
Undersampling ($\omega_M = 1, \omega_s = 1.5 < 2\omega_M$): the sum of overlapping replicas (blue) no longer matches the original triangle (red dashed) inside $|\omega| < \omega_s/2$ — aliasing.

> **Common Pitfall — sampling exactly at twice the highest frequency**
>
> Sampling at $f_s = 2f_M$ is not enough for a sinusoid at f_M: $\sin(2\pi f_M nT) = \sin(\pi n) = 0$ for all n, so the tone is invisible, and $\cos(\pi n + \theta) = \cos\theta\,(-1)^n$ cannot distinguish amplitude from phase. The inequality in the sampling theorem is strict. (For a signal whose spectrum contains no impulse at $\pm\omega_M$, equality is harmless, but nothing is gained by relying on it.)

Non-ideal reconstruction: the zero-order hold

The interpolation formula needs the ideal, non-causal sinc kernel. The simplest causal alternative holds each sample constant for one interval. Mathematically this is the convolution of x_s with a unit pulse on $[0, T)$:

$$x_{\text{ZOH}}(t) = \sum_n x(nT)\,\text{rect}\left(\frac{t - nT - T/2}{T}\right) \;\leftrightarrow\; X_s(\omega)\cdot T\,\text{sinc}\left(\frac{\omega T}{2\pi}\right) e^{-j\omega T/2}.$$

Compared with the ideal reconstruction filter (flat gain T in the baseband), the hold introduces (i) a magnitude **droop** $\text{sinc}(\omega T/2\pi)$, which at the folding frequency is $\text{sinc}(\tfrac{1}{2}) = 2/\pi = 0.637$ (-3.9 dB); (ii) a pure delay of $T/2$ (linear phase); and (iii) incomplete suppression of the replicas, attenuated only by the sinc sidelobes. Each is read directly from the convolution theorem.

> **Engineering Note — anti-aliasing and oversampling**
>
> Real systems place an analog anti-aliasing low-pass filter before the sampler and oversample (for example $f_s = 2.5f_M$, as in audio at 44.1 kHz for a 20 kHz band) to leave a guard band for a realisable filter roll-off. Choosing the filter order and the sampling rate is a design application of the replication formula $X_s = \frac{1}{T}\sum_k X(\omega - k\omega_s)$: the attenuation the filter provides at $f_s - f_M$ is the attenuation of the worst alias that can land in band.

Summary

Concept	Formula
Forward transform	$X(\omega) = \int_{-\infty}^{\infty} x(t)e^{-j\omega t}dt$
Inverse transform	$x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X(\omega)e^{j\omega t}d\omega$ (midpoint at jumps)
Hz convention	$X_f(f) = X(2\pi f)$, $x(t) = \int X_f(f)e^{j2\pi ft}df$
Relation to Laplace	$X(\omega) = X_L(j\omega)$ if the ROC contains the $j\omega$-axis
DC values	$X(0) = \int x\,dt$, $x(0) = \frac{1}{2\pi}\int X\,d\omega$
Exponential	$e^{-at}u(t) \leftrightarrow 1/(a + j\omega)$; $e^{-a\lvert t\rvert} \leftrightarrow 2a/(a^2 + \omega^2)$
Rectangle / sinc	$\text{rect}(t/T) \leftrightarrow T\,\text{sinc}(\omega T/2\pi)$; $\sin(Wt)/(\pi t) \leftrightarrow \text{rect}(\omega/2W)$
Triangle	$\Lambda(t/T) \leftrightarrow T\,\text{sinc}^2(\omega T/2\pi)$
Gaussian	$e^{-t^2/2\sigma^2} \leftrightarrow \sigma\sqrt{2\pi}e^{-\sigma^2\omega^2/2}$
Generalized pairs	$\delta \leftrightarrow 1$, $1 \leftrightarrow 2\pi\delta(\omega)$, $u \leftrightarrow \pi\delta(\omega) + 1/(j\omega)$, $\text{sgn} \leftrightarrow 2/(j\omega)$
Sinusoids	$\cos\omega_0 t \leftrightarrow \pi[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)]$
Time shift / frequency shift	$x(t - t_0) \leftrightarrow e^{-j\omega t_0}X$; $e^{j\omega_0 t}x \leftrightarrow X(\omega - \omega_0)$
Modulation	$x\cos\omega_0 t \leftrightarrow \frac{1}{2}[X(\omega - \omega_0) + X(\omega + \omega_0)]$

Concept	Formula
Scaling	$x(at) \leftrightarrow X(\omega/a)/\lvert a\rvert$
Duality	$X(t) \leftrightarrow 2\pi x(-\omega)$
Differentiation / multiplication by t	$\dot{x} \leftrightarrow j\omega X$; $tx \leftrightarrow j\,dX/d\omega$
Integration	$\int_{-\infty}^{t} x\,d\tau \leftrightarrow X/(j\omega) + \pi X(0)\delta(\omega)$
Convolution / multiplication	$x * h \leftrightarrow XH$; $xy \leftrightarrow \frac{1}{2\pi} X * Y$
Real-signal symmetry	$X(-\omega) = X^*(\omega)$; $\lvert X\rvert$ even, $\angle X$ odd
Frequency response	$e^{j\omega t} \to H(\omega)e^{j\omega t}$, $H = \mathcal{F}\{h\}$
Distortionless system / group delay	$H = Ke^{-j\omega t_d}$; $\tau_g = -d\angle H/d\omega$
Uncertainty principle	$\Delta t\,\Delta\omega \geq \frac{1}{2}$, equality for the Gaussian
Periodic signal	$X = 2\pi\sum_k c_k\delta(\omega - k\omega_0)$, $c_k = X_1(k\omega_0)/T_0$
Windowing	$X_w = \frac{1}{2\pi} X * W$; resolution $\approx 1/T$ Hz
Hann window	$W_H = \frac{T}{2}\,\mathrm{sinc}(u)/(1-u^2)$, $u = \omega T/2\pi$
Parseval	$\int\lvert x\rvert^2 dt = \frac{1}{2\pi}\int\lvert X\rvert^2 d\omega$; $\int xy^*dt = \frac{1}{2\pi}\int XY^*d\omega$
ESD	$\Psi_x = \lvert X\rvert^2 \leftrightarrow R_x(\tau)$; $\Psi_y = \lvert H\rvert^2\Psi_x$
Band energy (real x)	$E_{[\omega_1,\omega_2]} = \frac{1}{\pi}\int_{\omega_1}^{\omega_2}\lvert X\rvert^2 d\omega$
Impulse train	$\sum_n \delta(t - nT) \leftrightarrow \omega_s\sum_k \delta(\omega - k\omega_s)$
Sampled spectrum	$X_s(\omega) = \frac{1}{T}\sum_k X(\omega - k\omega_s) = \sum_n x(nT)e^{-j\omega nT}$
Nyquist condition	$\omega_s > 2\omega_M$ ($f_s > 2f_M$)
Interpolation	$x(t) = \sum_n x(nT)\,\mathrm{sinc}((t-nT)/T)$
Alias frequency	$f_a = \lvert f_0 - kf_s\rvert$, k nearest integer to f_0/f_s

Chapter 17 — Z-Transforms

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 4–5 (sequences, series and integral calculus), Ch. 14 (Laplace transforms), Ch. 16 (Fourier transforms and sampling) **Learning outcomes:** After this chapter you can
>
> - describe discrete-time signals as sequences, manipulate them with shifts, folds and convolution sums, and classify them (energy/power, periodic, causal);
> - compute bilateral and unilateral Z-transforms of standard sequences and apply the transform properties instead of summing series;
> - determine and sketch the region of convergence (ROC) for right-sided, left-sided, two-sided and finite sequences, and read causality and stability from it;
> - invert Z-transforms by partial fractions, power-series (long) division and the residue theorem;
> - solve linear constant-coefficient difference equations with initial conditions using the unilateral transform;
> - represent discrete-time LTI systems by their system function $H(z)$, pole–zero plots and block diagrams, and analyse their stability and frequency response $H(e^{j\omega})$, relating them to continuous-time systems through $z = e^{sT}$.

The Laplace transform of Ch. 14 turns linear differential equations into algebra; the Fourier transform of Ch. 16 describes signals as superpositions of sinusoids. Digital electronics, however, does not deal in functions of a continuous variable t. An analogue-to-digital converter delivers a list of numbers $x[0], x[1], x[2], \ldots$, one per clock tick; a digital filter, a microcontroller control loop or a sigma-delta modulator computes each new output from a handful of past inputs and outputs. The governing equations are *difference* equations rather than differential equations, and the natural transform is the **Z-transform**, which converts a sequence into a function of a complex variable z by using the sequence values as the coefficients of a power series in z^{-1}.

Everything in this chapter has a continuous-time twin: the Z-transform plays the role of the Laplace transform, the unit circle $|z| = 1$ plays the role of the imaginary axis $s = j\omega$, the inside of the unit circle plays the role of the left half-plane, and the region of convergence is an annulus instead of a vertical strip. The dictionary between the two worlds is the single relation $z = e^{sT}$, derived in §17.7. Because $X(z)$ is a Laurent series, the deeper theory — why the inverse transform is a contour integral, why the ROC is an annulus, why residues compute the inverse — belongs to complex analysis and is completed in Ch. 18. Here we state what we need and use it.

17.1 Sequences and discrete-time functions

Why sequences?

A continuous-time signal $x(t)$ sampled every T seconds gives the numbers $x(nT)$, $n \in \mathbb{Z}$. Once in a processor the sampling interval is no longer visible: the processor sees only the index n. It is therefore convenient to define discrete-time signals abstractly, as functions on the integers, and to carry T along only when we need to translate back to seconds and hertz.

Discrete-time signal (sequence)

A **discrete-time signal** is a function $x : \mathbb{Z} \to \mathbb{C}$, written $x[n]$ with square brackets. The integer n is the **sample index**. When $x[n] = x_a(nT)$ comes from sampling an analogue signal $x_a(t)$, T is the **sampling interval** and $f_s = 1/T$ the **sampling rate**.

Square brackets are a deliberate visual cue: $x[n]$ is defined only at integers, and $x[1.5]$ is meaningless (not zero). A finite sequence is often listed with an arrow, or here with a subscript marker, under the $n = 0$ entry:

$$x[n] = \{\, 2,\ \underset{\uparrow}{1},\ -1,\ 3 \,\} \quad \Longleftrightarrow \quad x[-1] = 2,\ x[0] = 1,\ x[1] = -1,\ x[2] = 3,$$

with $x[n] = 0$ for all other n.

Elementary sequences

Unit impulse, unit step and unit ramp

$$\delta[n] = \begin{cases} 1, & n = 0 \\ 0, & n \neq 0 \end{cases} \qquad u[n] = \begin{cases} 1, & n \geq 0 \\ 0, & n < 0 \end{cases} \qquad r[n] = n\,u[n].$$

Unlike the Dirac delta of continuous time, the **Kronecker** (unit) impulse $\delta[n]$ is an ordinary function: it has the value 1 at one point. There is no limiting process, no distribution theory and no problem with $\delta[n]^2 = \delta[n]$. The three sequences are linked by differences and running sums, the discrete analogues of derivatives and integrals:

$$\delta[n] = u[n] - u[n-1], \qquad u[n] = \sum_{k=-\infty}^{n} \delta[k] = \sum_{k=0}^{\infty} \delta[n-k], \qquad r[n+1] - r[n] = u[n].$$

The sifting property is the discrete statement that any sequence is a weighted sum of shifted impulses:

$$x[n] = \sum_{k=-\infty}^{\infty} x[k]\,\delta[n-k].$$

This identity, trivial as it looks, is the foundation of the convolution sum below.

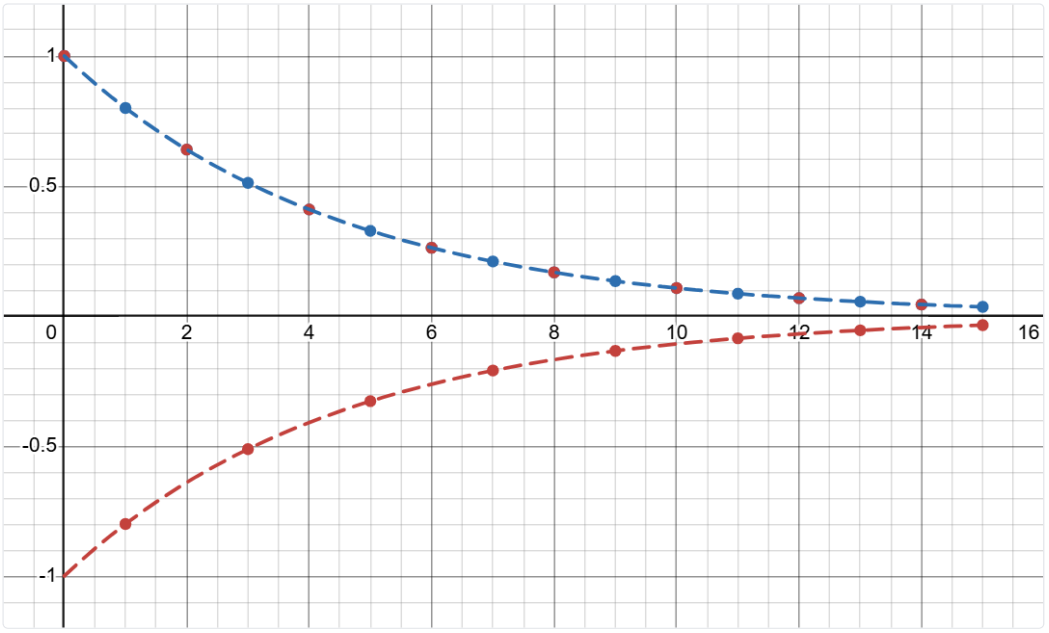
Exponential and sinusoidal sequences

The **complex exponential sequence** is $x[n] = A\,\alpha^n$ with $A, \alpha \in \mathbb{C}$. Writing $\alpha = re^{j\omega_0}$,

$$A\alpha^n = A\,r^n e^{j\omega_0 n} = A\,r^n\,(\cos\omega_0 n + j\sin\omega_0 n)\,.$$

For $r = 1$ this is a **discrete-time phasor** of frequency ω_0 (radians per sample); its real part $\cos(\omega_0 n + \theta)$ is a **sinusoidal sequence**.

The modulus $r = |\alpha|$ controls growth: $r < 1$ gives a decaying envelope, $r = 1$ a constant envelope, $r > 1$ a growing one. The angle ω_0 controls oscillation. For real α, $0 < \alpha < 1$ gives monotone decay, and $-1 < \alpha < 0$ gives decay with alternating sign — something a real continuous exponential e^{at} can never do, because $e^{aT} > 0$. A negative real pole is the discrete-time signature of oscillation at exactly half the sampling rate, $\omega_0 = \pi$.



The sequences $0.8^n u[n]$ (blue) and $(-0.8)^n u[n]$ (red) sampled at integers; both decay inside the envelope $\pm 0.8^n$ (dashed), but the negative base alternates in sign — oscillation at $\omega_0 = \pi$.

Discrete-time frequency is periodic

Two features of discrete-time sinusoids have no continuous-time counterpart, and both follow from the fact that n is an integer.

Frequency is only defined modulo 2π

For every integer k,

$$e^{j(\omega_0 + 2\pi k)n} = e^{j\omega_0 n}\,e^{j2\pi k n} = e^{j\omega_0 n}.$$

Hence the sequences with frequencies ω_0 and $\omega_0 + 2\pi k$ are *identical*. All distinct discrete-time frequencies lie in an interval of length 2π, conventionally $-\pi < \omega \le \pi$ or $0 \le \omega < 2\pi$.

In consequence, "high frequency" in discrete time means ω near $\pm\pi$ (the sequence alternates sign as fast as possible), and "low frequency" means ω near 0 or near any multiple of 2π. The sampled version of $\cos(\Omega t)$ with sampling interval T is $\cos(\Omega T n)$, so the discrete frequency is

$$\omega = \Omega T = 2\pi\frac{f}{f_s} \quad \text{rad/sample},$$

and the periodicity of ω is precisely the aliasing of §16.8: analogue frequencies f and $f + k f_s$ produce the same samples.

Periodicity of a discrete sinusoid

The sequence $e^{j\omega_0 n}$ is periodic with period N (a positive integer) if and only if $\omega_0 N = 2\pi m$ for some integer m, i.e. if and only if $\omega_0/2\pi = m/N$ is **rational**. The fundamental period is the smallest such N, obtained with m/N in lowest terms.

Proof. $e^{j\omega_0(n+N)} = e^{j\omega_0 n}$ for all n iff $e^{j\omega_0 N} = 1$ iff $\omega_0 N \in 2\pi\mathbb{Z}$. □

So $\cos(0.3\pi n)$ has $\omega_0/2\pi = 3/20$ and fundamental period $N = 20$ (it completes $m = 3$ cycles of the underlying cosine in 20 samples), whereas $\cos(n)$ — frequency 1 rad/sample — is *not periodic at all*, because $1/2\pi$ is irrational, even though its samples lie on a perfectly periodic continuous curve.

Operations on sequences

Operation	Definition	Remarks
Shift (delay by $n_0 > 0$)	$y[n] = x[n - n_0]$	moves the sequence n_0 samples right

Operation	Definition	Remarks
Advance	$y[n] = x[n + n_0]$	moves left; non-causal if used in real time
Fold (time reversal)	$y[n] = x[-n]$	mirror about $n = 0$
Decimation (downsampling by M)	$y[n] = x[Mn]$	keeps every Mth sample; information is lost
Expansion (upsampling by L)	$y[n] = x[n/L]$ if $L \mid n$, else 0	inserts $L - 1$ zeros between samples
First difference	$\nabla x[n] = x[n] - x[n-1]$	analogue of dx/dt (backward)
Accumulation	$y[n] = \sum_{k=-\infty}^{n} x[k]$	analogue of $\int_{-\infty}^{t} x\,d\tau$

When shift and fold are combined, the order matters: $x[-n+2] = x[-(n-2)]$ is $x[-n]$ shifted right by 2 — equivalently, $x[n]$ advanced by 2 and then folded. The safe method is to substitute: to sketch $y[n] = x[2-n]$, tabulate n, compute $2 - n$, and read off x.

Classes of sequences

- **Causal** (right-sided from 0): $x[n] = 0$ for $n < 0$. **Anticausal**: $x[n] = 0$ for $n > 0$.
- **Right-sided**: $x[n] = 0$ for $n < N_1$ for some N_1. **Left-sided**: $x[n] = 0$ for $n > N_2$. **Two-sided**: neither. **Finite-length**: both right- and left-sided.
- **Even**: $x[-n] = x[n]$; **odd**: $x[-n] = -x[n]$. Every sequence splits uniquely as $x_e[n] = \tfrac{1}{2}(x[n] + x[-n])$ plus $x_o[n] = \tfrac{1}{2}(x[n] - x[-n])$.
- **Energy**: $E_x = \sum_n |x[n]|^2$. **Average power**: $P_x = \lim_{N\to\infty} \frac{1}{2N+1} \sum_{n=-N}^{N} |x[n]|^2$. An **energy signal** has $0 < E_x < \infty$ (so $P_x = 0$); a **power signal** has $0 < P_x < \infty$ (so $E_x = \infty$).
- **Absolutely summable**: $\sum_n |x[n]| < \infty$ (written $x \in \ell^1$). **Bounded**: $|x[n]| \le B$ for all n.

The right/left/two-sided classification looks bookkeeping-level here, but in §17.3 it will determine the *shape* of the region of convergence.

Worked Example 17.1 — Energy and power of standard sequences

Classify (a) $x_1[n] = (0.5)^n u[n]$, (b) $x_2[n] = u[n]$, (c) $x_3[n] = \cos(0.3\pi n)$, (d) $x_4[n] = n\,u[n]$.

(a) $E = \sum_{n=0}^{\infty} 0.25^n = \dfrac{1}{1-0.25} = \dfrac{4}{3}$. Finite, so an energy signal; $P = 0$.

(b) $E = \sum_{n\ge 0} 1 = \infty$. For power, $\sum_{n=-N}^{N} u[n]^2 = N + 1$, so $P = \lim (N+1)/(2N+1) = \tfrac{1}{2}$. A power signal.

(c) $\cos^2\theta = \tfrac{1}{2}(1 + \cos 2\theta)$, and over a full period of 20 samples $\sum \cos(0.6\pi n) = 0$, so the average of $\cos^2(0.3\pi n)$ over one period is exactly $\tfrac{1}{2}$. Hence $P = \tfrac{1}{2}$: a power signal (as for any sinusoid of unit amplitude).

(d) $\sum_{n=0}^{N} n^2 \approx N^3/3$, so $P = \lim N^3/(3(2N+1)) = \infty$. Neither an energy nor a power signal.

Check: numerically, $\sum_{n=0}^{50} 0.25^n = 1.33333$ and $\frac{1}{40}\sum_{n=0}^{39} \cos^2(0.3\pi n) = 0.5000$.

Discrete-time systems and the convolution sum

A **discrete-time system** maps an input sequence $x[n]$ to an output sequence $y[n] = \mathcal{T}\{x[n]\}$. The properties of Ch. 14 carry over verbatim:

- **Linear**: $\mathcal{T}\{ax_1 + bx_2\} = a\mathcal{T}\{x_1\} + b\mathcal{T}\{x_2\}$.
- **Time-invariant** (shift-invariant): if $x[n] \mapsto y[n]$, then $x[n - n_0] \mapsto y[n - n_0]$ for every integer n_0.
- **Causal**: $y[n]$ depends only on $x[k]$ with $k \le n$.
- **BIBO stable**: every bounded input produces a bounded output.

For a linear time-invariant (LTI) system, define the **impulse response** $h[n] = \mathcal{T}\{\delta[n]\}$. Applying $\mathcal{T}$ to the sifting identity, linearity moves $\mathcal{T}$ inside the sum and time invariance turns $\mathcal{T}\{\delta[n-k]\}$ into $h[n-k]$:

Convolution sum

The output of an LTI system with impulse response $h[n]$ is

$$y[n] = \sum_{k=-\infty}^{\infty} x[k]\,h[n-k] = \sum_{k=-\infty}^{\infty} h[k]\,x[n-k] \;\equiv\; (x * h)[n].$$

Discrete convolution is commutative, associative and distributive over addition, and $\delta[n]$ is its identity: $x * \delta = x$, $x * \delta[n-n_0] = x[n-n_0]$.

Derivation. $y[n] = \mathcal{T}\{\sum_k x[k]\delta[n-k]\} = \sum_k x[k]\,\mathcal{T}\{\delta[n-k]\} = \sum_k x[k]h[n-k]$. The substitution $m = n - k$ gives the second form. □

Unlike the convolution integral, the convolution sum can be evaluated exactly by hand for short sequences. Two practical methods:

1. **Flip-and-slide.** Fold $h[k]$ to $h[-k]$, shift it to $h[n-k]$, multiply pointwise with $x[k]$, and add.
2. **Polynomial multiplication.** For finite sequences starting at $n = 0$, y has the coefficients of the product of the polynomials $\sum x[n]w^n$ and $\sum h[n]w^n$. This is not a coincidence: it is the convolution theorem of the Z-transform in disguise (§17.2).

Worked Example 17.2 — Convolution of finite sequences

Compute $y = x * h$ for $x[n] = \{\underset{\uparrow}{1}, 2, 3\}$ and $h[n] = \{\underset{\uparrow}{1}, -1, 2\}$.

Polynomial method. $(1 + 2w + 3w^2)(1 - w + 2w^2) = 1 + (2-1)w + (3 - 2 + 2)w^2 + (-3+4)w^3 + 6w^4$, so

$$y[n] = \{\underset{\uparrow}{1},\ 1,\ 3,\ 1,\ 6\}.$$

Check by flip-and-slide at $n = 2$: $y[2] = x[0]h[2] + x[1]h[1] + x[2]h[0] = 2 - 2 + 3 = 3$. ✓

Length rule. A length-L_1 sequence convolved with a length-L_2 sequence has length $L_1 + L_2 - 1 = 5$; if the first starts at N_1 and the second at N_2, the result starts at $N_1 + N_2$.

Worked Example 17.3 — Step response of a first-order system by convolution

An LTI system has $h[n] = a^n u[n]$ with $a \neq 1$. Find its step response $s[n] = (u * h)[n]$.

For $n < 0$, every term of $\sum_k h[k]u[n-k]$ has either $k < 0$ (so $h[k] = 0$) or $n - k < 0$ (so $u[n-k] = 0$); thus $s[n] = 0$. For $n \geq 0$ the product is non-zero only for $0 \leq k \leq n$:

$$s[n] = \sum_{k=0}^{n} a^k = \frac{1 - a^{n+1}}{1 - a}, \qquad n \geq 0.$$

If $|a| < 1$, $s[n] \to 1/(1-a)$, the **DC gain**. With $a = 0.5$: $s[0..4] = 1,\ 1.5,\ 1.75,\ 1.875,\ 1.9375 \to 2$.

Check: direct recursion $s[n] = 0.5\, s[n-1] + 1$ from $s[-1] = 0$ gives the same values.

Engineering Note — Sampled circuits are sequences

When an ADC samples the capacitor voltage of an RC circuit with time constant τ every T seconds, the free response $v(t) = V_0 e^{-t/\tau}$ becomes $v[n] = V_0 \left(e^{-T/\tau}\right)^n$: a geometric sequence with base $a = e^{-T/\tau}$. The ratio between consecutive samples, not the time constant, is what the processor sees. This is our first glimpse of $z = e^{sT}$: the continuous pole $s = -1/\tau$ becomes the discrete pole $a = e^{-T/\tau}$.

Common Pitfall — "Sampling a periodic signal gives a periodic sequence"

Only if f/f_s is rational. A 1 kHz tone sampled at $f_s = 44.1$ kHz gives $\omega_0/2\pi = 10/441$, periodic with $N = 441$ samples; a tone at $1000\sqrt{2}$ Hz sampled at the same rate gives a sequence that never repeats exactly. Algorithms that assume an integer number of samples per period (e.g. some RMS meters) then show leakage errors.

