3$:

$$\sum_{n=-3}^{3} |c_n|^2 = 1.25^2 + 2\big(1.1254^2 + 0.7958^2 + 0.3751^2\big) = 1.5625 + 2(1.2665 + 0.6333 + 0.1407) = 5.6435\ \mathrm{V}^2,$$

which is 90.3% of the total. The DC term alone carries $1.5625/6.25 = 25\%$.

For the square wave, the fraction in the odd harmonics up to N is $\frac{8}{\pi^2}\sum_{\text{odd } n\le N}\frac{1}{n^2}$: fundamental 81.06%; up to the 5th 93.31%; up to the 19th 97.98%.

Interpretation. Power converges far faster than the waveform does pointwise: the 19-harmonic square-wave approximation of Worked Example 15.19 has a 9% overshoot at every edge, yet it carries 98% of the power. "Bandwidth containing 90% of the power" is a standard practical definition of signal bandwidth.

Pitfall — adding RMS values linearly, or adding powers of the same frequency

RMS values of *different* harmonics add in quadrature, never linearly: 10 A at 50 Hz plus 3 A at 150 Hz is 10.44 A, not 13 A. But two components at the *same* frequency (two sources' 5th-harmonic currents meeting at a bus, say) must first be combined as phasors — their cross term does not average to zero, and the result can be anywhere between the difference and the sum of their amplitudes.

Engineering note — "true RMS" meters

An average-responding meter measures $\overline{|x|}$ and multiplies by the sinusoidal form factor 1.1107. On a square wave ($\overline{|x|} = A$, true RMS A) it reads $1.11A$, 11% high; on the narrow, peaky current of a capacitor-input rectifier (crest factor 2.5–3) it typically reads 20–40% low. A true-RMS meter computes $\sqrt{\overline{x^2}}$ directly, which by Parseval is the quadrature sum of all harmonics within its bandwidth.

15.9 Applications to periodic signals

Motivation

Section 15.1 promised that Fourier series would turn the response of a linear system to a periodic input into a list of multiplications. This section keeps that promise, states the conditions under which it is valid, and works through the standard situations: filtering a switching waveform, resonance with one harmonic of a non-sinusoidal drive, and ripple at the output of a rectifier. The applications are motivation; the method is general and applies equally to mechanical, thermal and acoustic systems described by linear differential equations with constant coefficients.

Steady-state response of an LTI system

Periodic steady state of an LTI system

Let a stable LTI system with frequency response $H(j\omega)$ be driven by a T_0-periodic input $x(t) = \sum_n c_n e^{jn\omega_0 t}$ with finite power. Then the output, after transients have decayed, is the T_0-periodic signal

$$y_{\mathrm{ss}}(t) = \sum_{n=-\infty}^{\infty} c_n\, H(jn\omega_0)\, e^{jn\omega_0 t},$$

i.e. the output coefficients are $d_n = c_n H(jn\omega_0)$. For real signals, in amplitude–phase form,

$$y_{\mathrm{ss}}(t) = A_0 H(0) + \sum_{n=1}^{\infty} A_n\, |H(jn\omega_0)| \cos\big(n\omega_0 t + \phi_n + \angle H(jn\omega_0)\big).$$

The output power is $P_y = \sum_n |c_n|^2 |H(jn\omega_0)|^2$.

Justification. Stability means $\int |h| < \infty$, so $H(j\omega)$ is bounded and continuous. The periodic steady state is $y_{\mathrm{ss}}(t) = \int_{-\infty}^{\infty} h(\tau)x(t-\tau)\,d\tau$ (the input applied for all past time). Writing the infinite convolution as a periodic convolution with the periodised impulse response $h_{T_0}(t) = \sum_k h(t - kT_0)$, whose Fourier coefficients are $\frac{1}{T_0}H(jn\omega_0)$, the periodic-convolution property of §15.7 gives $d_n = T_0 \cdot c_n \cdot \frac{1}{T_0}H(jn\omega_0) = c_n H(jn\omega_0)$. Because H is bounded, $\sum |d_n|^2 \le \max|H|^2 \sum |c_n|^2 <$

∞, so the output series converges in mean square; if $H(j\omega)$ falls off at high frequency, it converges faster than the input series. □

The **complete** response to an input switched on at $t = 0$ is y_{ss} plus a transient determined by the system's poles and initial conditions; for a stable system the transient decays and $y \to y_{ss}$. The Laplace transform (Ch. 14) gives both together; the Fourier series gives the steady state directly, which is usually what is wanted. The procedure is:

1. Find the input's Fourier coefficients (§15.2–15.7), using symmetry and tables.
2. Find $H(j\omega)$ — from impedances, from the differential equation by $d/dt \to j\omega$, or from $H(s)$ at $s = j\omega$.
3. Multiply harmonic by harmonic: $d_n = c_n H(jn\omega_0)$.
4. Recombine, or — more often — stop at step 3 and read off amplitudes, power, THD or ripple directly.

For a linear constant-coefficient ODE $\sum_k \alpha_k y^{(k)} = \sum_m \beta_m x^{(m)}$ the frequency response is $H(j\omega) = \sum_m \beta_m (j\omega)^m / \sum_k \alpha_k (j\omega)^k$, because d/dt acts on $e^{jn\omega_0 t}$ as multiplication by $jn\omega_0$ (the differentiation rule of §15.7).

Worked Example 15.31 — RC low-pass filter driven by a square wave

A ± 1 V, 1 kHz square wave drives an RC low-pass filter with $RC = 159.15\ \mu$s (corner frequency $f_c = 1/(2\pi RC) = 1$ kHz). Find the first four non-zero output harmonics, the output RMS value and THD, and the peak output voltage. Check the peak against a time-domain solution.

Solution. *Input:* $x(t) = \frac{4}{\pi}\sum_{\text{odd}} \frac{\sin n\omega_0 t}{n}$ (Worked Example 15.3), $\omega_0 = 2\pi \times 1000$ rad/s.

Frequency response: $H(j\omega) = \frac{1}{1+j\omega RC}$; at the harmonics $\omega_0 RC = 1$, so $H(jn\omega_0) = \frac{1}{1+jn}$, $|H| = \frac{1}{\sqrt{1+n^2}}$, $\angle H = -\arctan n$.

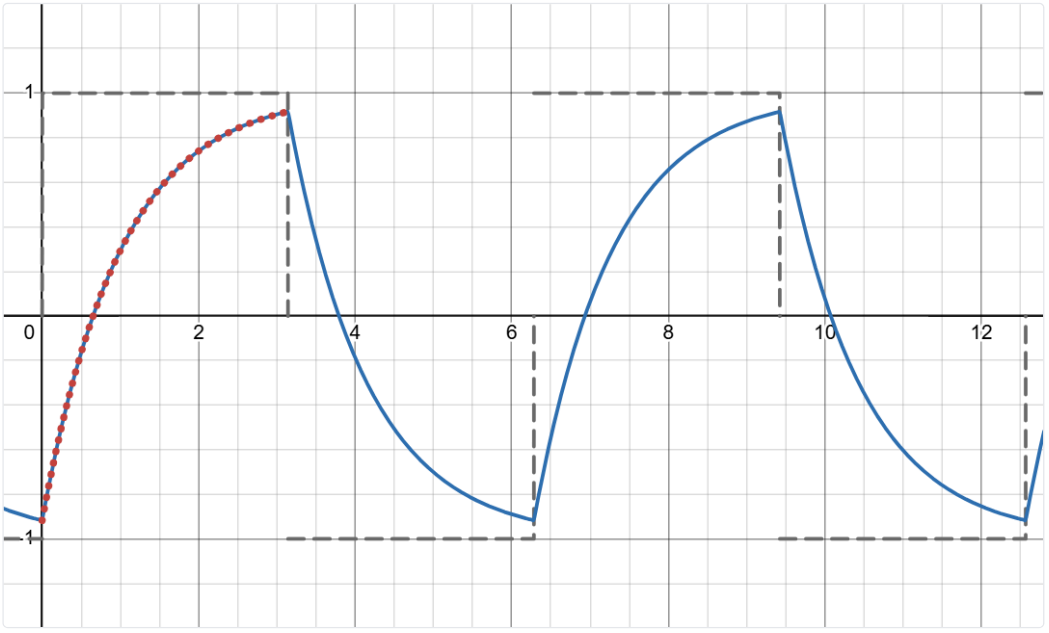
n	input amplitude $\frac{4}{n\pi}$ (V)	$\lvert H\rvert$	output amplitude (V)	phase shift
1	1.2732	0.7071	0.9003	$-45.0°$
3	0.4244	0.3162	0.1342	$-71.6°$
5	0.2546	0.1961	0.0499	$-78.7°$
7	0.1819	0.1414	0.0257	$-81.9°$

So $y_{ss}(t) = 0.9003\sin(\omega_0 t - 45°) + 0.1342\sin(3\omega_0 t - 71.6°) + 0.0499\sin(5\omega_0 t - 78.7°) + \cdots$ V. For large n the output amplitude is $\approx \frac{4}{\pi n^2}$: the filter converts the $1/n$ decay of the square wave into the $1/n^2$ decay of a waveform with kinks but no jumps — as it must, since a capacitor voltage cannot jump.

RMS and THD by Parseval: $Y^2 = \sum_{\text{odd}} \frac{1}{2}\left(\frac{4}{\pi n}\right)^2 \frac{1}{1+n^2} = 0.41612$ V² (summing to $n = 2\times 10^5$), so $Y = 0.6451$ V. The fundamental contributes $\frac{1}{2}(0.9003)^2 = 0.40528$ V², hence $\text{THD}_y = \sqrt{0.41612/0.40528 - 1} = 16.4\%$, down from 48.3% at the input.

Peak value: the output peaks at the end of each positive half-cycle, $t = T_0/2$. Summing the series there to 10^5 harmonics gives 0.91715 V.

Time-domain check. In the periodic steady state the capacitor charges towards $+1$ for half a period from $-V_p$ and must end at $+V_p$: $V_p = 1 - (1 + V_p)e^{-T_0/(2RC)}$, so $V_p = \frac{1-e^{-T_0/2RC}}{1+e^{-T_0/2RC}} = \tanh\frac{T_0}{4RC} = \tanh\frac{\pi}{2} = 0.917152$ V. ✓ The exact steady-state waveform $1 - (1 + V_p)e^{-t/RC}$ on the half-period also has RMS 0.64508 V. ✓



Steady-state RC filter output for a square-wave input with $\omega_0 RC = 1$ (horizontal axis $\omega_0 t$): the Fourier sum through the 119th harmonic (blue) and the exact exponential charging curve on the first half-period (red, dotted) coincide.

Worked Example 15.32 — Resonance with a harmonic

A lightly damped second-order system $\ddot{y} + 0.2\dot{y} + 25y = x(t)$ (natural frequency $\omega_n = 5$ rad/s, $\zeta = 0.02$) is driven by the unit square wave of period 2π s ($\omega_0 = 1$ rad/s). Find the steady-state response.

Solution. $H(j\omega) = \frac{1}{25 - \omega^2 + 0.2j\omega}$. With $b_n = \frac{4}{\pi n}$ for odd n:

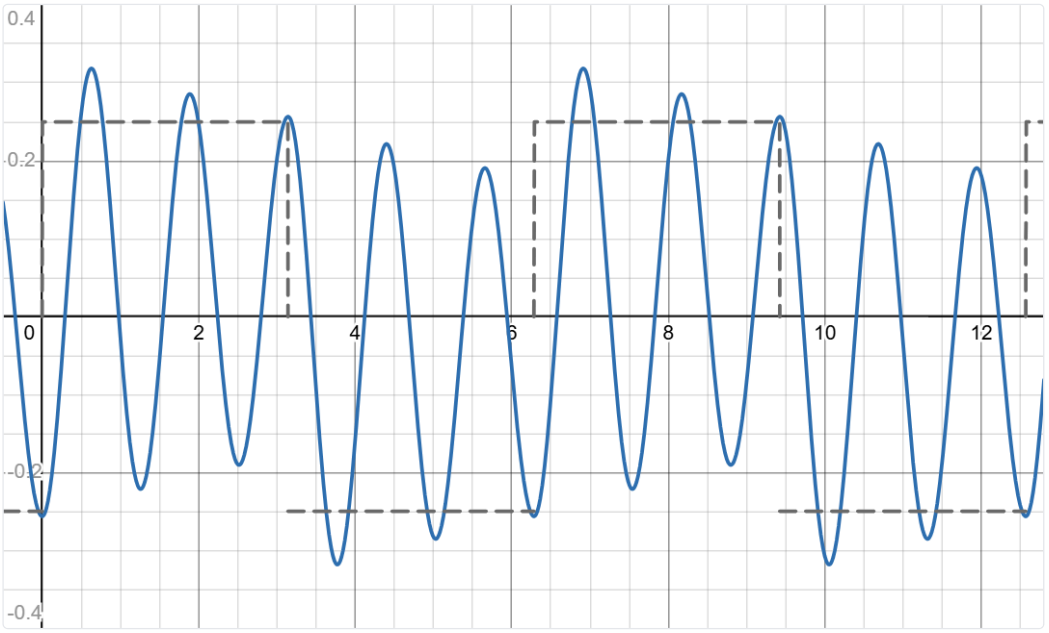
n	b_n	$\lvert H(jn)\rvert$	output amplitude	phase of H
1	1.2732	0.04167	0.05305	-0.5°
3	0.4244	0.06246	0.02651	-2.1°
5	0.2546	1.0000	**0.25465**	-90.0°
7	0.1819	0.04160	0.00757	-176.7°
9	0.1415	0.01786	0.00252	-178.2°

At $n = 5$ the denominator is $25 - 25 + 0.2j \cdot 5 = j$, so $H(j5) = -j$. The steady state is

$$y_{\text{ss}}(t) \approx 0.0531 \sin t + 0.0265 \sin 3t - 0.2546 \cos 5t + 0.0076 \sin(7t - 176.7^\circ) + \cdots .$$

The 5th harmonic, only 20% of the input fundamental, is amplified by the resonance until it dominates the output: Parseval gives the output mean square 0.034214, of which 94.8% is in the 5th harmonic. The system responds at *five times* the drive frequency.

The undamped limit. With no damping, $H(j5) = \frac{1}{25-25}$ is infinite: there is no periodic steady state, and the true solution contains a term growing like $t\cos 5t$ (Ch. 12, resonance). In general, $\ddot{y} + \omega_n^2 y = x(t)$ has a T_0-periodic solution if and only if the input has **no component at the resonant frequency**: either ω_n/ω_0 is not an integer, or $c_{\pm n} = 0$ for $n = \omega_n/\omega_0$. Had the system been tuned to $\omega_n = 4$, an even harmonic, the square wave (which has none) would drive it without resonance.



Steady-state response of $\ddot{y} + 0.2\dot{y} + 25y = x(t)$ to a unit square wave of period 2π (blue; the input is shown scaled by 0.25, dashed). The output oscillates five times per input period: the system has picked out the resonant 5th harmonic.

Worked Example 15.33 — Ripple at the output of a rectifier filter

A full-wave rectifier fed from 230 V RMS, 50 Hz ($V_m = 325$ V) supplies an LC filter: series inductor $L = 0.5$ H, shunt capacitor $C = 1000\ \mu$F, with a light load that can be neglected in computing the ripple. Assuming the rectifier output is the ideal $V_m|\sin \omega t|$, find the DC output and the ripple amplitudes.

Solution. *Input series* (Worked Example 15.25), fundamental of the rectified wave at 100 Hz:

$$v_r(t) = \frac{2V_m}{\pi} - \frac{4V_m}{\pi}\sum_{k\ge 1}\frac{\cos(2k\omega t)}{4k^2-1} = 206.90 - 137.93\cos(2\omega t) - 27.59\cos(4\omega t) - 11.82\cos(6\omega t) - \cdots \text{ V}.$$

Filter (unloaded LC divider): $H(j\Omega) = \frac{1/(j\Omega C)}{j\Omega L + 1/(j\Omega C)} = \frac{1}{1-\Omega^2 LC}$, with $H(0) = 1$.

component	Ω (rad/s)	input (V)	$\lvert H\rvert$	output (V)
DC	0	206.90	1	206.90
100 Hz	628.3	137.93	0.005092	0.702
200 Hz	1256.6	27.59	0.001268	0.035
300 Hz	1885.0	11.82	0.000563	0.0067

At 100 Hz, $\Omega^2 LC = 628.3^2 \times 0.5 \times 10^{-3} = 197.4$. The output is 206.9 V DC with 0.70 V of 100 Hz ripple; the RMS ripple by Parseval is 0.497 V, a ripple factor of 0.24%.

Interpretation. The second-order filter attenuates by $\approx 1/(\Omega^2 LC)$, i.e. 40 dB/decade, while the rectified-sine harmonics themselves fall as $1/k^2$; the combination makes the 200 Hz and higher ripple negligible. Only the lowest ripple harmonic matters for the design, which is why rectifier filter formulas are written for the 100 Hz (or 120 Hz) component alone.

Worked Example 15.34 — Choosing a filter from a harmonic specification

A 1 kHz, ± 1 V square wave is to be converted to a sine wave by a filter that leaves the fundamental essentially unchanged. What attenuation is needed at 3 kHz and above for the output THD to be below 1%? Is a second-order Butterworth low-pass with $f_c = 1$ kHz sufficient?

Solution. The output harmonics are $\frac{4}{\pi n}|H(jn\omega_0)|$. If the filter's attenuation grows at least as fast as n^2 beyond the 3rd harmonic, the 3rd dominates the THD and the requirement is approximately $\frac{1}{3}\frac{|H(j3\omega_0)|}{|H(j\omega_0)|} \le 0.01$, i.e. a relative attenuation of at least 33.3, or 30.5 dB, at 3 kHz.

A second-order Butterworth filter has $|H(j\omega)| = 1/\sqrt{1+(\omega/\omega_c)^4}$. With $f_c = 1$ kHz: $|H(j\omega_0)| = 0.7071$ and $|H(j3\omega_0)| = 1/\sqrt{82} = 0.1104$, a relative attenuation of only 6.4 (16 dB). Output harmonic ratios: 3rd $\frac{1}{3}\cdot\frac{0.1104}{0.7071} = 5.2\%$, 5th $\frac{1}{5}\cdot\frac{0.0400}{0.7071} = 1.1\%$, 7th 0.4%. THD $\approx \sqrt{5.2^2 + 1.1^2 + 0.4^2 + \cdots}\% \approx 5.3\%$. Not sufficient.

Moving the corner down to $f_c = 400$ Hz: $|H(j\omega_0)| = 1/\sqrt{1+2.5^4} = 0.1580$ and $|H(j3\omega_0)| = 1/\sqrt{1+7.5^4} = 0.01778$; 3rd-harmonic ratio $\frac{1}{3}\cdot\frac{0.01778}{0.1580} = 3.75\%$ — better, but the fundamental is now attenuated by 16 dB, and the filter still falls short. In fact, for this Butterworth filter the relative attenuation $|H(j\omega_0)|/|H(j3\omega_0)| = \sqrt{(1+81r^4)/(1+r^4)}$, $r = f_0/f_c$, can never exceed 9 (19 dB, the 40 dB/decade asymptote over a factor of 3 in frequency), whatever the corner. Since the 3rd harmonic needs 30.5 dB more attenuation than the fundamental, a much steeper roll-off is required: a filter of order 4 or more (e.g. a 4th-order Butterworth with $f_c \approx 1$ kHz gives a relative attenuation of $\sqrt{(1+3^8)/2} = 57.3$, 35 dB) or a band-pass tuned to 1 kHz.

Lesson. Harmonic specifications translate directly into frequency-response requirements at a few discrete frequencies — a far easier design problem than specifying a time-domain waveform.

Other uses of the same idea

- **Partial differential equations.** Separation of variables for the heat, wave and Laplace equations (Ch. 13) expands the initial or boundary data in a half-range sine or cosine series (§15.4); each spatial harmonic then evolves independently, decaying like $e^{-\kappa(n\pi/L)^2 t}$ in the heat equation. This is the same "multiply harmonic by harmonic" principle with the role of $H(jn\omega_0)$ played by the time evolution of each mode.
- **Periodic signals and the Fourier transform.** A periodic signal has the generalised Fourier transform $X(\omega) = 2\pi\sum_n c_n\delta(\omega - n\omega_0)$ — a train of impulses whose areas are the line-spectrum coefficients (Ch. 16, §16.6). The ideal impulse-train sampler of §16.8 is analysed exactly this way: its Fourier series has $c_n = 1/T_s$ for all n.
- **Nonlinear devices with periodic inputs.** A memoryless nonlinearity maps a periodic input to a periodic output with the same fundamental, whose coefficients follow from the multiplication rule (§15.7) or directly from the Euler integrals of the distorted waveform. Describing-function analysis of nonlinear feedback loops keeps only the fundamental of the output.
- **Switching power converters.** Their waveforms are piecewise linear (§15.7, jump method), and harmonic analysis of the switch-node voltage predicts ripple and EMI; the "average model" of a converter is exactly the $n = 0$ term.

Pitfall — the steady-state formula hides the transient and assumes stability

The harmonic-by-harmonic result describes only the periodic steady state of a *stable* system. It says nothing about the start-up transient (which can be much larger, e.g. inrush currents), and it fails outright for marginally stable systems driven at a resonance, as in the undamped case of Worked Example 15.32. Use the Laplace transform (Ch. 14) when the transient matters.

Engineering note — harmonic power flow studies

Power-system harmonic studies apply this section's theorem at network scale: each nonlinear load is modelled as a set of harmonic current sources I_n, the network as an impedance matrix $\mathbf{Z}(jn\omega_0)$ computed separately for each harmonic, and the harmonic bus voltages as $\mathbf{V}_n = \mathbf{Z}(jn\omega_0)\mathbf{I}_n$. Parallel resonances between line inductance and power-factor-correction capacitors, at which $|Z|$ peaks near the 5th or 7th harmonic, are the network-scale analogue of Worked Example 15.32.