17.2 Definition and properties

Motivation: eigenfunctions of LTI systems

Feed the geometric sequence $x[n] = z^n$, with z any non-zero complex number, into an LTI system with impulse response $h[n]$. The convolution sum gives

$$y[n] = \sum_k h[k]\, z^{n-k} = z^n \sum_k h[k]\, z^{-k} = H(z)\, z^n,$$

provided the sum converges. The output is the input multiplied by a complex constant $H(z)$: geometric sequences are **eigenfunctions** of every LTI system, and $H(z)$ is the corresponding eigenvalue. Exactly as e^{st} led to the Laplace transform in continuous time, z^n leads to the Z-transform. Decomposing an input into geometric sequences and multiplying each by $H(z)$ is the whole strategy of this chapter.

Definition

Bilateral Z-transform

The (bilateral, or two-sided) **Z-transform** of a sequence $x[n]$ is the function of the complex variable z

$$X(z) = \mathcal{Z}\{x[n]\} = \sum_{n=-\infty}^{\infty} x[n]\, z^{-n},$$

defined on the set of z for which the series converges absolutely. That set is the **region of convergence** (ROC). We write $x[n] \overset{\mathcal{Z}}{\longleftrightarrow} X(z)$, ROC $= R_x$.

Unilateral Z-transform

The **unilateral** (one-sided) Z-transform is

$$\mathcal{X}(z) = \mathcal{Z}_u\{x[n]\} = \sum_{n=0}^{\infty} x[n]\, z^{-n}.$$

It ignores $x[n]$ for $n < 0$. For causal sequences the two transforms coincide. The unilateral form is the tool for difference equations with initial conditions (§17.5), just as the unilateral Laplace transform is for differential equations.

Writing $z = re^{j\omega}$,

$$X(re^{j\omega}) = \sum_{n} \left(x[n]\, r^{-n}\right) e^{-j\omega n},$$

so the Z-transform on the circle of radius r is the discrete-time Fourier transform (DTFT) of the exponentially weighted sequence $x[n]r^{-n}$. The weighting r^{-n} plays the role of the factor $e^{-\sigma t}$ in the Laplace transform: choosing r large tames sequences that grow as $n \to +\infty$; choosing r small tames those that grow as $n \to -\infty$. On the unit circle, $r = 1$, the Z-transform *is* the DTFT:

$$X(e^{j\omega}) = \sum_{n} x[n]\, e^{-j\omega n} \quad \text{(if the unit circle lies in the ROC)}.$$

The notation $X(e^{j\omega})$ — rather than $X(\omega)$ — is standard and deliberate: it reminds us that the DTFT is $X(z)$ evaluated at $z = e^{j\omega}$ and that it is 2π-periodic in ω.

The fundamental pair: the geometric sequence

Worked Example 17.4 — Transform of $a^n u[n]$

Let $x[n] = a^n u[n]$. Then

$$X(z) = \sum_{n=0}^{\infty} a^n z^{-n} = \sum_{n=0}^{\infty} \left(az^{-1}\right)^n = \frac{1}{1 - az^{-1}} = \frac{z}{z - a},$$

by the geometric series, which converges absolutely if and only if $|az^{-1}| < 1$, i.e. $|z| > |a|$.

ROC: the exterior of the circle of radius $|a|$. $X(z)$ has a **zero** at $z = 0$ and a **pole** at $z = a$; the pole lies on the inner boundary of the ROC.

Check ($a = 0.5$, $z = 2$): $\sum_{n=0}^{60} (0.25)^n = 1.33333 = 2/(2 - 0.5)$. ✓

Worked Example 17.5 — Transform of $-a^n u[-n-1]$

Let $x[n] = -a^n u[-n-1]$, which is non-zero only for $n \le -1$. Substituting $m = -n$,

$$X(z) = -\sum_{n=-\infty}^{-1} a^n z^{-n} = -\sum_{m=1}^{\infty} \left(a^{-1}z\right)^m = -\frac{a^{-1}z}{1 - a^{-1}z} = \frac{z}{z - a},$$

converging if and only if $|a^{-1}z| < 1$, i.e. $|z| < |a|$.

The same algebraic expression $z/(z-a)$ as in Example 17.4, but with ROC the *interior* of the circle $|z| = |a|$.

These two examples carry the most important lesson of the chapter: **a Z-transform is the pair (formula, ROC)**. The formula alone does not determine the sequence. In practice the ROC is often implied by context — causal signals in real-time processing have exterior ROCs — but whenever two-sided or non-causal sequences are possible it must be stated.

Table of standard pairs

Each pair below follows from the geometric series and the properties derived next.

$x[n]$	$X(z)$	ROC
$\delta[n]$	1	all z
$\delta[n - n_0]$, $n_0 > 0$	z^{-n_0}	$z \neq 0$
$\delta[n + n_0]$, $n_0 > 0$	z^{n_0}	all finite z ($z \neq \infty$)
$u[n]$	$\dfrac{1}{1 - z^{-1}} = \dfrac{z}{z - 1}$	$\lvert z\rvert > 1$
$-u[-n-1]$	$\dfrac{z}{z - 1}$	$\lvert z\rvert < 1$
$a^n u[n]$	$\dfrac{z}{z - a}$	$\lvert z\rvert > \lvert a\rvert$
$-a^n u[-n-1]$	$\dfrac{z}{z - a}$	$\lvert z\rvert < \lvert a\rvert$
$n\, u[n]$	$\dfrac{z}{(z-1)^2}$	$\lvert z\rvert > 1$
$n\, a^n u[n]$	$\dfrac{az}{(z-a)^2}$	$\lvert z\rvert > \lvert a\rvert$
$\binom{n+m-1}{m-1} a^n u[n]$	$\dfrac{z^m}{(z-a)^m}$	$\lvert z\rvert > \lvert a\rvert$
$\cos(\omega_0 n)\, u[n]$	$\dfrac{z(z - \cos\omega_0)}{z^2 - 2z\cos\omega_0 + 1}$	$\lvert z\rvert > 1$
$\sin(\omega_0 n)\, u[n]$	$\dfrac{z \sin\omega_0}{z^2 - 2z\cos\omega_0 + 1}$	$\lvert z\rvert > 1$
$r^n \cos(\omega_0 n)\, u[n]$	$\dfrac{z(z - r\cos\omega_0)}{z^2 - 2rz\cos\omega_0 + r^2}$	$\lvert z\rvert > r$
$r^n \sin(\omega_0 n)\, u[n]$	$\dfrac{zr \sin\omega_0}{z^2 - 2rz\cos\omega_0 + r^2}$	$\lvert z\rvert > r$
a^n for $0 \le n \le N-1$, else 0	$\dfrac{1 - a^N z^{-N}}{1 - az^{-1}}$	$z \neq 0$

Engineering Note — Write transforms in z^{-1} for implementation, in z for algebra

DSP texts and filter-design software (for example the coefficient vectors `b`, `a` passed to MATLAB's `filter` or SciPy's `lfilter`) write rational transforms as ratios of polynomials in z^{-1}, because z^{-1} is a one-sample delay that can be built from a register. Pole–zero and partial-fraction work is cleaner in positive powers of z. Converting is just multiplying numerator and denominator by the same power of z — but keep track of the poles or zeros at $z = 0$ that this creates or removes.

Linearity

Linearity

If $x_1 \leftrightarrow X_1$ (ROC R_1) and $x_2 \leftrightarrow X_2$ (ROC R_2), then

$$a\,x_1[n] + b\,x_2[n] \;\longleftrightarrow\; a\,X_1(z) + b\,X_2(z), \qquad \text{ROC} \supseteq R_1 \cap R_2.$$

The ROC can be larger than the intersection when poles cancel. For example $a^n u[n] - a^n u[n-1] = \delta[n]$: each term has ROC $|z| > |a|$, but the difference $\frac{z}{z-a} - \frac{a}{z-a} = 1$ converges everywhere.

Linearity immediately gives the sinusoid pairs. By Euler, $\cos(\omega_0 n)u[n] = \frac{1}{2}\left(e^{j\omega_0 n} + e^{-j\omega_0 n}\right)u[n]$, so with $a = e^{\pm j\omega_0}$:

$$\frac{1}{2}\left(\frac{z}{z - e^{j\omega_0}} + \frac{z}{z - e^{-j\omega_0}}\right) = \frac{z}{2}\cdot\frac{2z - 2\cos\omega_0}{z^2 - 2z\cos\omega_0 + 1} = \frac{z(z - \cos\omega_0)}{z^2 - 2z\cos\omega_0 + 1},$$

with ROC $|z| > 1$. The two poles $e^{\pm j\omega_0}$ sit *on* the unit circle at angle $\pm\omega_0$: a pole on the unit circle at angle ω_0 is an undamped oscillation at frequency ω_0.

Time shifting

Time shift (bilateral)

$$x[n - n_0] \;\longleftrightarrow\; z^{-n_0}X(z),$$

with the same ROC as X, except possibly for the addition or removal of $z = 0$ or $z = \infty$.

Proof. $\sum_n x[n-n_0]z^{-n} = \sum_m x[m]z^{-(m+n_0)} = z^{-n_0}X(z)$ with $m = n - n_0$. □

So a delay of one sample is multiplication by z^{-1} — the **unit-delay operator** in a block diagram. For the *unilateral* transform the shift rule must account for samples that cross $n = 0$; it is derived in §17.5 where it is needed.

Multiplication by an exponential (scaling in z)

Exponential multiplication

$$a^n x[n] \;\longleftrightarrow\; X\!\left(\frac{z}{a}\right), \qquad \text{ROC} = |a|R_x.$$

Every pole and zero p of X moves to ap: the pole–zero pattern is scaled by $|a|$ and rotated by $\angle a$.

Proof. $\sum_n a^n x[n] z^{-n} = \sum_n x[n](z/a)^{-n}$. □

With $a = e^{j\omega_0}$ this is **modulation**: $e^{j\omega_0 n}x[n] \leftrightarrow X(e^{-j\omega_0}z)$, a rotation of the pole–zero plot by ω_0, i.e. a frequency shift of the DTFT. With $a = r$ real it gives the damped sinusoid pairs in the table from the undamped ones: replace z by z/r in the $\cos(\omega_0 n)u[n]$ pair and simplify.

Differentiation in z

Multiplication by n

$$n\,x[n] \;\longleftrightarrow\; -z\frac{dX(z)}{dz}, \qquad \text{same ROC (up to } 0, \infty).$$

Proof. Inside its ROC a power series may be differentiated term by term (Ch. 18): $\frac{dX}{dz} = \sum_n (-n)x[n]z^{-n-1}$; multiply by $-z$. □

Applied to $a^n u[n]$:

$$-z\frac{d}{dz}\frac{z}{z-a} = -z\cdot\frac{(z-a) - z}{(z-a)^2} = \frac{az}{(z-a)^2},$$

the $na^n u[n]$ entry in the table. Applying the rule repeatedly produces $n^2 a^n u[n]$, and so on, and hence the double, triple, … pole pairs needed in partial-fraction inversion.

Time reversal and conjugation

Time reversal and conjugation

$$x[-n] \;\longleftrightarrow\; X(1/z), \quad \text{ROC} = 1/R_x; \qquad x^*[n] \;\longleftrightarrow\; X^*(z^*), \quad \text{ROC} = R_x.$$

Reversal maps a pole at p to a pole at $1/p$ and turns an exterior ROC $|z| > r$ into an interior one $|z| < 1/r$. The conjugation property implies that for **real** sequences $X(z^*) = X^*(z)$: poles and zeros are real or occur in complex-conjugate pairs, and on the unit circle $X(e^{-j\omega}) = X^*(e^{j\omega})$ — the magnitude response is even in ω and the phase is odd.

Convolution

Convolution theorem

$$(x * h)[n] \;\longleftrightarrow\; X(z)\,H(z), \qquad \text{ROC} \supseteq R_x \cap R_h.$$

Proof. Take $z \in R_x \cap R_h$, so both series converge absolutely and the order of summation may be exchanged:

$$\sum_{n}\sum_{k} x[k]h[n-k]z^{-n} = \sum_{k} x[k]z^{-k}\sum_{n} h[n-k]z^{-(n-k)} = X(z)H(z). \;\square$$

The polynomial-multiplication trick of Example 17.2 is this theorem with $w = z^{-1}$. More important, the theorem turns the output of an LTI system into a product, $Y(z) = H(z)X(z)$, which is the starting point of §17.6.

Accumulation and first difference

Because $\sum_{k=-\infty}^{n} x[k] = (x * u)[n]$ and $\mathcal{Z}\{u\} = z/(z-1)$:

$$\sum_{k=-\infty}^{n} x[k] \;\longleftrightarrow\; \frac{z}{z-1}X(z) = \frac{1}{1-z^{-1}}X(z), \qquad x[n] - x[n-1] \;\longleftrightarrow\; (1-z^{-1})X(z).$$

The accumulator has a pole at $z = 1$ — the discrete analogue of the integrator's pole at $s = 0$ — and the first difference has a zero there, like the differentiator's zero at $s = 0$.

Parseval's relation

For two sequences whose ROCs both contain the unit circle, the convolution theorem applied to $x[n]$ and $y^*[-n]$, evaluated at $n = 0$, gives

$$\sum_{n=-\infty}^{\infty} x[n]\,y^*[n] = \frac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\omega})\,Y^*(e^{j\omega})\,d\omega, \qquad E_x = \sum_{n}|x[n]|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi}|X(e^{j\omega})|^2 d\omega.$$

It is the discrete-time counterpart of the energy theorem of §16.7; the only difference is that the frequency integral runs over one period, 2π, rather than over the whole real line. For $x[n] = 0.5^n u[n]$, $|X(e^{j\omega})|^2 = 1/(1.25 - \cos\omega)$ and the integral evaluates to $\frac{1}{2\pi}\cdot\frac{2\pi}{\sqrt{1.25^2-1}} = \frac{1}{0.75} = \frac{4}{3}$, matching Example 17.1(a).

Initial and final value theorems

Initial value theorem

If $x[n]$ is causal, then

$$x[0] = \lim_{z\to\infty} X(z).$$

More generally $x[1] = \lim_{z\to\infty} z\,(X(z) - x[0])$, and so on.

Proof. $X(z) = x[0] + x[1]z^{-1} + x[2]z^{-2} + \cdots$; every term but the first vanishes as $z \to \infty$. $\square$

Final value theorem

If $x[n]$ is causal and $(z-1)X(z)$ has all its poles strictly inside the unit circle, then

$$\lim_{n\to\infty} x[n] = \lim_{z\to 1}(z-1)X(z) = \lim_{z\to 1}\left(1 - z^{-1}\right)X(z).$$

Proof sketch. $\mathcal{Z}\{x[n] - x[n-1]\} = (1-z^{-1})X(z)$. Summing the differences, $x[N] = \sum_{n=0}^{N}(x[n] - x[n-1])$; letting $N \to \infty$, $\lim x[N] = \lim_{z\to 1}\sum_{n\ge 0}(x[n] - x[n-1])z^{-n}$, the interchange of limits being justified by the pole condition, which guarantees the differences decay geometrically. $\square$

The hypothesis is essential: $X(z) = z/(z+1)$ (the sequence $(-1)^n u[n]$) gives $\lim_{z\to 1}(z-1)X(z) = 0$, yet $(-1)^n$ has no limit. The pole of $(z-1)X(z)$ at $z = -1$ lies on the unit circle, so the theorem does not apply.

Summary table of properties

Property	Sequence	Transform	ROC
Linearity	$ax_1 + bx_2$	$aX_1 + bX_2$	$\supseteq R_1 \cap R_2$
Time shift	$x[n - n_0]$	$z^{-n_0}X(z)$	R_x (except $0, \infty$)
Exponential scaling	$a^n x[n]$	$X(z/a)$	$\lvert a\rvert R_x$
Modulation	$e^{j\omega_0 n}x[n]$	$X(e^{-j\omega_0}z)$	R_x
Multiplication by n	$nx[n]$	$-z\,X'(z)$	R_x
Time reversal	$x[-n]$	$X(1/z)$	$1/R_x$

Property	Sequence	Transform	ROC
Conjugation	$x^*[n]$	$X^*(z^*)$	R_x
Convolution	$x * h$	XH	$\supseteq R_x \cap R_h$
Accumulation	$\sum_{k\le n} x[k]$	$X/(1-z^{-1})$	$\supseteq R_x \cap \{\lvert z\rvert > 1\}$
First difference	$x[n]-x[n-1]$	$(1-z^{-1})X$	$\supseteq R_x \cap \{\lvert z\rvert > 0\}$
Initial value (causal)	$x[0]$	$\lim_{z\to\infty} X(z)$	—
Final value (causal)	$x[\infty]$	$\lim_{z\to 1}(z-1)X(z)$	poles of $(z-1)X$ inside $\lvert z\rvert = 1$

Worked examples

Worked Example 17.6 — A finite sequence

Find $X(z)$ for $x[n] = \{2, \underset{\uparrow}{1}, -1, 3\}$.

Directly from the definition:

$$X(z) = 2z + 1 - z^{-1} + 3z^{-2} = \frac{2z^3 + z^2 - z + 3}{z^2}.$$

ROC. The positive power $2z$ diverges as $z \to \infty$, and the negative powers diverge at $z = 0$, so the ROC is $0 < \lvert z\rvert < \infty$. A finite sequence always has an ROC of the entire plane, except possibly 0 and/or ∞.

Check: at $z = 1$, $X(1) = 2 + 1 - 1 + 3 = 5 = \sum_n x[n]$, as it must be: the Z-transform at $z = 1$ is the sum of the sequence.

Worked Example 17.7 — A damped sinusoid via scaling

Find the Z-transform of $x[n] = (0.8)^n \cos(\pi n/3)\, u[n]$.

Step 1. Start from the cosine pair with $\cos(\pi/3) = \frac{1}{2}$:

$$\cos\left(\tfrac{\pi}{3}n\right) u[n] \longleftrightarrow \frac{z(z-0.5)}{z^2 - z + 1}, \quad \lvert z\rvert > 1.$$

Step 2. Multiply by 0.8^n, i.e. replace z by $z/0.8$:

$$X(z) = \frac{(z/0.8)(z/0.8 - 0.5)}{(z/0.8)^2 - z/0.8 + 1} = \frac{z(z-0.4)}{z^2 - 0.8z + 0.64}, \quad \lvert z\rvert > 0.8.$$

Poles at $z = 0.4 \pm j0.4\sqrt{3} = 0.8e^{\pm j\pi/3}$: radius 0.8 (the damping), angle $\pm\pi/3$ (the oscillation frequency). **Zeros** at 0 and 0.4.

Check at $z = 2$: the formula gives $2(1.6)/(4 - 1.6 + 0.64) = 3.2/3.04 = 1.052632$; summing $\sum_{n=0}^{80} 0.8^n \cos(\pi n/3)\, 2^{-n}$ numerically gives 1.052632. ✓

Worked Example 17.8 — Using several properties together

Find $X(z)$ for $x[n] = n\,(0.5)^{n-2} u[n-2]$.

Step 1. Let $g[n] = (0.5)^{n-2}u[n-2]$, the sequence $0.5^n u[n]$ delayed by 2. Then $G(z) = z^{-2} \cdot \dfrac{z}{z-0.5} = \dfrac{1}{z(z-0.5)}$, $\lvert z\rvert > 0.5$.

Step 2. $x[n] = n\,g[n]$, so

$$X(z) = -z\,\frac{d}{dz}\left[\frac{1}{z^2 - 0.5z}\right] = -z \cdot \frac{-(2z - 0.5)}{(z^2 - 0.5z)^2} = \frac{2z - 0.5}{z(z-0.5)^2}, \quad \lvert z\rvert > 0.5.$$

Check by leading coefficients. $x[0] = x[1] = 0$, $x[2] = 2$, $x[3] = 3(0.5) = 1.5$. Expanding $X(z)$ for large z: $X = 2z^{-2}\left(1 - \frac{0.25}{z}\right)\left(1 + \frac{1}{z} + \cdots\right) = 2z^{-2} + 1.5z^{-3} + \cdots$ ✓.

Worked Example 17.9 — Initial and final values without inversion

A causal sequence has $Y(z) = \dfrac{z^2}{(z-1)(z-0.5)}$. Find $y[0]$ and $\lim_{n\to\infty} y[n]$.

Initial value. $\lim_{z\to\infty} \dfrac{z^2}{z^2 - 1.5z + 0.5} = 1$, so $y[0] = 1$.

Final value. $(z-1)Y(z) = \dfrac{z^2}{z - 0.5}$ has its only pole at 0.5, inside the unit circle, so the theorem applies: $\lim_{z\to 1} \dfrac{z^2}{z-0.5} = \dfrac{1}{0.5} = 2$.

This Y is $\dfrac{z}{z-1} \cdot \dfrac{z}{z-0.5}$, the step response of $h[n] = 0.5^n u[n]$ (Example 17.3), whose values $1, 1.5, 1.75, \cdots \to 2$ confirm both results.

Common Pitfall — Dropping the ROC

Writing "$\mathcal{Z}\{x\} = z/(z-a)$" without an ROC is incomplete: Examples 17.4 and 17.5 show two different sequences with this transform. Tables in most texts list only causal sequences and silently assume the exterior ROC; when you invert, you must know whether that assumption is right for your problem.

17.3 Region of convergence

Why the ROC deserves its own section

Section 17.2 showed that $z/(z-a)$ is the transform of two different sequences. The ROC is what tells them apart, and it carries physical information: whether the sequence is right- or left-sided, whether the system it describes is causal, and whether it is stable. In continuous time the Laplace ROC is a vertical strip $\sigma_1 < \operatorname{Re} s < \sigma_2$; in discrete time it is an **annulus** $r_1 < |z| < r_2$, because the convergence of $\sum x[n]z^{-n}$ depends only on $|z|$.

The ROC is an annulus

Absolute convergence of $\sum_n x[n]z^{-n}$ means

$$\sum_{n=-\infty}^{\infty} |x[n]|\, r^{-n} < \infty, \qquad r = |z|.$$

The angle of z does not appear, so if one point on a circle centred at the origin is in the ROC, the whole circle is. Split the sum into the **causal part** $n \geq 0$ and the **anticausal part** $n < 0$:

$$\underbrace{\sum_{n=0}^{\infty} |x[n]|\, r^{-n}}_{\text{converges for } r > r_1} + \underbrace{\sum_{m=1}^{\infty} |x[-m]|\, r^{m}}_{\text{converges for } r < r_2}.$$

The first is a power series in $1/r$; by the root test (Ch. 4) it converges for $1/r < 1/r_1$, i.e. $r > r_1$, where

$$r_1 = \limsup_{n\to\infty} |x[n]|^{1/n}.$$

The second is a power series in r and converges for $r < r_2$, where $1/r_2 = \limsup_{m\to\infty} |x[-m]|^{1/m}$. Both must converge, so:

Shape of the region of convergence

The ROC of a Z-transform is an annulus centred at the origin,

$$R_x = \{\, z : \; r_1 < |z| < r_2 \,\}, \qquad 0 \leq r_1,\; r_2 \leq \infty,$$

possibly including one or both boundary circles, and possibly empty (when $r_1 \geq r_2$). The rate of growth of $x[n]$ as $n \to +\infty$ sets the inner radius r_1; the rate of growth as $n \to -\infty$ sets the outer radius r_2.

On the open annulus $X(z)$ is a convergent Laurent series and is therefore analytic (Ch. 18). An analytic function has no poles, which gives the next property.

Properties of the ROC

Properties of the ROC

1. **No poles inside.** The ROC contains no poles of $X(z)$. For rational $X(z)$ the ROC is bounded by poles (or extends to 0 or ∞).
2. **Finite-length sequences:** the ROC is the whole z-plane, except possibly $z = 0$ (if $x[n] \neq 0$ for some $n > 0$) and $z = \infty$ (if $x[n] \neq 0$ for some $n < 0$).
3. **Right-sided sequences:** the ROC is the **exterior** of a circle, $|z| > r_1$ — for rational X, outside the outermost pole. It includes $z = \infty$ if and only if the sequence is causal.
4. **Left-sided sequences:** the ROC is the **interior** of a circle, $|z| < r_2$ — for rational X, inside the innermost (non-zero) pole. It includes $z = 0$ if and only if the sequence is anticausal ($x[n] = 0$ for $n > 0$).
5. **Two-sided sequences:** the ROC is a **ring** $r_1 < |z| < r_2$ between two consecutive pole radii, or empty.
6. **Connectedness:** the ROC is a single connected region.

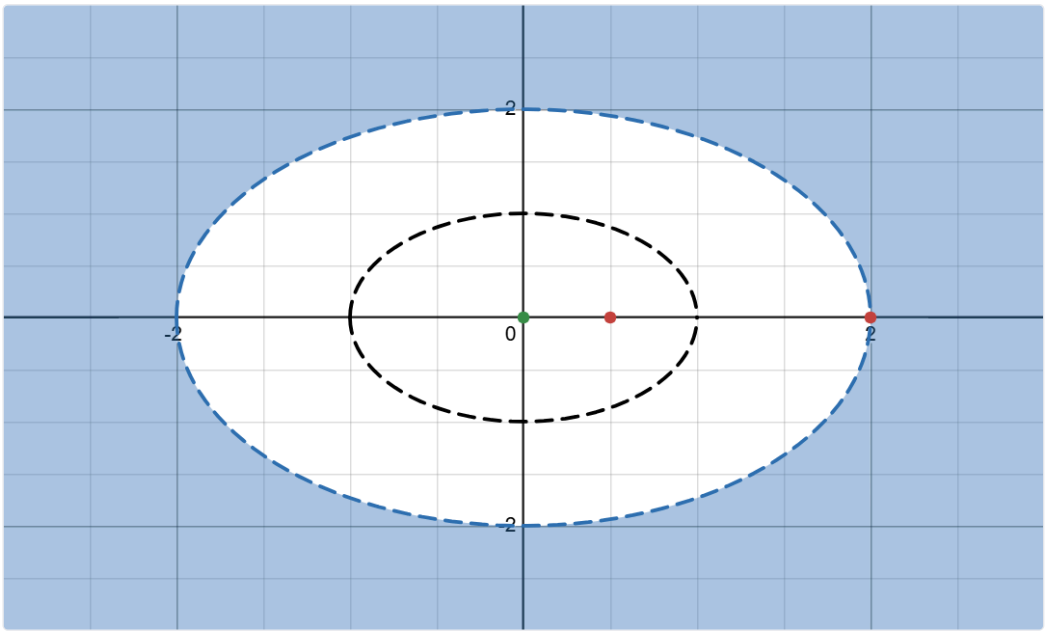
Proof of 3. If $x[n] = 0$ for $n < N_1$, the anticausal part has finitely many terms, so $r_2 = \infty$ (if $N_1 \geq 0$, even $z = \infty$ is allowed, because every term $x[n]z^{-n}$ with $n \geq 0$ stays finite as $z \to \infty$). Only r_1 is constrained: the ROC is $|z| > r_1$. Since there can be no poles in it, every pole has $|p| \leq r_1$, and the boundary must pass through the outermost pole. Property 4 is the mirror image. □

ROC sketches

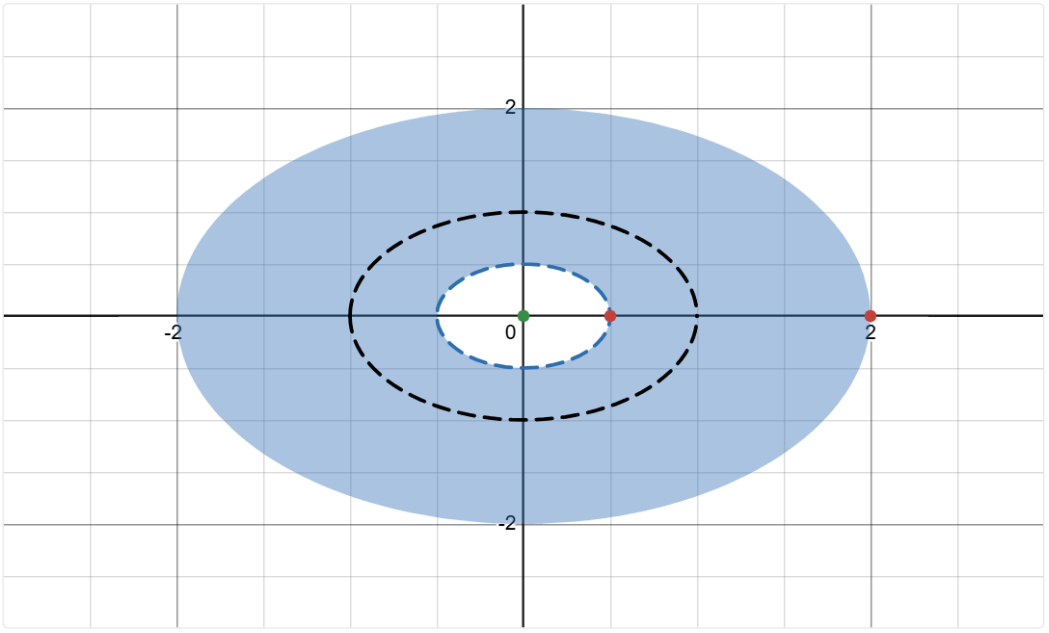
A sketch of the ROC consists of the pole–zero plot (poles $\times$, zeros $\circ$), the unit circle (for reference) and the shaded convergence region. Consider the rational function with poles at $z = 0.5$ and $z = 2$,

$$X(z) = \frac{z}{(z-0.5)(z-2)}.$$

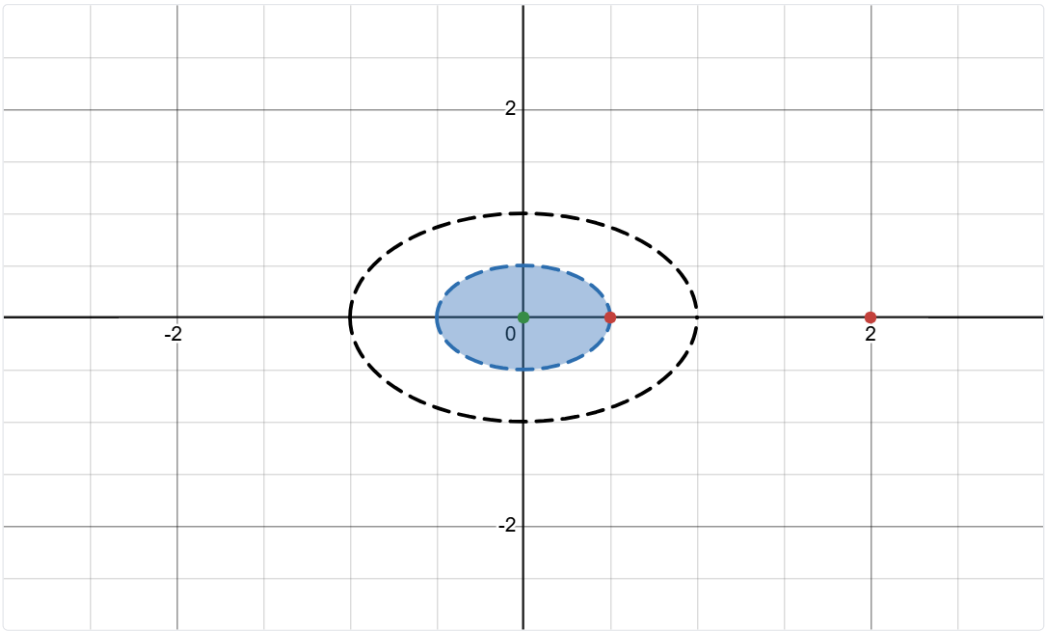
Its ROC must be an annulus bounded by pole radii, so there are exactly three possibilities.



ROC $|z| > 2$ (shaded): the right-sided (here causal) sequence $x[n] = \frac{2}{3}\left(2^n - 0.5^n\right) u[n]$. The ROC lies outside the outermost pole and excludes the unit circle (dashed), so the sequence grows without bound.



ROC $0.5 < |z| < 2$ (shaded ring): the two-sided sequence $x[n] = -\frac{2}{3}\,0.5^n u[n] - \frac{2}{3}\,2^n u[-n-1]$. The ring contains the unit circle, so this sequence is absolutely summable and has a DTFT.



ROC $|z| < 0.5$ (shaded disc): the left-sided sequence $x[n] = \frac{2}{3}\left(0.5^n - 2^n\right) u[-n-1]$, which blows up as $n \to -\infty$.

The three sequences are derived in Example 17.12 below; the point here is that one rational function has three inverse transforms, selected by the ROC.

Causality and stability read from the ROC

When $X(z) = H(z)$ is the transform of an impulse response, two system properties translate into ROC statements.

Causality and stability from the ROC

Let $h[n]$ have transform $H(z)$ with ROC R_h.

- The system is **causal** ($h[n] = 0$ for $n < 0$) if and only if R_h is the exterior of a circle *including* $z = \infty$. For rational $H(z)$: the ROC is outside the outermost pole, *and* the numerator degree does not exceed the denominator degree (in positive powers of z).
- The system is **BIBO stable** ($\sum |h[n]| < \infty$) if and only if R_h **includes the unit circle** $|z| = 1$.
- Consequently, a causal rational system is stable if and only if **all its poles lie strictly inside the unit circle**.

Proof of the stability statement. On $|z| = 1$, $\sum_n |h[n] z^{-n}| = \sum_n |h[n]|$. So the unit circle is in the ROC precisely when h is absolutely summable, which (§17.7) is precisely BIBO stability. □

The degree condition in the causality statement is what excludes $z = \infty$ from being a pole: $H(z) = z^2/(z - 0.5)$ has ROC $|z| > 0.5$ as a right-sided sequence, but it equals $z + 0.5 + \frac{0.25}{z - 0.5}$, whose polynomial part z is an advance $\delta[n+1]$. The sequence starts at $n = -1$: right-sided, but not causal.

Engineering Note — The unit circle is the frequency axis

Every real-time digital filter is causal, so its ROC is the exterior of its outermost pole. Stability then requires that exterior to contain the unit circle, i.e. every pole inside $|z| < 1$. This single picture — poles inside the circle — is the discrete-time version of "poles in the left half-plane". The distance of the outermost pole from the circle is the stability margin: a pole at radius 0.999 in a fixed-point implementation may cross the circle after coefficient quantisation.

Worked examples

Worked Example 17.10 — ROC of a sum of right-sided sequences

Find $X(z)$ and its ROC for $x[n] = (0.5)^n u[n] + \left(-\frac{1}{3}\right)^n u[n]$.

Step 1. Each term is right-sided:

$$(0.5)^n u[n] \leftrightarrow \frac{z}{z - 0.5}, \ |z| > 0.5; \qquad \left(-\tfrac{1}{3}\right)^n u[n] \leftrightarrow \frac{z}{z + \frac{1}{3}}, \ |z| > \tfrac{1}{3}.$$

Step 2. Add, over a common denominator:

$$X(z) = \frac{z(z + \frac{1}{3}) + z(z - 0.5)}{(z - 0.5)(z + \frac{1}{3})} = \frac{2z\left(z - \frac{1}{12}\right)}{(z - 0.5)(z + \frac{1}{3})}.$$

Step 3. ROC is the intersection, $|z| > 0.5$: outside the outermost pole, as it must be for a right-sided sequence. It contains the unit circle and $z = \infty$: the sequence is causal and absolutely summable.

Check: $X(\infty) = 2 = x[0] = 1 + 1$ ✓ (initial value theorem).

Worked Example 17.11 — The two-sided exponential $a^{|n|}$

Find the Z-transform of $x[n] = a^{|n|}$ for real a, and state when it exists.

Step 1. Split. $a^{|n|} = a^n u[n] + a^{-n} u[-n-1]$.

Step 2. Causal part. $a^n u[n] \leftrightarrow \dfrac{z}{z-a}$, ROC $|z| > |a|$.

Step 3. Anticausal part. $a^{-n} u[-n-1] = (1/a)^n u[-n-1]$. By Example 17.5 with base $1/a$, $-(1/a)^n u[-n-1] \leftrightarrow \dfrac{z}{z-1/a}$ for $|z| < 1/|a|$; hence $(1/a)^n u[-n-1] \leftrightarrow -\dfrac{z}{z-1/a}$.

Step 4. Combine.

$$X(z) = \frac{z}{z-a} - \frac{z}{z-1/a} = \frac{(a-1/a)\,z}{(z-a)(z-1/a)}, \qquad |a| < |z| < \frac{1}{|a|}.$$

Existence. The ring is non-empty only if $|a| < 1/|a|$, i.e. $|a| < 1$. For $|a| \geq 1$ the sequence grows (or fails to decay) in both directions and has **no** Z-transform. When it exists the ring always contains the unit circle, as it must for an absolutely summable sequence.

Check ($a = 0.5$, $z = 1$): $\sum_n 0.5^{|n|} = 1 + 2\sum_{n\geq 1} 0.5^n = 3$; the formula gives $(-1.5)(1)/((0.5)(-1)) = 3$ ✓.

Worked Example 17.12 — One formula, three sequences

For $X(z) = \dfrac{z}{(z-0.5)(z-2)}$, find the sequence for each possible ROC and say which is causal and which is stable.

Step 1. Partial fractions of $X(z)/z$ (method of §17.4):

$$\frac{X(z)}{z} = \frac{1}{(z-0.5)(z-2)} = \frac{-2/3}{z-0.5} + \frac{2/3}{z-2} \quad\Longrightarrow\quad X(z) = -\frac{2}{3}\frac{z}{z-0.5} + \frac{2}{3}\frac{z}{z-2}.$$

Step 2. Assign each pole's term according to the ROC. A pole *inside* the inner boundary of the ROC (the ROC lies outside it) gives a right-sided term $p^n u[n]$; a pole *outside* the outer boundary gives a left-sided term $-p^n u[-n-1]$.

ROC	pole 0.5	pole 2	$x[n]$	causal	stable
$\|z\| > 2$	right	right	$\frac{2}{3}\left(2^n - 0.5^n\right) u[n]$	yes	no
$0.5 < \|z\| < 2$	right	left	$-\frac{2}{3}\,0.5^n u[n] - \frac{2}{3}\,2^n u[-n-1]$	no	yes
$\|z\| < 0.5$	left	left	$\frac{2}{3}\left(0.5^n - 2^n\right) u[-n-1]$	no	no

Step 3. Interpret. No ROC makes this system both causal and stable, because one pole is outside the unit circle. The stable choice is two-sided and equals $-\frac{2}{3}\,0.5^{|n|}$ — compare Example 17.11 with $a = 0.5$, where X was -1.5 times this one.

Check (middle ROC): evaluating the inverse contour integral (§17.4) numerically on $|z| = 1$ gives $x[0] = -0.6667$, $x[1] = x[-1] = -0.3333$, $x[3] = x[-3] = -0.0833$, matching $-\frac{2}{3}(0.5)^{|n|}$.

Worked Example 17.13 — An empty ROC

Does $x[n] = 2^n u[n] - (0.5)^n u[-n-1]$ have a Z-transform?

The causal part needs $|z| > 2$; the anticausal part needs $|z| < 0.5$. The intersection is empty, so **no Z-transform exists** — even though the formal sum of the two rational expressions, $\frac{z}{z-2} + \frac{z}{z-0.5}$, can be written down. Likewise $x[n] = 1$ for all n (or $\cos\omega_0 n$ for all n) has no bilateral Z-transform: the causal part needs $|z| > 1$, the anticausal part $|z| < 1$. Such sequences are handled by the DTFT with impulses (as in §16.4) or, for $n \geq 0$ only, by the unilateral transform.

Common Pitfall — Choosing the ROC from the formula alone

Students often pick "$|z| >$ largest pole" automatically. That is right only if the sequence is known to be right-sided (e.g. a causal system). If instead you are told the system is *stable*, the ROC must contain the unit circle — which, with poles on both sides of it, produces a two-sided impulse response. Read the problem's physical constraints first, then choose the ROC.

17.4 Inverse Z-transform

The inversion integral

Recovering $x[n]$ from $X(z)$ is the step that turns an algebraic answer into a sequence you can plot or implement. The general formula is a contour integral, and every practical method is a shortcut for evaluating it.

Inverse Z-transform

If $X(z)$ has ROC R_x and C is any counter-clockwise circle $|z| = r$ lying in R_x, then

$$x[n] = \frac{1}{2\pi j} \oint_C X(z)\, z^{\,n-1}\, dz, \qquad n \in \mathbb{Z}.$$

Derivation. Substitute the series for X and integrate term by term (legitimate on a circle inside the ROC, where convergence is uniform):

$$\frac{1}{2\pi j} \oint_C \sum_k x[k] z^{-k} z^{n-1}\, dz = \sum_k x[k]\, \frac{1}{2\pi j} \oint_C z^{\,n-k-1}\, dz.$$

With $z = re^{j\theta}$, $dz = jz\, d\theta$, the inner integral is $\frac{r^{n-k}}{2\pi} \int_0^{2\pi} e^{j(n-k)\theta} d\theta = \delta[n-k]$. Only the $k = n$ term survives, leaving $x[n]$. $\square$

On the unit circle ($r = 1$, $z = e^{j\omega}$, $dz = jz\, d\omega$) the formula becomes the inverse DTFT,

$$x[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(e^{j\omega})\, e^{j\omega n}\, d\omega,$$

the discrete-time counterpart of the inverse Fourier integral of §16.2. The Z-transform and its inverse are simply the Laurent-series expansion of X in the annulus R_x and the formula for its coefficients — which is why the choice of annulus (the ROC) changes the answer.

There are four practical methods:

1. **Inspection** using the table of pairs and properties;
2. **Partial-fraction expansion**, for rational $X(z)$ — the workhorse;
3. **Power-series expansion**, including **long division** — gives numerical values sample by sample and handles non-rational X;
4. **Residues** — evaluates the inversion integral directly; elegant for closed-form answers, especially with repeated poles.

Method 1: partial fractions

For a rational $X(z) = N(z)/D(z)$, the aim is to write X as a sum of terms $\frac{z}{z-p}$ (and $\frac{z}{(z-p)^m}$ for repeated poles), each of which inverts by the table. Because the table entries carry a factor z in the numerator, the cleanest procedure expands $X(z)/z$, not $X(z)$.

Partial-fraction procedure (expansion of $X(z)/z$)

1. Write $X(z)$ in positive powers of z and factor the denominator: poles $p_1, \dots, p_K$.
2. Form $F(z) = X(z)/z$. If F is improper (numerator degree $\geq$ denominator degree), first divide out the polynomial part.
3. Expand $F(z) = \sum_i \dfrac{A_i}{z - p_i}$ (+ repeated-pole terms), with **cover-up** residues for simple poles

$$A_i = (z - p_i) F(z)\big|_{z = p_i},$$

and for a pole of order m at p, the coefficients of $\frac{1}{(z-p)^k}$,

$$C_k = \frac{1}{(m-k)!} \frac{d^{\,m-k}}{dz^{\,m-k}} \Big[(z-p)^m F(z) \Big]\Big|_{z=p}, \quad k = 1, \dots, m.$$

4. Multiply back by z: $X(z) = \sum_i A_i \dfrac{z}{z - p_i} + \cdots$.
5. Invert each term using the ROC: for $|z| > |p|$, $\frac{z}{z-p} \to p^n u[n]$; for $|z| < |p|$, $\frac{z}{z-p} \to -p^n u[-n-1]$. Repeated poles use $\dfrac{z}{(z-p)^2} \to n\, p^{\,n-1} u[n]$ and $\dfrac{z}{(z-p)^3} \to \frac{n(n-1)}{2} p^{\,n-2} u[n]$ (right-sided case).

Dividing by z first has two advantages: a pole at $z = 0$, if created, simply produces a $\delta[n]$ term; and no separate polynomial division is needed when the numerator and denominator of X have equal degree — the common case for causal systems.

An equivalent route, preferred in DSP texts, expands X in powers of $w = z^{-1}$: $X = \sum_i A_i/(1 - p_i z^{-1})$ with $A_i = (1 - p_i z^{-1}) X\big|_{z = p_i}$. Both give the same coefficients when X is proper in z^{-1}.

Worked Example 17.14 — Distinct real poles

Find the causal sequence with $X(z) = \dfrac{z}{(z - 0.5)(z - 0.25)}$.

Step 1. $F(z) = \dfrac{X}{z} = \dfrac{1}{(z - 0.5)(z - 0.25)}$.

Step 2. Cover-up. $A_1 = \dfrac{1}{0.5 - 0.25} = 4$, $A_2 = \dfrac{1}{0.25 - 0.5} = -4$.

Step 3. $X(z) = 4\dfrac{z}{z - 0.5} - 4\dfrac{z}{z - 0.25}$; causal means $|z| > 0.5$, so both terms are right-sided:

$$x[n] = 4\left[(0.5)^n - (0.25)^n\right] u[n].$$

Check: $x[0] = 0$ (and $X(\infty) = 0$ ✓); $x[1] = 4(0.25) = 1$, $x[2] = 4(0.25 - 0.0625) = 0.75$. Running the recursion $x[n] = 0.75x[n-1] - 0.125x[n-2] + \delta[n-1]$ gives $0,\ 1,\ 0.75,\ 0.4375,\ 0.2344, \dots$, identical to the formula.

Worked Example 17.15 — A repeated pole

Find the causal inverse of $X(z) = \dfrac{z^2}{(z-1)(z-0.5)^2}$.

Step 1. $F(z) = \dfrac{z}{(z-1)(z-0.5)^2} = \dfrac{A}{z-1} + \dfrac{B}{z-0.5} + \dfrac{C}{(z-0.5)^2}$.

Step 2. Simple pole. $A = \left.\dfrac{z}{(z-0.5)^2}\right|_{z=1} = \dfrac{1}{0.25} = 4$.

Step 3. Double pole. With $G(z) = (z-0.5)^2 F(z) = \dfrac{z}{z-1}$:

$$C = G(0.5) = \frac{0.5}{-0.5} = -1, \qquad B = G'(0.5) = \left.\frac{-1}{(z-1)^2}\right|_{0.5} = -4.$$

Step 4. $X(z) = 4\dfrac{z}{z-1} - 4\dfrac{z}{z-0.5} - \dfrac{z}{(z-0.5)^2}$, and with $\dfrac{z}{(z-0.5)^2} \leftrightarrow n(0.5)^{n-1}u[n] = 2n(0.5)^n u[n]$:

$$x[n] = \left[4 - 4(0.5)^n - 2n(0.5)^n\right] u[n].$$

Check: $x[0..5] = 0,\ 1,\ 2,\ 2.75,\ 3.25,\ 3.5625$ from both the formula and a direct recursion; $x[n] \to 4$, which the final value theorem confirms: $\lim_{z\to 1}(z-1)X = 1/0.25 = 4$.

Worked Example 17.16 — Complex-conjugate poles

Find the causal inverse of $X(z) = \dfrac{z}{z^2 - z + 0.5}$.

Step 1. Poles. $z = \frac{1}{2} \pm \frac{1}{2}j = \frac{1}{\sqrt{2}}e^{\pm j\pi/4}$: radius $r = 1/\sqrt{2} \approx 0.707$, angle $\omega_0 = \pi/4$.

Step 2. Match the damped-sine pair $\dfrac{zr\sin\omega_0}{z^2 - 2rz\cos\omega_0 + r^2}$. Here $2r\cos\omega_0 = 2 \cdot \frac{1}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} = 1$ ✓ and $r^2 = 0.5$ ✓, while $r\sin\omega_0 = 0.5$. So $X(z) = 2 \times \dfrac{0.5\,z}{z^2 - z + 0.5}$ and

$$x[n] = 2\left(\tfrac{1}{\sqrt{2}}\right)^n \sin\left(\tfrac{\pi n}{4}\right) u[n].$$

Alternative (complex partial fractions). $F = X/z = \dfrac{1}{(z-p)(z-p^*)}$, $A = \dfrac{1}{p - p^*} = \dfrac{1}{j} = -j$, and the conjugate pole has $A^* = j$. Then $x[n] = -jp^n + jp^{*n} = 2\,\mathrm{Im}\{p^n\} = 2r^n\sin(\omega_0 n)$, the same answer. In general a conjugate pair with residues A, A^* contributes $2|A|r^n\cos(\omega_0 n + \angle A)\,u[n]$.

Check: $x[0..7] = 0,\ 1,\ 1,\ 0.5,\ 0,\ -0.25,\ -0.25,\ -0.125$, agreeing with the recursion $x[n] = x[n-1] - 0.5x[n-2] + \delta[n-1]$.

Worked Example 17.17 — Equal-degree numerator and a pole at the origin

Find the causal inverse of $X(z) = \dfrac{z^2 + 1}{z^2 - 0.25}$.

Step 1. $F(z) = \dfrac{z^2+1}{z(z-0.5)(z+0.5)}$: dividing by z creates a pole at 0, and F is now proper.

Step 2. Cover-up. $A_0 = \dfrac{1}{-0.25} = -4$, $A_{0.5} = \dfrac{1.25}{0.5 \cdot 1} = 2.5$, $A_{-0.5} = \dfrac{1.25}{(-0.5)(-1)} = 2.5$.

Step 3. $X(z) = -4 + 2.5\dfrac{z}{z-0.5} + 2.5\dfrac{z}{z+0.5}$, so

$$x[n] = -4\,\delta[n] + 2.5\left[(0.5)^n + (-0.5)^n\right] u[n].$$

The two exponentials cancel at odd n and add at even n: $x = 1,\ 0,\ 1.25,\ 0,\ 0.3125,\ 0, \ldots$.

Check: in powers of z^{-1}, $X = \dfrac{1 + z^{-2}}{1 - 0.25z^{-2}} = (1 + z^{-2})(1 + 0.25z^{-2} + 0.0625z^{-4} + \cdots) = 1 + 1.25z^{-2} + 0.3125z^{-4} + \cdots$ ✓.

Method 2: power series and long division

Since $X(z) = \sum x[n]z^{-n}$, any method that expands X as a power series in the ROC reads off $x[n]$ as the coefficients. For rational X the expansion is obtained by **polynomial long division**:

- For a **right-sided** (causal) ROC $|z| > r_1$, expand in *descending* powers of z, i.e. ascending powers of z^{-1}: arrange numerator and denominator in decreasing powers of z and divide.
- For a **left-sided** ROC $|z| < r_2$, expand in *ascending* powers of z: arrange both polynomials in increasing powers of z and divide.

Long division does not normally produce a closed form, but it is foolproof for the first few samples, it is how a computer "inverts" (it is the recursion of the difference equation), and it is the method of choice for checking a partial-fraction answer.

Worked Example 17.18 — Causal long division

Find the first four samples of the causal sequence with $X(z) = \dfrac{z}{z^2 - 0.75z + 0.125}$ (Example 17.14).

Divide z by $z^2 - 0.75z + 0.125$ in descending powers:

Step	Quotient term	Remainder after subtraction
$z \div z^2$	z^{-1}	$z - (z - 0.75 + 0.125z^{-1}) = 0.75 - 0.125z^{-1}$
$0.75 \div z^2$	$0.75z^{-2}$	$-0.125z^{-1} - (-0.5625z^{-1} + 0.09375z^{-2}) = 0.4375z^{-1} - 0.09375z^{-2}$
$0.4375z^{-1} \div z^2$	$0.4375z^{-3}$	$\dots$

So $X = 0 + z^{-1} + 0.75z^{-2} + 0.4375z^{-3} + \cdots$, giving $x[0..3] = 0,\ 1,\ 0.75,\ 0.4375$ — exactly the partial-fraction result.

Worked Example 17.19 — Anticausal long division

Expand $X(z) = \dfrac{z}{z - a}$ with ROC $|z| < |a|$.

Arrange in ascending powers of z: $\dfrac{z}{-a + z}$. Dividing, the first quotient term is $z/(-a) = -a^{-1}z$; the remainder is $z - (-a^{-1}z)(-a + z) = a^{-1}z^2$; the next quotient term is $-a^{-2}z^2$, and so on:

$$X(z) = -a^{-1}z - a^{-2}z^2 - a^{-3}z^3 - \cdots = \sum_{n=-\infty}^{-1} (-a^n)\, z^{-n}.$$

Hence $x[n] = -a^n u[-n-1]$, in agreement with Example 17.5.