Summary

Topic	Key formula or fact
Fundamental	T_0, $f_0 = 1/T_0$, $\omega_0 = 2\pi/T_0$; nth harmonic at $n\omega_0$
Inner product, RMS	$\langle x, y\rangle = \frac{1}{T_0}\int_{T_0} xy^*dt$; $\|x\| = X_{\text{rms}}$
Orthogonality	$\frac{1}{T_0}\int_{T_0} e^{jm\omega_0 t}e^{-jn\omega_0 t}dt = \delta_{mn}$
Trigonometric series	$x \sim \frac{a_0}{2} + \sum_{n\geq 1}(a_n\cos n\omega_0 t + b_n \sin n\omega_0 t)$
Euler formulas	$a_n = \frac{2}{T_0}\int_{T_0} x\cos n\omega_0 t\,dt$, $b_n = \frac{2}{T_0}\int_{T_0} x\sin n\omega_0 t\,dt$
Amplitude–phase form	$A_n = \sqrt{a_n^2+b_n^2}$, $\phi_n = \operatorname{atan2}(-b_n, a_n)$, $x \sim A_0 + \sum A_n\cos(n\omega_0 t + \phi_n)$
Complex series	$x \sim \sum_n c_n e^{jn\omega_0 t}$, $c_n = \frac{1}{T_0}\int_{T_0} xe^{-jn\omega_0 t}dt$
Conversions	$c_n = \frac{a_n - jb_n}{2}$, $c_0 = \frac{a_0}{2}$; real x: $c_{-n} = c_n^*$, $A_n = 2\|c_n\|$, $\phi_n = \angle c_n$
One-period transform	$c_n = \frac{1}{T_0}X_1(jn\omega_0)$, $X_1(s) = \int_0^{T_0} xe^{-st}dt$
Best approximation	S_N minimises $\|x-p\|$; error $= \|x\|^2 - \sum_{\|n\|\leq N}\|c_n\|^2$
Even / odd	even: cosines, $a_n = \frac{4}{T_0}\int_0^{T_0/2} x\cos$; odd: sines, $b_n = \frac{4}{T_0}\int_0^{T_0/2} x\sin$
Half-wave symmetry	$x(t+\frac{T_0}{2}) = -x(t) \iff$ odd harmonics only
Quarter-wave symmetry	odd n only, $\frac{8}{T_0}\int_0^{T_0/4}$
Half-range series on $(0, L)$	sine: $b_n = \frac{2}{L}\int_0^L f\sin\frac{n\pi x}{L}$; cosine: $a_n = \frac{2}{L}\int_0^L f\cos\frac{n\pi x}{L}$
Standard series	square $\frac{4A}{\pi}\sum_{\text{odd}}\frac{\sin n\omega_0 t}{n}$; triangle $\frac{8A}{\pi^2}\sum_{\text{odd}}\frac{\cos n\omega_0 t}{n^2}$; pulse train $c_n = AD\operatorname{sinc}(nD)$
Rectified sines	half-wave: $\frac{V_m}{\pi} + \frac{V_m}{2}\sin\omega_0 t - \frac{2V_m}{\pi}\sum_k\frac{\cos 2k\omega_0 t}{4k^2-1}$; full-wave: $\frac{2V_m}{\pi} - \frac{4V_m}{\pi}\sum_k\frac{\cos 2k\omega_0 t}{4k^2-1}$
Dirichlet theorem	$S_N(t) \to \frac{1}{2}[x(t^+) + x(t^-)]$
Uniform convergence	x continuous and piecewise smooth, or $\sum\|c_n\| < \infty$
Mean-square convergence	$\|x - S_N\| \to 0$ for every finite-power x
Gibbs phenomenon	overshoot $\to (\frac{1}{\pi}\operatorname{Si}(\pi) - \frac{1}{2})J = 0.0895J$; square wave peak $\frac{2}{\pi}\operatorname{Si}(\pi)A = 1.179A$
Shift, modulation	$x(t-t_0) \leftrightarrow e^{-jn\omega_0 t_0}c_n$; $e^{jm\omega_0 t}x \leftrightarrow c_{n-m}$
Differentiation, integration	$x' \leftrightarrow jn\omega_0 c_n$; $\int x \leftrightarrow c_n/(jn\omega_0)$ if $c_0 = 0$
Convolution, product	$\frac{1}{T_0}\int_{T_0} x(\tau)y(t-\tau)d\tau \leftrightarrow c_n d_n$; $xy \leftrightarrow \sum_m c_m d_{n-m}$
Jump formula	$c_n = \frac{1}{jn\omega_0 T_0}\sum_i J_i e^{-jn\omega_0 t_i} + \frac{1}{jn\omega_0}c_n(x'_{\text{reg}})$
Decay rate	jump in $x^{(k)}$, lower derivatives continuous $\Rightarrow \|c_n\| = O(1/n^{k+1})$
DFT aliasing	$\tilde{c}_n = \frac{1}{N}\sum_k x_k e^{-j2\pi nk/N} = \sum_m c_{n+mN}$
Parseval	$\frac{1}{T_0}\int_{T_0}\|x\|^2dt = \sum_n\|c_n\|^2 = A_0^2 + \sum_{n\geq 1}\frac{A_n^2}{2}$
Average power	$P = V_0 I_0 + \sum_{n\geq 1} V_{n,\text{rms}} I_{n,\text{rms}}\cos\theta_n$
THD	$\text{THD}_F = \sqrt{\sum_{n\geq 2} X_n^2}/X_1 = \sqrt{X^2/X_1^2 - 1}$; $\text{THD}_R = \text{THD}_F/\sqrt{1+\text{THD}_F^2}$
Power factor (sinusoidal v)	$\text{PF} = \frac{I_1}{I}\cos\theta_1 = \frac{\cos\theta_1}{\sqrt{1+\text{THD}_i^2}}$
THD values	square 48.3%, sawtooth 80.3%, six-step 31.1%, triangle 12.1%
LTI steady state	$d_n = c_n H(jn\omega_0)$; $P_y = \sum_n\|c_n\|^2\|H(jn\omega_0)\|^2$

Chapter 16 — Fourier Transforms

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 5 (integral calculus), Ch. 14 (Laplace transforms), Ch. 15 (Fourier series and Fourier analysis) **Learning outcomes:** After this chapter you can
>
> - compute forward and inverse Fourier transforms of standard signals, including generalized transforms of impulses, steps, constants and sinusoids;
> - derive and apply the transform properties (linearity, shift, scaling, duality, differentiation, integration, modulation) so that most transforms are found without integrating;
> - use the convolution and multiplication theorems to analyse linear time-invariant systems and products of signals in the frequency domain;
> - interpret magnitude and phase spectra, frequency responses, group delay and bandwidth, including the time–bandwidth (uncertainty) trade-off;
> - analyse periodic and finite-length signals spectrally, including windowing, leakage and resolution;
> - compute energy and energy spectral density with Parseval's theorem, and state the mathematics of ideal sampling: impulse-train spectra, aliasing, the Nyquist condition and sinc reconstruction.

The Fourier series of Ch. 15 represents a *periodic* signal as a sum of harmonics at the discrete frequencies $k\omega_0$. Most signals an engineer meets are not periodic: a single radar pulse, a transient on a power line, a spoken word, a step applied to an amplifier, a bit of data on a cable. To describe such signals in terms of frequency we let the period grow without bound. The harmonics crowd together, their spacing ω_0 shrinks to $d\omega$, the sum becomes an integral, and we obtain the **Fourier transform**: a representation of an *aperiodic* signal as a continuum of complex exponentials $e^{j\omega t}$.

The Fourier transform sits between the two neighbouring chapters. It is the Laplace transform of Ch. 14 restricted to the imaginary axis $s = j\omega$ (whenever that axis lies in the region of convergence), and when a signal is sampled it becomes, after a change of variable, the discrete-time Fourier transform and the Z-transform of Ch. 17 on the unit circle. Compared with the Laplace transform it gives up the ability to handle growing signals directly, but gains a perfectly symmetric inverse, a clean physical meaning (the frequency content of the signal), and an energy theorem (Parseval) that makes "how much of the signal lies in this band?" a well-posed question.

Throughout this chapter $x(t)$ is a real or complex function of continuous time t (in seconds), ω is angular frequency in rad/s, and $f = \omega/2\pi$ is frequency in Hz. Wherever a voltage example helps, $x(t)$ is a voltage in volts.

16.1 Continuous Fourier transform

Motivation: from series to integral

A sinusoid $\cos(\omega t)$ passing through a linear circuit comes out as a sinusoid of the same frequency, scaled and phase-shifted; that is the whole content of phasor analysis. If we can write an arbitrary input as a superposition of sinusoids — or, more conveniently, of complex exponentials $e^{j\omega t}$ — then the response of any linear time-invariant circuit to that input is the same superposition of scaled exponentials. For periodic inputs, the Fourier series supplies the superposition. For aperiodic inputs we need a *continuous* superposition, and the weight given to each frequency is the Fourier transform.

Heuristic derivation. Let $x(t)$ be zero outside $|t| < T_0/2$, and let $\tilde{x}(t)$ be its periodic extension with period T_0 and fundamental $\omega_0 = 2\pi/T_0$. The exponential Fourier coefficients of $\tilde{x}$ (Ch. 15) are

$$c_k = \frac{1}{T_0}\int_{-T_0/2}^{T_0/2} x(t)\, e^{-jk\omega_0 t}\, dt.$$

Define the function

$$X(\omega) = \int_{-\infty}^{\infty} x(t)\, e^{-j\omega t}\, dt,$$

which, because x vanishes outside one period, gives $c_k = X(k\omega_0)/T_0$. The series becomes

$$\tilde{x}(t) = \sum_{k=-\infty}^{\infty} \frac{1}{T_0} X(k\omega_0)\, e^{jk\omega_0 t} = \frac{1}{2\pi}\sum_{k=-\infty}^{\infty} X(k\omega_0)\, e^{jk\omega_0 t}\, \omega_0.$$

Now let $T_0 \to \infty$. Then $\tilde{x} \to x$ (the neighbouring copies move off to infinity), the spacing ω_0 becomes the differential $d\omega$, the discrete frequencies $k\omega_0$ become a continuous variable ω, and the sum is a Riemann sum for

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\, e^{j\omega t}\, d\omega.$$

Two facts come out of this argument and are worth keeping:

1. **The Fourier series coefficients of a periodic signal are samples of the transform of one period**, divided by the period: $c_k = X(k\omega_0)/T_0$.
2. As T_0 grows each individual coefficient c_k shrinks like $1/T_0$, but the *density* $T_0 c_k$ stays finite. The transform is that density — it is an amplitude *per unit frequency*, not an amplitude.

Definition

Fourier transform (angular-frequency convention)

For a signal $x(t)$, the Fourier transform is

$$X(\omega) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{\infty} x(t)\, e^{-j\omega t}\, dt,$$

where ω is angular frequency in rad/s. We write $x(t) \leftrightarrow X(\omega)$ and call x and X a **transform pair**.

$X(\omega)$ is in general complex even when $x(t)$ is real, and we write it in polar form $X(\omega) = |X(\omega)|e^{j\angle X(\omega)}$. If $x(t)$ is a voltage in V, then $X(\omega)$ has units V·s = V/Hz: it is a **spectral density**. Two immediate special values are useful checks on every computation:

$$X(0) = \int_{-\infty}^{\infty} x(t)\, dt \quad \text{(the area of } x\text{)}, \qquad x(0) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\, d\omega \quad \text{(the area of } X\text{, divided by } 2\pi\text{)}.$$

The second follows from the inverse formula (Section 16.2) at $t = 0$.

Relation to the Laplace transform. The bilateral Laplace transform is $X_L(s) = \int x(t)e^{-st}dt$ with $s = \sigma + j\omega$. Setting $\sigma = 0$ gives the Fourier transform: $X(\omega) = X_L(j\omega)$, *provided the region of convergence (ROC) of X_L contains the imaginary axis*. For a causal signal this means all poles of $X_L(s)$ lie strictly in the left half-plane — the same condition as BIBO stability of an impulse response. If the ROC does not contain the $j\omega$-axis, the Fourier transform either does not exist or exists only as a generalized function (Section 16.2).

Existence

The integral defining $X(\omega)$ is improper on both ends, so we need conditions under which it makes sense.

Sufficient conditions for existence (Dirichlet conditions)

Suppose

1. $x(t)$ is **absolutely integrable**: $\int_{-\infty}^{\infty}|x(t)|\,dt < \infty$;
2. in every finite interval $x(t)$ has finitely many maxima and minima and finitely many finite discontinuities.

Then $X(\omega)$ exists for every ω, is continuous and bounded, $|X(\omega)| \le \int|x|\,dt$, and $X(\omega) \to 0$ as $|\omega| \to \infty$ (the **Riemann–Lebesgue lemma**).

Proof sketch. Since $|e^{-j\omega t}| = 1$, $|X(\omega)| \le \int|x(t)|dt < \infty$, which is the bound. Continuity follows because $|X(\omega+h) - X(\omega)| \le \int|x(t)|\,|e^{-jht} - 1|dt$, and the integrand tends to zero for each t while being dominated by $2|x(t)|$. For Riemann–Lebesgue, approximate x by a step function; for a single rectangle $\int_a^b e^{-j\omega t}dt = (e^{-j\omega a} - e^{-j\omega b})/(j\omega) \to 0$, and the approximation error can be made arbitrarily small uniformly in ω. □

There is a second, equally important class.

Finite-energy signals (Plancherel)

If $x(t)$ has finite energy, $\int_{-\infty}^{\infty}|x(t)|^2dt < \infty$, then the truncated transforms $X_T(\omega) = \int_{-T}^{T} x(t)e^{-j\omega t}dt$ converge **in mean square** to a function $X(\omega)$ as $T \to \infty$, the inverse formula holds in the same mean-square sense, and Parseval's theorem (Section 16.7) holds.

Absolute integrability and finite energy are different conditions. The sinc pulse $\sin(t)/t$ has finite energy but is not absolutely integrable (its envelope decays only as $1/|t|$); its transform exists in the mean-square sense and turns out to be a rectangle — discontinuous, which is consistent with the Dirichlet theorem *not* applying. Conversely $1/\sqrt{|t|}$ on $|t| < 1$ is absolutely integrable but has infinite energy.

Signals such as 1, $u(t)$, $\cos\omega_0 t$ and $\operatorname{sgn}(t)$ are neither absolutely integrable nor of finite energy. They are nevertheless indispensable — a DC supply, a switch closing, a carrier wave — and they have **generalized transforms** containing Dirac impulses $\delta(\omega)$, developed in Section 16.2.

Standard functions: rect, sinc, triangle, signum

We use the following standard shapes throughout the chapter.

Rectangle, sinc, triangle and signum

$$\operatorname{rect}(t) = \begin{cases} 1, & |t| < \tfrac{1}{2} \\ \tfrac{1}{2}, & |t| = \tfrac{1}{2} \\ 0, & |t| > \tfrac{1}{2} \end{cases}, \qquad \operatorname{sinc}(x) = \frac{\sin(\pi x)}{\pi x}, \quad \operatorname{sinc}(0) = 1,$$

$$\Lambda(t) = \max\bigl(0,\, 1 - |t|\bigr), \qquad \operatorname{sgn}(t) = \begin{cases} 1, & t > 0 \\ 0, & t = 0 \\ -1, & t < 0 \end{cases}.$$

So $\operatorname{rect}(t/T)$ is a unit-height pulse of width T centred on $t = 0$, and $\Lambda(t/T)$ is a unit-height triangle of base $2T$. This is the **normalized** sinc: its zeros are at the nonzero integers and $\int_{-\infty}^{\infty}\operatorname{sinc}(x)\,dx = 1$.

Common Pitfall — two sinc conventions

Mathematics texts and some circuits books define $\operatorname{sinc}(x) = \sin(x)/x$ (unnormalized, zeros at $x = k\pi$). This book uses $\sin(\pi x)/(\pi x)$, the convention of numerical libraries such as NumPy and MATLAB. Whenever a formula containing "sinc" is copied from another source, check which one it uses; the safest habit is to write the explicit ratio $2\sin(\omega T/2)/\omega$ when there is any doubt.

Worked examples

Worked Example 16.1 — the one-sided exponential

Find the transform of $x(t) = e^{-at}u(t)$, $a > 0$, and its magnitude and phase.

Step 1 — integrate. Only $t > 0$ contributes:

$$X(\omega) = \int_0^\infty e^{-at}e^{-j\omega t}\,dt = \int_0^\infty e^{-(a+j\omega)t}dt = \left[\frac{-e^{-(a+j\omega)t}}{a+j\omega}\right]_0^\infty = \frac{1}{a+j\omega}.$$

The upper limit vanishes because $|e^{-(a+j\omega)t}| = e^{-at} \to 0$; this is where $a > 0$ is used.

Step 2 — polar form. Multiply numerator and denominator by the conjugate, or read off directly:

$$|X(\omega)| = \frac{1}{\sqrt{a^2+\omega^2}}, \qquad \angle X(\omega) = -\arctan\frac{\omega}{a}.$$

Step 3 — interpret. $X(0) = 1/a$, which equals $\int_0^\infty e^{-at}dt$ ✓. At $\omega = a$ the magnitude is $1/(a\sqrt{2})$, i.e. $1/\sqrt{2}$ of its DC value (-3 dB), and the phase is $-45°$. For $\omega \gg a$, $|X| \approx 1/|\omega|$ and the phase approaches $-90°$. The result equals the Laplace transform $1/(s+a)$ at $s = j\omega$, which is legitimate because the ROC $\operatorname{Re}\{s\} > -a$ contains the $j\omega$-axis.

Numerical check ($a = 2$, $\omega = 2$): $X = 1/(2+2j) = 0.25 - 0.25j$, $|X| = 0.3536 = 1/(2\sqrt{2})$ ✓, $\angle X = -45°$ ✓.

Worked Example 16.2 — the rectangular pulse

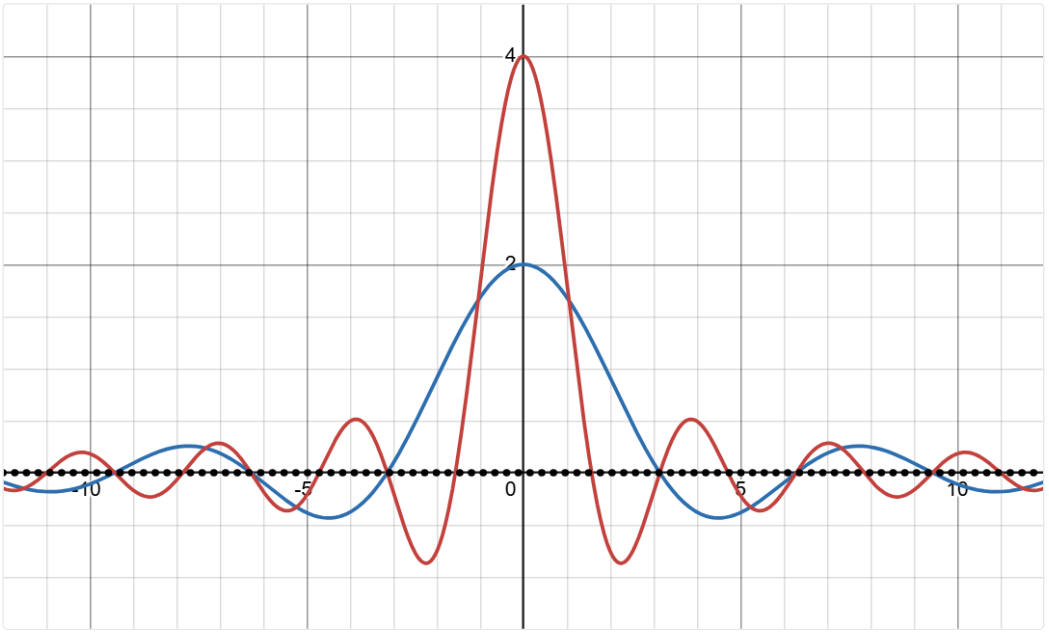
Find the transform of $x(t) = A\,\mathrm{rect}(t/T)$, a pulse of height A and width T.

$$X(\omega) = A\int_{-T/2}^{T/2} e^{-j\omega t}\,dt = A\,\frac{e^{j\omega T/2} - e^{-j\omega T/2}}{j\omega} = \frac{2A\sin(\omega T/2)}{\omega} = AT\,\operatorname{sinc}\left(\frac{\omega T}{2\pi}\right).$$

The last step writes $2\sin(\omega T/2)/\omega = T\sin(\pi u)/(\pi u)$ with $u = \omega T/2\pi$.

- $X(0) = AT$, the pulse area ✓.
- Zeros occur where $\omega T/2 = k\pi$, i.e. $\omega = 2\pi k/T$, $k = \pm 1, \pm 2, \ldots$ (in Hz: $f = k/T$).
- The main lobe runs from $-2\pi/T$ to $2\pi/T$: width $4\pi/T$ rad/s. **Halving the pulse width doubles the spectral width.**
- X is real because x is real and even; its sign alternates between lobes, so the phase alternates between 0 and $\pm\pi$.
- The envelope decays as $2A/|\omega|$ — slowly, because x has jump discontinuities.

For a 1 µs pulse ($T = 10^{-6}$ s) the first null is at $f = 1$ MHz: a rule of thumb used everywhere in pulse and digital-signal work is that a pulse of duration T needs a bandwidth of order $1/T$ Hz.