Non-rational transforms are inverted by known series. The logarithm is the classic case.

Worked Example 17.20 — A logarithmic transform

Find the right-sided $x[n]$ with $X(z) = \ln\left(1 + az^{-1}\right)$, $|z| > |a|$.

Use $\ln(1+w) = \sum_{n=1}^{\infty} \dfrac{(-1)^{n+1}}{n} w^n$ for $|w| < 1$ with $w = az^{-1}$ (valid exactly when $|z| > |a|$):

$$X(z) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1} a^n}{n} z^{-n} \quad \Longrightarrow \quad x[n] = \frac{(-1)^{n+1} a^n}{n}\, u[n-1].$$

Cross-check via the differentiation property: $-z\,X'(z) = \dfrac{az^{-1}}{1 + az^{-1}} = \dfrac{a}{z + a}$, whose inverse is $a(-a)^{n-1}u[n-1]$; dividing by n reproduces $x[n]$. Sequences of this type appear in cepstral analysis of speech and echo signals.

Method 3: residues

When $X(z)$ is rational, the integrand $X(z)z^{n-1}$ of the inversion integral is analytic everywhere except at finitely many poles, and the residue theorem (Ch. 18) evaluates the integral as a sum.

Residue formula for the inverse Z-transform

$$x[n] = \sum_{\text{poles } p_k \text{ inside } C} \operatorname{Res}_{z=p_k} \left[X(z)\, z^{n-1} \right],$$

where C is a circle in the ROC. For a pole of order m at p,

$$\operatorname{Res}_{z=p} F(z) = \frac{1}{(m-1)!} \frac{d^{m-1}}{dz^{m-1}} \Big[(z-p)^m F(z) \Big] \Big|_{z=p}; \qquad m = 1: \ \operatorname{Res} = (z-p)F(z)|_{z=p}.$$

Two practical remarks:

- For a **causal** X and $n \geq 0$, the poles inside C are just the poles of X; but for $n < 0$ the factor z^{n-1} adds a pole of order $1 - n$ at the origin. Rather than computing those awkward residues, use the fact that the sum of all residues, including the one at infinity, is zero: $x[n] = -\sum(\text{residues outside } C)$. For a causal X there are no poles outside C and, for $n < 0$, no residue at infinity, so $x[n] = 0$ — confirming causality.
- Even for $n \geq 0$, a factor z^{n-1} with $n = 0$ creates a pole at $z = 0$ if $X(0) \neq 0$. That is the $n = 0$ case requiring care; the $X(z)/z$ partial-fraction method handles it automatically.

Worked Example 17.21 — Residues for simple poles

Invert $X(z) = \dfrac{z}{(z-0.5)(z-0.25)}$, $|z| > 0.5$, by residues.

For $n \geq 0$, $X(z)z^{n-1} = \dfrac{z^n}{(z-0.5)(z-0.25)}$ has poles only at 0.5 and 0.25 (no pole at the origin, because the factor z in X cancels the z^{-1}):

$$\text{Res}_{0.5} = \frac{0.5^n}{0.25} = 4(0.5)^n, \qquad \text{Res}_{0.25} = \frac{0.25^n}{-0.25} = -4(0.25)^n.$$

Sum: $x[n] = 4(0.5^n - 0.25^n)$ for $n \geq 0$. For $n < 0$ there are no poles outside C (taken just larger than 0.5), so $x[n] = 0$. Same as Example 17.14.

Worked Example 17.22 — Residues for a repeated pole, and the $n = 0$ subtlety

(a) Invert $X(z) = \dfrac{z}{(z-a)^2}$, $|z| > |a|$.

For $n \geq 0$, $Xz^{n-1} = \dfrac{z^n}{(z-a)^2}$ has a double pole at a:

$$x[n] = \left.\frac{d}{dz} z^n\right|_{z=a} = n\,a^{n-1}, \qquad n \geq 0,$$

confirming the table entry $z/(z-a)^2 \leftrightarrow na^{n-1}u[n]$ with no differentiation of transforms needed.

(b) Invert $X(z) = \dfrac{1}{z-0.5}$, $|z| > 0.5$. Here $Xz^{n-1} = \dfrac{z^{n-1}}{z-0.5}$.

- $n \geq 1$: only the pole at 0.5; $x[n] = 0.5^{n-1}$.
- $n = 0$: $\dfrac{1}{z(z-0.5)}$ has poles at 0 and 0.5, with residues $\dfrac{1}{-0.5} = -2$ and $\dfrac{1}{0.5} = 2$. Sum: $x[0] = 0$.

So $x[n] = 0.5^{n-1}u[n-1]$ — the delayed geometric sequence, as the shift property predicts ($z^{-1} \cdot \frac{z}{z-0.5}$). Forgetting the pole at the origin would give the wrong value $x[0] = 2$.

Comparing the methods

Method	Gives	Best for	Weakness
Inspection / table	closed form	standard shapes, combined with properties	needs recognition
Partial fractions	closed form	any rational X; two-sided ROCs	repeated and complex poles need care
Long division	numbers, sample by sample	checking, first few samples, computer implementation	no closed form; errors accumulate by hand
Power series	closed form or numbers	non-rational X (logs, exponentials)	requires a known series
Residues	closed form	repeated poles; theory	pole at origin for small n

Common Pitfall — Expanding $X(z)$ instead of $X(z)/z$

Expanding $X(z) = \frac{z}{(z-0.5)(z-0.25)}$ directly gives $\frac{2}{z-0.5} - \frac{1}{z-0.25}$, whose terms are $\frac{1}{z-p} = z^{-1}\frac{z}{z-p} \leftrightarrow p^{n-1}u[n-1]$ — correct, but only if you remember the delay. Inverting $\frac{2}{z-0.5}$ as "$2(0.5)^n$" is a classic one-sample error. Dividing by z first avoids it.

Engineering Note — Numerical inversion

In software, a rational $X(z)$ in powers of z^{-1} is inverted by running the difference equation it defines with an impulse input (MATLAB `impz`, SciPy `signal.dimpulse` or `lfilter(b, a, impulse)`), and partial fractions are computed by `residuez`. Root-finding for high-order denominators is ill-conditioned; for orders above about ten, factor the filter into second-order sections rather than computing all poles of the full polynomial.

17.5 Difference equations

Where difference equations come from

A **linear constant-coefficient difference equation** (LCCDE) relates the present output of a discrete-time system to past outputs and present and past inputs:

$$\sum_{k=0}^{N} a_k\, y[n-k] = \sum_{k=0}^{M} b_k\, x[n-k], \qquad a_0 \neq 0.$$

The **order** is N, the number of past outputs the system remembers. Difference equations arise in three ways that an electrical engineer meets constantly:

- **By design**: a digital filter *is* its difference equation; the coefficients a_k, b_k are what the designer chooses and the processor stores.
- **By discretisation**: replacing derivatives in a differential equation by finite differences (Ch. 22) — for instance a forward-Euler model of an RC circuit — produces an LCCDE.
- **By counting**: recurrences in sampled-data control, compound-interest-like growth, ladder networks of identical sections and combinatorial counts (Fibonacci) are naturally indexed by an integer.

Normalising so that $a_0 = 1$, the equation can be solved for $y[n]$:

$$y[n] = -\sum_{k=1}^{N} a_k\, y[n-k] + \sum_{k=0}^{M} b_k\, x[n-k].$$

This is a **recursion**: given N initial values $y[-1], \dots, y[-N]$ and the input, it computes $y[0], y[1], \dots$ one after another. Unlike a differential equation, a difference equation can therefore always be "solved" numerically with nothing more than multiplication and addition. What the Z-transform supplies is the **closed form** — the formula valid for every n at once — and with it insight into the modes, stability and steady state.

The unilateral shift theorem

The bilateral shift rule $x[n-1] \leftrightarrow z^{-1}X(z)$ assumes knowledge of the whole sequence. In an initial-value problem we know $y[n]$ for $n \geq 0$ only through the equation, plus a few stored values $y[-1], y[-2], \dots$. The unilateral transform keeps exactly this information.

Unilateral time-shift (delay and advance)

With $\mathcal{Y}(z) = \sum_{n\geq 0} y[n] z^{-n}$:

$$\begin{aligned}
y[n-1] &\longleftrightarrow z^{-1}\mathcal{Y}(z) + y[-1],\\
y[n-2] &\longleftrightarrow z^{-2}\mathcal{Y}(z) + z^{-1}y[-1] + y[-2],\\
y[n-k] &\longleftrightarrow z^{-k}\mathcal{Y}(z) + \sum_{m=1}^{k} y[-m]\, z^{-(k-m)},\\
y[n+1] &\longleftrightarrow z\,\mathcal{Y}(z) - z\,y[0],\\
y[n+2] &\longleftrightarrow z^{2}\mathcal{Y}(z) - z^{2}y[0] - z\,y[1].
\end{aligned}$$

Derivation for one delay. $\sum_{n\geq 0} y[n-1]z^{-n} = y[-1] + \sum_{n\geq 1} y[n-1]z^{-n} = y[-1] + z^{-1}\sum_{m\geq 0} y[m]z^{-m}$. *For one advance:* $\sum_{n\geq 0} y[n+1]z^{-n} = z\sum_{m\geq 1} y[m]z^{-m} = z(\mathcal{Y} - y[0])$. The others follow by repeating. □

The parallel with the Laplace derivative rule $\mathcal{L}\{\dot y\} = sY - y(0^-)$ is exact: delays bring in *past* values ($y[-1]$, $y[-2]$), advances bring in *initial* values ($y[0]$, $y[1]$). Use the delay form when the equation is written with $y[n-k]$ and the data are $y[-1], y[-2], \dots$; use the advance form when it is written with $y[n+k]$ and the data are $y[0], y[1], \dots$.

For a **causal input** applied at $n = 0$, $x[-1] = x[-2] = \cdots = 0$, so the input terms shift without extra terms.

The solution procedure

Solving an LCCDE with the unilateral Z-transform

1. Take the unilateral transform of every term, using the shift theorem to bring in the initial conditions.
2. Solve the resulting **algebraic** equation for $\mathcal{Y}(z)$.
3. Invert by partial fractions of $\mathcal{Y}(z)/z$ (ROC: exterior of the outermost pole, since y is considered for $n \geq 0$).
4. Check $y[0]$ (and $y[1]$) against a direct run of the recursion.

Step 2 always produces the structure

$$\mathcal{Y}(z) = \underbrace{\frac{B(z)}{A(z)}\,\mathcal{X}(z)}_{\text{zero-state response}} + \underbrace{\frac{C(z)}{A(z)}}_{\text{zero-input response}}, \qquad A(z) = \sum_{k=0}^{N} a_k z^{-k}, \quad B(z) = \sum_{k=0}^{M} b_k z^{-k},$$

where $C(z)$ is a polynomial built from the initial conditions. The **zero-state response** (ZSR) is what the input produces from rest; the **zero-input response** (ZIR) is what the stored initial conditions produce with no input. Both share the denominator $A(z)$, whose roots — the **characteristic roots** or **natural modes** — are the same as those of the classical characteristic equation $\lambda^N + a_1\lambda^{N-1} + \cdots + a_N = 0$. The ratio B/A is the system function $H(z)$ of §17.6.

A second, equally useful split is into **natural** (transient) and **forced** (steady-state) parts: the natural response collects the terms from the poles of H, the forced response those from the poles of $\mathcal{X}$.

Worked examples

Worked Example 17.23 — First order with a step input

Solve $y[n] - 0.5\,y[n-1] = u[n]$ with $y[-1] = 1$.

Step 1. Transform. $\mathcal{Y} - 0.5\left(z^{-1}\mathcal{Y} + y[-1]\right) = \dfrac{z}{z-1}$.

Step 2. Solve. $\mathcal{Y}\left(1 - 0.5z^{-1}\right) = 0.5 + \dfrac{z}{z-1}$, so

$$\mathcal{Y}(z) = \underbrace{\frac{0.5z}{z-0.5}}_{\text{ZIR}} + \underbrace{\frac{z^2}{(z-1)(z-0.5)}}_{\text{ZSR}}.$$

Step 3. Invert. The ZIR is $0.5(0.5)^n = (0.5)^{n+1}$. For the ZSR, $\dfrac{z}{(z-1)(z-0.5)} = \dfrac{2}{z-1} - \dfrac{1}{z-0.5}$, so ZSR $= 2 - (0.5)^n$. Adding,

$$y[n] = 2 - (0.5)^n + (0.5)^{n+1} = 2 - (0.5)^{n+1}, \qquad n \geq 0.$$

Step 4. Check. Recursion: $y[0] = 0.5(1) + 1 = 1.5$, $y[1] = 0.5(1.5) + 1 = 1.75$, $y[2] = 1.875$; formula: $2 - 0.5 = 1.5$, $2 - 0.25 = 1.75$, $2 - 0.125 = 1.875$ ✓. The forced response is the constant $2 = H(1)$, the DC gain; the natural response $-(0.5)^{n+1}$ decays.

Worked Example 17.24 — Second order: ZIR, ZSR, natural and forced parts

Solve $y[n] - 0.75\,y[n-1] + 0.125\,y[n-2] = u[n]$ with $y[-1] = 1$, $y[-2] = 2$.

Step 1. Transform.

$$\mathcal{Y} - 0.75\left(z^{-1}\mathcal{Y} + 1\right) + 0.125\left(z^{-2}\mathcal{Y} + z^{-1}\cdot 1 + 2\right) = \frac{z}{z-1}.$$

Step 2. Collect. The initial-condition terms give $0.75 - 0.125z^{-1} - 0.25 = 0.5 - 0.125z^{-1}$, so

$$\mathcal{Y}\left(1 - 0.75z^{-1} + 0.125z^{-2}\right) = \frac{z}{z-1} + 0.5 - 0.125z^{-1}.$$

With $1 - 0.75z^{-1} + 0.125z^{-2} = (1 - 0.5z^{-1})(1 - 0.25z^{-1})$:

$$\mathcal{Y}_{\text{zi}} = \frac{0.5(1 - 0.25z^{-1})}{(1 - 0.5z^{-1})(1 - 0.25z^{-1})} = \frac{0.5z}{z - 0.5}, \qquad \mathcal{Y}_{\text{zs}} = \frac{z^3}{(z-1)(z-0.5)(z-0.25)}.$$

The initial conditions happen to cancel the 0.25 mode in the ZIR.

Step 3. Invert. ZIR: $0.5(0.5)^n$. ZSR: expanding $\mathcal{Y}_{\text{zs}}/z$ by cover-up,

$$A_1 = \frac{1}{0.5 \cdot 0.75} = \frac{8}{3}, \quad A_{0.5} = \frac{0.25}{(-0.5)(0.25)} = -2, \quad A_{0.25} = \frac{0.0625}{(-0.75)(-0.25)} = \frac{1}{3},$$

so ZSR $= \frac{8}{3} - 2(0.5)^n + \frac{1}{3}(0.25)^n$. Total:

$$y[n] = \underbrace{\tfrac{8}{3}}_{\text{forced}} \underbrace{- 1.5(0.5)^n + \tfrac{1}{3}(0.25)^n}_{\text{natural}}, \qquad n \geq 0.$$

Step 4. Check. Formula: $y[0] = 2.6667 - 1.5 + 0.3333 = 1.5$; $y[1] = 2.6667 - 0.75 + 0.0833 = 2.0$; $y[2] = 2.6667 - 0.375 + 0.0208 = 2.3125$. Recursion: $y[0] = 0.75(1) - 0.125(2) + 1 = 1.5$, $y[1] = 0.75(1.5) - 0.125(1) + 1 = 2.0$, $y[2] = 0.75(2) - 0.125(1.5) + 1 = 2.3125$ ✓. The steady state $8/3 = 1/(1 - 0.75 + 0.125) = H(1)$.

Worked Example 17.25 — The Fibonacci recurrence (advance form)

Solve $y[n+2] = y[n+1] + y[n]$ with $y[0] = 0$, $y[1] = 1$.

Step 1. Advance rule. $\left(z^2\mathcal{Y} - z^2 y[0] - z y[1]\right) = \left(z\mathcal{Y} - z y[0]\right) + \mathcal{Y}$, i.e. $z^2\mathcal{Y} - z = z\mathcal{Y} + \mathcal{Y}$.

Step 2. $\mathcal{Y}(z) = \dfrac{z}{z^2 - z - 1} = \dfrac{z}{(z-\varphi)(z-\psi)}$, with $\varphi = \dfrac{1+\sqrt{5}}{2} \approx 1.618$ and $\psi = \dfrac{1-\sqrt{5}}{2} \approx -0.618$.

Step 3. $\dfrac{\mathcal{Y}}{z} = \dfrac{1}{\varphi - \psi}\left(\dfrac{1}{z-\varphi} - \dfrac{1}{z-\psi}\right)$ with $\varphi - \psi = \sqrt{5}$, so

$$y[n] = \frac{\varphi^n - \psi^n}{\sqrt{5}} \qquad \text{(Binet's formula)}.$$

Check: $y[10] = (122.992 - 0.00813)/2.23607 = 55.000$ ✓. One characteristic root lies outside the unit circle, so the sequence grows geometrically, by the factor φ per step: as a "system" this recursion is unstable.

Worked Example 17.26 — Input at a natural frequency (discrete resonance)

Solve $y[n] - 0.5\,y[n-1] = (0.5)^n u[n]$ from rest.

$\mathcal{Y}(1 - 0.5z^{-1}) = \dfrac{z}{z-0.5}$, so $\mathcal{Y} = \dfrac{z^2}{(z-0.5)^2}$, a **double** pole: the input mode coincides with the natural mode. From the table ($m=2$): $\dfrac{z^2}{(z-a)^2} \leftrightarrow (n+1)a^n u[n]$, so

$$y[n] = (n+1)(0.5)^n, \qquad n \geq 0.$$

The factor $(n+1)$ is the discrete counterpart of the te^{-at} term in a continuous system driven at its own pole. *Check:* $y[0]=1$, $y[1] = 0.5(1)+0.5 = 1$, $y[2] = 0.5(1)+0.25 = 0.75$; formula $1,\ 1,\ 0.75$ ✓.

Worked Example 17.27 — Forward-Euler model of an RC low-pass circuit

An RC low-pass filter obeys $\tau\,\dot{v} = x - v$, $\tau = RC$. Approximating $\dot{v}(nT) \approx \left(v[n+1] - v[n]\right)/T$ gives

$$v[n+1] = \left(1 - \frac{T}{\tau}\right) v[n] + \frac{T}{\tau}\, x[n].$$

Find the step response for $\tau = 1$ ms, $T = 0.25$ ms, $v[0] = 0$, and compare with the exact samples $1 - e^{-nT/\tau}$.

Step 1. With $\alpha = T/\tau = 0.25$ and $x[n] = u[n]$, the advance rule gives $z\mathcal{V} - zv[0] = 0.75\mathcal{V} + 0.25\dfrac{z}{z-1}$, so

$$\mathcal{V}(z) = \frac{0.25z}{(z-1)(z-0.75)}.$$

Step 2. $\mathcal{V}/z = \dfrac{1}{z-1} - \dfrac{1}{z-0.75}$, so $v[n] = 1 - (0.75)^n$.

Step 3. Compare. The exact samples are $1 - (e^{-0.25})^n = 1 - (0.7788)^n$. At $n = 4$ ($t = \tau$): Euler gives 0.6836, exact 0.6321. The discrete pole 0.75 approximates the exact $e^{-T/\tau} = 0.7788$ — a first-order Taylor approximation of $z = e^{sT}$ (§17.7).

Step 4. Numerical stability. The pole $1 - T/\tau$ lies inside the unit circle only if $0 < T/\tau < 2$. With $T > 2\tau$ the simulation diverges although the circuit is perfectly stable — the origin of the step-size limits studied in Ch. 22.

Classical solution, for comparison

The method of undetermined coefficients works for difference equations exactly as for differential equations: the homogeneous solution is $\sum c_i \lambda_i^n$ over the characteristic roots λ_i (with $n^k\lambda^n$ for repeated roots), a particular solution is guessed in the form of the input, and the constants are fitted to the initial conditions. For Example 17.24: characteristic roots $0.5, 0.25$; particular solution $y_p = K$ with $K(1 - 0.75 + 0.125) = 1$, $K = 8/3$; then $y = \frac{8}{3} + c_1(0.5)^n + c_2(0.25)^n$ fitted to $y[0] = 1.5$, $y[1] = 2$ gives $c_1 = -1.5$, $c_2 = \frac{1}{3}$. The Z-transform does the same work but builds the initial conditions in automatically and handles resonant inputs (Example 17.26) without a separate rule.

Common Pitfall — Using $y[0]$ where the delay rule needs $y[-1]$

The delay rule needs the values *before* the input is applied ($y[-1], y[-2]$); the advance rule needs $y[0], y[1]$. If a problem gives $y[0]$ for an equation written in delays, first back-solve the recursion for $y[-1]$ (with the known $x[0]$) or rewrite the equation in advance form. Mixing them silently shifts the answer by one sample.

Engineering Note — Initial conditions are register contents

In an implemented IIR filter, $y[-1]$ and $y[-2]$ are literally the numbers sitting in the delay registers when processing starts. Clearing them (zero state) at power-up gives the zero-state response; a filter that is switched between coefficient sets on the fly carries its old register contents as initial conditions, and the resulting zero-input transient is the "click" heard when audio equaliser settings change abruptly.

17.6 System-function representation

The system function

For an LTI system with impulse response $h[n]$, the convolution theorem gives $Y(z) = H(z)X(z)$. The transform of the impulse response therefore characterises the system completely, in the same way the transfer function $H(s)$ does in continuous time.

System function (transfer function)

The **system function** of a discrete-time LTI system is

$$H(z) = \mathcal{Z}\{h[n]\} = \frac{Y(z)}{X(z)} \quad \text{(zero initial state)},$$

together with its ROC. Evaluated on the unit circle, $H(e^{j\omega})$ is the **frequency response**.

For a system described by the LCCDE $\sum_{k=0}^{N} a_k y[n-k] = \sum_{k=0}^{M} b_k x[n-k]$, transforming with zero initial conditions (bilateral shift rule) gives

$$H(z) = \frac{\displaystyle\sum_{k=0}^{M} b_k z^{-k}}{\displaystyle\sum_{k=0}^{N} a_k z^{-k}} = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{a_0 + a_1 z^{-1} + \cdots + a_N z^{-N}}.$$

The coefficients of the difference equation are the coefficients of the numerator and denominator polynomials, read off directly. Going the other way, any rational $H(z)$ written in powers of z^{-1} is a difference equation: cross-multiply $Y \cdot A(z) = X \cdot B(z)$ and interpret each z^{-k} as a k-sample delay.

An LCCDE alone does not fix the ROC. If the system is known to be causal (the usual case), the ROC is the exterior of the outermost pole; if it is known to be stable, the ROC contains the unit circle. These two pieces of information, plus $H(z)$, determine $h[n]$ uniquely.

Pole–zero (factored) form

Factoring numerator and denominator,

$$H(z) = b_0\, z^{N-M}\, \frac{\prod_{k=1}^{M}(z - q_k)}{\prod_{k=1}^{N}(z - p_k)} \qquad (a_0 = 1),$$

with **zeros** q_k, **poles** p_k, and $|N - M|$ extra zeros or poles at $z = 0$. The **pole–zero plot** — poles marked $\times$, zeros $\circ$, with the unit circle drawn for reference — together with the gain b_0 is a complete description. It shows at a glance:

- **stability** of a causal system: all poles inside the unit circle;
- **modes** of the natural response: each pole $p = re^{j\theta}$ contributes r^n-weighted oscillation at θ rad/sample;
- **frequency selectivity**: poles near the unit circle at angle θ produce gain peaks near $\omega = \theta$; zeros on or near the circle produce nulls (§17.7).

Worked Example 17.28 — From difference equation to pole–zero plot

A causal system obeys $y[n] = 0.9\,y[n-1] - 0.81\,y[n-2] + x[n] - x[n-2]$. Find $H(z)$, its poles and zeros, and its ROC.

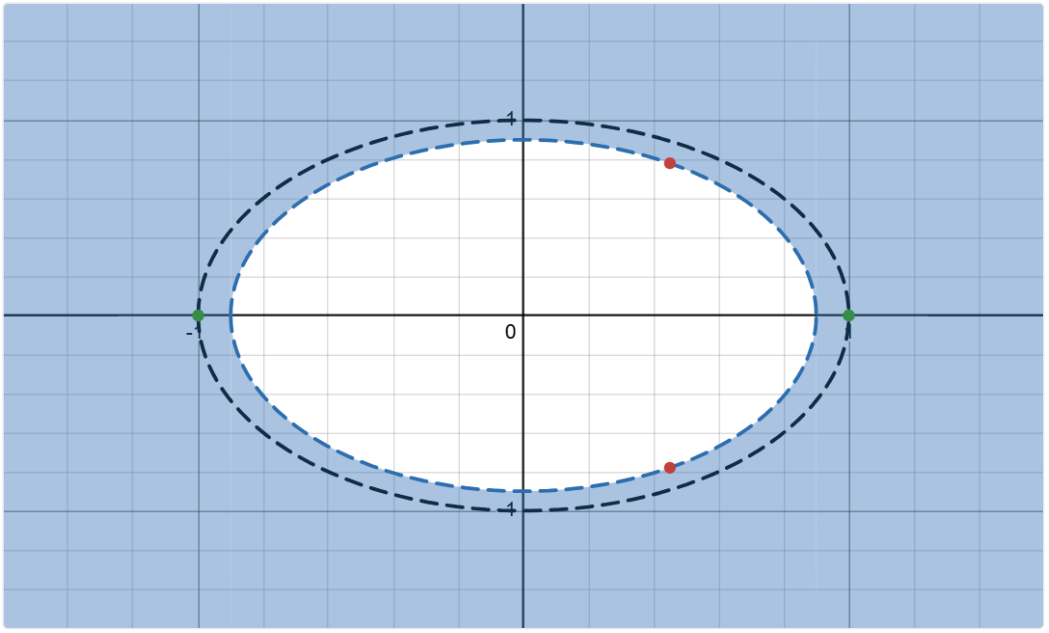
Step 1. Rearranged, $y[n] - 0.9y[n-1] + 0.81y[n-2] = x[n] - x[n-2]$, so

$$H(z) = \frac{1 - z^{-2}}{1 - 0.9z^{-1} + 0.81z^{-2}} = \frac{z^2 - 1}{z^2 - 0.9z + 0.81}.$$

Step 2. Zeros: $z^2 = 1$, i.e. $z = \pm 1$ — on the unit circle at $\omega = 0$ and $\omega = \pi$.