Spectra $T\,\operatorname{sinc}(\omega T/2\pi) = 2\sin(\omega T/2)/\omega$ of unit-height rectangular pulses of width $T = 2$ (blue) and $T = 4$ (red): the longer pulse has twice the peak and half the main-lobe width.

Worked Example 16.3 — the two-sided exponential

Find the transform of $x(t) = e^{-a|t|}$, $a > 0$.

Split the integral at $t = 0$:

$$X(\omega) = \int_{-\infty}^{0} e^{(a-j\omega)t}dt + \int_{0}^{\infty} e^{-(a+j\omega)t}dt = \frac{1}{a-j\omega} + \frac{1}{a+j\omega} = \frac{2a}{a^2+\omega^2}.$$

The result is real and even, as it must be for a real even signal, and positive for all ω. Its value at the origin is $X(0) = 2/a = \int e^{-a|t|}dt$ ✓. The decay is $1/\omega^2$, one power faster than for the one-sided exponential: $e^{-a|t|}$ is continuous (only its derivative jumps), whereas $e^{-at}u(t)$ itself jumps at $t = 0$. This shape is called a **Lorentzian**; it appears again as the power spectrum of a first-order Gauss–Markov process in Ch. 21.

Worked Example 16.4 — the Gaussian pulse

Find the transform of $x(t) = e^{-t^2/(2\sigma^2)}$, $\sigma > 0$.

Step 1 — complete the square in the exponent:

$$-\frac{t^2}{2\sigma^2} - j\omega t = -\frac{1}{2\sigma^2}\left(t + j\sigma^2\omega\right)^2 - \frac{\sigma^2\omega^2}{2}.$$

(Expand the square: $-(t^2 + 2j\sigma^2\omega t - \sigma^4\omega^2)/(2\sigma^2) = -t^2/(2\sigma^2) - j\omega t + \sigma^2\omega^2/2$; subtracting $\sigma^2\omega^2/2$ restores the original.)

Step 2 — shift the contour. Then

$$X(\omega) = e^{-\sigma^2\omega^2/2}\int_{-\infty}^{\infty} e^{-(t+j\sigma^2\omega)^2/(2\sigma^2)}\,dt.$$

The remaining integral is a Gaussian integral along a line parallel to the real axis. Because $e^{-z^2/(2\sigma^2)}$ is analytic and decays rapidly as $|\mathrm{Re}\, z| \to \infty$ in any horizontal strip, Cauchy's theorem (Ch. 18) lets us move the line back to the real axis without changing the value, giving $\int e^{-t^2/(2\sigma^2)}dt = \sigma\sqrt{2\pi}$.

$$e^{-t^2/(2\sigma^2)} \;\leftrightarrow\; \sigma\sqrt{2\pi}\, e^{-\sigma^2\omega^2/2}.$$

Interpretation. The transform of a Gaussian is a Gaussian. Its width in ω is $1/\sigma$: a pulse of time-width σ has frequency-width $1/\sigma$. With $\sigma = 1$ the pair is self-reciprocal up to the factor $\sqrt{2\pi}$. Because the Gaussian is infinitely smooth, its spectrum decays faster than any power of ω.

Numerical check ($\sigma = 0.5$, $\omega = 2$): formula gives $0.5\sqrt{2\pi}e^{-0.5} = 0.7602$; numerical integration of $\int e^{-2t^2}\cos(2t)\,dt$ (the sine part vanishes by oddness) also gives 0.7602 ✓.

Engineering Note — what the transform tells a circuit designer

The magnitude $|X(\omega)|$ shows which frequency bands the signal occupies, and therefore what bandwidth an amplifier, cable or filter must pass to reproduce it. The rectangle's $1/\omega$ tail is why sharp-edged digital signals radiate interference far above their clock rate; rounding the edges (Gaussian or raised-cosine shaping) converts that tail into a much faster decay. The phase $\angle X(\omega)$ records *when* each component occurs: a delay shows up purely in the phase (Section 16.3).

16.2 Inverse transform

Statement

The derivation in Section 16.1 already suggested how to recover $x(t)$ from $X(\omega)$. The precise statement is the **Fourier integral theorem**.

Inverse Fourier transform (Fourier integral theorem)

If $x(t)$ satisfies the Dirichlet conditions of Section 16.1, then

$$x(t) = \mathcal{F}^{-1}\{X(\omega)\} = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\, e^{j\omega t}\, d\omega$$

at every point of continuity of x, where the integral is understood as the limit $\lim_{W\to\infty}\frac{1}{2\pi}\int_{-W}^{W}$. At a jump discontinuity the integral converges to the midpoint $\frac{1}{2}[x(t^-) + x(t^+)]$.

The inverse has exactly the same form as the forward transform except for the sign of the exponent and the factor $1/(2\pi)$. The factor appears because we integrate over angular frequency: $d\omega = 2\pi\, df$. In words, the inverse formula says that $x(t)$ is a superposition of complex exponentials $e^{j\omega t}$, the one at frequency ω having complex weight $X(\omega)\, d\omega/2\pi$.

Proof sketch. Insert the definition of X into the truncated inverse and exchange the order of integration (justified by absolute integrability of x and the finite range in ω):

$$x_W(t) = \frac{1}{2\pi}\int_{-W}^{W}\left[\int_{-\infty}^{\infty} x(\tau)e^{-j\omega\tau}d\tau\right]e^{j\omega t}d\omega = \int_{-\infty}^{\infty} x(\tau)\, D_W(t-\tau)\, d\tau, \qquad D_W(s) = \frac{\sin Ws}{\pi s}.$$

The kernel D_W is the continuous-time analogue of the Dirichlet kernel of Fourier series. For every W it has total area $\int D_W(s)\,ds = 1$, and as $W \to \infty$ it oscillates ever faster away from $s = 0$ while its central peak (height W/π, width about $2\pi/W$) grows. By the Riemann–Lebesgue lemma the contribution away from $s = 0$ tends to zero, so D_W acts in the limit like $\delta(s)$ and $x_W(t) \to x(t)$ at points of continuity. At a jump, half of the kernel's area lies on each side of $s = 0$

(it is even), so the limit is the average of the one-sided limits. □

The truncation x_W is exactly what an ideal low-pass filter of bandwidth W does to x, and near a jump it overshoots by about 9 % of the jump no matter how large W is — the **Gibbs phenomenon**, inherited unchanged from Fourier series.

The hertz convention

Many communications and optics texts (for example Bracewell) use frequency f in Hz instead of ω:

$$X_f(f) = \int_{-\infty}^{\infty} x(t)\, e^{-j2\pi f t}\, dt, \qquad x(t) = \int_{-\infty}^{\infty} X_f(f)\, e^{j2\pi f t}\, df.$$

The two are related by $X_f(f) = X(2\pi f)$. The Hz form is symmetric (no 2π outside either integral), which removes 2π factors from duality, the multiplication theorem and Parseval's theorem; the ω form matches the Laplace variable $s = \sigma + j\omega$ and circuit phasors. **This book uses ω throughout.** To convert a result from a Hz-convention source, substitute $f = \omega/2\pi$ in the transform and, in any integral over frequency, $df = d\omega/2\pi$. (A third, "unitary" convention puts $1/\sqrt{2\pi}$ in front of both integrals; it is common in physics and is not used here.)

Methods of inversion

1. **Table lookup plus properties.** This is the usual method. A short table of pairs (below) combined with the properties of Section 16.3 covers almost every signal met in practice.
2. **Partial fractions** for rational functions of $j\omega$, exactly as for Laplace transforms. Treat $j\omega$ as the variable, expand, and use

$$\frac{1}{(a + j\omega)^m} \;\leftrightarrow\; \frac{t^{m-1}}{(m-1)!}\, e^{-at} u(t), \qquad \operatorname{Re}\{a\} > 0.$$

If a term has $\operatorname{Re}\{a\} < 0$, the corresponding absolutely integrable time function is anticausal: $1/(a + j\omega) \leftrightarrow -e^{-at}u(-t)$ for $\operatorname{Re}\{a\} < 0$. A Fourier transform, unlike a unilateral Laplace transform, needs no separately stated ROC because the $j\omega$-axis *is* the ROC; the sign of $\operatorname{Re}\{a\}$ decides causal versus anticausal. 3. **Direct integration**, often by contour integration and residues (Ch. 18), which is how rational spectra with mixed left- and right-half-plane poles are inverted systematically.

Worked examples

Worked Example 16.5 — ideal low-pass spectrum

Let $X(\omega) = \operatorname{rect}(\omega/2W)$, i.e. $X = 1$ for $|\omega| < W$ and 0 otherwise. Find $x(t)$.

$$x(t) = \frac{1}{2\pi}\int_{-W}^{W} e^{j\omega t}\, d\omega = \frac{1}{2\pi}\cdot\frac{e^{jWt} - e^{-jWt}}{jt} = \frac{\sin(Wt)}{\pi t} = \frac{W}{\pi}\operatorname{sinc}\!\left(\frac{Wt}{\pi}\right).$$

Checks: $x(0) = W/\pi$, which equals $\frac{1}{2\pi}\int X\, d\omega = 2W/2\pi$ ✓. The zeros are at $t = k\pi/W$, $k \neq 0$.

If X is the frequency response of a filter, x is its impulse response. The ideal ("brick-wall") low-pass filter therefore has a sinc impulse response that extends over all $t < 0$: it responds before the impulse arrives. It is **non-causal** and hence not physically realisable — a fact read directly from the inverse transform. Realisable filters approximate the brick wall with a delayed, truncated sinc or with rational responses.

Worked Example 16.6 — partial fractions with distinct poles

Invert $X(\omega) = \dfrac{j\omega + 3}{(j\omega + 1)(j\omega + 2)}$.

Write $X = \dfrac{A}{1 + j\omega} + \dfrac{B}{2 + j\omega}$. By cover-up,

$$A = \left.\frac{j\omega + 3}{j\omega + 2}\right|_{j\omega = -1} = 2, \qquad B = \left.\frac{j\omega + 3}{j\omega + 1}\right|_{j\omega = -2} = -1.$$

Both poles are in the left half-plane ($a = 1, 2 > 0$), so both terms are causal:

$$x(t) = \left(2e^{-t} - e^{-2t}\right) u(t).$$

Check at $\omega = 0$: $X(0) = 3/2$ and $\int_0^\infty (2e^{-t} - e^{-2t})dt = 2 - \tfrac{1}{2} = \tfrac{3}{2}$ ✓. Check at $t = 0^+$: $x(0^+) = 1$, and the initial-value rule $x(0^+) = \lim_{\omega\to\infty} j\omega X(\omega) = 1$ ✓.

Worked Example 16.7 — complex poles, and a two-sided signal

(a) Invert $X(\omega) = \dfrac{1}{(j\omega)^2 + 2j\omega + 5}$.

Complete the square: $(j\omega)^2 + 2j\omega + 5 = (j\omega + 1)^2 + 4$. From the pair $e^{-at}\sin(bt)u(t) \leftrightarrow b/[(a + j\omega)^2 + b^2]$ (the Laplace pair at $s = j\omega$, valid since $a = 1 > 0$),

$$x(t) = \tfrac{1}{2}e^{-t}\sin(2t)\,u(t).$$

Check: $X(0) = 1/5$, and $\int_0^\infty \tfrac{1}{2}e^{-t}\sin 2t\,dt = \tfrac{1}{2}\cdot\tfrac{2}{1+4} = \tfrac{1}{5}$ ✓.

(b) Invert $Y(\omega) = \dfrac{6}{(2 + j\omega)(3 - j\omega)}$.

Partial fractions in $j\omega$: $Y = \dfrac{A}{2 + j\omega} + \dfrac{B}{3 - j\omega}$ with $A = 6/(3 + 2) = 6/5$ (set $j\omega = -2$) and $B = 6/(2 + 3) = 6/5$ (set $j\omega = 3$). The first term is causal. The second, $1/(3 - j\omega)$, is the transform of $e^{3t}u(-t)$ (replace $t \to -t$ in $e^{-3t}u(t) \leftrightarrow 1/(3 + j\omega)$, which replaces $\omega \to -\omega$). Hence

$$y(t) = \tfrac{6}{5}\left[e^{-2t}u(t) + e^{3t}u(-t)\right],$$

a two-sided signal that decays in both directions. Check: $Y(0) = 1$ and $\int y\,dt = \tfrac{6}{5}(\tfrac{1}{2} + \tfrac{1}{3}) = 1$ ✓. A unilateral Laplace table cannot produce this answer; the Fourier transform handles it naturally because its "ROC" is fixed to be the $j\omega$-axis.

Generalized transforms

Many important signals — constants, steps, sinusoids — are not absolutely integrable. They acquire transforms when we allow the Dirac impulse in the frequency domain. The cleanest route is to compute transforms of impulses directly and then use the inverse formula.

Impulse. By the sifting property, $\mathcal{F}\{\delta(t - t_0)\} = \int \delta(t - t_0)e^{-j\omega t}dt = e^{-j\omega t_0}$. In particular $\delta(t) \leftrightarrow 1$: an impulse contains all frequencies with equal weight, which is why an impulse response characterises an LTI system completely.

Complex exponential and constant. Apply the inverse formula to $X(\omega) = 2\pi\delta(\omega - \omega_0)$:

$$\frac{1}{2\pi}\int_{-\infty}^{\infty} 2\pi\delta(\omega - \omega_0)\,e^{j\omega t}\,d\omega = e^{j\omega_0 t}.$$

Hence

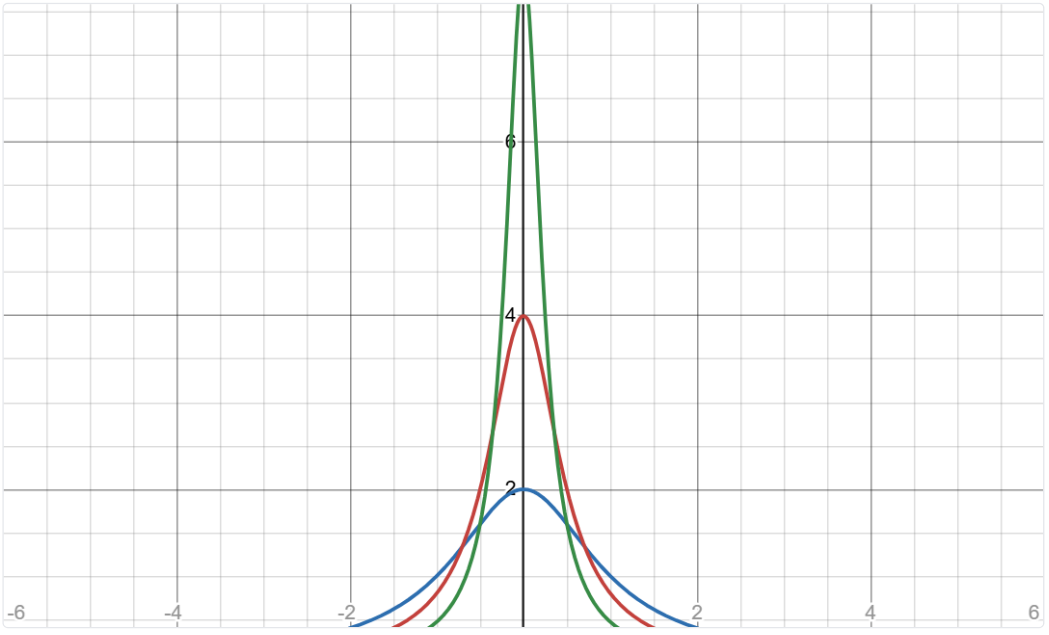
$$e^{j\omega_0 t} \leftrightarrow 2\pi\delta(\omega - \omega_0), \qquad 1 \leftrightarrow 2\pi\delta(\omega),$$

and by Euler's formula

$$\cos\omega_0 t \leftrightarrow \pi[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)], \qquad \sin\omega_0 t \leftrightarrow -j\pi[\delta(\omega - \omega_0) - \delta(\omega + \omega_0)].$$

A pure tone has all its spectral content concentrated at $\pm\omega_0$, with impulse areas π (not $\tfrac{1}{2}$: the areas are 2π times the Fourier-series coefficients $\tfrac{1}{2}$).

A limiting argument. The same pair can be obtained without the inverse formula by viewing 1 as the limit of $e^{-a|t|}$ as $a \to 0^+$. Its transform $2a/(a^2 + \omega^2)$ has area $\int 2a/(a^2 + \omega^2)\,d\omega = 2\pi$ for every a, and as $a \to 0$ it becomes an ever taller, narrower peak at $\omega = 0$. Its limit is therefore $2\pi\delta(\omega)$ ✓.



The transforms $2a/(a^2 + \omega^2)$ of $e^{-a|t|}$ for $a = 1$ (blue), 0.5 (red) and 0.25 (green): every curve has area 2π, and as $a \to 0$ they converge to the impulse $2\pi\delta(\omega)$, the transform of the constant 1.

Signum. Write $\operatorname{sgn}(t) = \lim_{a\to 0^+}[e^{-at}u(t) - e^{at}u(-t)]$. The bracket has transform

$$\frac{1}{a+j\omega}-\frac{1}{a-j\omega}=\frac{-2j\omega}{a^2+\omega^2}\xrightarrow{a\to 0}\frac{-2j\omega}{\omega^2}=\frac{2}{j\omega}.$$

There is no impulse at $\omega=0$ because the bracket is odd, so its transform is odd and integrates to zero across the origin. Thus $\operatorname{sgn}(t)\leftrightarrow 2/(j\omega)$.

Unit step. Since $u(t)=\tfrac{1}{2}[1+\operatorname{sgn}(t)]$,

$$u(t)\leftrightarrow \pi\delta(\omega)+\frac{1}{j\omega}.$$

The impulse $\pi\delta(\omega)$ carries the average (DC) value $\tfrac{1}{2}$ of the step; the $1/(j\omega)$ term carries the jump.

Common Pitfall — substituting $s=j\omega$ outside the ROC

The Fourier transform of $u(t)$ is **not** obtained by putting $s=j\omega$ in $1/s$: the ROC of $\mathcal{L}\{u(t)\}$ is $\operatorname{Re}\{s\}>0$, which excludes the $j\omega$-axis. The extra $\pi\delta(\omega)$ accounts for the DC value $\tfrac{1}{2}$ of $u(t)$. Similarly $\mathcal{F}\{\cos(\omega_0 t)u(t)\}=\dfrac{j\omega}{\omega_0^2-\omega^2}+\dfrac{\pi}{2}[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]$, not just $s/(s^2+\omega_0^2)$ at $s=j\omega$. Substitute $s=j\omega$ only when the ROC strictly contains the imaginary axis. When simple poles lie *on* the axis, each pole at $s=j\omega_p$ with residue r contributes an extra $\pi r\,\delta(\omega-\omega_p)$.

Worked Example 16.8 — a DC-plus-tone signal and a switched constant

(a) $x(t)=3+2\cos(5t)-\sin(5t)$. Term by term:

$$X(\omega)=6\pi\delta(\omega)+2\pi[\delta(\omega-5)+\delta(\omega+5)]+j\pi[\delta(\omega-5)-\delta(\omega+5)]=6\pi\delta(\omega)+(2+j)\pi\,\delta(\omega-5)+(2-j)\pi\,\delta(\omega+5).$$

The impulse weights at ±5 are complex conjugates, as they must be for a real signal. Dividing by 2π gives the Fourier-series coefficients $c_{\pm1}=1\pm j/2$, whose magnitude $\sqrt{5}/2$ is half the amplitude $\sqrt{2^2+1^2}=\sqrt{5}$ of the combined sinusoid $\sqrt{5}\cos(5t+26.6^\circ)$ ✓.

(b) $y(t)=V_0\,u(t-t_0)$, a supply switched on at t_0. By the time-shift property (Section 16.3),

$$Y(\omega)=V_0e^{-j\omega t_0}\left[\pi\delta(\omega)+\frac{1}{j\omega}\right]=\pi V_0\delta(\omega)+\frac{V_0e^{-j\omega t_0}}{j\omega},$$

where we used $e^{-j\omega t_0}\delta(\omega)=\delta(\omega)$ (the exponential equals 1 at $\omega=0$).

Table of standard pairs

$x(t)$	$X(\omega)$	Condition
$\delta(t)$	1	
$\delta(t-t_0)$	$e^{-j\omega t_0}$	
1	$2\pi\delta(\omega)$	
$u(t)$	$\pi\delta(\omega)+1/(j\omega)$	
$\operatorname{sgn}(t)$	$2/(j\omega)$	
$e^{-at}u(t)$	$1/(a+j\omega)$	$\operatorname{Re}\{a\}>0$
$te^{-at}u(t)$	$1/(a+j\omega)^2$	$\operatorname{Re}\{a\}>0$
$\dfrac{t^{m-1}}{(m-1)!}e^{-at}u(t)$	$1/(a+j\omega)^m$	$\operatorname{Re}\{a\}>0$
$e^{-at}\sin(bt)\,u(t)$	$b/[(a+j\omega)^2+b^2]$	$a>0$
$e^{-at}\cos(bt)\,u(t)$	$(a+j\omega)/[(a+j\omega)^2+b^2]$	$a>0$
$e^{-a\lvert t\rvert}$	$2a/(a^2+\omega^2)$	$a>0$
$1/(a^2+t^2)$	$(\pi/a)\,e^{-a\lvert\omega\rvert}$	$a>0$
$e^{-t^2/(2\sigma^2)}$	$\sigma\sqrt{2\pi}\,e^{-\sigma^2\omega^2/2}$	$\sigma>0$
$\operatorname{rect}(t/T)$	$T\operatorname{sinc}(\omega T/2\pi)=2\sin(\omega T/2)/\omega$	
$\Lambda(t/T)$	$T\operatorname{sinc}^2(\omega T/2\pi)$	
$\sin(Wt)/(\pi t)$	$\operatorname{rect}(\omega/2W)$	
$e^{j\omega_0 t}$	$2\pi\delta(\omega-\omega_0)$	
$\cos\omega_0 t$	$\pi[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]$	
$\sin\omega_0 t$	$-j\pi[\delta(\omega-\omega_0)-\delta(\omega+\omega_0)]$	
$\sum_n\delta(t-nT)$	$\omega_s\sum_k\delta(\omega-k\omega_s)$	$\omega_s=2\pi/T$

16.3 Transform properties

Why properties matter

Evaluating $\int x(t)e^{-j\omega t}dt$ from scratch for every signal is slow and error-prone. In practice one memorises a dozen pairs and a dozen properties; together they generate hundreds of transforms by pure algebra. The properties are also where the physics lives: "a delay is a linear phase", "differentiation boosts high frequencies", "compressing a pulse spreads its spectrum", "multiplying by a carrier shifts the spectrum" are each one line of this section.

Throughout, $x(t) \leftrightarrow X(\omega)$ and $y(t) \leftrightarrow Y(\omega)$.

Property	Time domain	Frequency domain
Linearity	$ax(t) + by(t)$	$aX(\omega) + bY(\omega)$
Time shift	$x(t - t_0)$	$e^{-j\omega t_0}X(\omega)$
Frequency shift	$e^{j\omega_0 t}x(t)$	$X(\omega - \omega_0)$
Modulation	$x(t)\cos\omega_0 t$	$\tfrac{1}{2}[X(\omega-\omega_0) + X(\omega+\omega_0)]$
Scaling	$x(at)$, $a \neq 0$ real	$\dfrac{1}{\lvert a\rvert}X(\omega/a)$
Reversal	$x(-t)$	$X(-\omega)$
Conjugation	$x^*(t)$	$X^*(-\omega)$
Duality	$X(t)$	$2\pi x(-\omega)$
Differentiation in time	$d^n x/dt^n$	$(j\omega)^n X(\omega)$
Integration	$\int_{-\infty}^{t} x(\tau)d\tau$	$X(\omega)/(j\omega) + \pi X(0)\delta(\omega)$
Multiplication by t	$t^n\, x(t)$	$j^n\, d^n X/d\omega^n$
Convolution	$x * y$	$X(\omega)Y(\omega)$
Multiplication	$x(t)y(t)$	$\dfrac{1}{2\pi}(X * Y)(\omega)$
Parseval	$\int \lvert x\rvert^2 dt$	$\dfrac{1}{2\pi}\int \lvert X\rvert^2 d\omega$

The convolution, multiplication and Parseval rows are the subject of Sections 16.5 and 16.7. The others are derived now.

Derivations

Linearity is inherited from linearity of the integral.

Time shift. Substitute $\tau = t - t_0$:

$$\int x(t - t_0)e^{-j\omega t}dt = \int x(\tau)e^{-j\omega(\tau + t_0)}d\tau = e^{-j\omega t_0}X(\omega).$$

A delay multiplies the transform by a unit-magnitude factor: $\lvert X\rvert$ is unchanged and the phase acquires a term $-\omega t_0$, **linear in frequency**. Each frequency component is delayed by the same time t_0, which requires a phase lag proportional to its frequency.

Frequency shift. $\int e^{j\omega_0 t}x(t)e^{-j\omega t}dt = \int x(t)e^{-j(\omega-\omega_0)t}dt = X(\omega - \omega_0)$. Multiplying by a complex exponential slides the whole spectrum by ω_0. The **modulation** property follows by writing $\cos\omega_0 t = \tfrac{1}{2}(e^{j\omega_0 t} + e^{-j\omega_0 t})$; similarly $x(t)\sin\omega_0 t \leftrightarrow \tfrac{1}{2j}[X(\omega-\omega_0) - X(\omega+\omega_0)]$.

Scaling. For $a > 0$ substitute $\tau = at$, $dt = d\tau/a$:

$$\int x(at)e^{-j\omega t}dt = \frac{1}{a}\int x(\tau)e^{-j(\omega/a)\tau}d\tau = \frac{1}{a}X\left(\frac{\omega}{a}\right).$$

For $a < 0$ the substitution reverses the limits, producing a minus sign that turns $1/a$ into $1/\lvert a\rvert$. With $a = -1$ this gives the **reversal** property. Compressing in time ($\lvert a\rvert > 1$) expands the spectrum horizontally and lowers it by $1/\lvert a\rvert$; the factor keeps the area $\frac{1}{2\pi}\int X\,d\omega = x(0)$ unchanged, as it must be since $x(at)$ and $x(t)$ have the same value at $t = 0$.

Conjugation. $\int x^*(t)e^{-j\omega t}dt = \left[\int x(t)e^{j\omega t}dt\right]^* = X^*(-\omega)$. For real x this gives $X(-\omega) = X^*(\omega)$, the conjugate symmetry studied in Section 16.4.

Duality. Write the inverse formula with t replaced by $-t$ and multiply by 2π:

$$2\pi x(-t) = \int_{-\infty}^{\infty} X(\omega)e^{-j\omega t}d\omega.$$

Now rename the integration variable $\omega \to \tau$ and the free variable $t \to \omega$: $2\pi x(-\omega) = \int X(\tau)e^{-j\omega\tau}d\tau = \mathcal{F}\{X(t)\}$. So **if** $x(t) \leftrightarrow X(\omega)$ **then** $X(t) \leftrightarrow 2\pi x(-\omega)$. Every pair in the table therefore yields a second pair for free; the rectangle–sinc and sinc–rectangle pairs are duals.

Differentiation. Differentiate the inverse formula under the integral sign:

$$\frac{dx}{dt} = \frac{d}{dt}\frac{1}{2\pi}\int X(\omega)e^{j\omega t}d\omega = \frac{1}{2\pi}\int j\omega X(\omega)e^{j\omega t}d\omega,$$

so $dx/dt \leftrightarrow j\omega X(\omega)$; repeating gives $(j\omega)^n$. Differentiation multiplies the spectrum by $\lvert\omega\rvert$: it **emphasises high frequencies** and destroys DC. (Equivalently, integrate $\int \dot{x}e^{-j\omega t}dt$ by parts, the boundary terms vanishing because $x \to 0$ at $\pm\infty$.)

Multiplication by t. Differentiate the forward formula with respect to ω: $dX/d\omega = \int (-jt)x(t)e^{-j\omega t}dt$, so $t\,x(t) \leftrightarrow j\,dX/d\omega$. This is the dual of the differentiation property.

Integration. Let $y(t) = \int_{-\infty}^{t} x(\tau)d\tau$. Then $y = x * u$, and the convolution theorem (Section 16.5) with $u \leftrightarrow \pi\delta(\omega) + 1/(j\omega)$ gives

$$Y(\omega) = X(\omega)\left[\pi\delta(\omega) + \frac{1}{j\omega}\right] = \frac{X(\omega)}{j\omega} + \pi X(0)\delta(\omega).$$

The impulse term is present whenever x has nonzero area, because then $y(t) \to X(0)$ as $t \to \infty$ and y has a DC component $X(0)/2$ (it rises from 0 to $X(0)$).

Moment theorems. Setting $\omega = 0$ in the forward formula and in the t^n property gives

$$\int_{-\infty}^{\infty} t^n x(t)\,dt = j^n \left.\frac{d^n X}{d\omega^n}\right|_{\omega=0}.$$

The area, centroid and spread of a pulse can therefore be read from the value, slope and curvature of its transform at DC.

Worked examples

Worked Example 16.9 — shift and duality

Find the transforms of $x(t) = e^{-2(t-1)}u(t-1)$ and of $g(t) = \dfrac{1}{1+t^2}$.

(a) x is $e^{-2t}u(t)$ delayed by $t_0 = 1$. From $e^{-2t}u(t) \leftrightarrow 1/(2+j\omega)$ and the time-shift property:

$$X(\omega) = \frac{e^{-j\omega}}{2+j\omega}, \qquad |X| = \frac{1}{\sqrt{4+\omega^2}}, \qquad \angle X = -\omega - \arctan\frac{\omega}{2}.$$

The magnitude is that of the undelayed pulse; only the phase gained the linear term $-\omega$.

(b) From $e^{-|t|} \leftrightarrow 2/(1+\omega^2)$, duality gives $\dfrac{2}{1+t^2} \leftrightarrow 2\pi e^{-|-\omega|} = 2\pi e^{-|\omega|}$. Dividing by 2:

$$\frac{1}{1+t^2} \leftrightarrow \pi e^{-|\omega|}.$$

Check: $G(0) = \pi = \int_{-\infty}^{\infty} \frac{dt}{1+t^2} = [\arctan t]_{-\infty}^{\infty}$ ✓. Scaling then gives the general table entry $1/(a^2+t^2) \leftrightarrow (\pi/a)e^{-a|\omega|}$. Evaluating this integral directly requires residues (Ch. 18); duality did it in one line.

Worked Example 16.10 — combining scaling and shifting

(a) Find the transform of a unit pulse that starts at $t = 0$ and ends at $t = T$.

The pulse is rect $\big((t - T/2)/T\big)$, the centred pulse delayed by $T/2$:

$$X(\omega) = T\,\mathrm{sinc}\left(\frac{\omega T}{2\pi}\right)e^{-j\omega T/2} = \frac{1 - e^{-j\omega T}}{j\omega}.$$

(The second form is the direct integral $\int_0^T e^{-j\omega t}dt$; factoring $e^{-j\omega T/2}$ out of $1 - e^{-j\omega T}$ leaves $2j\sin(\omega T/2)$, confirming the first form.)

(b) Given $x(t) \leftrightarrow X(\omega)$, find the transform of $y(t) = x(2t - 3)$.

Write $y(t) = x\big(2(t - \tfrac{3}{2})\big)$. First scale: $x(2t) \leftrightarrow \tfrac{1}{2}X(\omega/2)$. Then delay *the scaled signal* by $\tfrac{3}{2}$:

$$Y(\omega) = \tfrac{1}{2}X\left(\frac{\omega}{2}\right)e^{-j3\omega/2}.$$

Alternatively shift first: $v(t) = x(t-3) \leftrightarrow e^{-j3\omega}X(\omega)$, and $y(t) = v(2t) \leftrightarrow \tfrac{1}{2}e^{-j3\omega/2}X(\omega/2)$ — the same answer, because scaling acts on *every* ω in the expression, including the one in the exponential.

Check with $x = \mathrm{rect}(t)$: $y = \mathrm{rect}(2t-3)$ is a pulse of width $\tfrac{1}{2}$ centred at $t = \tfrac{3}{2}$, so directly $Y = \tfrac{1}{2}\,\mathrm{sinc}(\omega/4\pi)e^{-j3\omega/2}$; the formula gives $\tfrac{1}{2}\,\mathrm{sinc}(\omega/4\pi)e^{-j3\omega/2}$ ✓.

Common Pitfall — the delay in $x(at - b)$

The delay of $x(at - b)$ is b/a, not b. Writing $e^{-j\omega b}$ instead of $e^{-j\omega b/a}$ is the single most common error with these two properties. Always rewrite the argument as $a(t - b/a)$ first.

Worked Example 16.11 — the triangle by differentiation

Find the transform of $x(t) = \Lambda(t/T)$ without integrating.

Step 1 — differentiate until only impulses remain. The triangle has slope $1/T$ on $(-T, 0)$ and $-1/T$ on $(0, T)$, so $\dot{x} = \frac{1}{T}[\text{rect on } (-T,0)] - \frac{1}{T}[\text{rect on } (0,T)]$. Differentiating again, each jump of the slope becomes an impulse:

$$\ddot{x}(t) = \frac{1}{T}\left[\delta(t+T) - 2\delta(t) + \delta(t-T)\right].$$

Step 2 — transform. By the shift property,

$$(j\omega)^2 X(\omega) = \frac{1}{T}\left[e^{j\omega T} - 2 + e^{-j\omega T}\right] = \frac{2\cos\omega T - 2}{T} = -\frac{4\sin^2(\omega T/2)}{T}.$$

Step 3 — divide. Since $(j\omega)^2 = -\omega^2$,

$$X(\omega) = \frac{4\sin^2(\omega T/2)}{T\omega^2} = T\,\mathrm{sinc}^2\!\left(\frac{\omega T}{2\pi}\right).$$

Division by ω^2 is safe here because x has finite area, so X has no impulse at the origin; the value $X(0) = T$ (by L'Hôpital or the sinc limit) equals the triangle's area $\frac{1}{2}\cdot 2T \cdot 1$ ✓. The method works for any **piecewise-polynomial** signal: differentiate until the result is a sum of impulses, transform, divide by $(j\omega)^n$, and fix the DC value by the area.

Worked Example 16.12 — multiplication by t

(a) From $e^{-at}u(t) \leftrightarrow (a + j\omega)^{-1}$,

$$te^{-at}u(t) \leftrightarrow j\frac{d}{d\omega}(a+j\omega)^{-1} = j\cdot(-1)(a+j\omega)^{-2}\cdot j = \frac{1}{(a+j\omega)^2},$$

confirming the table entry. Repeating gives the $t^{m-1}/(m-1)!$ pairs used for repeated poles.

(b) Find the transform of the "Gaussian monocycle" $x(t) = t\,e^{-t^2/2}$ (an ultra-wideband pulse shape).

From $e^{-t^2/2} \leftrightarrow \sqrt{2\pi}e^{-\omega^2/2}$:

$$X(\omega) = j\frac{d}{d\omega}\left(\sqrt{2\pi}e^{-\omega^2/2}\right) = -j\sqrt{2\pi}\,\omega\,e^{-\omega^2/2}.$$

The result is purely imaginary and odd, as it must be for a real odd signal, and it vanishes at DC (the monocycle has zero area). Its magnitude peaks where $\frac{d}{d\omega}(\omega e^{-\omega^2/2}) = 0$, i.e. at $\omega = 1$ rad/s, where $|X| = \sqrt{2\pi}e^{-1/2} = 1.520$. Equivalently, $x = -\frac{d}{dt}e^{-t^2/2}$, and the differentiation property gives $-j\omega\sqrt{2\pi}e^{-\omega^2/2}$ — the same answer by a second route ✓.

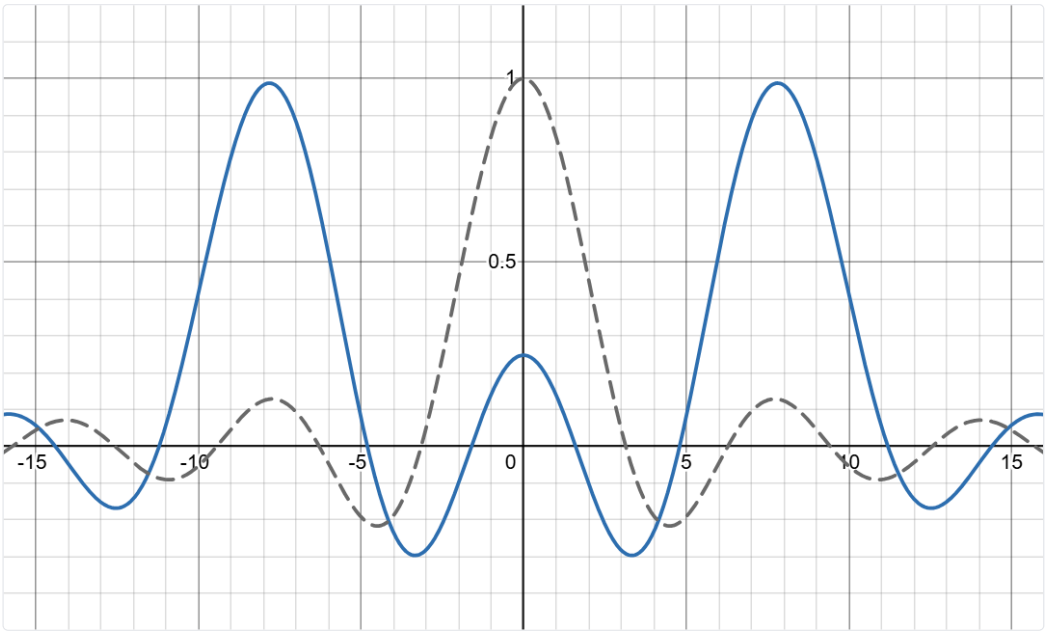
Worked Example 16.13 — an RF pulse

A radar transmitter emits $x(t) = A\,\mathrm{rect}(t/T)\cos(\omega_c t)$ with $\omega_c \gg 2\pi/T$. Find and sketch its spectrum.

By the modulation property applied to $A\,\mathrm{rect}(t/T) \leftrightarrow AT\,\mathrm{sinc}(\omega T/2\pi)$:

$$X(\omega) = \frac{AT}{2}\left[\mathrm{sinc}\!\left(\frac{(\omega-\omega_c)T}{2\pi}\right) + \mathrm{sinc}\!\left(\frac{(\omega+\omega_c)T}{2\pi}\right)\right].$$

The spectrum consists of two copies of the pulse spectrum, each of half the height, centred on $\pm\omega_c$. The main lobe around ω_c has null-to-null width $4\pi/T$ rad/s, or $2/T$ Hz. For $A = 1$ V, $T = 1$ µs, $f_c = 10$ MHz: peaks of 0.5 µV·s at ± 10 MHz, first nulls at 9 and 11 MHz. The two copies interfere slightly with each other through their sidelobes; the condition $\omega_c \gg 2\pi/T$ makes this negligible.



Modulation shifts the spectrum: the baseband pulse spectrum (grey dashed, $T = 2$, peak normalised to 1) is copied to $\pm\omega_c = \pm 8$ rad/s with half the height (blue).

Engineering Note — differentiation turns ODEs into algebra

For a circuit described by $a_2\ddot{y} + a_1\dot{y} + a_0 y = b_1\dot{x} + b_0 x$, the differentiation property gives $[a_2(j\omega)^2 + a_1 j\omega + a_0]Y = (b_1 j\omega + b_0)X$, so

$$Y(\omega) = H(\omega)X(\omega), \qquad H(\omega) = \frac{b_0 + jb_1\omega}{a_0 - a_2\omega^2 + ja_1\omega}.$$

This is the phasor method of AC circuit analysis, extended from single sinusoids to arbitrary spectra: an inductor's impedance $j\omega L$ and a capacitor's $1/(j\omega C)$ are the differentiation and integration properties applied to $v = L\,di/dt$ and $v = \frac{1}{C}\int i\,dt$. The Fourier method gives the zero-state response of a stable system; initial conditions and unstable systems are the territory of the Laplace transform (Ch. 14).

16.4 Frequency-domain representation

A signal and its transform are two complete descriptions of the same object. This section is about reading the frequency-domain description: what the magnitude and phase spectra mean, what symmetry a real signal forces on them, how an LTI system acts on them, and how "width" in one domain constrains width in the other.

Magnitude and phase spectra

The pair $|X(\omega)|$ (the **magnitude** or **amplitude spectrum**) and $\angle X(\omega)$ (the **phase spectrum**) is the frequency-domain representation of $x(t)$. Equivalently one may use the real and imaginary parts $X_R(\omega) = \mathrm{Re}\{X\}$, $X_I(\omega) = \mathrm{Im}\{X\}$.

- Magnitudes spanning many decades are plotted in decibels, $20\log_{10}|X(\omega)|$ (relative to a stated reference), against $\log\omega$ — the Bode format. A factor of 2 in magnitude is about 6 dB; a factor of 10 is 20 dB.
- Phase is defined only modulo 2π. Numerical routines return the **principal value** in $(-\pi, \pi]$, producing artificial jumps of 2π; **unwrapping** removes them by adding multiples of 2π to make the phase continuous wherever $|X| \neq 0$. Where X passes through zero and changes sign (the nulls of a sinc), the phase genuinely jumps by π.
- Phase matters as much as magnitude. Two signals with the same $|X|$ but different phases can look entirely different in time: an impulse and a "chirp" can share a flat magnitude spectrum.

Symmetry of real signals

Conjugate symmetry

If $x(t)$ is real then

$$X(-\omega) = X^*(\omega),$$

so $|X(\omega)|$ and $\mathrm{Re}\{X(\omega)\}$ are **even**, while $\angle X(\omega)$ and $\mathrm{Im}\{X(\omega)\}$ are **odd**. Moreover:

- x real and even $\Rightarrow$ X real and even;
- x real and odd $\Rightarrow$ X purely imaginary and odd;
- for any real x with even part $x_e(t) = \frac{1}{2}[x(t) + x(-t)]$ and odd part $x_o(t) = \frac{1}{2}[x(t) - x(-t)]$: $x_e \leftrightarrow \mathrm{Re}\{X\}$ and $x_o \leftrightarrow j\,\mathrm{Im}\{X\}$.

Proof. For real x, $X^*(\omega) = \int x(t)e^{+j\omega t}dt = X(-\omega)$. Writing $e^{-j\omega t} = \cos\omega t - j\sin\omega t$,

$$X(\omega) = \int x(t)\cos\omega t\,dt - j\int x(t)\sin\omega t\,dt.$$

The cosine integral sees only the even part of x (the odd part integrates to zero against an even function), and the sine integral sees only the odd part. This gives the even/odd statements; the cosine integral is even in ω, the sine integral odd. $\square$

Consequently, for real signals the negative-frequency half of the spectrum carries no new information. Engineers often plot only $\omega \geq 0$ (a **one-sided** spectrum), remembering to double energies when integrating over $\omega > 0$ only (Section 16.7). Negative frequencies are not a physical mystery: $\cos \omega_0 t$ is the sum of two counter-rotating phasors $e^{\pm j\omega_0 t}/2$, and the transform simply accounts for both.