Step 3. Poles: $z = \dfrac{0.9 \pm \sqrt{0.81 - 3.24}}{2} = 0.45 \pm j0.7794 = 0.9e^{\pm j\pi/3}$ (check: $2r\cos\theta = 2(0.9)(0.5) = 0.9$ ✓, $r^2 = 0.81$ ✓).

Step 4. ROC. Causal $\Rightarrow |z| > 0.9$, which contains the unit circle: the system is stable. The zeros block DC and $\omega = \pi$; the poles near the circle at $\pm 60°$ boost $\omega \approx \pi/3$. This is a **second-order band-pass resonator**; its magnitude response is drawn in §17.7.



Pole–zero plot of $H(z) = (z^2 - 1)/(z^2 - 0.9z + 0.81)$ with the causal ROC $|z| > 0.9$ shaded. Poles (red) at radius 0.9 and angle $\pm\pi/3$; zeros (green) on the unit circle at ± 1.

FIR and IIR systems

FIR and IIR

A system is **finite impulse response (FIR)** if $h[n]$ has finitely many non-zero samples. For a causal FIR system $H(z) = \sum_{k=0}^{M} b_k z^{-k}$: all poles are at $z = 0$, so an FIR system is always stable. Its difference equation has no feedback: $y[n] = \sum_k b_k x[n-k]$, and $h[n] = b_n$.

A system is **infinite impulse response (IIR)** if $h[n]$ has infinitely many non-zero samples — for rational H, when there is at least one pole not cancelled by a zero away from the origin. IIR systems need feedback ($a_k \neq 0$ for some $k \geq 1$) and may be unstable.

Worked Example 17.29 — The moving-average filter: FIR with a recursive form

The 4-point moving average is $y[n] = \frac{1}{4}\left(x[n] + x[n-1] + x[n-2] + x[n-3]\right)$.

Step 1. $H(z) = \frac{1}{4}\left(1 + z^{-1} + z^{-2} + z^{-3}\right)$. By the geometric sum,

$$H(z) = \frac{1}{4}\,\frac{1 - z^{-4}}{1 - z^{-1}} = \frac{1}{4}\,\frac{z^4 - 1}{z^3(z - 1)}.$$

Step 2. Zeros: the fourth roots of unity $1, j, -1, -j$; **poles:** three at $z = 0$ and one at $z = 1$. The pole at 1 cancels the zero at 1, leaving zeros at $\omega = \pm\pi/2$ and π on the unit circle — frequencies that are completely rejected.

Step 3. Recursive implementation. The ratio form corresponds to the difference equation $y[n] = y[n-1] + \frac{1}{4}\left(x[n] - x[n-4]\right)$: one addition and one subtraction per sample regardless of length (the **running-sum** or CIC structure), instead of M additions. Its impulse response is still finite, because the pole is cancelled.

Check: $|H(e^{j0})| = 1$ (unit DC gain), $|H(e^{j\pi/2})| = 0$, $|H(e^{j\pi/4})| = 0.653$.

From impulse response to system function, and back

Worked Example 17.30 — Identifying a system from its impulse response

A causal system has $h[n] = \left[2(0.5)^n - (0.25)^n\right] u[n]$. Find $H(z)$ and the difference equation.

Step 1.

$$H(z) = \frac{2z}{z - 0.5} - \frac{z}{z - 0.25} = \frac{z\left[2(z - 0.25) - (z - 0.5)\right]}{(z - 0.5)(z - 0.25)} = \frac{z^2}{z^2 - 0.75z + 0.125}.$$

Step 2. In powers of z^{-1}: $H = \dfrac{1}{1 - 0.75z^{-1} + 0.125z^{-2}}$, so

$$y[n] = 0.75\,y[n-1] - 0.125\,y[n-2] + x[n].$$

Check: $h[0] = 2 - 1 = 1$ and the recursion gives $h[0] = 1$; $h[1] = 1 - 0.25 = 0.75$ and the recursion gives $0.75(1) = 0.75$ ✓. This is the system of Example 17.24, whose step response had steady state $H(1) = 1/0.375 = 8/3$.

Block diagrams and realisations

Three primitives build every LCCDE: the **adder**, the **multiplier** (gain) and the **unit delay** z^{-1}. Because the same $H(z)$ can be wired in many ways, the choice of **realisation** (structure) matters for memory, arithmetic and — above all in fixed-point hardware — sensitivity to coefficient rounding.

Direct forms

Write $H(z) = B(z) \cdot \dfrac{1}{A(z)}$.

- **Direct form I** implements $B(z)$ (a tapped delay line on x, M delays) followed by $1/A(z)$ (a tapped delay line on y with feedback, N delays): $M + N$ delays.
- **Direct form II** reverses the order, $\dfrac{1}{A(z)}$ then $B(z)$. Both sections then delay the same intermediate signal $w[n]$, so the delay lines merge: $w[n] = x[n] - \sum_{k=1}^{N} a_k w[n-k]$, $y[n] = \sum_{k=0}^{M} b_k w[n-k]$ — only $\max(M, N)$ delays, the minimum possible (**canonical**).
- **Transposed direct form II** reverses every arrow and swaps inputs and outputs (transposition preserves H); it is often preferred in floating point because the adders see smaller dynamic range.

Writing the DF-II equations for Example 17.28 ($b = [1, 0, -1]$, $a = [1, -0.9, 0.81]$):

$$w[n] = x[n] + 0.9\,w[n-1] - 0.81\,w[n-2], \qquad y[n] = w[n] - w[n-2],$$

two delays (storing $w[n-1]$, $w[n-2]$), three multiplications and three additions per sample.

Cascade and parallel forms

- **Cascade (series) form:** factor $H(z) = G\prod_k H_k(z)$ into first- and second-order sections ("biquads"), each with real coefficients — complex-conjugate pole and zero pairs are kept together. This is the standard implementation of IIR filters of order above two.
- **Parallel form:** a partial-fraction expansion in z^{-1}, $H(z) = C + \sum_k \dfrac{\beta_{0k} + \beta_{1k}z^{-1}}{1 + \alpha_{1k}z^{-1} + \alpha_{2k}z^{-2}}$, sums the outputs of independent sections.

The reason for cascades is numerical: the roots of a high-degree polynomial are extremely sensitive to its coefficients (Ch. 22). A 10th-order narrow-band filter stored as one denominator polynomial may become unstable after rounding its coefficients to 16 bits, while the same filter as five biquads, each with its own well-conditioned quadratic, stays stable.

Interconnections

The algebra of system functions mirrors that of Laplace transfer functions:

Connection	System function
Cascade H_1 then H_2	$H_1(z)H_2(z)$ (order irrelevant for LTI)
Parallel	$H_1(z) + H_2(z)$
Negative feedback, forward G, feedback F	$\dfrac{G(z)}{1 + G(z)F(z)}$
Inverse system	$H^{-1}(z) = 1/H(z)$

Worked Example 17.31 — A digital feedback loop

A digital integrating controller with a one-sample computation delay has forward path $G(z) = \dfrac{Kz^{-1}}{1 - z^{-1}} = \dfrac{K}{z - 1}$ in a unity negative-feedback loop. Find the closed-loop system function, the range of K for stability, and the step response for $K = 0.5$.

Step 1.

$$T(z) = \frac{G}{1 + G} = \frac{K/(z-1)}{1 + K/(z-1)} = \frac{K}{z - 1 + K} = \frac{Kz^{-1}}{1 - (1-K)z^{-1}}.$$

Step 2. Stability. The single closed-loop pole is $z = 1 - K$; stability requires $|1 - K| < 1$, i.e. $0 < K < 2$. The loop is unstable for too much gain, as a sampled control loop always is — the computation delay limits the achievable bandwidth.

Step 3. Step response ($K = 0.5$, pole 0.5): $Y = \dfrac{0.5}{z - 0.5}\cdot\dfrac{z}{z-1}$, $Y/z = \dfrac{1}{z-1} - \dfrac{1}{z-0.5}$, so $y[n] = [1 - (0.5)^n]\,u[n]$, with zero steady-state error ($T(1) = 1$) thanks to the integrator.

Check: simulated outputs $0,\ 0.5,\ 0.75,\ 0.875,\ 0.9375$ ✓. With $K = 1$ the pole is at 0 and the output reaches 1 in one step and stays there (a **deadbeat** response, impossible in continuous time); with $K = 1.5$ the pole is at -0.5 and the response overshoots with alternating sign: $0,\ 1.5,\ 0.75,\ 1.125,\ 0.9375, \ldots$.

Inverse systems and minimum phase

The inverse of $H(z)$ has the zeros of H as its poles. For the inverse to be **both causal and stable**, those poles — the zeros of H — must lie inside the unit circle.

Minimum-phase system

A causal, stable rational system is **minimum phase** if all its zeros are also strictly inside the unit circle. Exactly the minimum-phase systems have causal, stable inverses.

For example $H(z) = \dfrac{1 - 0.5z^{-1}}{1 - 0.8z^{-1}}$ (zero 0.5, pole 0.8) is minimum phase; its inverse $\dfrac{1 - 0.8z^{-1}}{1 - 0.5z^{-1}}$ is causal and stable. By contrast $H(z) = 1 - 2z^{-1}$ (zero at 2) has the inverse $1/(1 - 2z^{-1})$, which is either causal and unstable (ROC $|z| > 2$) or stable and anticausal (ROC $|z| < 2$). Channel equalisers in communication receivers face exactly this choice, and solve it by allowing a delay.

Common Pitfall — Pole–zero cancellation hides instability

Cancelling a factor $(z - p)$ between numerator and denominator is legitimate algebra, but if $|p| \geq 1$ and the cancellation occurs between two separately built subsystems (e.g. an unstable plant and a controller zero placed on its pole), the internal signal still contains the growing mode p^n. Any mismatch — and there always is one in hardware — lets it appear at the output. Cancel unstable poles on paper only.

Engineering Note — Reading a filter specification sheet

Coefficients exported by filter-design tools come either as `(b, a)` polynomials, as `(z, p, k)` zeros, poles and gain, or as a matrix of second-order sections `sos`, one row $[b_0, b_1, b_2, 1, a_1, a_2]$ per biquad. All three describe the same $H(z)$; the `sos` form is the one to implement.

17.7 Discrete-time system analysis

This section collects the analysis questions that the system function answers: Is the system stable? How does it respond to sinusoids? What is its frequency response, and how can it be read from the pole–zero plot? And how does all of this relate to the continuous-time system that a digital system usually imitates or controls?

BIBO stability

BIBO stability of LTI systems

A discrete-time LTI system is bounded-input bounded-output stable if and only if its impulse response is absolutely summable:

$$S = \sum_{n=-\infty}^{\infty} |h[n]| < \infty.$$

Equivalently, the ROC of $H(z)$ contains the unit circle. For a **causal** system with rational $H(z)$: stable $\iff$ every pole satisfies $|p_k| < 1$.

Proof. **Sufficiency.** If $|x[n]| \le B$ then $|y[n]| = |\sum_k h[k]x[n-k]| \le B\sum_k |h[k]| = BS$. **Necessity.** Suppose $S = \infty$. For real h, choose the bounded input $x[k] = \operatorname{sgn}(h[-k])$ (with $\operatorname{sgn} 0 = 0$). Then $y[0] = \sum_k h[k]x[-k] = \sum_k |h[k]| = \infty$, so a bounded input produces an unbounded output. **Pole form.** A causal rational $h[n]$ is a finite sum of terms $c\,n^m p^n u[n]$. Each is absolutely summable iff $|p| < 1$ (the ratio test: $|(n+1)^m p^{n+1}|/|n^m p^n| \to |p|$). $\square$

Three cases are worth naming for causal systems:

Pole location	Natural response	Classification
all $\lvert p\rvert < 1$	decays geometrically	**stable**
simple poles on $\lvert z\rvert = 1$, none outside	bounded, non-decaying (constant, $(-1)^n$, sinusoid)	**marginally stable** — *not* BIBO stable
any $\lvert p\rvert > 1$, or repeated poles on $\lvert z\rvert = 1$	grows	**unstable**

The accumulator $H(z) = 1/(1 - z^{-1})$ is the canonical marginal case: its impulse response $u[n]$ is bounded, but the bounded step input produces the unbounded ramp $(n+1)u[n]$ — the double pole of $Y = z^2/(z-1)^2$ on the unit circle.

Stability tests without factoring

For high-order denominators, root finding is avoidable. Write the denominator in positive powers as $D(z) = z^N + a_1 z^{N-1} + \cdots + a_N$.

Necessary conditions (any order)

If all roots of the real monic polynomial $D(z)$ lie strictly inside the unit circle, then

$$D(1) > 0, \qquad (-1)^N D(-1) > 0, \qquad |a_N| < 1.$$

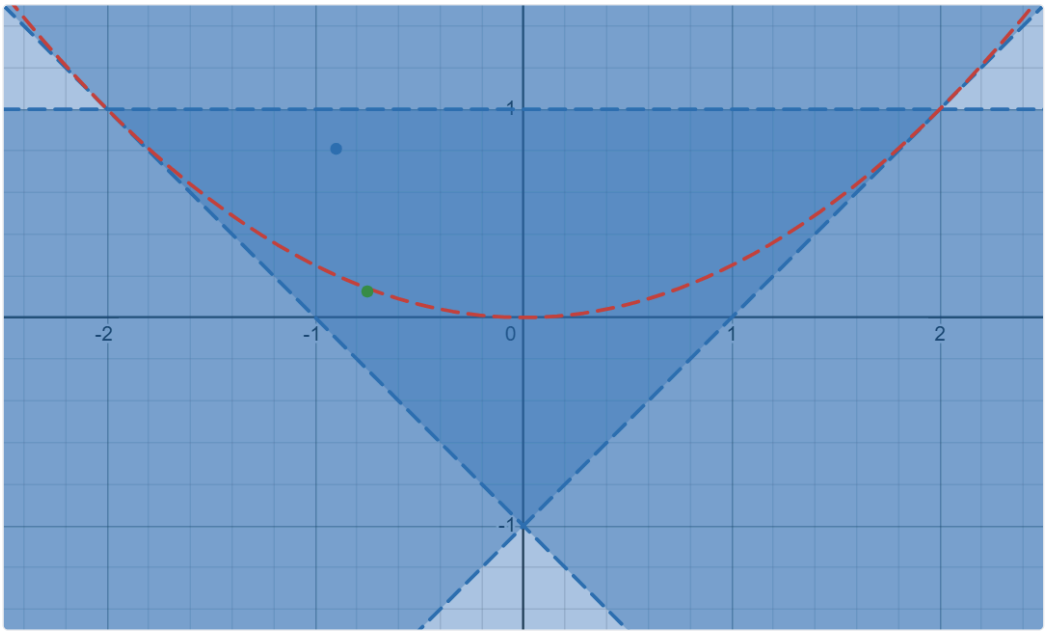
Reason. $D(1) = \prod(1 - p_k)$; for real roots in $(-1, 1)$ every factor is positive, and conjugate pairs contribute $|1 - p|^2 > 0$. Likewise $(-1)^N D(-1) = \prod(1 + p_k) > 0$. And $|a_N| = \prod |p_k| < 1$. $\square$

Second-order stability triangle

The polynomial $z^2 + a_1 z + a_2$ has both roots strictly inside the unit circle if and only if

$$|a_2| < 1 \qquad \text{and} \qquad |a_1| < 1 + a_2.$$

For $N = 2$ the necessary conditions above are also sufficient. The roots are complex for $a_2 > a_1^2/4$, in which case their radius is $\sqrt{a_2}$.



The stability triangle in the (a_1, a_2) plane for $z^2 + a_1 z + a_2$: the region where all three shadings overlap is stable. Above the dashed parabola $a_2 = a_1^2/4$ the poles are complex with radius $\sqrt{a_2}$; below it they are real. Both systems marked are stable.

For third and higher order, the **Jury** (or **Schur–Cohn**) table extends the test by a recursive construction; for a cubic $z^3 + a_1 z^2 + a_2 z + a_3$ it adds to the three necessary conditions the single extra inequality

$$\left|a_3^2 - 1\right| > \left|a_3 a_1 - a_2\right| .$$

The **bilinear map** $z = (1 + w)/(1 - w)$ sends the unit disc onto the left half w-plane, so applying the Routh–Hurwitz test of Ch. 14 to the transformed polynomial is an alternative route.

Worked Example 17.32 — Testing cubics

(a) $D(z) = z^3 - 1.2z^2 + 0.5z - 0.1$. Conditions: $D(1) = 1 - 1.2 + 0.5 - 0.1 = 0.2 > 0$ ✓; $-D(-1) = -(-1 - 1.2 - 0.5 - 0.1) = 2.8 > 0$ ✓; $|a_3| = 0.1 < 1$ ✓; $|0.01 - 1| = 0.99 > |0.12 - 0.5| = 0.38$ ✓. **Stable.** *Check:* the roots are 0.682 and $0.259 \pm j0.282$ (radius 0.383).

(b) $D(z) = z^3 - 1.5z^2 + 1.1z - 0.6$. $D(1) = 1 - 1.5 + 1.1 - 0.6 = 0$: the first condition fails with equality, so there is a root *on* the unit circle at $z = 1$. Dividing it out, $D = (z - 1)(z^2 - 0.5z + 0.6)$, whose quadratic factor has roots of radius $\sqrt{0.6} = 0.775$. **Marginally stable** (a simple pole at $z = 1$ makes the system an accumulator in disguise).

Frequency response

Sinusoidal steady state

Let a stable LTI system with real impulse response have frequency response $H(e^{j\omega}) = |H(e^{j\omega})| e^{j\angle H(e^{j\omega})}$. Then:

1. The eternal input $x[n] = e^{j\omega_0 n}$ produces exactly $y[n] = H(e^{j\omega_0})\, e^{j\omega_0 n}$.
2. The eternal input $x[n] = A\cos(\omega_0 n + \phi)$ produces

$$y[n] = A\left|H(e^{j\omega_0})\right| \cos\!\left(\omega_0 n + \phi + \angle H(e^{j\omega_0})\right) .$$

3. A causal input $A\cos(\omega_0 n + \phi)u[n]$ produces this response plus a transient made of the system's natural modes, which decays because the poles are inside the unit circle.

Derivation. Statement 1 is the eigenfunction property of §17.2 with $z = e^{j\omega_0}$ — the sum converges because the unit circle is in the ROC. For 2, write the cosine as $\frac{A}{2}\left(e^{j\phi}e^{j\omega_0 n} + e^{-j\phi}e^{-j\omega_0 n}\right)$ and use $H(e^{-j\omega_0}) = H^*(e^{j\omega_0})$ for real h. For 3, the partial-fraction expansion of $Y(z) = H(z)X(z)$ separates the terms with the input's poles $e^{\pm j\omega_0}$ (the steady state) from those with the poles of H (the transient). □

Properties of $H(e^{j\omega})$ that follow from §17.2:

- **Periodicity:** $H(e^{j(\omega + 2\pi)}) = H(e^{j\omega})$; only $-\pi < \omega \le \pi$ needs plotting.
- **Symmetry** (real h): $|H|$ is even and $\angle H$ is odd, so $0 \le \omega \le \pi$ suffices. In physical units $\omega = \pi$ corresponds to the Nyquist frequency $f_s/2$.
- **DC and Nyquist gains:** $H(e^{j0}) = H(1) = \sum h[n]$ and $H(e^{j\pi}) = H(-1) = \sum (-1)^n h[n]$.
- **Group delay:** $\tau_g(\omega) = -\dfrac{d\angle H(e^{j\omega})}{d\omega}$, in samples. A **linear-phase** FIR filter with symmetric coefficients $b_k = b_{M-k}$ has $\angle H = -\omega M/2$ (plus jumps of π at zeros), i.e. a constant delay of $M/2$ samples for all frequencies.

Worked Example 17.33 — First-order low-pass: the frequency response

The "exponential smoother" $y[n] = a\,y[n-1] + (1-a)\,x[n]$, $0 < a < 1$, has $H(z) = \dfrac{1-a}{1-az^{-1}}$.

Step 1. Magnitude. On $z = e^{j\omega}$: $|1 - a e^{-j\omega}|^2 = (1 - a\cos\omega)^2 + a^2\sin^2\omega = 1 - 2a\cos\omega + a^2$, so

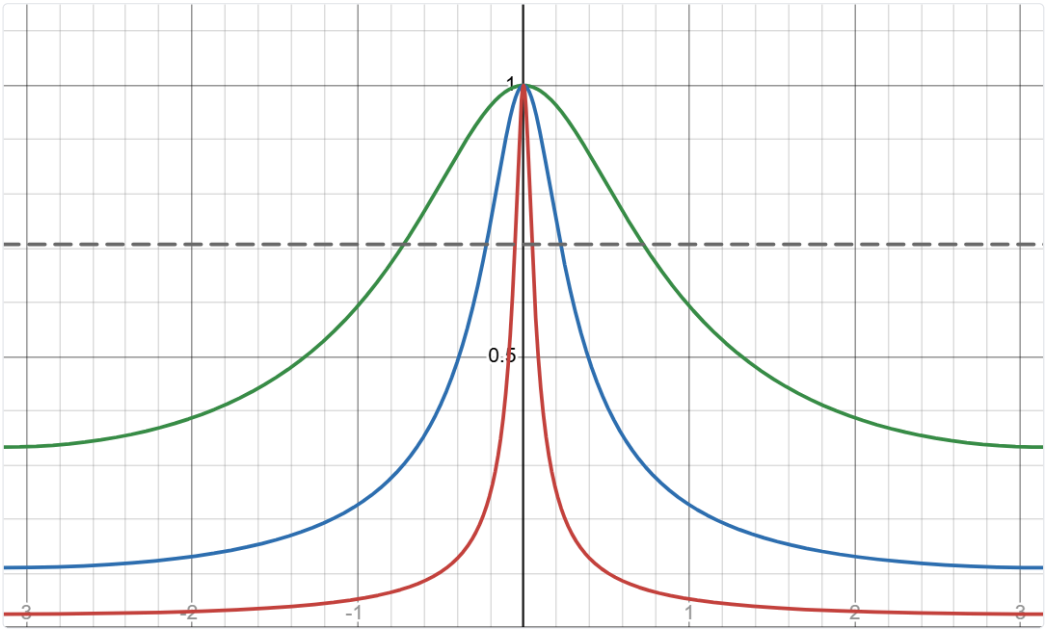
$$|H(e^{j\omega})| = \frac{1-a}{\sqrt{1 - 2a\cos\omega + a^2}}, \qquad \angle H(e^{j\omega}) = -\arctan\frac{a\sin\omega}{1 - a\cos\omega}.$$

Step 2. Values for $a = 0.8$. DC: $|H| = 0.2/0.2 = 1$. Nyquist ($\omega = \pi$): $0.2/1.8 = 0.111$, i.e. -19.1 dB.

Step 3. 3-dB frequency. Setting $|H|^2 = \tfrac{1}{2}$: $1 - 2a\cos\omega_c + a^2 = 2(1-a)^2$, so

$$\cos\omega_c = 1 - \frac{(1-a)^2}{2a} = 1 - \frac{0.04}{1.6} = 0.975, \qquad \omega_c = 0.2241 \text{ rad/sample}.$$

At $f_s = 10$ kHz this is $f_c = \omega_c f_s / 2\pi = 357$ Hz.



Magnitude responses $|H(e^{j\omega})| = (1-a)/\sqrt{1-2a\cos\omega+a^2}$ of the first-order smoother for $a = 0.5$ (green), 0.8 (blue) and 0.95 (red), plotted over one period $-\pi < \omega \le \pi$. As the pole approaches $z = 1$ the pass-band narrows; the dashed line is the -3 dB level.

Geometric evaluation from the pole–zero plot

Write H in factored form and set $z = e^{j\omega}$:

$$|H(e^{j\omega})| = |b_0|\,\frac{\prod_k |e^{j\omega} - q_k|}{\prod_k |e^{j\omega} - p_k|}, \qquad \angle H(e^{j\omega}) = \angle b_0 + (N-M)\omega + \sum_k \angle\left(e^{j\omega} - q_k\right) - \sum_k \angle\left(e^{j\omega} - p_k\right).$$

Each factor $e^{j\omega} - c$ is the vector from the pole or zero c to the point $e^{j\omega}$ on the unit circle. As ω sweeps from 0 to π, the point travels along the upper half of the circle, and:

- the **magnitude** is (gain) × (product of zero-vector lengths) / (product of pole-vector lengths);
- passing close to a **pole** makes a denominator length small: a **peak**, sharper the closer the pole is to the circle;
- passing through a **zero** on the circle makes the magnitude exactly **zero**;
- poles and zeros at the origin have vectors of length 1 for all ω: they affect only the phase (a pure delay).

For a pole at radius r close to 1, the 3-dB bandwidth of the peak it creates is approximately

$$\Delta\omega_{3\,\text{dB}} \approx 2(1-r) \quad \text{rad/sample},$$

because near the pole the unit circle is almost straight, and the pole-vector length grows by $\sqrt{2}$ when the point has moved a distance $1-r$ either side of the closest approach. This rule makes pole placement a design tool.