Worked Example 16.14 — even and odd parts of the one-sided exponential

For $x(t) = e^{-at}u(t)$, $X = \dfrac{1}{a + j\omega} = \dfrac{a}{a^2+\omega^2} - j\dfrac{\omega}{a^2+\omega^2}$.

The even part of x is $x_e = \tfrac{1}{2}e^{-a|t|}$, whose transform is $\tfrac{1}{2}\cdot\dfrac{2a}{a^2+\omega^2} = \dfrac{a}{a^2+\omega^2} = \operatorname{Re}\{X\}$ ✓. The odd part is $x_o = \tfrac{1}{2}\operatorname{sgn}(t)e^{-a|t|}$, which must therefore have transform $j\operatorname{Im}\{X\} = -j\omega/(a^2+\omega^2)$. As $a \to 0$ this tends to $-j/\omega = 1/(j\omega)$, which is indeed the transform of $\tfrac{1}{2}\operatorname{sgn}(t)$ ✓.

This example shows a deeper fact: for a **causal** signal, $x_o(t) = \operatorname{sgn}(t)\, x_e(t)$, so the odd part is determined by the even part and hence $\operatorname{Im}\{X\}$ is determined by $\operatorname{Re}\{X\}$. (The precise relation is a Hilbert transform; for minimum-phase systems it also links the magnitude and phase of a frequency response.)

Frequency response of LTI systems

Complex exponentials are **eigenfunctions** of linear time-invariant (LTI) systems. If the impulse response is $h(t)$, the input $e^{j\omega t}$ produces

$$y(t) = \int_{-\infty}^{\infty} h(\tau)e^{j\omega(t-\tau)}d\tau = \left[\int h(\tau)e^{-j\omega\tau}d\tau\right] e^{j\omega t} = H(\omega)\, e^{j\omega t}, \qquad H(\omega) = \mathcal{F}\{h(t)\}.$$

The output is the input multiplied by a complex constant; the constant (the eigenvalue) is the **frequency response** $H(\omega)$. For a real system (h real), the input $\cos(\omega_0 t + \theta)$ — the real part of $e^{j\theta}e^{j\omega_0 t}$ — produces

$$y(t) = |H(\omega_0)|\cos\big(\omega_0 t + \theta + \angle H(\omega_0)\big).$$

The **magnitude response** $|H|$ is the gain and the **phase response** $\angle H$ the phase shift at each frequency. For a general input, superposition over all frequencies gives $Y(\omega) = H(\omega)X(\omega)$, proved formally as the convolution theorem in Section 16.5.

Worked Example 16.15 — RC low-pass filter

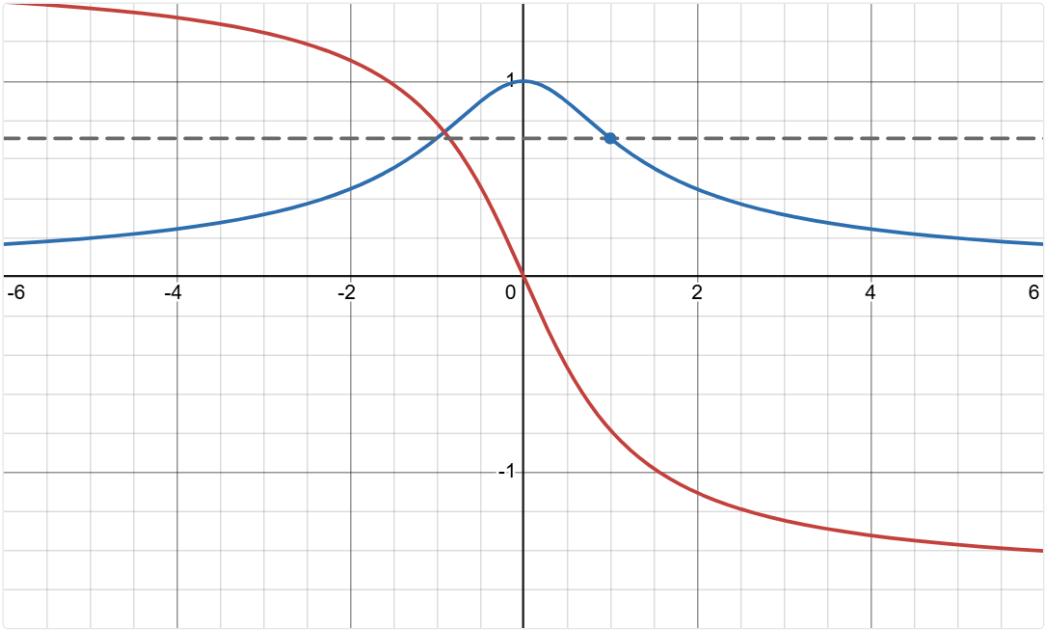
For a series R with shunt C, output across C: $RC\dot{y} + y = x$, so by the differentiation property

$$H(\omega) = \frac{1}{1 + j\omega RC}, \qquad h(t) = \frac{1}{RC}e^{-t/RC}u(t).$$

With $R = 1\ \text{k}\Omega$, $C = 1\ \mu\text{F}$: $RC = 1$ ms, so the cutoff is $\omega_c = 1/RC = 1000$ rad/s ($f_c \approx 159$ Hz).

For the input $\cos(2000t)$: $|H| = 1/\sqrt{1+2^2} = 0.447$ (-7.0 dB), $\angle H = -\arctan 2 = -63.4^\circ$, so in steady state $y(t) = 0.447\cos(2000t - 63.4^\circ)$.

For the input $\cos(100t)$: $|H| = 1/\sqrt{1.01} = 0.995$, $\angle H = -5.7^\circ$: frequencies well below cutoff pass almost unaltered. Far above cutoff $|H| \approx \omega_c/\omega$, a fall of 20 dB per decade.



Magnitude $|H| = 1/\sqrt{1+\omega^2}$ (blue, even) and phase $\angle H = -\arctan\omega$ in radians (red, odd) for $H = 1/(1+j\omega)$, with ω normalised to ω_c.

Worked Example 16.16 — a resonant second-order response

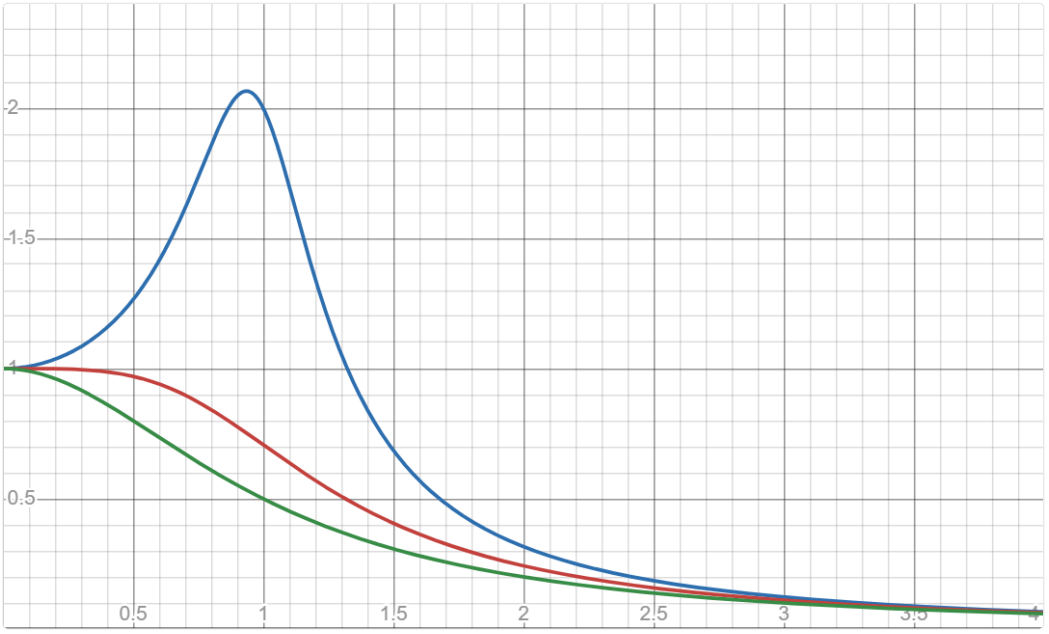
A series RLC circuit with output across C satisfies $LC\ddot{y} + RC\dot{y} + y = x$, so

$$H(\omega) = \frac{1}{1 - \omega^2 LC + j\omega RC} = \frac{1}{1 - (\omega/\omega_0)^2 + j(\omega/\omega_0)/Q}, \qquad \omega_0 = \frac{1}{\sqrt{LC}},\ Q = \frac{\omega_0 L}{R}.$$

Take $L = 10$ mH, $C = 1$ µF, $R = 50\ \Omega$: $\omega_0 = 1/\sqrt{10^{-8}} = 10^4$ rad/s ($f_0 = 1.59$ kHz) and $Q = 10^4 \cdot 0.01/50 = 2$.

ω	$\lvert H\rvert$	$\angle H$
$\omega_0/2 = 5000$	1.265	-18.4°
$\omega_0 = 10^4$	$2.000 = Q$	-90°
$2\omega_0 = 2\times 10^4$	0.316	-161.6°

(At $\omega_0/2$: denominator $= 0.75 + 0.25j$, magnitude 0.7906, so $\lvert H\rvert = 1.265$ and $\angle H = -\arctan(1/3)$. At $2\omega_0$: denominator $= -3 + j$, magnitude $\sqrt{10}$.) At resonance the real part of the denominator vanishes, the gain equals Q, and the phase passes through -90°. The magnitude response peaks near ω_0 and falls as $1/\omega^2$ (40 dB/decade) above it.



Magnitude of the second-order low-pass response against ω/ω_0 for $Q = 2$ (blue, resonant peak), $Q = 0.707$ (red, maximally flat) and $Q = 0.5$ (green, critically damped).

Distortionless transmission, phase delay and group delay

Distortionless system

A system is **distortionless** if every input emerges scaled and delayed but otherwise unchanged: $y(t) = Kx(t - t_d)$. By the time-shift property this is equivalent to

$$H(\omega) = Ke^{-j\omega t_d}: \qquad \lvert H(\omega)\rvert = K \ \text{(flat)}, \qquad \angle H(\omega) = -\omega t_d \ \text{(linear phase)}.$$

It suffices that these hold over the band occupied by the signal.

Departures from flat magnitude are **amplitude distortion**; departures from linear phase are **phase (delay) distortion**. Two delays characterise a non-ideal phase response $\phi(\omega) = \angle H(\omega)$:

$$\tau_p(\omega) = -\frac{\phi(\omega)}{\omega} \quad \text{(phase delay)}, \qquad \tau_g(\omega) = -\frac{d\phi}{d\omega} \quad \text{(group delay)}.$$

The phase delay is the delay of a single sinusoid at ω. The group delay is the delay of the **envelope** of a narrow-band signal centred at ω. To see why, let $x(t) = m(t)\cos\omega_c t$ with m slowly varying, so that X is concentrated near $\pm\omega_c$. Expand $\phi(\omega) \approx \phi(\omega_c) + \phi'(\omega_c)(\omega - \omega_c)$ near ω_c and take $\lvert H\rvert \approx \lvert H(\omega_c)\rvert$ there. Applying the shift and modulation properties to each term gives

$$y(t) \approx \lvert H(\omega_c)\rvert\, m\big(t - \tau_g(\omega_c)\big)\cos\big(\omega_c(t - \tau_p(\omega_c))\big).$$

The envelope travels at the group delay and the carrier at the phase delay. Both are equal (to t_d) for linear phase.

Worked Example 16.17 — group delay of an RC filter and of an all-pass section

(a) For $H = 1/(1 + j\omega RC)$, $\phi = -\arctan(\omega RC)$, so

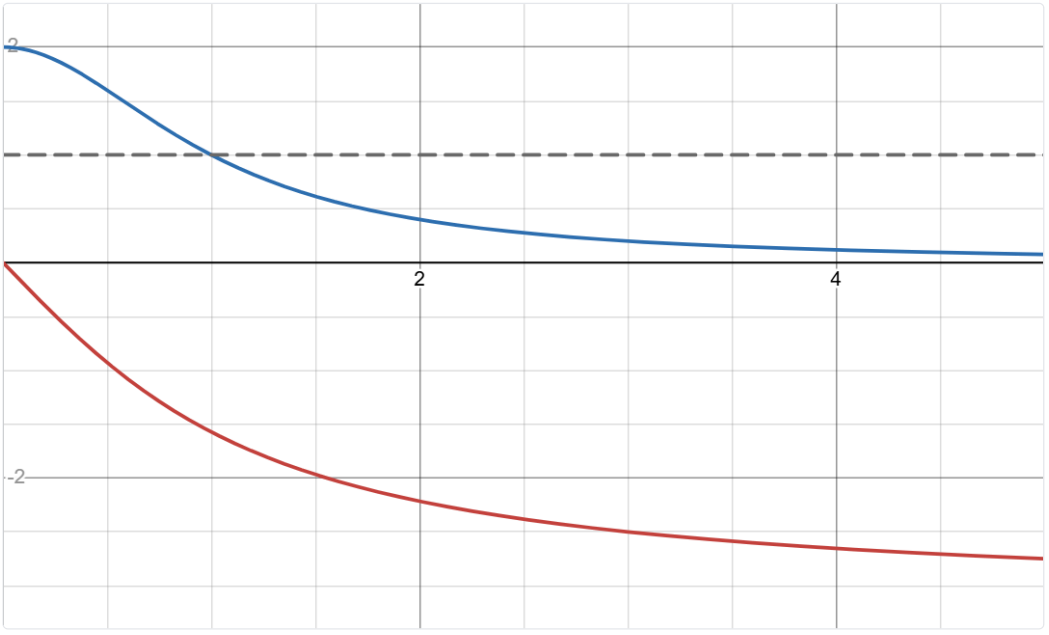
$$\tau_g(\omega) = \frac{RC}{1 + \omega^2 R^2 C^2}.$$

At DC the group delay is RC (1 ms for the values of Worked Example 16.15); at the cutoff it has halved to $RC/2$. A pulse whose spectrum lies well inside the passband is delayed by about RC with little distortion; a pulse that extends past cutoff suffers both amplitude and phase distortion.

(b) The first-order **all-pass** section $H(\omega) = \dfrac{a - j\omega}{a + j\omega}$, $a > 0$, has $|H| = 1$ for all ω — numerator and denominator are conjugates — so there is no amplitude distortion at all. Its phase is $\phi = -2\arctan(\omega/a)$ and

$$\tau_g(\omega) = \frac{2a}{a^2 + \omega^2},$$

which is $2/a$ at DC and falls towards zero at high frequency. With $a = 10^3$ s^{-1}: $\tau_g(0) = 2$ ms, $\tau_g(10^3) = 1$ ms, $\tau_g(10^4) = 19.8$ µs. A broadband pulse through this "flat" filter is dispersed, its low-frequency components arriving later than its high-frequency ones. All-pass sections are used to *equalise* group delay, i.e. to cancel the delay variation of another filter.



First-order all-pass with $a = 1$: flat magnitude 1 (grey dashed), phase $-2\arctan\omega$ in radians (red) and group delay $2/(1+\omega^2)$ in seconds (blue). Flat magnitude does not imply distortionless transmission.

Bandwidth and the time–bandwidth trade-off

Bandwidth measures. For a low-pass spectrum, common definitions are:

- the **3-dB bandwidth**, where $|X|$ first falls to $|X(0)|/\sqrt{2}$;
- the **null-to-null** or first-null bandwidth (for a rectangular pulse of width T: $2\pi/T$ rad/s one-sided);
- the **essential bandwidth**, containing a stated fraction (say 95 % or 99 %) of the energy (Section 16.7);
- the **RMS bandwidth** $\Delta\omega$ defined below.

For band-pass spectra the same measures are applied to the band around the centre frequency. No single definition is "correct"; a specification must say which one it uses.

The trade-off. The scaling property already implies that duration and bandwidth vary inversely: replacing $x(t)$ by $x(at)$ multiplies every width in time by $1/a$ and every width in frequency by a, leaving their product unchanged. The product depends only on the *shape*. How small can it be? With the root-mean-square widths

$$(\Delta t)^2 = \frac{\int t^2 |x(t)|^2 dt}{\int |x(t)|^2 dt}, \qquad (\Delta\omega)^2 = \frac{\int \omega^2 |X(\omega)|^2 d\omega}{\int |X(\omega)|^2 d\omega},$$

for a signal centred at $t = 0$ and $\omega = 0$:

Uncertainty principle (time–bandwidth inequality)

If $\sqrt{|t|}\,x(t) \to 0$ as $|t| \to \infty$ and the widths are finite, then

$$\Delta t\,\Delta\omega \;\geq\; \frac{1}{2},$$

with equality if and only if $x(t)$ is a Gaussian, $x(t) = Ce^{-t^2/(2\sigma^2)}$.

Proof sketch (real x). Let $E = \int x^2 dt$. By Parseval (Section 16.7) and $\dot{x} \leftrightarrow j\omega X$, $\int \omega^2 |X|^2 d\omega/2\pi = \int \dot{x}^2 dt$, so $(\Delta\omega)^2 = \int \dot{x}^2 dt / E$. The Cauchy–Schwarz inequality gives

$$\left(\int t\, x\, \dot{x}\, dt \right)^2 \le \int t^2 x^2 dt \int \dot{x}^2 dt = E^2 (\Delta t)^2 (\Delta\omega)^2.$$

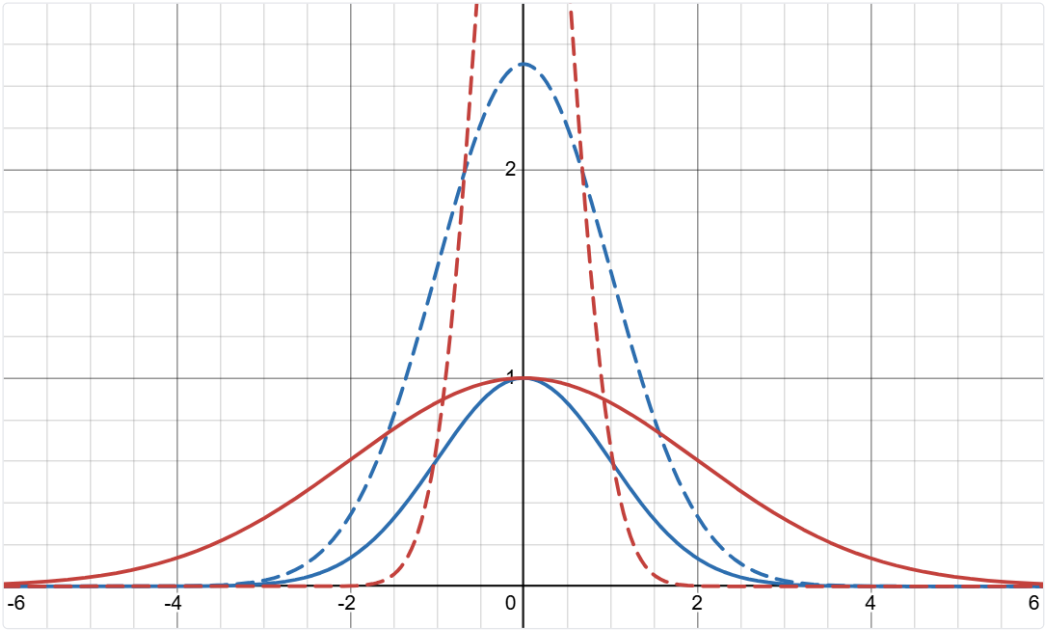
Integrating by parts, $\int t\, x\dot{x}\, dt = \int t\, \tfrac{1}{2} \tfrac{d}{dt}(x^2)\, dt = \left[\tfrac{1}{2} t x^2\right] - \tfrac{1}{2}\int x^2 dt = -E/2$, the boundary term vanishing by hypothesis. Hence $E^2/4 \le E^2 (\Delta t\, \Delta\omega)^2$. Equality in Cauchy–Schwarz requires $\dot{x} = -ctx$, whose solutions are Gaussians. □

Worked Example 16.18 — time–bandwidth products

(a) Gaussian. For $x = e^{-t^2/(2\sigma^2)}$, $x^2 = e^{-t^2/\sigma^2}$ is proportional to a normal density of variance $\sigma^2/2$, so $\Delta t = \sigma/\sqrt{2}$. Similarly $|X|^2 \propto e^{-\sigma^2\omega^2}$ has variance $1/(2\sigma^2)$, so $\Delta\omega = 1/(\sigma\sqrt{2})$. The product is $\tfrac{1}{2}$ exactly ✓.

(b) Two-sided exponential. For $x = e^{-|t|}$: $\int t^2 e^{-2|t|} dt = \tfrac{1}{2}$ and $\int e^{-2|t|} dt = 1$, so $(\Delta t)^2 = \tfrac{1}{2}$. In frequency, $(\Delta\omega)^2 = \int \dot{x}^2 dt / E = 1$ (because $\dot{x}^2 = e^{-2|t|}$). So $\Delta t\, \Delta\omega = 1/\sqrt{2} \approx 0.707 > \tfrac{1}{2}$ ✓.

(c) Rectangular pulse. $|X|^2 \propto \sin^2(\omega T/2)/\omega^2$, so $\omega^2 |X|^2$ does not decay and $\Delta\omega = \infty$: by the RMS measure a signal with jumps has infinite bandwidth, even though 90 % of its energy lies in the main lobe (Section 16.7). The RMS measure is sensitive to tails; the essential bandwidth is not.



Gaussian pulses (solid) and their transforms (dashed): $\sigma = 1$ (blue) gives a transform of the same width; $\sigma = 2$ (red) is twice as long in time and half as wide in frequency.

Smoothness and spectral decay

The examples so far display a pattern: the rectangle (jumps) has a spectrum decaying as $1/|\omega|$; the triangle and two-sided exponential (continuous, with jumps in the first derivative) decay as $1/\omega^2$; the Gaussian (infinitely smooth) decays faster than any power.