Worked Example 17.34 — The resonator of Example 17.28

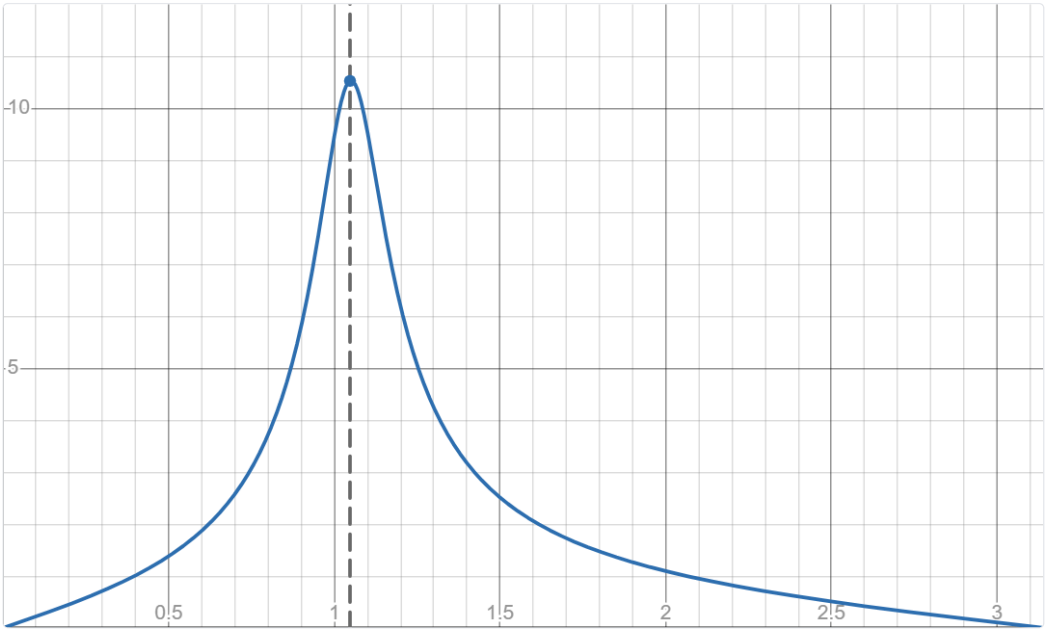
Analyse $H(z) = \dfrac{z^2 - 1}{z^2 - 0.9z + 0.81}$, poles $0.9e^{\pm j\pi/3}$, zeros ± 1.

Step 1. Geometric reading. At $\omega = 0$ and $\omega = \pi$ the point $e^{j\omega}$ sits on a zero: $|H| = 0$. Near $\omega = \pi/3$ it passes within $1 - r = 0.1$ of a pole: a peak, of approximate width $2(0.1) = 0.2$ rad.

Step 2. Peak value. At $\omega = \pi/3$: the zero vectors have lengths $|e^{j\pi/3} - 1| = 1$ and $|e^{j\pi/3} + 1| = \sqrt{3}$; the near pole vector has length 0.1; the far pole vector is $|e^{j\pi/3} - 0.9e^{-j\pi/3}| = |0.05 + j1.6454| = 1.6462$. So

$$|H(e^{j\pi/3})| = \frac{1 \cdot \sqrt{3}}{0.1 \times 1.6462} = 10.52.$$

Step 3. Steady-state response. For $x[n] = \cos(\pi n/3)$, a numerical evaluation gives $H(e^{j\pi/3}) = 10.52\, e^{j0.030}$, so in steady state $y[n] = 10.52\cos(\pi n/3 + 0.030)$. The exact maximum of $|H|$ is 10.53, at $\omega = 0.334\pi$, very slightly above $\pi/3$ (the far pole and the zeros tilt the peak).



Magnitude response of the resonator $H(z) = (1 - z^{-2})/(1 - 0.9z^{-1} + 0.81z^{-2})$ for $0 \le \omega \le \pi$: zeros at $z = \pm 1$ force nulls at DC and at Nyquist; the poles at $0.9e^{\pm j\pi/3}$ produce a peak at $\omega \approx \pi/3$ with bandwidth ≈ 0.2 rad.

Worked Example 17.35 — Designing a 50 Hz notch filter by pole–zero placement

Remove 50 Hz mains hum from an ECG sampled at $f_s = 1$ kHz, with a notch about 15 Hz wide.

Step 1. Notch frequency. $\omega_0 = 2\pi \cdot 50/1000 = 0.1\pi$ rad/sample.

Step 2. Zeros on the circle at $e^{\pm j\omega_0}$ give exact nulls: numerator $1 - 2\cos\omega_0 z^{-1} + z^{-2}$.

Step 3. Poles just inside, at the same angle, $re^{\pm j\omega_0}$, restore unit gain away from ω_0 (each pole nearly cancels the effect of its zero except near the notch). Bandwidth $2(1 - r) \approx 2\pi \cdot 15/1000 = 0.094$ rad gives $r \approx 0.95$:

$$H(z) = \frac{1 - 1.9021z^{-1} + z^{-2}}{1 - 1.8070z^{-1} + 0.9025z^{-2}}.$$

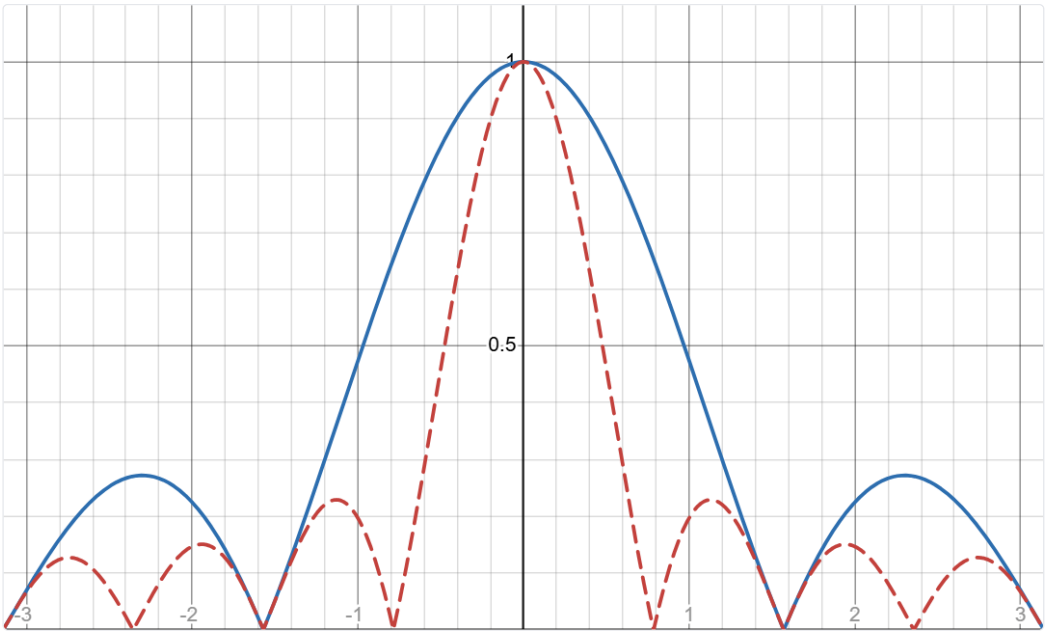
Step 4. Check. Numerically, $|H| = 0$ at 50 Hz, 1.025 at DC and 1.052 at Nyquist (scale by $1/1.025$ if exact unit DC gain is wanted), and the -3 dB notch width is 0.0936 rad $= 14.9$ Hz. The poles have radius 0.95: stable.

Worked Example 17.36 — Moving average and linear phase

For the 4-point moving average of Example 17.29,

$$H(e^{j\omega}) = \frac{1}{4}\,\frac{1 - e^{-j4\omega}}{1 - e^{-j\omega}} = \frac{1}{4}\,\frac{e^{-j2\omega}\,(2j\sin 2\omega)}{e^{-j\omega/2}\,\left(2j\sin\frac{\omega}{2}\right)} = e^{-j3\omega/2}\,\frac{\sin 2\omega}{4\sin(\omega/2)}.$$

The magnitude is the **Dirichlet kernel** $\left|\dfrac{\sin 2\omega}{4\sin(\omega/2)}\right|$, with zeros at $\omega = \pi/2, \pi$; the phase is -1.5ω (plus π jumps where the real factor changes sign) — **linear phase**, a constant group delay of $M/2 = 1.5$ samples, because the coefficients are symmetric.



Magnitude responses of the 4-point (blue) and 8-point (red, dashed) moving averages: crude low-pass filters with nulls at multiples of $2\pi/M$. Doubling the length halves the main-lobe width.

All-pass systems

The geometric picture shows how to build a filter with *flat* magnitude: place each zero at the **conjugate reciprocal** $1/p^*$ of a pole p. Then for $|z| = 1$,

$$H_{\text{ap}}(z) = \frac{z^{-1} - p^*}{1 - pz^{-1}}, \qquad |H_{\text{ap}}(e^{j\omega})| = \frac{|e^{-j\omega} - p^*|}{|1 - pe^{-j\omega}|} = \frac{|e^{-j\omega}|\,|1 - p^* e^{j\omega}|}{|1 - pe^{-j\omega}|} = 1,$$

since the last numerator is the conjugate of the denominator. All-pass sections change only the phase; they are used as phase equalisers, as building blocks of fractional delays, and in the theorem that **every rational stable system factors as (minimum phase) × (all-pass)**: reflecting a zero from outside the circle to its conjugate reciprocal inside leaves $|H|$ unchanged and reduces the phase lag, hence "minimum phase".

Relation to the Laplace transform: $z = e^{sT}$

Suppose $x[n] = x_a(nT)$ are samples of a continuous signal. Represent the sampled signal, as in §16.8, by the impulse train

$$x_s(t) = \sum_n x_a(nT)\,\delta(t - nT).$$

Its Laplace transform, using $\mathcal{L}\{\delta(t - nT)\} = e^{-snT}$, is

$$X_s(s) = \sum_n x[n]\,e^{-snT} = X(z)\big|_{z = e^{sT}}.$$

The s-to-z map

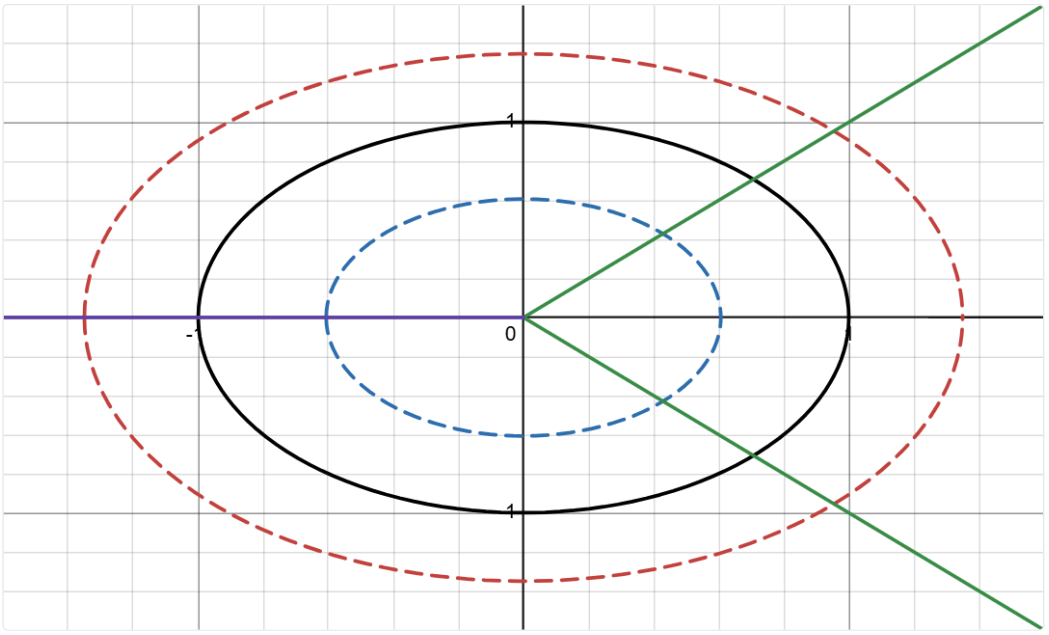
The Z-transform of the samples equals the Laplace transform of the impulse-sampled signal under the substitution

$$z = e^{sT}, \qquad s = \sigma + j\Omega \implies |z| = e^{\sigma T}, \quad \angle z = \Omega T.$$

In particular:

- the imaginary axis $\sigma = 0$ maps onto the unit circle, with digital frequency $\omega = \Omega T$;
- the open left half-plane $\sigma < 0$ maps into the open unit disc $|z| < 1$; the right half-plane maps outside it;
- a continuous pole at $s = -\alpha \pm j\Omega_d$ appears in the sampled signal as a pole at $z = e^{-\alpha T} e^{\pm j\Omega_d T}$;
- the map is **not one-to-one**: s and $s + jk\,2\pi/T$ give the same z. Each horizontal strip of height $\Omega_s = 2\pi/T$ covers the whole z-plane once.

The last statement is aliasing seen from the s-plane: frequencies Ω and $\Omega + k\Omega_s$ are indistinguishable after sampling, and so are poles that differ by $jk\Omega_s$. The **primary strip** $-\pi/T < \Omega \le \pi/T$ is the set of continuous frequencies that sampling represents faithfully, and its edges $\Omega = \pm\pi/T$ map to the negative real axis $z < 0$ — the Nyquist frequency.



Images under $z = e^{sT}$: the $j\Omega$ axis maps to the unit circle (black); the vertical lines $\sigma T = -0.5$ and $\sigma T = +0.3$ map to circles of radius $e^{-0.5} = 0.607$ (blue) and $e^{0.3} = 1.35$ (red); the horizontal lines $\Omega T = \pm\pi/4$ map to rays at $\pm 45^\circ$ (green); $\Omega T = \pm\pi$ maps to the negative real axis (purple).

Useful landmarks of the map: constant damping $\sigma \leftrightarrow$ circles; constant frequency $\Omega \leftrightarrow$ rays; the point $s = 0$ (DC) $\leftrightarrow z = 1$; $s = -\infty \leftrightarrow z = 0$. Fast continuous poles (large αT) crowd towards the origin; slow ones (small αT) crowd towards $z = 1$, which is why high sampling rates push all poles of a digital controller into a small, numerically delicate neighbourhood of $z = 1$.

Worked Example 17.37 — Mapping a damped oscillation

A continuous-time system has poles $s = -200 \pm j1000$ s⁻¹ and is sampled at $f_s = 4$ kHz ($T = 0.25$ ms). Where are the poles of the sampled system, and what are its digital damping and frequency?

Step 1. $\sigma T = -200 \times 0.25 \times 10^{-3} = -0.05$, $\Omega T = 1000 \times 0.25 \times 10^{-3} = 0.25$ rad.

Step 2. $z = e^{-0.05} e^{\pm j0.25} = 0.9512\, e^{\pm j0.25} = 0.9217 \pm j0.2353$.

Step 3. The pole radius $0.951 < 1$ confirms stability (left half-plane → inside the circle). The digital oscillation frequency 0.25 rad/sample corresponds to $0.25\, f_s/2\pi = 159$ Hz $= 1000/2\pi$ Hz, as it must. If the same system were sampled at only $f_s = 150$ Hz, the pole angle $\Omega T = 6.667$ rad would wrap to $6.667 - 2\pi = 0.384$ rad — an alias at 9.2 Hz.

Discretising continuous-time systems

The substitution $z = e^{sT}$ cannot be applied directly to a rational $H(s)$ — it would produce a non-rational $H(z)$. Practical discretisation methods are rational approximations that preserve different features.

Impulse invariance. Sample the analogue impulse response: $h[n] = T\, h_a(nT)$. For $H_a(s) = \sum_k \dfrac{A_k}{s - s_k}$, $h_a(t) = \sum_k A_k e^{s_k t} u(t)$, so

$$H(z) = \sum_k \frac{T A_k}{1 - e^{s_k T} z^{-1}}.$$

Each analogue pole s_k maps exactly to $e^{s_k T}$, but the frequency response is the aliased sum $H(e^{j\omega}) = \sum_k H_a\!\left(j\tfrac{\omega + 2\pi k}{T}\right)$, so the method suits only band-limited (low-pass, band-pass) prototypes.

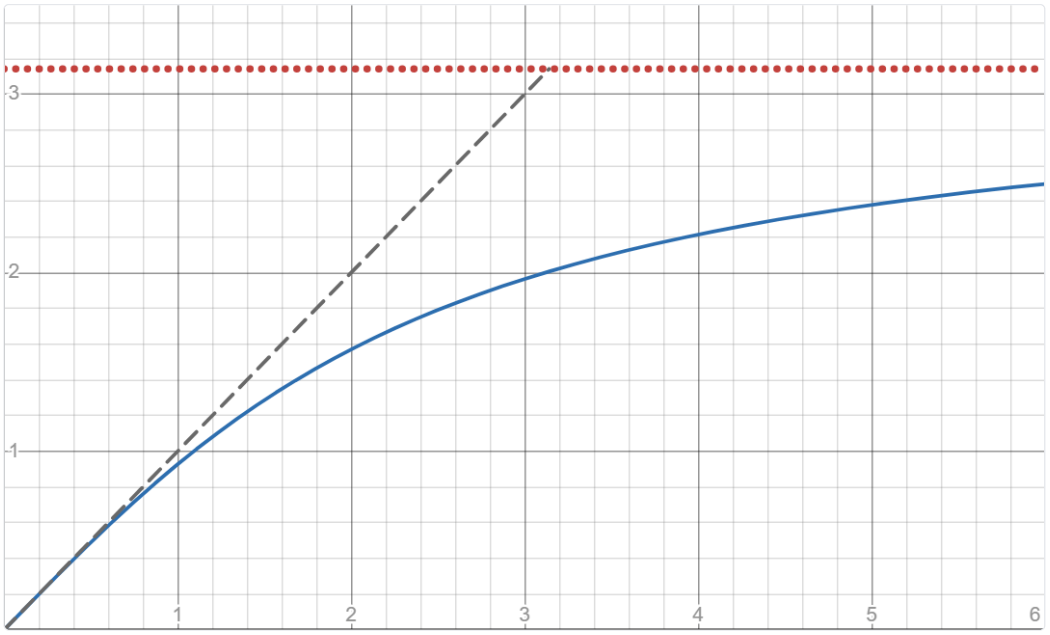
Bilinear transform. Replace s by the first-order rational approximation of $s = \frac{1}{T}\ln z$ (from the trapezoidal rule of integration):

$$s = \frac{2}{T}\,\frac{1 - z^{-1}}{1 + z^{-1}}, \qquad z = \frac{1 + sT/2}{1 - sT/2}.$$

It maps the left half-plane *exactly* onto the unit disc (so stable analogue filters always give stable digital ones) and the whole $j\Omega$ axis onto the unit circle *once* — no aliasing. The price is **frequency warping**: with $z = e^{j\omega}$,

$$s = \frac{2}{T}\,\frac{1 - e^{-j\omega}}{1 + e^{-j\omega}} = j\,\frac{2}{T}\tan\frac{\omega}{2} \quad\Longrightarrow\quad \Omega = \frac{2}{T}\tan\frac{\omega}{2}, \qquad \omega = 2\arctan\frac{\Omega T}{2}.$$

Critical frequencies are therefore **pre-warped**: to place a digital cutoff at ω_c, design the analogue prototype with cutoff $\Omega_c = \frac{2}{T}\tan\frac{\omega_c}{2}$.



Bilinear frequency warping, $\omega = 2\arctan(\Omega T/2)$ (blue) against the ideal $\omega = \Omega T$ (dashed): the two agree at low frequency, but the whole infinite analogue axis is compressed into $0 \le \omega < \pi$ (red dotted line).

Worked Example 17.38 — Impulse invariance versus bilinear for an RC low-pass

Discretise $H_a(s) = \dfrac{1}{1+s\tau}$ with $\tau = 1$ ms and $T = 0.25$ ms.

Impulse invariance. $h_a(t) = \frac{1}{\tau}e^{-t/\tau}u(t)$, so $h[n] = \frac{T}{\tau}\left(e^{-T/\tau}\right)^n u[n]$ and

$$H_{\text{ii}}(z) = \frac{0.25}{1 - 0.7788 z^{-1}}.$$

The pole $e^{-T/\tau} = 0.7788$ is exact (compare the Euler pole 0.75 of Example 17.27), but the DC gain is $0.25/(1-0.7788) = 1.130$, not 1: the analogue response is not band-limited, so aliased spectral copies add to the gain. In practice one rescales by $1/1.130$.

Bilinear. With $\frac{2}{T} = 8000\ \text{s}^{-1}$ and $\tau = 10^{-3}$ s: $1 + s\tau = 1 + 8\,\dfrac{1-z^{-1}}{1+z^{-1}} = \dfrac{9 - 7z^{-1}}{1+z^{-1}}$, so

$$H_{\text{bl}}(z) = \frac{1+z^{-1}}{9-7z^{-1}} = \frac{0.1111\,(1+z^{-1})}{1 - 0.7778 z^{-1}}.$$

DC gain $H(1) = 2/2 = 1$ exactly; $H(-1) = 0$ — the Nyquist frequency is a transmission zero, the image of $s = \infty$.

Worked Example 17.39 — Bilinear design with pre-warping

Design a first-order digital low-pass with 3-dB cutoff $f_c = 1$ kHz at $f_s = 8$ kHz.

Step 1. Digital cutoff. $\omega_c = 2\pi f_c / f_s = \pi/4$.

Step 2. Pre-warp. $\Omega_c = \dfrac{2}{T}\tan\dfrac{\omega_c}{2} = 16000\tan(\pi/8) = 6627$ rad/s (the naive value would be $2\pi \cdot 1000 = 6283$ rad/s). Then $\Omega_c T = 2\tan(\pi/8) = 0.8284$.

Step 3. Prototype $H_a(s) = \dfrac{\Omega_c}{s + \Omega_c}$. Substituting the bilinear map and multiplying through by $T(1+z^{-1})$:

$$H(z) = \frac{\Omega_c T\,(1+z^{-1})}{(2 + \Omega_c T) + (\Omega_c T - 2)z^{-1}} = \frac{0.2929\,(1+z^{-1})}{1 - 0.4142 z^{-1}}.$$

Step 4. Check. $|H(e^{j\pi/4})| = 0.7071$ exactly, i.e. -3 dB at 1 kHz ✓; $H(1) = 0.5858/0.5858 = 1$ ✓. Without pre-warping the cutoff would land at $\omega = 2\arctan(6283/16000) = 0.748$ rad, i.e. 952 Hz.

Common Pitfall — Confusing rad/sample with rad/s

ω (digital, rad/sample, periodic with period 2π) and Ω (analogue, rad/s) differ by the factor T. A digital filter "with cutoff 0.2" is meaningless until f_s is known, and design software variously normalises frequency to π rad/sample, to $f_s/2$ ("1.0 = Nyquist") or to f_s. Always convert with $\omega = 2\pi f/f_s$ and check that $\omega_c < \pi$.

Engineering Note — What the unit-circle picture buys a designer

Every specification of a digital filter translates into a pole–zero picture: stopband frequencies become zeros on the circle, passband peaks become poles near the circle at the corresponding angle, the sharpness of a feature becomes the distance $1-r$, and stability is the single constraint $r<1$. The magnitude plot is then the shadow of these poles and zeros on the circle. Sophisticated design methods (Butterworth, Chebyshev, elliptic prototypes transformed bilinearly; Parks–McClellan FIR design) are simply systematic ways of choosing those positions.

Summary

Concept	Formula
Discrete frequency	$\omega=\Omega T=2\pi f/f_s$ rad/sample; $e^{j(\omega+2\pi)n}=e^{j\omega n}$
Convolution sum	$y[n]=\sum_k x[k]h[n-k]$
Bilateral Z-transform	$X(z)=\sum_{n=-\infty}^{\infty}x[n]z^{-n}$, with ROC
Unilateral Z-transform	$\mathcal{X}(z)=\sum_{n=0}^{\infty}x[n]z^{-n}$
Geometric pairs	$a^nu[n]\leftrightarrow\frac{z}{z-a}$, $\lvert z\rvert>\lvert a\rvert$; $-a^nu[-n-1]\leftrightarrow\frac{z}{z-a}$, $\lvert z\rvert<\lvert a\rvert$
Repeated pole	$na^nu[n]\leftrightarrow\frac{az}{(z-a)^2}$
Damped cosine	$r^n\cos(\omega_0 n)u[n]\leftrightarrow\frac{z(z-r\cos\omega_0)}{z^2-2rz\cos\omega_0+r^2}$
Shift / scaling / multiply by n	$z^{-n_0}X(z)$; $a^nx[n]\leftrightarrow X(z/a)$; $nx[n]\leftrightarrow -zX'(z)$
Reversal / convolution	$x[-n]\leftrightarrow X(1/z)$; $x*h\leftrightarrow XH$
Initial / final value	$x[0]=\lim_{z\to\infty}X$; $x[\infty]=\lim_{z\to1}(z-1)X$
Parseval	$\sum\lvert x[n]\rvert^2=\frac{1}{2\pi}\int_{-\pi}^{\pi}\lvert X(e^{j\omega})\rvert^2d\omega$
ROC shapes	right-sided: $\lvert z\rvert>r_1$; left-sided: $\lvert z\rvert<r_2$; two-sided: $r_1<\lvert z\rvert<r_2$; finite: all z (except $0,\infty$)
Inversion integral	$x[n]=\frac{1}{2\pi j}\oint_C X(z)z^{n-1}dz=\sum\text{Res}\left[Xz^{n-1}\right]$
Partial fractions	expand $X(z)/z$; $A_i=(z-p_i)X(z)/z\,\lvert_{p_i}$
Unilateral delay	$y[n-1]\leftrightarrow z^{-1}\mathcal{Y}+y[-1]$; $y[n-2]\leftrightarrow z^{-2}\mathcal{Y}+z^{-1}y[-1]+y[-2]$
Unilateral advance	$y[n+1]\leftrightarrow z\mathcal{Y}-zy[0]$
System function	$H(z)=\dfrac{\sum b_kz^{-k}}{\sum a_kz^{-k}}=\dfrac{Y}{X}$
Feedback	$\dfrac{G}{1+GF}$
Stability (causal)	all poles $\lvert p_k\rvert<1\iff\sum\lvert h[n]\rvert<\infty$
Second-order test	$z^2+a_1z+a_2$: $\lvert a_2\rvert<1$, $\lvert a_1\rvert<1+a_2$
Frequency response	$H(e^{j\omega})$; $\cos\omega_0n\mapsto\lvert H\rvert\cos(\omega_0n+\angle H)$
Pole bandwidth	$\Delta\omega_{3\,\text{dB}}\approx2(1-r)$
s–z map	$z=e^{sT}$: LHP $\to\lvert z\rvert<1$, $j\Omega$ axis $\to$ unit circle
Impulse invariance	$\frac{A}{s-s_k}\to\frac{TA}{1-e^{s_kT}z^{-1}}$
Bilinear transform	$s=\frac{2}{T}\frac{1-z^{-1}}{1+z^{-1}}$, $\Omega=\frac{2}{T}\tan\frac{\omega}{2}$

Chapter 18 — Complex Analysis

> **Prerequisites:** Ch. 2 (complex numbers), Ch. 5 (integral calculus), Ch. 6 (multivariable calculus), Ch. 7 (vector calculus: Green's theorem), Ch. 14 (Laplace transforms), Ch. 17 (Z-transforms) **Learning outcomes:** After this chapter you can
>
> - treat a function $w = f(z)$ as a mapping of the plane, compute its real and imaginary parts, and picture what it does to grid lines (conformal mapping);
> - test a function for analyticity with the Cauchy–Riemann equations and construct harmonic conjugates;
> - parametrize contours, evaluate contour integrals, and bound them with the ML inequality;
> - apply Cauchy's integral theorem and integral formula, including contour deformation;
> - expand functions in Taylor and Laurent series on discs and annuli, and classify isolated singularities;
> - compute residues and use the residue theorem to evaluate real integrals (rational, trigonometric, Fourier-type via Jordan's lemma), to invert Laplace and Z-transforms, and to count zeros and poles with the argument principle — the mathematics behind the Nyquist stability criterion.