Smoothness and decay

If $x, \dot{x}, \ldots, x^{(n-1)}$ are continuous and absolutely integrable and $x^{(n)}$ is absolutely integrable (possibly with finitely many jumps), then $|X(\omega)| \le C/|\omega|^n$ for large $|\omega|$. If $x^{(n)}$ has jumps, $X(\omega)$ decays *exactly* as $1/|\omega|^{n+1}$.

Reason. $x^{(n)} \leftrightarrow (j\omega)^n X$, and the transform of an absolutely integrable function is bounded; if $x^{(n)}$ has a jump, its derivative contains an impulse whose transform does not decay, so $(j\omega)^{n+1} X$ stays bounded but nonzero at infinity.

Engineering Note — smooth edges, narrow spectra

The spectral occupancy of a digital waveform is set by its edges, not its bit rate alone. Trapezoidal edges (continuous signal, jumps in slope) give $1/\omega^2$ (40 dB/decade) decay beyond a corner frequency of roughly $1/(\pi t_r)$ for rise time t_r; raised-cosine edges give $1/\omega^3$. Electromagnetic-compatibility estimates and pulse-shaping filters in data links are applications of this theorem.

16.5 Convolution and multiplication

Motivation

The output of an LTI system with impulse response $h(t)$ to an input $x(t)$ is the **convolution**

$$y(t) = (x * h)(t) = \int_{-\infty}^{\infty} x(\tau)\, h(t-\tau)\, d\tau.$$

Each input value $x(\tau)\,d\tau$ launches a scaled, delayed copy of the impulse response, and the output is their sum. Convolution integrals are tedious to evaluate directly — the integrand changes form as t moves the flipped h across x — and the single most useful fact about the Fourier transform is that it turns convolution into multiplication. The dual statement, that multiplication in time becomes convolution in frequency, describes modulation, windowing and sampling.

The two theorems

Convolution theorem

If x and h have Fourier transforms X and H (for instance both absolutely integrable), and $y = x * h$, then

$$Y(\omega) = X(\omega)H(\omega).$$

Proof. By definition,

$$Y(\omega) = \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} x(\tau)h(t-\tau)\,d\tau\right]e^{-j\omega t}\,dt.$$

Exchange the order of integration (absolutely convergent when x, h are absolutely integrable) and in the inner integral put $t = \tau + \sigma$, $dt = d\sigma$:

$$Y(\omega) = \int x(\tau)\left[\int h(\sigma)e^{-j\omega(\tau+\sigma)}d\sigma\right]d\tau = \int x(\tau)e^{-j\omega\tau}d\tau \cdot \int h(\sigma)e^{-j\omega\sigma}d\sigma = X(\omega)H(\omega).\ \square$$

Algebraic properties of convolution follow at once from those of multiplication: $x * h = h * x$ (commutative), $(x * h) * g = x * (h * g)$ (associative — cascaded systems multiply their frequency responses), $x * (h + g) = x * h + x * g$ (parallel systems add), and $x * \delta = x$ (because $\mathcal{F}\{\delta\} = 1$). Also $x(t - t_1) * h(t - t_2) = y(t - t_1 - t_2)$, since delays multiply as $e^{-j\omega t_1}e^{-j\omega t_2}$.

Multiplication (modulation) theorem

$$x(t)\,y(t) \;\leftrightarrow\; \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\lambda)\,Y(\omega-\lambda)\,d\lambda = \frac{1}{2\pi}(X * Y)(\omega).$$

Proof. Write x via the inverse formula and compute the transform of the product:

$$\int\left[\frac{1}{2\pi}\int X(\lambda)e^{j\lambda t}d\lambda\right]y(t)e^{-j\omega t}dt = \frac{1}{2\pi}\int X(\lambda)\left[\int y(t)e^{-j(\omega-\lambda)t}dt\right]d\lambda = \frac{1}{2\pi}\int X(\lambda)Y(\omega-\lambda)d\lambda.\ \square$$

The $1/(2\pi)$ is the price of the angular-frequency convention; in the Hz convention it disappears. The two theorems are duals: **convolution in one domain is multiplication in the other.** The modulation property of Section 16.3 is the special case $y = \cos\omega_0 t$, for which Y is a pair of impulses and convolution with an impulse is a shift: $X(\omega) * \delta(\omega - \omega_0) = X(\omega - \omega_0)$.

Common Pitfall — the 2π in the multiplication theorem

Forgetting the $1/(2\pi)$ is the commonest error with this theorem. A quick test: take $y(t) = 1$. Then $x \cdot 1$ must transform to X, and indeed $\frac{1}{2\pi}X * 2\pi\delta = X$ ✓. Without the factor you would get $2\pi X$.

Worked examples

Worked Example 16.19 — convolution by transforms

Find $y = x * h$ for $x(t) = e^{-t}u(t)$ and $h(t) = e^{-2t}u(t)$.

$$Y(\omega) = \frac{1}{(1+j\omega)(2+j\omega)} = \frac{1}{1+j\omega} - \frac{1}{2+j\omega} \;\Rightarrow\; y(t) = \left(e^{-t} - e^{-2t}\right)u(t).$$

Direct check: for $t > 0$, $\int_0^t e^{-\tau}e^{-2(t-\tau)}d\tau = e^{-2t}\int_0^t e^{\tau}d\tau = e^{-2t}(e^t - 1) = e^{-t} - e^{-2t}$ ✓. Also $Y(0) = \tfrac{1}{2} = X(0)H(0) = 1 \cdot \tfrac{1}{2}$, consistent with the general rule that **areas multiply under convolution**.

Worked Example 16.20 — triangle from rectangles

Show that $\mathrm{rect}(t/T) * \mathrm{rect}(t/T) = T\,\Lambda(t/T)$ and deduce the transform of the triangle.

Time domain. The flipped rectangle $\mathrm{rect}((t-\tau)/T)$ overlaps $\mathrm{rect}(\tau/T)$ on an interval of length $T - |t|$ when $|t| < T$ and not at all otherwise. So the convolution is $\max(0, T - |t|) = T\Lambda(t/T)$, a triangle of height T and base $2T$.

Frequency domain. By the convolution theorem, $T\Lambda(t/T) \leftrightarrow \left[T\,\mathrm{sinc}(\omega T/2\pi)\right]^2$, hence

$$\Lambda(t/T) \leftrightarrow T\,\mathrm{sinc}^2(\omega T/2\pi),$$

confirming Worked Example 16.11 by a third route. The sinc² decays as $1/\omega^2$ rather than $1/\omega$ because the triangle is continuous while the rectangle has jumps — **convolution smooths, and smoother signals have faster-decaying spectra.** Each further convolution with the rectangle multiplies the spectrum by another sinc and adds one more order of smoothness; the n-fold convolution tends to a Gaussian shape (the central limit theorem of Ch. 19 in transform form).

Worked Example 16.21 — an RC filter driven by a pulse

A unit pulse of width T starting at $t = 0$, $x(t) = u(t) - u(t - T)$, drives the RC low-pass filter $H(\omega) = 1/(1 + j\omega\tau)$, $\tau = RC$. Find the output.

Step 1 — transforms. From Worked Example 16.10, $X(\omega) = (1 - e^{-j\omega T})/(j\omega)$. So

$$Y(\omega) = \left(1 - e^{-j\omega T}\right) G_0(\omega), \qquad G_0(\omega) = \frac{1}{j\omega(1 + j\omega\tau)}.$$

Step 2 — recognise the step response. The step response $g(t) = h * u$ has transform $H(\omega)[\pi\delta(\omega) + 1/(j\omega)] = \pi\delta(\omega) + G_0(\omega)$. In Y the factor $1 - e^{-j\omega T}$ vanishes at $\omega = 0$, so adding the impulse terms changes nothing: $Y = (1 - e^{-j\omega T})[\pi\delta + G_0] = G(\omega) - e^{-j\omega T}G(\omega)$, i.e.

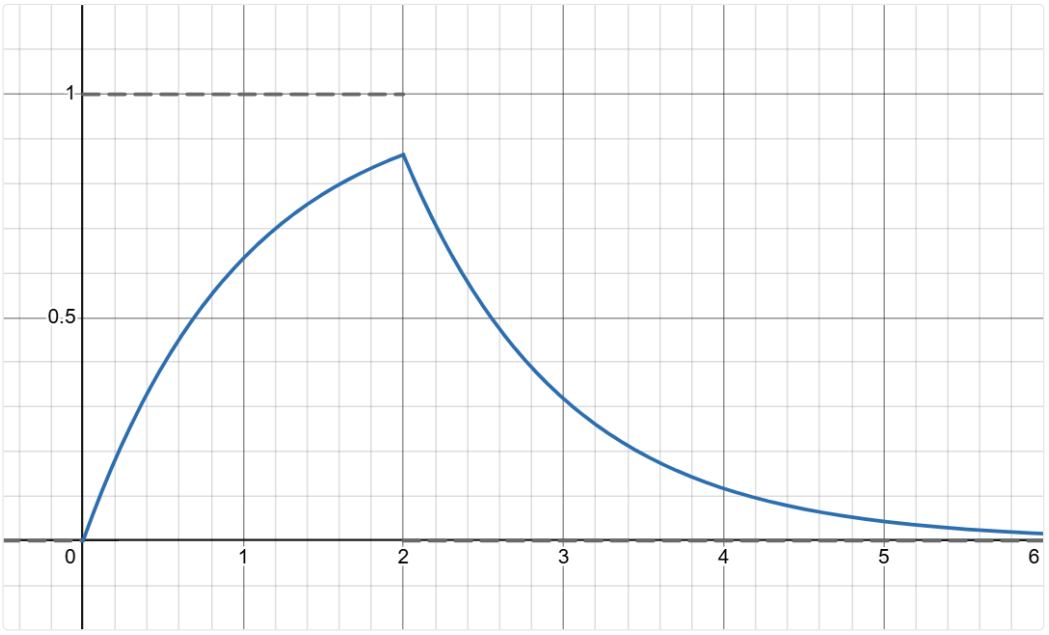
$$y(t) = g(t) - g(t - T).$$

Step 3 — find g. Partial fractions, $G_0 = \dfrac{1}{j\omega} - \dfrac{\tau}{1 + j\omega\tau}$, so $G = \pi\delta + \dfrac{1}{j\omega} - \dfrac{1}{1/\tau + j\omega}$, giving $g(t) = u(t) - e^{-t/\tau}u(t) = (1 - e^{-t/\tau})u(t)$.

Result.

$$y(t) = \left(1 - e^{-t/\tau}\right) u(t) - \left(1 - e^{-(t-T)/\tau}\right) u(t - T).$$

With $\tau = 1$ ms and $T = 2$ ms the output reaches $1 - e^{-2} = 0.865$ at the end of the pulse and then decays as $0.865\, e^{-(t-T)/\tau}$. Check: the output area is $X(0)H(0) = T \cdot 1 = 2$ ms, and integrating the result gives $\int_0^T (1 - e^{-t/\tau})dt + 0.865\tau = (T - \tau + \tau e^{-2}) + 0.865\tau = T$ ✓.



Rectangular input of width $T = 2\tau$ (grey dashed) and RC filter output (blue), time in units of τ: the output rises to 0.865 and decays exponentially — the low-pass filter has rounded the edges, removing the slow-decaying high-frequency content of the rectangle.

Worked Example 16.22 — the multiplication theorem

Find the transform of $x(t) = \left(\dfrac{\sin Wt}{\pi t}\right)^2$.

From Worked Example 16.5, $\sin(Wt)/(\pi t) \leftrightarrow \text{rect}(\omega/2W)$, a rectangle of width $2W$ in ω. By the multiplication theorem and Worked Example 16.20 (with $T = 2W$, variable ω),

$$X(\omega) = \frac{1}{2\pi}\,\text{rect}\left(\frac{\omega}{2W}\right) * \text{rect}\left(\frac{\omega}{2W}\right) = \frac{2W}{2\pi}\,\Lambda\left(\frac{\omega}{2W}\right) = \frac{W}{\pi}\Lambda\left(\frac{\omega}{2W}\right).$$

The squared sinc occupies **twice** the bandwidth of the sinc ($|\omega| < 2W$): squaring a signal doubles its bandwidth, which is why nonlinear devices generate new frequencies.

Check by $X(0) = \int x\,dt$: $\int \sin^2(Wt)/(\pi^2 t^2)\,dt = \pi W/\pi^2 = W/\pi$ (using $\int \sin^2(u)/u^2 du = \pi$) ✓.

Worked Example 16.23 — modulation and coherent demodulation

A message $m(t)$ band-limited to $|\omega| < \omega_M$ is transmitted as $s(t) = m(t)\cos\omega_c t$ with $\omega_c > \omega_M$ (double-sideband suppressed-carrier modulation). At the receiver it is multiplied again by $\cos\omega_c t$. Show that a low-pass filter recovers m.

Transmitter. $S(\omega) = \tfrac{1}{2}[M(\omega-\omega_c) + M(\omega+\omega_c)]$: two half-height copies of M centred on $\pm\omega_c$, occupying $\omega_c - \omega_M < |\omega| < \omega_c + \omega_M$.

Receiver. $r(t) = s(t)\cos\omega_c t = m(t)\cos^2\omega_c t = \tfrac{1}{2}m(t) + \tfrac{1}{2}m(t)\cos 2\omega_c t$, so

$$R(\omega) = \tfrac{1}{2}M(\omega) + \tfrac{1}{4}\left[M(\omega-2\omega_c) + M(\omega+2\omega_c)\right].$$

The baseband term occupies $|\omega| < \omega_M$ and the other two occupy $2\omega_c - \omega_M < |\omega| < 2\omega_c + \omega_M$. Since $\omega_c > \omega_M$, the gap $\omega_M < |\omega| < 2\omega_c - \omega_M$ separates them, and an ideal low-pass filter with gain 2 and any cutoff in that gap outputs exactly $m(t)$.

If the receiver's oscillator has a phase error, $\cos(\omega_c t + \theta)$, the baseband term becomes $\tfrac{1}{2}m(t)\cos\theta$: the output fades as $\theta \to 90^\circ$. This is why coherent receivers need carrier synchronisation — a conclusion reached entirely by the multiplication theorem.

Engineering Note — where the two theorems appear

- *Filtering* is multiplication of spectra: cascaded amplifier stages multiply gains, and in dB they add.
- *Mixing* (multiplying by a local oscillator) shifts spectra; superheterodyne receivers, frequency synthesisers and lock-in amplifiers are all the modulation property.
- *Windowing* a measured record (Section 16.6) and *sampling* (Section 16.8) are both multiplications in time and hence convolutions in frequency.
- Fast convolution in digital filters computes $x * h$ as $\mathcal{F}^{-1}\{XH\}$ with the FFT (Ch. 24), because a product is far cheaper than a convolution sum.

16.6 Spectral analysis

Spectral analysis asks: *which frequencies does a signal contain, and how strongly?* The Fourier transform answers it exactly for idealised signals defined for all time. A measured signal, however, is only ever observed for a finite time, and that limitation is itself a multiplication in time, so it changes the spectrum we see in a precisely calculable way. This section unifies periodic and aperiodic signals under one transform and then quantifies the effect of finite observation: resolution, leakage and windows.

Transforms of periodic signals

A periodic signal with Fourier series $x(t) = \sum_k c_k e^{jk\omega_0 t}$ (Ch. 15) has, term by term from $e^{jk\omega_0 t} \leftrightarrow 2\pi\delta(\omega - k\omega_0)$, the generalized transform

$$X(\omega) = 2\pi \sum_{k=-\infty}^{\infty} c_k\, \delta(\omega - k\omega_0),$$

a **line spectrum** of impulses at the harmonics, with areas $2\pi c_k$.

There is a second, illuminating derivation. Let $x_1(t)$ be one period of x (zero outside $|t| < T_0/2$), with transform $X_1(\omega)$. Then x is x_1 convolved with an impulse train, $x = x_1 * \sum_n \delta(t - nT_0)$, and the impulse-train pair (proved in Section 16.8) gives

$$X(\omega) = X_1(\omega)\cdot\omega_0\sum_k \delta(\omega - k\omega_0) = 2\pi\sum_k \frac{X_1(k\omega_0)}{T_0}\,\delta(\omega - k\omega_0).$$

Comparing, $c_k = X_1(k\omega_0)/T_0$ — the result found heuristically in Section 16.1, now as a theorem. **Periodicity in time is sampling in frequency.** The single-period spectrum $X_1(\omega)$ is the *envelope* of the line spectrum.

Aperiodic signals have continuous spectra; periodic ones have discrete spectra; a signal with both parts (a pulse plus a sinusoid, or a periodic signal plus a transient) has a mixed spectrum, and the transform handles all three with the same formulas.

Worked Example 16.24 — a rectangular pulse train

A clock signal consists of unit pulses of width $\tau = 1$ ms repeating every $T_0 = 4$ ms (duty cycle 25 %). Find its line spectrum.

One period is $x_1 = \mathrm{rect}(t/\tau)$, with $X_1(\omega) = \tau\,\mathrm{sinc}(\omega\tau/2\pi)$. With $\omega_0 = 2\pi/T_0$,

$$c_k = \frac{X_1(k\omega_0)}{T_0} = \frac{\tau}{T_0}\,\mathrm{sinc}\!\left(\frac{k\tau}{T_0}\right) = 0.25\,\mathrm{sinc}(0.25k).$$

k	0	±1	±2	±3	±4	±5
c_k	0.2500	0.2251	0.1592	0.0750	0	-0.0450

The DC value $c_0 = 0.25$ is the average of the waveform ✓. Every fourth harmonic vanishes because it falls on a null of the envelope ($k\tau/T_0$ an integer). The transform is $X(\omega) = 2\pi\sum_k c_k\delta(\omega - 2\pi k/T_0)$: lines every 250 Hz under a sinc envelope whose first null is at $1/\tau = 1$ kHz. Making the pulses narrower (smaller duty cycle) spreads the envelope and makes the lines denser relative to it; making the period longer packs the lines closer together under the same envelope shape — and in the limit $T_0 \to \infty$ they merge into the continuous spectrum of a single pulse.

Finite observation: windowing and leakage

Observing $x(t)$ only for $|t| < T/2$ is multiplication by a **window** $w(t) = \mathrm{rect}(t/T)$. By the multiplication theorem the spectrum we actually compute is

$$X_w(\omega) = \mathcal{F}\{x(t)w(t)\} = \frac{1}{2\pi}(X * W)(\omega), \qquad W(\omega) = T\,\mathrm{sinc}\left(\frac{\omega T}{2\pi}\right).$$

The true spectrum is blurred by the window's transform. A single spectral line, $2\pi c\,\delta(\omega-\omega_1)$, becomes $c\,W(\omega-\omega_1)$: an impulse is smeared into a sinc.

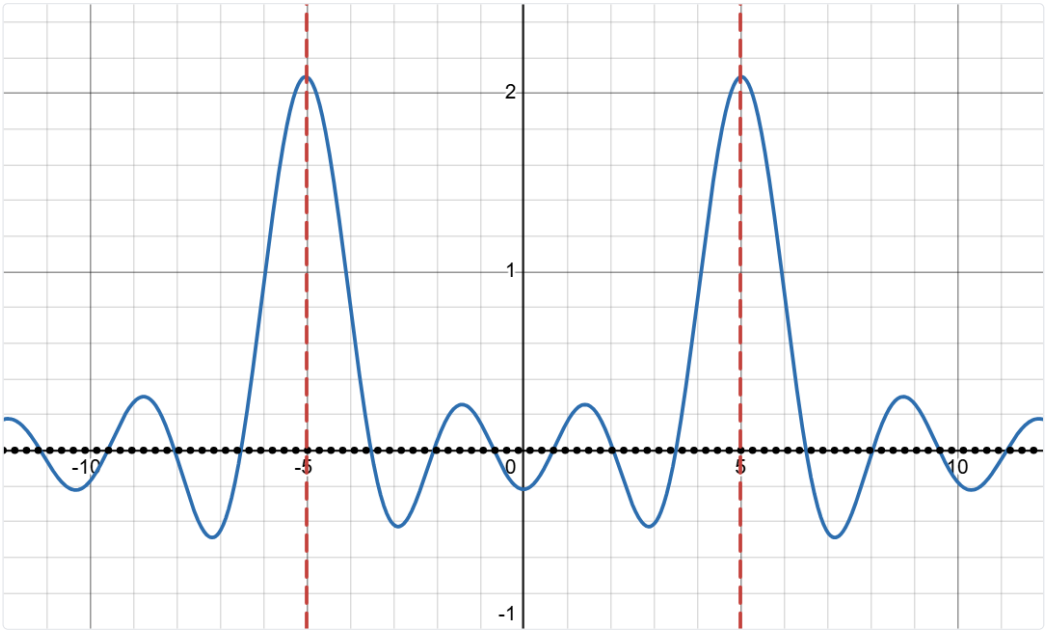
Worked Example 16.25 — a truncated cosine

Find the spectrum of $x(t) = \cos(\omega_0 t)\,\mathrm{rect}(t/T)$.

With $\cos\omega_0 t \leftrightarrow \pi[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]$ and convolution with an impulse being a shift,

$$X_w(\omega) = \frac{T}{2}\left[\mathrm{sinc}\left(\frac{(\omega-\omega_0)T}{2\pi}\right) + \mathrm{sinc}\left(\frac{(\omega+\omega_0)T}{2\pi}\right)\right] = \frac{\sin\left((\omega-\omega_0)T/2\right)}{\omega-\omega_0} + \frac{\sin\left((\omega+\omega_0)T/2\right)}{\omega+\omega_0}.$$

Instead of two impulses we see two sinc lobes of peak $T/2$ (growing with observation time, as an impulse is approached) and main-lobe width $4\pi/T$, plus **sidelobes** whose largest is 0.217 of the peak (-13.3 dB), located about 1.43 bins ($1.43\times 2\pi/T$ rad/s) from the centre. This spreading of energy away from the true frequency is called **spectral leakage**.



Spectrum of $\cos(5t)$ observed for $T = 4$ s: the ideal lines at $\omega = \pm 5$ (red dashed) become sinc lobes of width $4\pi/T \approx 3.1$ rad/s with sidelobe leakage.

Two consequences govern every practical spectrum analysis.

- **Resolution.** Two sinusoids closer than about one main-lobe half-width, $2\pi/T$ rad/s (i.e. $1/T$ Hz), merge into a single lobe. Finer resolution requires a longer record: **frequency resolution is the reciprocal of observation time.** This is the time–bandwidth trade-off of Section 16.4 applied to measurement.
- **Leakage.** Sidelobes of a strong component can mask a weak component nearby. The rectangular window's sidelobes decay only as $1/|\omega|$ because the window has jumps.

Tapered windows

Leakage is reduced by replacing the abrupt rectangle with a window that goes smoothly to zero at its ends. By the smoothness theorem of Section 16.4, a smoother window has faster-decaying sidelobes. The standard example is the **Hann (raised-cosine) window**

$$w_H(t) = \tfrac{1}{2}\left[1+\cos\frac{2\pi t}{T}\right]\mathrm{rect}\left(\frac{t}{T}\right).$$

Its transform follows from the modulation property: the rectangle contributes $\frac{1}{2}W(\omega)$ and the cosine term contributes two shifted half-height copies $\frac{1}{4}W(\omega \mp 2\pi/T)$. With $u = \omega T/2\pi$,

$$W_H(\omega) = \frac{T}{2}\,\mathrm{sinc}(u) + \frac{T}{4}\left[\mathrm{sinc}(u-1)+\mathrm{sinc}(u+1)\right] = \frac{T}{2}\,\frac{\mathrm{sinc}(u)}{1-u^2}.$$

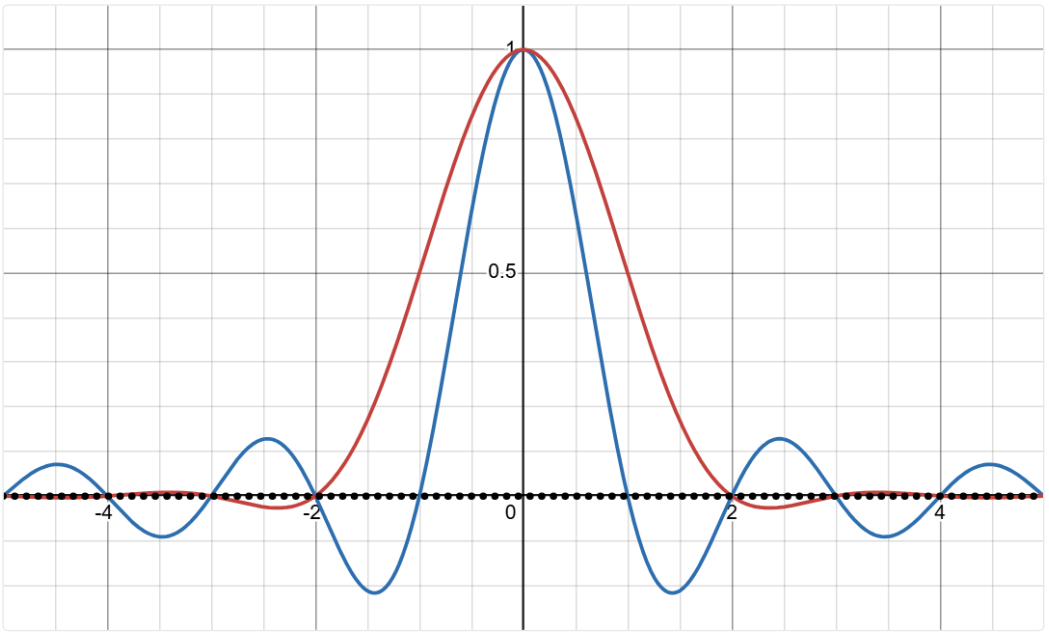
The three shifted sincs are arranged so that their sidelobes largely cancel. Compared with the rectangle:

- the first null moves from $u=1$ to $u=2$ (the main lobe is **twice as wide**);
- the highest sidelobe falls from -13.3 dB to -31.5 dB;
- the sidelobes decay as $1/|u|^3$ instead of $1/|u|$ (the Hann window is continuous with a continuous first derivative);
- the peak is $T/2$ instead of T (the window's area is halved).

Window	First null (u)	3-dB half-width (u)	Highest sidelobe	Sidelobe decay
Rectangular	1	0.44	-13.3 dB	$1/\lvert u\rvert$
Hann	2	0.72	-31.5 dB	$1/\lvert u\rvert^3$

Window	First null (u)	3-dB half-width (u)	Highest sidelobe	Sidelobe decay
Hamming ($0.54 + 0.46\cos$)	2	0.65	-42.7 dB	$1/\lvert u\rvert$
Blackman	3	0.82	-58.1 dB	$1/\lvert u\rvert^3$

The trade-off is universal: **lower sidelobes cost a wider main lobe**, i.e. better dynamic range costs resolution, because a window cannot be both short in time and narrow in frequency.



Normalised window transforms against $u = \omega T/2\pi$: rectangular $\operatorname{sinc}(u)$ (blue) and Hann $\operatorname{sinc}(u)/(1-u^2)$ (red). The Hann main lobe is twice as wide, but its sidelobes are almost invisible on this scale.

Worked Example 16.26 — choosing a record length and window

A signal contains a strong tone at 1000 Hz and a weak tone, 40 dB below it, at 1200 Hz. The analysis record is $T = 0.1$ s long. Can the weak tone be seen (a) with a rectangular window, (b) with a Hann window?

The frequency offset is $\Delta f = 200$ Hz, i.e. $u = \Delta f\, T = 20$ bins from the strong tone.

(a) Rectangular. The sidelobe envelope is $|\operatorname{sinc}(u)| \le 1/(\pi u)$; at $u = 20$ this is $1/(20\pi) = 0.0159$, i.e. -36.0 dB. The leakage from the strong tone at 1200 Hz is up to -36 dB, *above* the weak tone at -40 dB. The weak tone is masked.

(b) Hann. The envelope is $1/(\pi u(u^2-1))$; at $u = 20$ this is 4.0×10^{-5}, i.e. -88.0 dB. The weak tone stands about 48 dB above the leakage floor and is clearly visible. Its main lobe (null-to-null $4/T = 40$ Hz) is far narrower than the 200 Hz separation, so the wider Hann lobe costs nothing here.

(c) Resolution check. If instead the second tone were at 1015 Hz with equal amplitude, $u = 1.5$. With the rectangle the two main lobes (half-width 1 bin) are just separable; with Hann (half-width 2 bins) they merge. Either lengthen the record to $T \ge 0.2$ s, or accept the rectangle's leakage. Resolution and dynamic range compete, and the record length is the only free lunch.

Common Pitfall — reading peak heights from windowed spectra

The height of a windowed line depends on the window: it is $c\,W(0)$, i.e. proportional to the window's area (T for rectangular, $T/2$ for Hann). Amplitude estimates must be divided by the window's area (its "coherent gain"), and the frequency of a tone lying between computed frequency points is underestimated in height ("scalloping"). These are consequences of $X_w = \frac{1}{2\pi} X * W$, not instrument faults.

Time-varying spectra

The Fourier transform integrates over all time, so it cannot say *when* a frequency occurred: a chirp and a time-reversed chirp have the same magnitude spectrum. Sliding a short window along the signal and transforming each segment gives the **short-time Fourier transform**

$$X(\tau, \omega) = \int_{-\infty}^{\infty} x(t)\, w(t-\tau)\, e^{-j\omega t}\, dt,$$

whose magnitude squared (the spectrogram) is the standard picture of speech, radar returns and vibration. Its time and frequency resolutions are bounded by the window's duration and bandwidth, and the uncertainty principle forbids making both arbitrarily fine.

Engineering Note — from continuous theory to the FFT

A spectrum analyser's resolution bandwidth, and an FFT's bin spacing $1/T$ Hz, are both manifestations of $W(\omega)$. The discrete computation (DFT/FFT) evaluates samples of X_w, and its windowing behaviour is exactly the continuous theory above; the algorithms themselves are treated in Ch. 24.

16.7 Energy spectral density

Energy signals and power signals

How much energy does a pulse deliver, and how is that energy distributed over frequency? These questions decide how much bandwidth a channel must have to pass "most" of a pulse, how much noise a filter admits, and how much interference a transmitter puts into a neighbouring band.

Energy and power of a signal

The **energy** of $x(t)$ is

$$E = \int_{-\infty}^{\infty} |x(t)|^2 \, dt.$$

If x is a voltage across (or a current through) a $1\ \Omega$ resistor, E is the energy dissipated in joules; for a real load R divide (or multiply) by R. The **average power** is $P = \lim_{T\to\infty} \frac{1}{T}\int_{-T/2}^{T/2} |x(t)|^2 dt$. A signal with $0 < E < \infty$ is an **energy signal** (and has $P = 0$); a signal with $0 < P < \infty$ is a **power signal** (and has $E = \infty$).

Pulses and transients are energy signals; sinusoids, periodic waveforms, and stationary noise are power signals. This section treats energy signals; the power-signal theory is outlined at the end and developed for random signals in Ch. 21.

Parseval's theorem

Parseval's (Rayleigh's) energy theorem

If x has finite energy, then

$$E = \int_{-\infty}^{\infty} |x(t)|^2 dt = \frac{1}{2\pi}\int_{-\infty}^{\infty} |X(\omega)|^2 d\omega.$$

More generally, for two finite-energy signals,

$$\int_{-\infty}^{\infty} x(t)\, y^*(t)\, dt = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)\, Y^*(\omega)\, d\omega.$$

Proof. Substitute the inverse formula for x and exchange the order of integration:

$$\int x(t) y^*(t)\, dt = \int \left[\frac{1}{2\pi}\int X(\omega) e^{j\omega t} d\omega\right] y^*(t)\, dt = \frac{1}{2\pi}\int X(\omega)\left[\int y(t) e^{-j\omega t} dt\right]^* d\omega = \frac{1}{2\pi}\int X(\omega) Y^*(\omega)\, d\omega.$$

Setting $y = x$ gives the energy theorem. (Alternatively, apply the multiplication theorem to $x(t)x^*(t)$, using $x^* \leftrightarrow X^*(-\omega)$, and evaluate the result at $\omega = 0$.) $\square$

The general form says the Fourier transform preserves inner products (up to the factor 2π): it is a *rotation* of function space, in the language of Ch. 15's orthogonal expansions. In particular, two signals are orthogonal in time if and only if their transforms are orthogonal in frequency; signals occupying disjoint frequency bands are automatically orthogonal, which is the mathematical basis of frequency-division multiplexing.

Energy spectral density

Energy spectral density

The **energy spectral density (ESD)** of x is

$$\Psi_x(\omega) = |X(\omega)|^2.$$

By Parseval, $\Psi_x(\omega)\, d\omega/2\pi$ is the energy contained in the frequency band $d\omega$ (equivalently, $\Psi_x\, df$ in a band df Hz).

Units: for a voltage, $|X|^2$ is in $\text{V}^2\cdot\text{s}^2 = (\text{V}^2\cdot\text{s})/\text{Hz}$, i.e. joules (into $1\ \Omega$) per hertz. The ESD discards phase, so many different signals share the same ESD; a pulse and its delayed or time-reversed version, for example.

For **real** x the ESD is even, so the energy in the band $\omega_1 < |\omega| < \omega_2$ — counting both the positive and negative frequencies that make up the real signal components — is

$$E_{[\omega_1,\omega_2]} = \frac{1}{2\pi}\cdot 2\int_{\omega_1}^{\omega_2} |X(\omega)|^2 d\omega = \frac{1}{\pi}\int_{\omega_1}^{\omega_2} |X(\omega)|^2 d\omega.$$

ESD through an LTI system. Since $Y = HX$,

$$\Psi_y(\omega) = |H(\omega)|^2\, \Psi_x(\omega), \qquad E_y = \frac{1}{2\pi}\int |H(\omega)|^2 |X(\omega)|^2 d\omega.$$

The output ESD depends only on the **magnitude** response; phase distortion reshapes a pulse but does not change its energy or the energy in any band. The quantity $|H|^2$ is the **power gain**, and an ideal band-pass filter with $|H|^2 = 1$ on a band and 0 elsewhere measures the energy in that band — which is how a spectrum analyser physically measures the ESD.

Worked examples

Worked Example 16.27 — energy and essential bandwidth of an exponential pulse

For $x(t) = e^{-at}u(t)$: directly, $E = \int_0^\infty e^{-2at}dt = \dfrac{1}{2a}$. By Parseval,

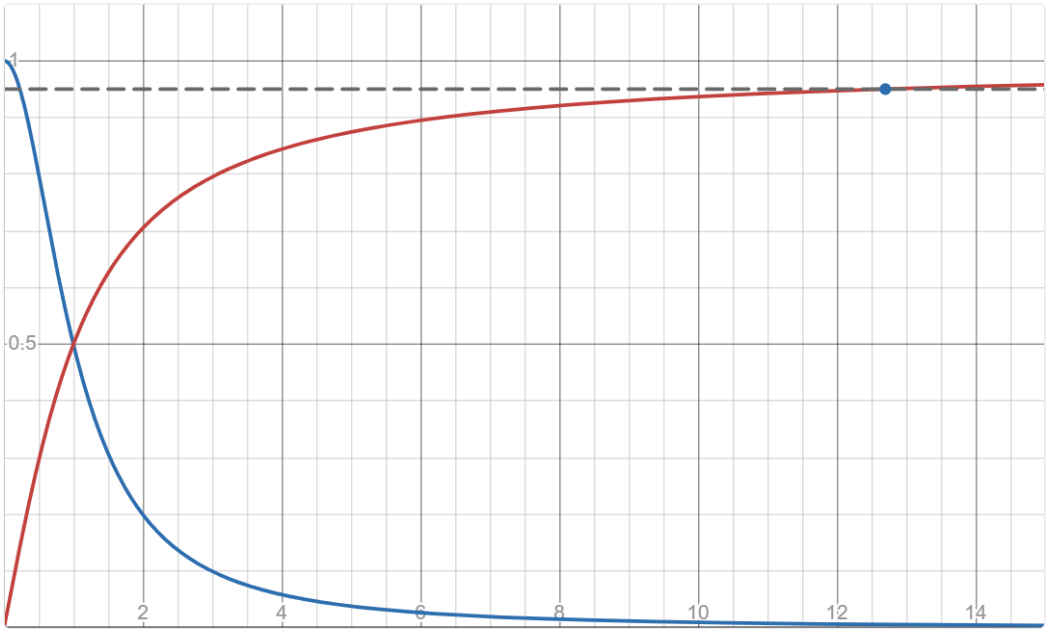
$$E = \frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{d\omega}{a^2+\omega^2} = \frac{1}{2\pi}\cdot\frac{\pi}{a} = \frac{1}{2a}\ \checkmark$$

The energy in $|\omega| < W$ is $\frac{1}{\pi}\int_0^W \frac{d\omega}{a^2+\omega^2} = \frac{1}{\pi a}\arctan\frac{W}{a}$, a fraction

$$\frac{E_W}{E} = \frac{2}{\pi}\arctan\frac{W}{a}.$$

At the 3-dB frequency $W = a$ this is exactly 50 %. For 95 %: $\arctan(W/a) = 0.95\pi/2$, so $W = a\tan(85.5^\circ) \approx 12.7a$. For 99 %, $W = a\tan(89.1^\circ) \approx 63.7a$. The slow $1/\omega^2$ decay of the ESD (caused by the jump at $t = 0$) makes the essential bandwidth very much larger than the 3-dB bandwidth.

With $a = 10^4$ s^{-1} (a 100 µs time constant), the 95 % essential bandwidth is 1.27×10^5 rad/s, about 20 kHz.



For $x = e^{-at}u(t)$ with ω in units of a: normalised ESD $a^2|X|^2 = 1/(1+\omega^2)$ (blue) and cumulative energy fraction $\frac{2}{\pi}\arctan\omega$ (red).

Worked Example 16.28 — the rectangular pulse and a sinc integral

(a) Use Parseval to evaluate $\displaystyle\int_{-\infty}^{\infty}\frac{\sin^2 u}{u^2}\,du$.

For $x = \mathrm{rect}(t)$, $E = 1$ and $X = 2\sin(\omega/2)/\omega$. Parseval gives $1 = \frac{1}{2\pi}\int\frac{4\sin^2(\omega/2)}{\omega^2}d\omega$. Put $u = \omega/2$, $d\omega = 2du$: $1 = \frac{1}{2\pi}\int\frac{4\sin^2 u}{4u^2}2\,du$, so

$$\int_{-\infty}^{\infty}\frac{\sin^2 u}{u^2}\,du = \pi.$$

(b) What fraction of the energy of a rectangular pulse of width T lies within its main lobe $|\omega| < 2\pi/T$?

$$\frac{E_{\text{main}}}{E} = \frac{1}{T}\cdot\frac{1}{\pi}\int_0^{2\pi/T}\frac{4\sin^2(\omega T/2)}{\omega^2}d\omega = \frac{2}{\pi}\int_0^{\pi}\frac{\sin^2 v}{v^2}dv \approx 0.903,$$

after substituting $v = \omega T/2$. The integral has no elementary closed form; numerical quadrature gives $\int_0^\pi \sin^2 v/v^2\,dv = 1.4182$, hence the fraction 0.903. So **about 90 % of the energy of a rectangular pulse lies in its main lobe**, even though its RMS bandwidth is infinite (Worked Example 16.18). A channel of bandwidth $1/T$ Hz passes 90 % of the energy of a pulse of duration T; it is the source of the "bandwidth ≈ 1/duration" rule.

Worked Example 16.29 — energy at the output of a filter

The pulse $x(t) = e^{-at}u(t)$ drives an RC low-pass filter $H = b/(b + j\omega)$, $b = 1/RC$. Find the output energy by Parseval and check it in the time domain.

Frequency domain. $|H|^2|X|^2 = \dfrac{b^2}{(b^2+\omega^2)(a^2+\omega^2)}$. With the partial-fraction identity

$$\frac{1}{(a^2+\omega^2)(b^2+\omega^2)} = \frac{1}{b^2-a^2}\left[\frac{1}{a^2+\omega^2} - \frac{1}{b^2+\omega^2}\right]$$

and $\int d\omega/(c^2+\omega^2) = \pi/c$, the integral is $\dfrac{\pi}{b^2-a^2}\left(\dfrac{1}{a}-\dfrac{1}{b}\right) = \dfrac{\pi}{ab(a+b)}$. Hence

$$E_y = \frac{1}{2\pi}\cdot b^2 \cdot \frac{\pi}{ab(a+b)} = \frac{b}{2a(a+b)}.$$

Time domain. For $a \neq b$, $y = x * h = \dfrac{b}{b-a}\left(e^{-at} - e^{-bt}\right)u(t)$, and

$$E_y = \frac{b^2}{(b-a)^2}\left[\frac{1}{2a} - \frac{2}{a+b} + \frac{1}{2b}\right] = \frac{b^2}{(b-a)^2}\cdot\frac{(b-a)^2}{2ab(a+b)} = \frac{b}{2a(a+b)}\ \checkmark$$

Numbers. $a = 500\ \text{s}^{-1}$, $b = 1000\ \text{s}^{-1}$: $E_x = 1/(2a) = 1.000\times10^{-3}$, $E_y = 1000/(2\cdot500\cdot1500) = 6.67\times10^{-4}$ (V²·s). The filter passes $E_y/E_x = b/(a+b) = 2/3$ of the input energy. As $b \to \infty$ (no filtering) the ratio tends to 1, and as $b \to 0$ to 0, as expected.

Worked Example 16.30 — essential bandwidth of a Gaussian pulse

For $x = e^{-t^2/(2\sigma^2)}$, $|X|^2 = 2\pi\sigma^2 e^{-\sigma^2\omega^2}$. The fraction of energy in $|\omega| < W$ is

$$\frac{E_W}{E} = \frac{\int_{-W}^{W} e^{-\sigma^2\omega^2}d\omega}{\int_{-\infty}^{\infty} e^{-\sigma^2\omega^2}d\omega} = \operatorname{erf}(\sigma W).$$

For 95 %, $\sigma W = \operatorname{erf}^{-1}(0.95) = 1.386$, so $W = 1.386/\sigma$. Compare the exponential pulse (Worked Example 16.27), whose 95 % bandwidth is 12.7 times its 3-dB bandwidth: the Gaussian's 3-dB bandwidth (where $e^{-\sigma^2\omega^2/2} = 1/\sqrt{2}$) is $\sqrt{\ln 2}/\sigma = 0.833/\sigma$, only a factor 1.66 below its 95 % bandwidth. Smooth pulses have compact spectra.

Autocorrelation and the energy Wiener–Khinchin relation

Deterministic autocorrelation

The autocorrelation of a finite-energy signal is

$$R_x(\tau) = \int_{-\infty}^{\infty} x(t+\tau)\,x^*(t)\,dt.$$

It measures the similarity of x with a copy of itself shifted by τ. For real x it is real and even, and $|R_x(\tau)| \le R_x(0) = E$ by the Cauchy–Schwarz inequality.