Every transform in Part V lives in the complex plane. The Laplace variable $s = \sigma + j\omega$ of Ch. 14, the Fourier frequency on the line $s = j\omega$ of Ch. 16, and the z of Ch. 17 are complex numbers, and the functions we manipulate — transfer functions $H(s)$, spectra $X(\omega)$, system functions $H(z)$ — are complex functions of a complex variable. Until now we have treated them algebraically: partial fractions, tables, pole–zero plots. This chapter supplies the analysis underneath. It explains *why* partial-fraction coefficients are what they are (they are residues), *why* the region of convergence of a Z-transform is an annulus (it is the annulus of a Laurent series), *why* the inverse Laplace transform is an integral along a vertical line (the Bromwich integral), and *why* counting encirclements of -1 by a Nyquist plot reveals closed-loop poles (the argument principle).

The central surprise of complex analysis is how rigid differentiable complex functions are. A real function can be differentiable once and nowhere twice; a complex function that is differentiable once in a region is differentiable infinitely often, equals its Taylor series, and is completely determined inside a closed curve by its values on the curve. That rigidity is what makes contour integration such a powerful computational tool.

Throughout, $z = x + jy = re^{j\theta}$ denotes the independent variable and $w = f(z) = u(x,y) + jv(x,y)$ the dependent one.

18.1 Complex functions

Why an engineer needs complex functions

A transfer function $H(s) = 1/(s^2 + 2\zeta\omega_n s + \omega_n^2)$ assigns to every complex frequency s a complex number: a gain and a phase. A Bode plot is a picture of H restricted to the imaginary axis; a root locus is a picture of where $1 + KH(s) = 0$; a Nyquist plot is the *image* of the imaginary axis under H. All three are statements about a function from $\mathbb{C}$ to $\mathbb{C}$. To use them fluently we must understand such functions as objects in their own right — in particular as *mappings* that carry curves in one plane to curves in another.

Complex function

Let $D \subseteq \mathbb{C}$. A **complex function** $f : D \to \mathbb{C}$ assigns to each $z \in D$ a complex number $w = f(z)$. Writing $z = x + jy$,

$$f(z) = u(x,y) + j\,v(x,y),$$

where $u = \operatorname{Re}\{f\}$ and $v = \operatorname{Im}\{f\}$ are real-valued functions of two real variables. In polar form $z = re^{j\theta}$ we may also write $f = u(r,\theta) + jv(r,\theta)$.

So a complex function is *a pair of real functions of two variables*. That viewpoint is honest but hides the structure; the payoff of complex analysis comes from treating z as a single variable.

Domains and regions. We will need a few words about sets in the plane.

- An **open disc** $|z - z_0| < \rho$ is a *neighbourhood* of z_0; the **punctured disc** $0 < |z - z_0| < \rho$ omits the centre.
- A set is **open** if every point has a neighbourhood inside the set. It is **connected** if any two points can be joined by a polygonal path inside it.
- A **domain** is an open connected set. A **region** is a domain possibly with some or all of its boundary points.
- A domain is **simply connected** if every closed curve in it can be shrunk continuously to a point without leaving it — informally, it has no holes. The disc $|z| < 1$ is simply connected; the annulus $1 < |z| < 2$ and the punctured plane $z \neq 0$ are not.

These distinctions are not pedantry: Cauchy's theorem (Section 18.5) holds on simply connected domains, and the Laurent series (Section 18.6) is the tool for annuli.

Elementary functions

Polynomials and rational functions. $P(z) = a_0 + a_1 z + \cdots + a_n z^n$ is defined everywhere. A rational function $R(z) = P(z)/Q(z)$ is defined except at zeros of Q — the *poles* of every transfer function you have met.

The exponential. Defined by

$$e^z = e^{x+jy} = e^x(\cos y + j \sin y),$$

so $|e^z| = e^x$ and $\angle e^z = y$. It agrees with the real exponential on the real axis and with Euler's formula on the imaginary axis. Key properties:

- $e^{z_1+z_2} = e^{z_1}e^{z_2}$, and $e^z \neq 0$ for every z;
- e^z is **periodic with period** $2\pi j$: $e^{z+2\pi j} = e^z$. The horizontal strip $-\pi < y \leq \pi$ already produces every nonzero value once.

Trigonometric and hyperbolic functions. Defined from the exponential,

$$\cos z = \frac{e^{jz}+e^{-jz}}{2}, \qquad \sin z = \frac{e^{jz}-e^{-jz}}{2j}, \qquad \cosh z = \frac{e^{z}+e^{-z}}{2}, \qquad \sinh z = \frac{e^{z}-e^{-z}}{2}.$$

Hence $\cos(jy) = \cosh y$ and $\sin(jy) = j\sinh y$, and

$$\cos(x+jy) = \cos x\cosh y - j\sin x\sinh y, \qquad \sin(x+jy) = \sin x\cosh y + j\cos x\sinh y.$$

A striking consequence: $|\sin z|^2 = \sin^2 x + \sinh^2 y$, which grows without bound as $|y|\to\infty$. **Complex sine and cosine are not bounded** — unlike their real versions. (Liouville's theorem in Section 18.5 will say no non-constant entire function can be bounded.)

The logarithm — the first multivalued function. We want $w = \log z$ to solve $e^w = z$. Write $z = re^{j\theta}$ and $w = u + jv$: then $e^u e^{jv} = re^{j\theta}$ gives $u = \ln r$ and $v = \theta + 2\pi k$. So

$$\log z = \ln|z| + j\arg z = \ln r + j(\theta + 2\pi k), \qquad k\in\mathbb{Z}.$$

Every nonzero z has infinitely many logarithms, differing by integer multiples of $2\pi j$. To get a genuine (single-valued) function we must choose.

Principal logarithm and branch cut

The **principal argument** $\operatorname{Arg} z \in (-\pi,\pi]$ and the **principal logarithm**

$$\operatorname{Log} z = \ln|z| + j\operatorname{Arg} z, \qquad z\neq 0,$$

define a single-valued function. It is continuous everywhere except on the negative real axis $\{x\le 0,\ y=0\}$, where Arg jumps by 2π. That excluded ray is a **branch cut**; $z=0$, around which the values wind, is a **branch point**. Any other choice of a ray from 0 and a 2π-wide interval of angles gives another **branch** of log.

Complex powers. For complex α, define $z^\alpha = e^{\alpha\log z}$; the **principal value** uses Log. If $\alpha = n$ is an integer this is single-valued; if $\alpha = p/q$ is rational in lowest terms there are exactly q distinct values (the q-th roots of Ch. 2); otherwise there are infinitely many. For example $z^{1/2}$ has two branches, $\pm\sqrt{r}\,e^{j\theta/2}$, which swap as z circles the origin.

Worked Example 18.1 — real and imaginary parts

Find u and v for (a) $f(z)=z^2$, (b) $f(z)=1/z$, (c) $f(z)=e^z$, and evaluate each at $z = 1+j$.

(a) $(x+jy)^2 = x^2 - y^2 + j\,2xy$, so $u = x^2-y^2$, $v = 2xy$. At $1+j$: $u=0$, $v=2$, i.e. $f = 2j$.

(b) Multiply by the conjugate:

$$\frac{1}{z} = \frac{\bar z}{|z|^2} = \frac{x-jy}{x^2+y^2}, \qquad u = \frac{x}{x^2+y^2}, \quad v = \frac{-y}{x^2+y^2}.$$

At $1+j$: $u = \tfrac12$, $v = -\tfrac12$, i.e. $f = \tfrac12 - \tfrac12 j$. Check: $(1+j)(\tfrac12 - \tfrac12 j) = \tfrac12 + \tfrac12 = 1$. ✓

(c) $u = e^x\cos y$, $v = e^x\sin y$. At $1+j$: $e\cos 1 = 1.4687$, $e\sin 1 = 2.2874$.

Worked Example 18.2 — logarithms and powers

Find (a) $\operatorname{Log}(-1-j)$, (b) all values of $\log(-1)$, (c) the principal value of j^j.

(a) $|-1-j| = \sqrt{2}$ and $-1-j$ lies in the third quadrant, so $\operatorname{Arg}(-1-j) = -3\pi/4$ (not $5\pi/4$, which lies outside $(-\pi,\pi]$). Hence $\operatorname{Log}(-1-j) = \tfrac12\ln 2 - j\tfrac{3\pi}{4} = 0.3466 - 2.3562j$.

(b) $|-1|=1$, $\arg(-1) = \pi + 2\pi k$, so $\log(-1) = j(2k+1)\pi$. The principal value is $j\pi$ — the logarithm of a negative real number is perfectly well defined in $\mathbb{C}$.

(c) $j^j = e^{j\operatorname{Log} j} = e^{j\cdot j\pi/2} = e^{-\pi/2} = 0.20788$. A complex number raised to a complex power can be real. The other values are $e^{-\pi/2 - 2\pi k}$.

Common Pitfall — "laws" that fail for multivalued functions

$\operatorname{Log}(z_1z_2) = \operatorname{Log}z_1 + \operatorname{Log}z_2$ is **false** in general. With $z_1 = z_2 = -1$: the left side is $\operatorname{Log}1 = 0$, the right side is $2\pi j$. The identity holds only modulo $2\pi j$. Likewise $(z_1z_2)^{1/2} \neq z_1^{1/2}z_2^{1/2}$ for principal branches in general, and $\sqrt{z^2}\neq z$. In software, `log`, `sqrt` and `angle` return principal values, so a phase computed as `angle(H)` jumps by 2π when the true phase crosses $\pm\pi$ — the reason phase plots must be *unwrapped*.

Functions as mappings

A real function $y = f(x)$ is pictured by its graph in the (x,y) plane. A complex function would need four real dimensions for its graph, so instead we draw **two planes**: the z-plane (coordinates x, y) and the w-plane (coordinates u, v), and we watch where f sends curves. A good test pattern is the rectangular grid $x =$ const, $y =$ const, or the polar grid $r =$ const, $\theta =$ const.

The map $w = z^2$. In polar form $w = r^2e^{j2\theta}$: moduli are squared and angles doubled. The first quadrant $0\le\theta\le\pi/2$ opens out to the whole upper half-plane. On the rectangular grid:

- the vertical line $x = a$ ($a\neq 0$) becomes $u = a^2 - y^2$, $v = 2ay$. Eliminating $y = v/(2a)$:

$$u = a^2 - \frac{v^2}{4a^2},$$

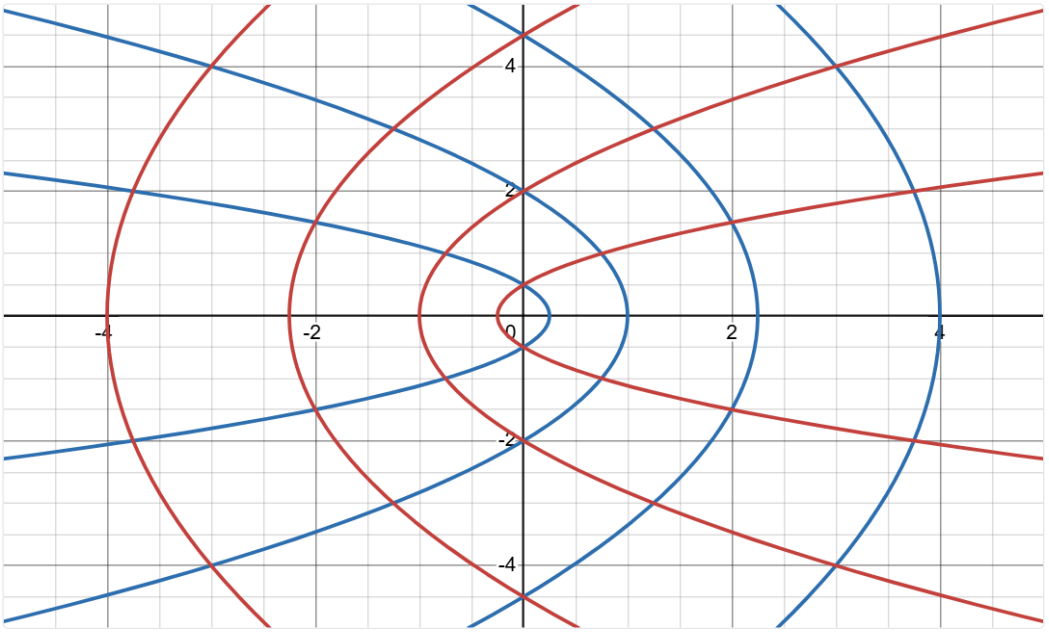
a parabola opening to the left with focus at the origin;

- the horizontal line $y = b$ ($b \neq 0$) becomes $u = x^2 - b^2$, $v = 2bx$, i.e.

$$u = \frac{v^2}{4b^2} - b^2,$$

a parabola opening to the right, also with focus at the origin.

The two families cross at right angles — exactly as the original grid lines did. That is not a coincidence: it is **conformality**, developed in Section 18.3.



Images under $w = z^2$ of the vertical lines $x = 0.5, 1, 1.5, 2$ (blue, left-opening parabolas) and horizontal lines $y = 0.5, 1, 1.5, 2$ (red, right-opening parabolas), drawn in the $w = u + jv$ plane; the two families of confocal parabolas meet at right angles.

The map $w = 1/z$ (inversion). In polar form $w = (1/r)e^{-j\theta}$: the modulus is inverted and the angle negated (reflection in the real axis). Points inside the unit circle go outside, and vice versa; the origin and the "point at infinity" swap. Using $u = x/(x^2 + y^2)$, $v = -y/(x^2 + y^2)$ and the inverse relations $x = u/(u^2 + v^2)$, $y = -v/(u^2 + v^2)$:

- the vertical line $x = a$ becomes $u/(u^2 + v^2) = a$, i.e.

$$\left(u - \frac{1}{2a}\right)^2 + v^2 = \frac{1}{4a^2},$$

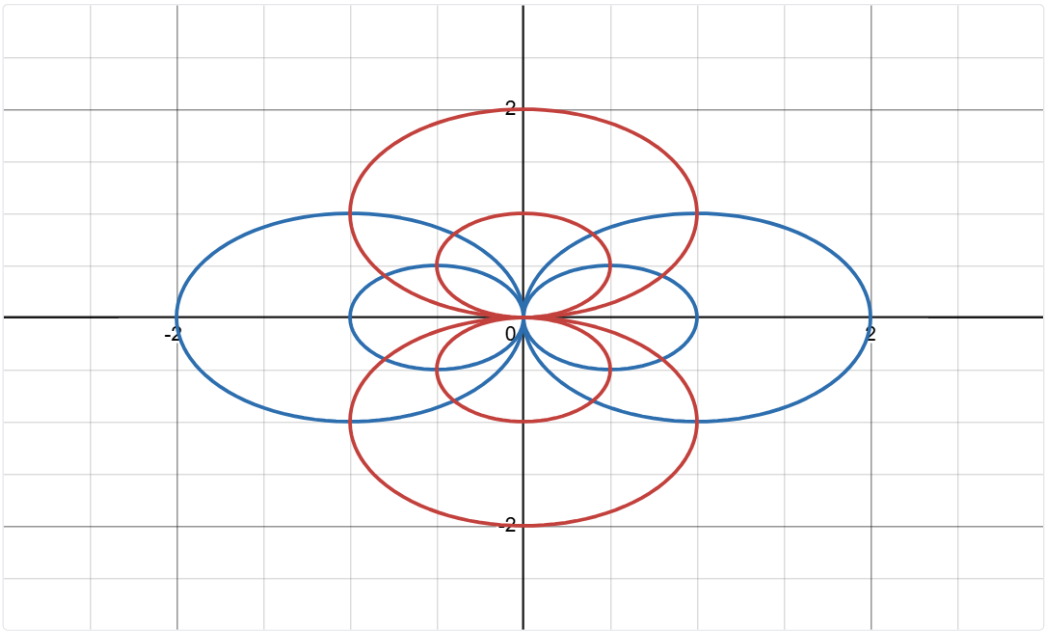
a circle through the origin with centre on the real axis;

- the horizontal line $y = b$ becomes

$$u^2 + \left(v + \frac{1}{2b}\right)^2 = \frac{1}{4b^2},$$

a circle through the origin with centre on the imaginary axis.

Lines map to circles through the origin (a line is a "circle through ∞", and $\infty \mapsto 0$). In general, **inversion maps circles-and-lines to circles-and-lines**, a property shared by all **Möbius (bilinear) transformations** $w = (az + b)/(cz + d)$, $ad - bc \neq 0$. The Smith chart is the Möbius map $\Gamma = (z_L - 1)/(z_L + 1)$ applied to the grid of normalized resistance and reactance; its circles are these circles.



Images under $w = 1/z$ of the lines $x = \pm 0.5, \pm 1$ (blue circles centred on the real axis) and $y = \pm 0.5, \pm 1$ (red circles centred on the imaginary axis); every circle passes through $w = 0$, the image of $z = \infty$, and blue meets red at right angles.

The map $w = e^z$. With $u + jv = e^x e^{jy}$: the vertical line $x = a$ maps to the circle $|w| = e^a$, traversed once each time y advances by 2π; the horizontal line $y = b$ maps to the ray $\angle w = b$. The exponential turns the Cartesian grid into the polar grid. Its inverse, Log, does the reverse: it straightens circles and rays into vertical and horizontal lines. That is exactly why the s-plane and z-plane of sampled systems are related by $z = e^{sT}$ (Ch. 17): the imaginary axis $s = j\omega$ wraps onto the unit circle, the left half-plane maps into the unit disc, and the strip $-\pi/T < \omega \le \pi/T$ is the primary strip that maps onto the whole z-plane once — the complex-analysis statement of aliasing.

Worked Example 18.3 — image of a region under e^z and z^2

(a) Find the image of the rectangle $0 \le x \le 1, 0 \le y \le \pi/2$ under $w = e^z$. (b) Find the image of the half-strip $0 < x < 1, y > 0$ under $w = z^2$.

(a) $|w| = e^x$ ranges over $[1, e]$ and $\angle w = y$ over $[0, \pi/2]$. The image is the quarter-annulus $1 \le |w| \le e, 0 \le \angle w \le \pi/2$. Its area is $\frac{1}{4}\pi(e^2 - 1) = 5.0180$, compared with $\pi/2 = 1.5708$ for the rectangle. The local area magnification is $|f'(z)|^2 = e^{2x}$, and indeed $\int_0^1 \int_0^{\pi/2} e^{2x}\, dy\, dx = \frac{\pi}{2} \cdot \frac{e^2-1}{2} = 5.0180$. ✓

(b) The boundary $x = 0, y > 0$ maps to $u = -y^2 \le 0, v = 0$: the negative real axis. The boundary $x = 1$ maps to the parabola $u = 1 - v^2/4$ with $v = 2y > 0$, the upper half of the left-opening parabola. The boundary segment $y = 0, 0 < x < 1$ maps to $0 < u < 1, v = 0$. The image is the region in the upper half-plane lying inside (to the left of) the parabola $u = 1 - v^2/4$ — test the interior point $z = 0.5 + 0.5j$: $w = 0.5j$, and $0 < 1 - 0.25/4$. ✓

Engineering Note — what a Nyquist plot really is

A Nyquist plot draws the curve $\{L(j\omega) : -\infty < \omega < \infty\}$ in the w-plane: the **image of the imaginary axis** under the loop transfer function $L(s)$. Similarly, a polar plot of an impedance $Z(j\omega)$ is the image of the frequency axis. Everything in this section — lines becoming circles, grids staying orthogonal — is what you are seeing in those plots. Section 18.9 uses the argument principle to read stability from such an image.

18.2 Analyticity

Why differentiability is special in the plane

In one real variable, x can approach x_0 only from the left or the right. In the complex plane, z can approach z_0 along infinitely many directions and along spirals. Demanding that a difference quotient have the *same* limit along every one of these paths is a far stronger condition than real differentiability, and the functions that meet it — analytic functions — inherit remarkable properties. The transfer functions, impedances and transforms of circuit theory are analytic away from their poles; this is why their behaviour on the $j\omega$-axis is tied so tightly to their pole–zero pattern.

Limits and continuity

Limit and continuity

$\lim_{z \to z_0} f(z) = L$ means: for every $\varepsilon > 0$ there is $\delta > 0$ such that $|f(z) - L| < \varepsilon$ whenever $0 < |z - z_0| < \delta$. The function is **continuous** at z_0 if $f(z_0)$ is defined and $\lim_{z \to z_0} f(z) = f(z_0)$.

Because $|z - z_0| < \delta$ is a disc, the limit must be the same however z approaches z_0. Writing $f = u + jv$ and $L = a + jb$, the complex limit exists if and only if $u \to a$ and $v \to b$ as two-variable limits. Sums, products, quotients (with nonzero denominator) and compositions of continuous functions are continuous; polynomials are continuous everywhere, rational functions wherever the denominator is nonzero.

Limits involving infinity. We say $f(z) \to \infty$ as $z \to z_0$ if $|f(z)| \to \infty$, regardless of direction. Adding a single point ∞ to $\mathbb{C}$ gives the **extended complex plane** (the Riemann sphere). Behaviour "at infinity" is studied by substituting $z = 1/\zeta$ and examining $\zeta \to 0$: for instance $H(s) = 1/(s+1)$ has $H(1/\zeta) = \zeta/(1+\zeta) \to 0$, a zero at infinity — the "strictly proper" property of transfer functions.

Worked Example 18.4 — a limit that does not exist

Does $\lim_{z\to 0} \dfrac{\bar{z}}{z}$ exist?

Along the real axis, $z = x$: $\bar{z}/z = x/x = 1$. Along the imaginary axis, $z = jy$: $\bar{z}/z = -jy/(jy) = -1$. Along the line $y = x$, $z = x(1+j)$: $\bar{z}/z = (1-j)/(1+j) = -j$. In polar form $\bar{z}/z = e^{-2j\theta}$, which takes every value on the unit circle depending on the direction of approach. The limit does not exist.

The complex derivative

Complex derivative

f is **differentiable** at z_0 if

$$f'(z_0) = \lim_{\Delta z \to 0} \frac{f(z_0 + \Delta z) - f(z_0)}{\Delta z}$$

exists (as a complex limit, independent of how $\Delta z \to 0$).

The algebra is identical to the real case, so all the familiar rules carry over: linearity, the product rule, the quotient rule, the chain rule, and $\dfrac{d}{dz} z^n = n z^{n-1}$ for integer n (with $z \neq 0$ when $n < 0$). For example, from $(z+\Delta z)^2 - z^2 = 2z\Delta z + (\Delta z)^2$ we get $(z^2)' = \lim(2z + \Delta z) = 2z$, independent of direction. Likewise $(e^z)' = e^z$, $(\sin z)' = \cos z$, $(\cos z)' = -\sin z$, and on its cut plane $(\operatorname{Log} z)' = 1/z$.

Differentiable implies continuous

If $f'(z_0)$ exists then f is continuous at z_0, since $f(z_0+\Delta z) - f(z_0) = \dfrac{f(z_0+\Delta z) - f(z_0)}{\Delta z} \cdot \Delta z \to f'(z_0) \cdot 0 = 0$.

The converse fails dramatically: there are continuous functions, like $\bar{z}$, that are differentiable nowhere.

Worked Example 18.5 — $\bar{z}$ and $|z|^2$

(a) Show $f(z) = \bar{z}$ is nowhere differentiable. (b) Show $g(z) = |z|^2$ is differentiable only at $z = 0$.

(a) $\dfrac{\overline{z+\Delta z} - \bar{z}}{\Delta z} = \dfrac{\overline{\Delta z}}{\Delta z}$, which by Example 18.4 has no limit as $\Delta z \to 0$. So $\bar{z}$ — a perfectly smooth map of the plane (a reflection) — has no complex derivative anywhere.

(b) $|z+\Delta z|^2 - |z|^2 = (z+\Delta z)(\bar{z} + \overline{\Delta z}) - z\bar{z} = \bar{z}\Delta z + z\overline{\Delta z} + \Delta z \overline{\Delta z}$. Dividing,

$$\frac{\Delta g}{\Delta z} = \bar{z} + z\frac{\overline{\Delta z}}{\Delta z} + \overline{\Delta z}.$$

The last term $\to 0$. The middle term has no limit unless $z = 0$. So $g'(0) = 0$ and $g'(z)$ does not exist for $z \neq 0$. Note that $g = x^2 + y^2$ is infinitely differentiable as a real function of (x, y) — real smoothness is not enough.