Substituting $s = -t$ shows $R_x(\tau) = x(\tau) * x^*(-\tau)$. Since $x^*(-t) \leftrightarrow X^*(\omega)$, the convolution theorem gives

Autocorrelation–ESD pair

$$R_x(\tau) \;\leftrightarrow\; |X(\omega)|^2 = \Psi_x(\omega), \qquad R_x(0) = E = \frac{1}{2\pi}\int \Psi_x(\omega)\,d\omega.$$

This is the energy-signal form of the **Wiener–Khinchin theorem**: the ESD is the Fourier transform of the autocorrelation. Because Ψ_x carries no phase information, neither does R_x; any two signals with the same magnitude spectrum have the same autocorrelation. Similarly the **cross-correlation** $R_{xy}(\tau) = \int x(t+\tau)y^*(t)\,dt$ transforms to the **cross-energy spectral density** $X(\omega)Y^*(\omega)$.

Worked Example 16.31 — autocorrelation of an exponential pulse

For $x = e^{-at}u(t)$ and $\tau \ge 0$: $R_x(\tau) = \int_0^\infty e^{-a(t+\tau)}e^{-at}dt = e^{-a\tau}/(2a)$. By evenness $R_x(\tau) = e^{-a|\tau|}/(2a)$. Its transform is $\dfrac{1}{2a}\cdot\dfrac{2a}{a^2+\omega^2} = \dfrac{1}{a^2+\omega^2} = |X(\omega)|^2$ ✓, and $R_x(0) = 1/(2a) = E$ ✓.

Power signals

For a power signal the ESD is infinite, and we work with power per unit bandwidth instead. Truncate the signal to $x_T(t) = x(t)\,\text{rect}(t/T)$, compute its ESD $|X_T(\omega)|^2$, divide by the duration and let $T \to \infty$:

$$S_x(\omega) = \lim_{T\to\infty}\frac{|X_T(\omega)|^2}{T}, \qquad P = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_x(\omega)\,d\omega.$$

This is the **power spectral density**. For a periodic signal it reduces to Parseval's theorem for Fourier series, $P = \sum_k |c_k|^2$, with $S_x(\omega) = 2\pi\sum_k |c_k|^2\delta(\omega - k\omega_0)$. For random signals, where the limit must be combined with an expectation, the PSD $S_{XX}(\omega)$ and its relation to the autocorrelation $R_{XX}(\tau)$ are the subject of Ch. 21.

Common Pitfall — one-sided versus two-sided spectra

Integrating $|X|^2$ over $\omega > 0$ only and forgetting the factor 2 halves every energy figure. Conversely, many instruments display a *one-sided* density that already includes the factor 2. Before comparing numbers, establish whether a density is per rad/s or per Hz (they differ by 2π) and one- or two-sided (they differ by 2).

Engineering Note — matched filtering

The generalized Parseval theorem underlies the **matched filter**: among all filters, the one with $H(\omega) = X^*(\omega)e^{-j\omega t_0}$ maximises the output peak relative to white noise, and its output at t_0 is $\frac{1}{2\pi}\int|X|^2 d\omega = E$, the pulse energy. Its impulse response $x(t_0 - t)$ makes the filter output the autocorrelation $R_x(t - t_0)$. Radar range resolution and digital-receiver detection both rest on these two facts.

16.8 Sampling-related mathematical foundations

Every digital system — a data converter, a software radio, a digital oscilloscope, a control loop running on a microcontroller — replaces a continuous signal $x(t)$ by its samples $x(nT)$. Whether anything is lost, and if so what, is a question about Fourier transforms. This section gives the mathematics of ideal (instantaneous) sampling: the spectrum of an impulse train, the spectral replication caused by sampling, the Nyquist condition under which the replicas do not overlap, aliasing when they do, and the interpolation formula that reconstructs $x(t)$. Converter hardware is outside the scope of this book; the discrete-time transforms that take over once the samples exist are the subject of Ch. 17.

Notation: T is the sampling interval, $f_s = 1/T$ the sampling rate in Hz and $\omega_s = 2\pi/T$ in rad/s.

The impulse train and its transform

Impulse train (Dirac comb)

For $p(t) = \sum_{n=-\infty}^{\infty} \delta(t - nT)$,

$$P(\omega) = \omega_s \sum_{k=-\infty}^{\infty} \delta(\omega - k\omega_s), \qquad \omega_s = \frac{2\pi}{T}.$$

An impulse train in time, of spacing T and unit areas, transforms to an impulse train in frequency, of spacing $\omega_s = 2\pi/T$ and areas ω_s.

Proof. $p(t)$ is periodic with period T. Its Fourier series coefficients are

$$c_k = \frac{1}{T}\int_{-T/2}^{T/2} \delta(t) e^{-jk\omega_s t} dt = \frac{1}{T} \quad \text{for every } k,$$

so $p(t) = \frac{1}{T}\sum_k e^{jk\omega_s t}$. Transforming term by term with $e^{jk\omega_s t} \leftrightarrow 2\pi\delta(\omega - k\omega_s)$ gives $P(\omega) = \frac{2\pi}{T}\sum_k \delta(\omega - k\omega_s)$. □

The comb is (up to scale) its own transform, and its spacings are reciprocal: **dense sampling in time means widely spaced lines in frequency.** The series $p(t) = \frac{1}{T}\sum_k e^{jk\omega_s t}$ does not converge in the ordinary sense; it is an identity between generalized functions, meaning that both sides give the same result when integrated against any smooth, rapidly decaying test function.

Poisson summation formula

For a sufficiently smooth and rapidly decaying $x(t)$ with transform $X(\omega)$,

$$\sum_{n=-\infty}^{\infty} x(nT)\, e^{-j\omega nT} = \frac{1}{T}\sum_{k=-\infty}^{\infty} X(\omega - k\omega_s),$$

and in particular (at $\omega = 0$) $T\sum_n x(nT) = \sum_k X(k\omega_s)$.

This is the impulse-train theorem integrated against x, and it is the analytic heart of everything that follows: the left side is computed from samples, the right side from the continuous spectrum.

Ideal sampling and spectral replication

Ideal (impulse) sampling of $x(t)$ at interval T is modelled as multiplication by the comb:

$$x_s(t) = x(t)\, p(t) = \sum_{n=-\infty}^{\infty} x(nT)\, \delta(t - nT).$$

The product keeps only the values $x(nT)$, each as the area of an impulse. By the multiplication theorem,

$$X_s(\omega) = \frac{1}{2\pi} X(\omega) * \omega_s \sum_k \delta(\omega - k\omega_s) = \frac{1}{T}\sum_{k=-\infty}^{\infty} X(\omega - k\omega_s).$$

Spectrum of a sampled signal

$$X_s(\omega) = \frac{1}{T}\sum_{k=-\infty}^{\infty} X(\omega - k\omega_s) = \sum_{n=-\infty}^{\infty} x(nT)\, e^{-j\omega nT}.$$

Sampling replicates the spectrum at every multiple of ω_s, scaled by $1/T$. The sampled spectrum is periodic in ω with period ω_s.

The second form follows by transforming x_s term by term ($\delta(t-nT) \leftrightarrow e^{-j\omega nT}$); the equality of the two forms is the Poisson summation formula. The second form is the bridge to discrete time: with the normalised frequency $\Omega = \omega T$ (radians per sample), $X_s = \sum_n x[n]e^{-j\Omega n}$ is the **discrete-time Fourier transform** of the sequence $x[n] = x(nT)$, and with $z = e^{sT}$ (so $z = e^{j\Omega}$ on the $j\omega$-axis) it is the Z-transform of Ch. 17 evaluated on the unit circle.

Periodicity in frequency is the dual of Section 16.6's statement that periodicity in time gives a line spectrum: **sampling in one domain is periodic repetition in the other.**

Worked Example 16.32 — the sampled spectrum of a two-sided exponential

Sample $x(t) = e^{-a|t|}$ (transform $2a/(a^2+\omega^2)$, not band-limited) at interval T. Find $X_s(\omega)$ in closed form and compare TX_s with X.

From the samples. With $r = e^{-aT} < 1$, $x(nT) = r^{|n|}$, and two geometric series give

$$X_s(\omega) = \sum_{n=0}^{\infty} r^n e^{-j\omega nT} + \sum_{n=1}^{\infty} r^n e^{j\omega nT} = \frac{1}{1 - re^{-j\omega T}} + \frac{re^{j\omega T}}{1 - re^{j\omega T}} = \frac{1 - r^2}{1 - 2r\cos\omega T + r^2}.$$

From the replication formula the same function must equal $\frac{1}{T}\sum_k \dfrac{2a}{a^2 + (\omega - k\omega_s)^2}$. With $a = 1$, $T = 0.5$ s ($r = 0.6065$) and $\omega = 1.3$ rad/s, the closed form gives 1.57173; summing the replicas numerically for $|k| \le 20000$ gives 1.57173 ✓.

Aliasing error. Ideally $TX_s = X$ in the band $|\omega| < \omega_s/2$. Here:

ω	$X(\omega)$	$TX_s(\omega)$
0	2.000	$T\frac{1+r}{1-r} = 2.041$
$\omega_s/2 = 2\pi$ rad/s	0.0494	$T\frac{1-r}{1+r} = 0.1225$

Near DC the error is 2 %, but at the folding frequency the sampled spectrum is about 2.5 times the true one: the tails of the replicas centred at $\pm\omega_s$ have folded onto the band edge. A signal whose spectrum decays slowly suffers aliasing at any finite sampling rate.

Nyquist condition and reconstruction

If $X(\omega) = 0$ for $|\omega| > \omega_M$, the replicas $X(\omega - k\omega_s)$ occupy the intervals $|\omega - k\omega_s| < \omega_M$. Adjacent replicas do not overlap provided $\omega_s - \omega_M > \omega_M$, i.e. $\omega_s > 2\omega_M$. In that case the baseband replica ($k = 0$) can be isolated by a low-pass filter, and $x(t)$ recovered exactly.

Sampling theorem (Shannon–Nyquist)

If $x(t)$ is band-limited, $X(\omega) = 0$ for $|\omega| > \omega_M$, and

$$\omega_s > 2\omega_M \qquad (\text{equivalently } f_s > 2f_M),$$

then $x(t)$ is uniquely determined by its samples $x(nT)$ and

$$x(t) = \sum_{n=-\infty}^{\infty} x(nT)\,\operatorname{sinc}\!\left(\frac{t - nT}{T}\right) = \sum_{n=-\infty}^{\infty} x(nT)\,\frac{\sin\big(\pi(t-nT)/T\big)}{\pi(t-nT)/T}.$$

$2\omega_M$ (or $2f_M$) is the **Nyquist rate**; $\omega_s/2$ (or $f_s/2$) is the **Nyquist (folding) frequency**.

Proof. Because the replicas do not overlap, $X(\omega) = T\,X_s(\omega)$ for $|\omega| < \omega_s/2$ and $X(\omega) = 0$ for $\omega_M < |\omega|$. So multiplying X_s by the ideal low-pass filter

$$H_r(\omega) = T\,\operatorname{rect}\!\left(\frac{\omega}{\omega_s}\right) \qquad (\text{gain } T,\ \text{cutoff } \omega_s/2)$$

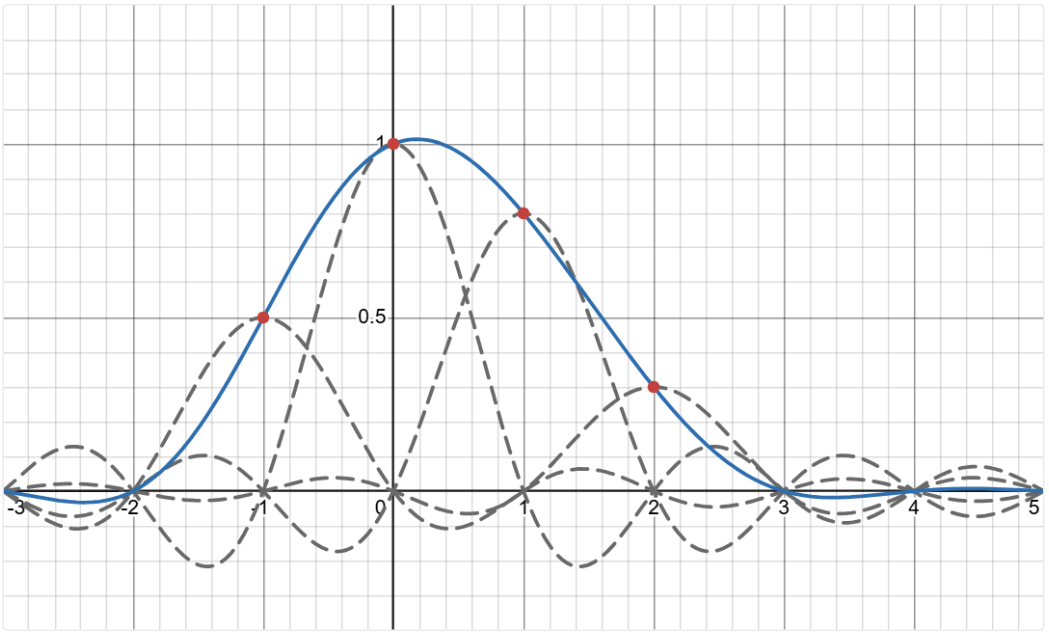
returns exactly X: $X(\omega) = H_r(\omega)X_s(\omega)$. By Worked Example 16.5 with $W = \omega_s/2 = \pi/T$, the impulse response of H_r is

$$h_r(t) = T \cdot \frac{\sin(\pi t/T)}{\pi t} = \operatorname{sinc}\!\left(\frac{t}{T}\right).$$

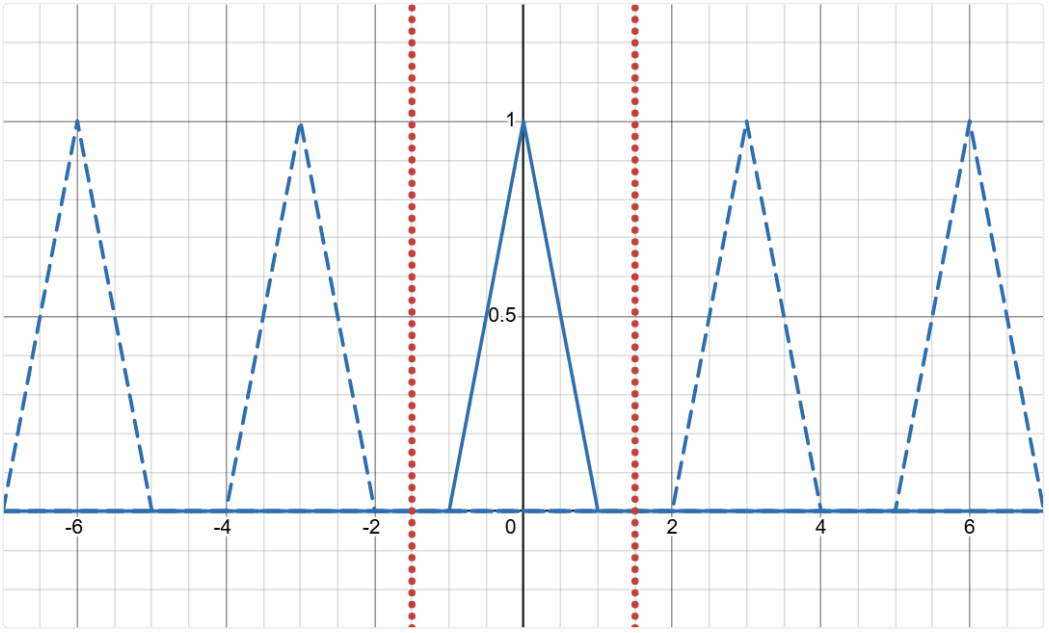
In the time domain, $x = h_r * x_s = h_r * \sum_n x(nT)\delta(t-nT) = \sum_n x(nT)h_r(t-nT)$, which is the interpolation formula. □

Two features of the interpolation formula deserve attention.

- **Interpolation property.** $\operatorname{sinc}((t-nT)/T)$ equals 1 at $t = nT$ and 0 at every other sample instant $t = mT$, $m \neq n$. So the formula passes exactly through every sample, and between samples each sinc contributes in proportion to its sample value.
- **Orthogonality.** The shifted sincs $\operatorname{sinc}((t-nT)/T)$ are mutually orthogonal, each with energy T. By the generalized Parseval theorem, with transforms $T\,\operatorname{rect}(\omega/\omega_s)e^{-j\omega nT}$, $\int \operatorname{sinc}\left(\frac{t-nT}{T}\right)\operatorname{sinc}\left(\frac{t-mT}{T}\right)dt = \frac{1}{2\pi}\int_{-\pi/T}^{\pi/T} T^2 e^{-j\omega(n-m)T}d\omega = T\,\delta_{nm}$, where δ_{nm} is the Kronecker delta. The sampling theorem is therefore an orthogonal expansion, like a Fourier series, in which the coefficients are simply the sample values: $x(nT) = \frac{1}{T}\int x(t)\operatorname{sinc}((t-nT)/T)\,dt$. It follows that $E = T\sum_n |x(nT)|^2$ for a band-limited signal sampled above the Nyquist rate.



Sinc interpolation with $T = 1$: four samples (red), the weighted sincs $x(nT)\,\mathrm{sinc}(t - n)$ (grey dashed), and their sum (blue), which passes through every sample because each sinc vanishes at the other sample instants.



Replicated spectrum $TX_s(\omega)$ for a triangular X with $\omega_M = 1$ and $\omega_s = 3 > 2\omega_M$: the replicas are separated by guard bands, so a low-pass filter with cutoff $\omega_s/2 = 1.5$ (red) recovers X exactly.

Worked Example 16.33 — Nyquist rates of derived signals

Let $x(t) = \dfrac{\sin(200\pi t)}{\pi t}$, band-limited to $\omega_M = 200\pi$ rad/s ($f_M = 100$ Hz). Find the Nyquist rate of each signal.

(a) $x(t)$ itself: $f_s > 2f_M = 200$ Hz.

(b) $x^2(t)$: by Worked Example 16.22 squaring doubles the bandwidth to $f_M = 200$ Hz, so $f_s > 400$ Hz.

(c) $x(t)\cos(1000\pi t)$: modulation moves the spectrum to $400 < |f| < 600$ Hz. Treated as a low-pass signal with highest frequency 600 Hz, $f_s > 1200$ Hz. (Band-pass sampling theory allows lower rates for such signals by exploiting the empty band below 400 Hz; the condition is that no replica lands on the occupied band.)

(d) $x(t) * y(t)$ with y band-limited to 50 Hz: the product $X(\omega)Y(\omega)$ vanishes outside the *narrower* band, so $f_s > 100$ Hz.

(e) $x(t) + x(t - t_0)$: delay does not change the band, so $f_s > 200$ Hz.

Multiplication widens bands (bandwidths add, by convolution of spectra); filtering and delay do not.

Worked Example 16.34 — reconstruction from samples, and truncation

The tone $x(t) = \cos(6\pi t)$ ($f_0 = 3$ Hz) is sampled at $f_s = 10$ Hz ($T = 0.1$ s), above its Nyquist rate of 6 Hz. Reconstruct $x(0.05)$, midway between two samples.

The samples are $x(nT) = \cos(0.6\pi n)$ and

$$x(0.05) = \sum_n \cos(0.6\pi n)\,\mathrm{sinc}(0.5 - n).$$

The exact value is $\cos(0.3\pi) = 0.587785$. Summing over $|n| \le N$:

N	5	50	500	5000
partial sum	0.584465	0.587725	0.587785	0.587785

The sum converges to the correct value, but slowly — the sinc tails decay only as $1/|n|$, so even 11 samples leave an error of 3×10^{-3}. Practical interpolators therefore use a faster-decaying kernel, which in turn requires sampling somewhat above the Nyquist rate so that a gentler filter edge fits into the guard band.

Aliasing

If $\omega_s < 2\omega_M$, adjacent replicas overlap. In the baseband $|\omega| < \omega_s/2$, $TX_s(\omega) = X(\omega) + X(\omega - \omega_s) + X(\omega + \omega_s) + \cdots$, and the extra terms are the high-frequency parts of X **folded** about $\pm\omega_s/2$. The folded content is indistinguishable from genuine low-frequency content: no processing of the samples can separate them. This is **aliasing**.

For a single sinusoid the effect is explicit. A tone of frequency f_0 sampled at f_s produces the same samples as one of frequency

$$f_a = |f_0 - k f_s|, \qquad k = \text{the integer nearest } f_0/f_s,$$

which lies in $[0, f_s/2]$. Indeed $\cos(2\pi f_0 nT + \theta) = \cos(2\pi(f_0 - kf_s)nT + \theta)$ because $2\pi k f_s nT = 2\pi kn$. When $f_0 - kf_s < 0$, writing the result in terms of the positive frequency f_a reverses the sign of the phase: a sine aliases to a *negated* sine.

Worked Example 16.35 — aliasing of a tone

A 7 kHz tone is sampled at $f_s = 10$ kHz. Here $f_0/f_s = 0.7$, so $k = 1$ and $f_a = |7 - 10| = 3$ kHz.

The samples are $\cos(2\pi \cdot 0.7n)$ and $\cos(2\pi \cdot 0.3n)$, which are identical since $0.7n = n - 0.3n$ and cosine is even: both sequences are $1,\ -0.309,\ -0.809,\ 0.809,\ 0.309,\ -1, \ldots$ For a sine, $\sin(2\pi \cdot 0.7n) = -\sin(2\pi \cdot 0.3n)$: the alias has inverted phase.

To avoid this, the signal must be band-limited to below $f_s/2 = 5$ kHz *before* sampling, or f_s must exceed 14 kHz. A tone at 13 kHz would alias to $|13 - 10| = 3$ kHz as well, and one at 17 kHz to $|17 - 20| = 3$ kHz: every frequency $kf_s \pm 3$ kHz lands on the same alias.