The lesson: a function that genuinely depends on $\bar{z}$ is not complex-differentiable. Analytic functions are, informally, functions of z alone. (One can make this precise with the Wirtinger derivative $\partial f/\partial \bar{z} = \frac{1}{2}(f_x + j f_y)$; the Cauchy–Riemann equations of Section 18.3 say exactly that it vanishes.)

Analytic functions

Differentiability at a single point, as in $|z|^2$ at 0, is a curiosity. What matters is differentiability throughout a neighbourhood.

Analytic (holomorphic) function

f is **analytic at** z_0 if it is differentiable at every point of some neighbourhood $|z - z_0| < \rho$. It is **analytic in a domain** D if it is analytic at every point of D. A function analytic in the whole finite plane is **entire**. A point where f fails to be analytic, but every neighbourhood of which contains points of analyticity, is a **singular point** (singularity) of f.

Examples:

- Polynomials, e^z, $\sin z$, $\cos z$, $\sinh z$, $\cosh z$ are entire.
- A rational function P/Q (in lowest terms) is analytic except at the zeros of Q, which are its singular points (poles).
- $\operatorname{Log} z$ is analytic in the plane cut along the negative real axis, $\mathbb{C} \setminus (-\infty, 0]$. Points on the cut are singular for this branch, though another branch is analytic there; $z = 0$ is singular for every branch.
- $\tan z = \sin z / \cos z$ is analytic except where $\cos z = 0$; since $|\cos z|^2 = \cos^2 x + \sinh^2 y$, these are exactly $z = \pi/2 + k\pi$ on the real axis — the complex extension creates no new singularities.
- $\bar{z}$, $\operatorname{Re} z$, $|z|$ are analytic nowhere.

Algebra of analytic functions

Sums, products and compositions of analytic functions are analytic; a quotient f/g is analytic wherever $g \neq 0$. If f is analytic and $f'(z) = 0$ throughout a domain, f is constant there.

Worked Example 18.6 — locating singular points

Where is $f(z) = \dfrac{z^2+1}{z^3+4z}$ analytic, and what is $f'(z)$?

The denominator is $z(z^2+4) = z(z-2j)(z+2j)$. The numerator $(z-j)(z+j)$ shares no factor with it, so f is analytic on $\mathbb{C} \setminus \{0, 2j, -2j\}$. By the quotient rule,

$$f'(z) = \frac{2z(z^3+4z) - (z^2+1)(3z^2+4)}{(z^3+4z)^2} = \frac{-z^4+z^2-4}{(z^3+4z)^2}.$$

Check at $z = 1$: the formula gives $-4/25 = -0.16$; a central difference quotient $[f(1.0001) - f(0.9999)]/0.0002$ also gives -0.16000. Because f is analytic at 1, the difference quotient taken in the imaginary direction, $[f(1+0.0001j) - f(1-0.0001j)]/(0.0002j)$, gives the same value -0.16000. ✓

Worked Example 18.7 — a real function explained by complex singularities

The real function $g(x) = 1/(1+x^2)$ is infinitely differentiable on all of $\mathbb{R}$, yet its Maclaurin series $1 - x^2 + x^4 - \dots$ converges only for $|x| < 1$. Why?

Nothing on the real axis explains the radius 1. Extend to $g(z) = 1/(1+z^2) = 1/[(z-j)(z+j)]$: it has singular points at $z = \pm j$, at distance 1 from the origin. We will prove in Section 18.6 that a Taylor series about z_0 converges in the largest disc about z_0 that avoids all singularities — here $|z| < 1$, whose intersection with the real line is $(-1, 1)$. The real series "feels" poles it cannot see. Expanding instead about $x_0 = 1$, the nearest singularities are at distance $|1 - j| = \sqrt{2}$, so that series converges for $|x - 1| < \sqrt{2} = 1.414$.

What analyticity buys

The results proved later in the chapter, previewed here, show how much the single hypothesis "analytic in D" delivers:

1. **Harmonic parts** (Section 18.3): u and v satisfy Laplace's equation $\nabla^2 u = \nabla^2 v = 0$.
2. **Conformality** (Section 18.3): wherever $f' \neq 0$, f preserves angles between curves.
3. **Path independence** (Section 18.5): $\oint_C f\,dz = 0$ around any closed curve in a simply connected D.
4. **Infinite differentiability** (Section 18.5): f' is analytic too, hence f'', f''', … all exist.
5. **Power series** (Section 18.6): f equals its Taylor series in the largest disc about z_0 contained in D.
6. **Identity theorem**: if two functions analytic in D agree on a segment of curve (or any set with a limit point in D), they agree on all of D. This underlies *analytic continuation*: the Laplace transform $1/(s+a)$, computed as an integral only for $\operatorname{Re} s > -a$, has a unique analytic extension to $\mathbb{C} \setminus \{-a\}$, and that is the function whose "poles" we speak of.

Engineering Note — causality, stability and analyticity

The Laplace transform $H(s) = \int_0^\infty h(t)e^{-st}dt$ of a causal impulse response is analytic throughout its region of convergence, a right half-plane $\operatorname{Re} s > \sigma_0$ (Ch. 14). A stable causal system has $\sigma_0 < 0$, so H is analytic on and to the right of the $j\omega$-axis. Analyticity in the right half-plane is therefore the mathematical signature of a *causal, stable* system, and it is what forces relationships between gain and phase (Bode's gain–phase relation, the Kramers–Kronig relations): you cannot specify $|H(j\omega)|$ and $\angle H(j\omega)$ independently.

Common Pitfall — "analytic at a point"

A function can be differentiable at a point without being analytic there ($|z|^2$ at 0). Analyticity is a neighbourhood property. When a theorem says "analytic inside and on C", it means analytic on some open set containing the curve and its interior.

18.3 Cauchy–Riemann equations

Motivation

The definition of the derivative is hard to check directly. We want a practical test in terms of u and v — something we can compute with ordinary partial derivatives. The test, the Cauchy–Riemann equations, does more than decide differentiability: it reveals that the real and imaginary parts of an analytic function are *harmonic* (they solve Laplace's equation, the equation of electrostatic potential, steady heat flow and ideal fluid flow) and that analytic maps preserve angles. Those two facts turn analytic functions into a toolkit for two-dimensional field problems.

Derivation

Suppose $f = u + jv$ is differentiable at $z_0 = x_0 + jy_0$. The limit defining $f'(z_0)$ must be the same along every path, in particular along the two coordinate directions.

Horizontal approach, $\Delta z = \Delta x$ real:

$$f'(z_0) = \lim_{\Delta x \to 0} \frac{u(x_0+\Delta x, y_0) - u(x_0, y_0)}{\Delta x} + j\frac{v(x_0+\Delta x, y_0) - v(x_0, y_0)}{\Delta x} = u_x + jv_x.$$

Vertical approach, $\Delta z = j\Delta y$:

$$f'(z_0) = \lim_{\Delta y \to 0} \frac{[u(x_0, y_0+\Delta y) - u] + j[v(x_0, y_0+\Delta y) - v]}{j\Delta y} = \frac{1}{j}(u_y + jv_y) = v_y - ju_y.$$

Equating real and imaginary parts of the two expressions gives the equations.

Cauchy–Riemann equations (necessary condition)

If $f = u + jv$ is differentiable at z_0, then the first partial derivatives of u and v exist at (x_0, y_0) and satisfy

$$u_x = v_y, \qquad u_y = -v_x.$$

Moreover $f'(z_0) = u_x + jv_x = v_y - ju_y$.

The equations are necessary but, on their own, not quite sufficient (there are pathological functions satisfying them at a point without being differentiable). A mild smoothness hypothesis closes the gap.

Sufficient condition

Let u and v have continuous first partial derivatives in a neighbourhood of z_0, and let them satisfy the Cauchy–Riemann equations at z_0. Then $f'(z_0)$ exists. If this holds at every point of a domain D, f is analytic in D.

Proof sketch. Continuity of the partials makes u and v differentiable as real functions, so $\Delta u = u_x\Delta x + u_y\Delta y + \varepsilon_1|\Delta z|$ and $\Delta v = v_x\Delta x + v_y\Delta y + \varepsilon_2|\Delta z|$ with $\varepsilon_{1,2} \to 0$. Substituting $u_y = -v_x$, $v_y = u_x$:

$$\Delta f = \Delta u + j\Delta v = (u_x + jv_x)(\Delta x + j\Delta y) + (\varepsilon_1 + j\varepsilon_2)|\Delta z|,$$

so $\Delta f/\Delta z \to u_x + jv_x$ because $|\Delta z|/\Delta z$ has modulus 1. $\square$

Matrix viewpoint. As a map of $\mathbb{R}^2$, f has Jacobian $\begin{pmatrix} u_x & u_y \\ v_x & v_y \end{pmatrix}$. Under Cauchy–Riemann it becomes $\begin{pmatrix} a & -b \\ b & a \end{pmatrix}$ with $a = u_x$, $b = v_x$ — a rotation by $\angle f'$ times a scaling by $|f'|$. That is precisely the matrix of multiplication by the complex number $f' = a + jb$. A complex-differentiable function is one whose local linear approximation is *multiplication by a complex number*, not an arbitrary 2×2 matrix. The Jacobian determinant is $a^2 + b^2 = |f'|^2$, the local area magnification used in Example 18.3.

Polar form. With $z = re^{j\theta}$ and $u(r,\theta)$, $v(r,\theta)$, the chain rule converts the equations to

$$u_r = \frac{1}{r}v_\theta, \qquad v_r = -\frac{1}{r}u_\theta, \qquad f'(z) = e^{-j\theta}(u_r + jv_r), \qquad r > 0.$$

These are convenient for functions built from r and θ, such as powers and logarithms.

Worked Example 18.8 — applying the test

Test (a) $f = z^2$, (b) $f = e^z$, (c) $f = \bar{z}$, (d) $f = x^2 + jy^2$, (e) $f = \operatorname{Log} z$.

(a) $u = x^2 - y^2$, $v = 2xy$: $u_x = 2x = v_y$, $u_y = -2y = -v_x$. ✓ everywhere; $f' = u_x + jv_x = 2x + 2jy = 2z$.

(b) $u = e^x\cos y$, $v = e^x \sin y$: $u_x = e^x\cos y = v_y$; $u_y = -e^x \sin y = -v_x$. ✓ everywhere, $f' = e^x\cos y + je^x \sin y = e^z$. The exponential is its own derivative in $\mathbb{C}$ too.

(c) $u = x$, $v = -y$: $u_x = 1$ but $v_y = -1$. ✗ everywhere — confirming Example 18.5.

(d) $u = x^2$, $v = y^2$: $u_x = 2x$, $v_y = 2y$, so the first equation needs $x = y$; the second, $0 = 0$, always holds. The partials are continuous, so f is differentiable exactly on the line $y = x$, with $f' = 2x$ there. A line has no interior, so f is **analytic nowhere**.

(e) $u = \ln r$, $v = \theta$ (principal branch, $-\pi < \theta < \pi$): $u_r = 1/r = \frac{1}{r}v_\theta$ and $v_r = 0 = -\frac{1}{r}u_\theta$. ✓ on the cut plane, $f' = e^{-j\theta}\cdot\frac{1}{r} = 1/z$.

Harmonic functions

Real and imaginary parts are harmonic

If $f = u + jv$ is analytic in D (and u, v have continuous second partials — automatically true, as Section 18.5 shows), then

$$\nabla^2 u = u_{xx} + u_{yy} = 0, \qquad \nabla^2 v = v_{xx} + v_{yy} = 0 \quad \text{in } D.$$

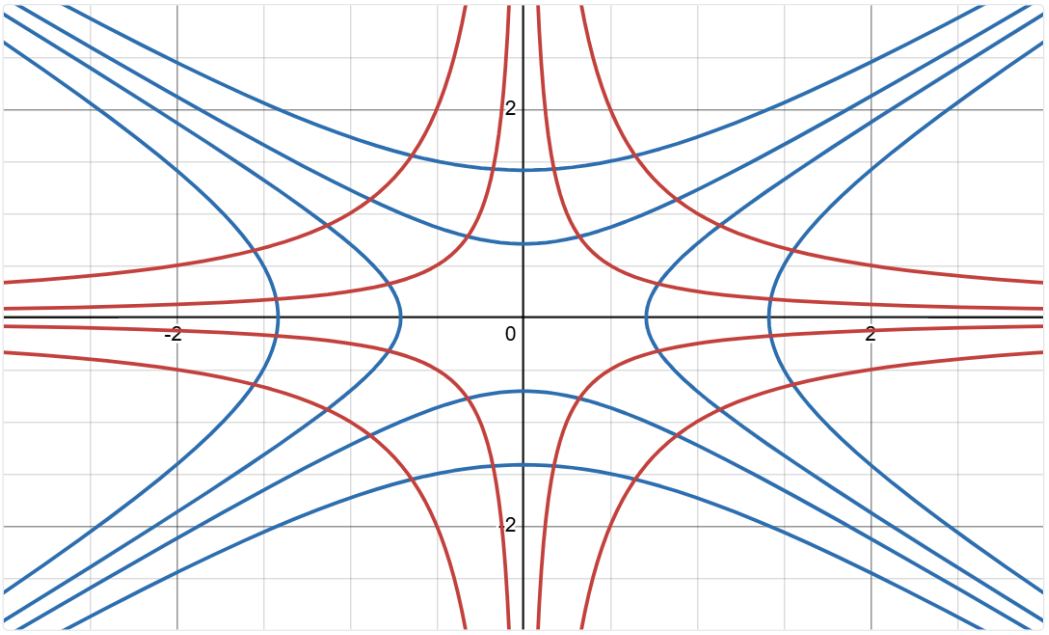
Proof. Differentiate $u_x = v_y$ with respect to x and $u_y = -v_x$ with respect to y: $u_{xx} = v_{yx}$ and $u_{yy} = -v_{xy}$. Adding, and using equality of mixed partials, $u_{xx} + u_{yy} = 0$. The same argument works for v. $\square$

A function satisfying Laplace's equation is **harmonic**. If u and v are harmonic and satisfy Cauchy–Riemann together, v is a **harmonic conjugate** of u. Every harmonic u on a simply connected domain has a harmonic conjugate, unique up to an additive constant, found by integrating the Cauchy–Riemann equations.

Orthogonality of level curves. The gradients are $\nabla u = (u_x, u_y)$ and $\nabla v = (v_x, v_y) = (-u_y, u_x)$, so

$$\nabla u \cdot \nabla v = -u_x u_y + u_y u_x = 0.$$

Where $f' \neq 0$, the curves $u = \text{const}$ and $v = \text{const}$ cross at right angles. In electrostatics, if u is the potential then $v = \text{const}$ are the field lines (flux lines); in fluid flow they are the equipotentials and streamlines.



Level curves of $u = \mathrm{Re}\{z^2\} = x^2 - y^2$ (blue) and $v = \mathrm{Im}\{z^2\} = 2xy$ (red): two families of hyperbolas that cross at right angles everywhere except at the critical point $z = 0$, where $f'(0) = 0$. They are the equipotentials and field lines near a right-angled conducting corner.

Worked Example 18.9 — constructing harmonic conjugates

(a) Show $u = x^2 - y^2 + 2x + 1$ is harmonic, find a harmonic conjugate v and the analytic f. (b) Repeat for $u = e^{-y}\cos x$. (c) Is $u = x^2 + y^2$ the real part of an analytic function?

(a) $u_{xx} + u_{yy} = 2 - 2 = 0$. ✓ From $v_y = u_x = 2x + 2$, integrate in y: $v = 2xy + 2y + h(x)$. Then $v_x = 2y + h'(x)$ must equal $-u_y = 2y$, so $h' = 0$ and $h = C$. Thus $v = 2xy + 2y + C$ and

$$f = u + jv = (x^2 - y^2 + 2x + 1) + j(2xy + 2y) + jC = (z + 1)^2 + jC.$$

Check at $z = j$: $(1 + j)^2 = 2j$, while $u(0, 1) = -1 + 1 = 0$ and $v(0, 1) = 2$. ✓

(b) $u_{xx} = -e^{-y}\cos x$, $u_{yy} = e^{-y}\cos x$; sum 0. ✓ From $v_y = u_x = -e^{-y}\sin x$: $v = e^{-y}\sin x + h(x)$. Then $v_x = e^{-y}\cos x + h'$ must equal $-u_y = e^{-y}\cos x$, so $h = C$. Hence $f = e^{-y}(\cos x + j\sin x) = e^{-y+jx} = e^{jz}$ (plus jC).

(c) $\nabla^2 u = 2 + 2 = 4 \neq 0$. Not harmonic, so it cannot be the real part of any analytic function.

A shortcut (Milne-Thomson). Since $f' = u_x - ju_y$, set $y = 0$ and $x = z$: $f'(z) = u_x(z, 0) - ju_y(z, 0)$, then integrate. In (a): $u_x(z, 0) = 2z + 2$, $u_y(z, 0) = 0$, so $f' = 2z + 2$ and $f = z^2 + 2z + c$ with $c = u(0, 0) = 1$ (up to jC). The method relies on the identity theorem: an analytic function is fixed by its values on the real axis.

Conformal mapping

Here is the geometric heart of the Cauchy–Riemann equations. Let a smooth curve $z(t)$ pass through $z_0 = z(t_0)$ with tangent vector $z'(t_0) \neq 0$. Its image $w(t) = f(z(t))$ has tangent, by the chain rule,

$$w'(t_0) = f'(z_0)\, z'(t_0).$$

Multiplying by the fixed complex number $f'(z_0) = |f'(z_0)|e^{j\alpha}$ rotates *every* tangent direction at z_0 by the same angle $\alpha = \angle f'(z_0)$ and stretches it by the same factor $|f'(z_0)|$. Two curves crossing at z_0 at angle β therefore have images crossing at angle β too.

Conformality of analytic maps

If f is analytic at z_0 and $f'(z_0) \neq 0$, then f is **conformal** at z_0: it preserves both the magnitude and the sense of the angle between any two smooth curves through z_0. Infinitesimally small figures near z_0 are rotated by $\angle f'(z_0)$ and scaled by $|f'(z_0)|$, so small squares map to (nearly) small squares, with area scaled by $|f'(z_0)|^2$.

At a **critical point**, where $f'(z_0) = 0$ and the first nonvanishing derivative is $f^{(m)}(z_0)$, angles are multiplied by m.

This is what the two graphs of Section 18.1 showed: the orthogonal grid stayed orthogonal under z^2 and $1/z$. At $z = 0$, $(z^2)' = 0$ with $m = 2$: the right angle between the positive real and imaginary axes opens into the straight angle between the positive and negative real w-axes.

Why conformal maps solve field problems. If $\Phi(u, v)$ is harmonic in the w-plane and $w = f(z)$ is analytic, then $\phi(x, y) = \Phi(u(x, y), v(x, y))$ is harmonic in the z-plane. (Locally $\Phi = \mathrm{Re}\, F(w)$ for analytic F, and $F(f(z))$ is analytic.) Conductor boundaries map to boundaries, and the boundary values carry over. So a hard geometry in the z-plane can be mapped to an easy one — parallel plates, a half-plane — solved there, and mapped back. The *complex potential* $\Omega = \phi + j\psi$ packages potential ϕ and flux function ψ into one analytic function.

Worked Example 18.10 — coaxial-line capacitance by conformal mapping

A coaxial line has inner conductor radius a at potential V_0 and outer radius b at 0, filled with dielectric ε. Find the capacitance per unit length by mapping to a parallel-plate geometry.

Use $w = \operatorname{Log} z = \ln r + j\theta$. The annulus $a < r < b$ maps to the rectangle $\ln a < u < \ln b$, $-\pi < v \le \pi$: the circle $r = a$ becomes the line $u = \ln a$ and $r = b$ the line $u = \ln b$. In the w-plane we have a parallel-plate capacitor of gap $d = \ln(b/a)$ and width 2π (per unit depth), whose edges $v = \pm\pi$ are glued together — so there are no fringing fields. The potential is linear in u:

$$\Phi = V_0 \frac{\ln b - u}{\ln(b/a)} \quad \Longrightarrow \quad \phi(r) = V_0 \frac{\ln(b/r)}{\ln(b/a)}.$$

A conformal map preserves capacitance (charge and potential are both preserved, since flux through corresponding curves is the same), so $C' = \varepsilon \cdot \dfrac{\text{width}}{\text{gap}} = \dfrac{2\pi\varepsilon}{\ln(b/a)}$.

Numerically, with $a = 0.5$ mm, $b = 1.75$ mm and $\varepsilon_r = 2.25$ (polyethylene): $C' = 2\pi(8.854 \times 10^{-12})(2.25)/\ln 3.5 = 99.9$ pF/m — the familiar value for a 50 Ω cable. Dimensions: ε in F/m divided by a pure number gives F/m. ✓

Engineering Note — where conformal maps appear

Microstrip and coplanar-waveguide impedance formulas come from Schwarz–Christoffel conformal maps (which send polygons to half-planes); the Smith chart is the Möbius map $\Gamma = (z_L - 1)/(z_L + 1)$; the bilinear transform $s = \frac{2}{T}\frac{z-1}{z+1}$ used to discretize analog filters is a conformal Möbius map of the left half s-plane onto the unit z-disc, which is why it preserves stability and why it warps frequency ($\omega_a = \frac{2}{T}\tan\frac{\omega_d T}{2}$).

Common Pitfall — checking only one equation, or only at one point

Both Cauchy–Riemann equations must hold, and they must hold throughout an open set for analyticity. $f = x^2 + jy^2$ satisfies them on a line and is analytic nowhere. Conversely, a function whose partials are discontinuous can satisfy the equations at a point and still fail to be differentiable there; quote the sufficiency theorem with its continuity hypothesis.

18.4 Contour integration

Motivation

The inverse Laplace transform is an integral along a vertical line in the s-plane; the inverse Z-transform is an integral around a circle in the z-plane; the Fourier integral is an integral along the $j\omega$-axis. These are integrals of complex functions along curves — *contour integrals*. This section defines them, shows how to compute them from a parametrization, and establishes the two workhorses: the antiderivative rule and the ML bound. The next sections show that for analytic integrands the curve can be deformed almost at will, which is where the power lies.

Curves and contours

Arcs, contours and orientation

A **smooth arc** is a curve $z(t) = x(t) + jy(t)$, $a \le t \le b$, with $z'(t)$ continuous and nonzero. A **contour** (piecewise smooth path) is a finite chain of smooth arcs joined end to end. A contour is **closed** if $z(b) = z(a)$, and **simple** if it does not cross itself (apart from the endpoints of a closed one). A simple closed contour is **positively oriented** if it is traversed counter-clockwise — the interior lies to the left of the direction of travel.

Standard parametrizations:

Curve	Parametrization
segment from z_1 to z_2	$z(t) = z_1 + (z_2 - z_1)t,\ 0 \le t \le 1$
circle $\lvert z - z_0\rvert = \rho$, counter-clockwise	$z(\theta) = z_0 + \rho e^{j\theta},\ 0 \le \theta \le 2\pi$
upper semicircle of radius R	$z(\theta) = Re^{j\theta},\ 0 \le \theta \le \pi$
vertical line $\operatorname{Re} z = \gamma$, upward	$z(\omega) = \gamma + j\omega,\ -\infty < \omega < \infty$

The last is the Bromwich contour of the inverse Laplace transform (Section 18.9). On a circle, $dz = j\rho e^{j\theta} d\theta = j(z - z_0)\, d\theta$, an identity used constantly.

Definition and evaluation

Contour integral

Let C be a contour $z(t)$, $a \le t \le b$, and f continuous on C. Then

$$\int_C f(z)\, dz = \int_a^b f\big(z(t)\big)\, z'(t)\, dt.$$

It is the limit of Riemann sums $\sum f(\zeta_k)\,\Delta z_k$ with $\Delta z_k = z_k - z_{k-1}$, and its value does not depend on which parametrization of C (with the same direction) is used. For a closed contour we write $\oint_C$.

Writing $f = u + jv$ and $dz = dx + j\,dy$ shows how the contour integral relates to the real line integrals of Ch. 7:

$$\int_C f\,dz = \int_C (u\,dx - v\,dy) + j\int_C (v\,dx + u\,dy).$$

This decomposition is what connects Cauchy's theorem to Green's theorem in the next section.

Properties

For contours C, C_1, C_2 and constants α, β:

1. Linearity: $\int_C (\alpha f + \beta g)\,dz = \alpha\int_C f\,dz + \beta\int_C g\,dz$.
2. Reversal: $\int_{-C} f\,dz = -\int_C f\,dz$, where $-C$ is C traversed backwards.
3. Additivity: $\int_{C_1+C_2} f\,dz = \int_{C_1} f\,dz + \int_{C_2} f\,dz$ for C_2 starting where C_1 ends.
4. Modulus bound: $\left|\int_C f\,dz\right| \le \int_C |f(z)|\,|dz|$, with $|dz| = |z'(t)|dt$ the element of arc length.

The fundamental integral

Worked Example 18.11 — integer powers around a circle

Let C be the circle $|z - z_0| = \rho$, counter-clockwise. Evaluate $\oint_C (z - z_0)^n\,dz$ for every integer n.

Parametrize $z = z_0 + \rho e^{j\theta}$, $dz = j\rho e^{j\theta} d\theta$:

$$\oint_C (z - z_0)^n\,dz = \int_0^{2\pi} \rho^n e^{jn\theta}\, j\rho e^{j\theta}\,d\theta = j\rho^{n+1}\int_0^{2\pi} e^{j(n+1)\theta}\,d\theta.$$

If $n \neq -1$, the integral of $e^{j(n+1)\theta}$ over a full period is 0. If $n = -1$, the integrand is 1 and the result is $2\pi j$:

$$\oint_C (z - z_0)^n\,dz = \begin{cases} 2\pi j, & n = -1 \\ 0, & n \neq -1. \end{cases}$$

The answer is independent of the radius ρ. This single computation is the seed of the whole residue theory: when a function is expanded in powers of $(z - z_0)$, only the $(z - z_0)^{-1}$ term survives integration around z_0.

Path dependence and the antiderivative rule

Worked Example 18.12 — z^2 versus $\bar{z}$ along two paths

Integrate from 0 to $1 + j$ along (i) the straight segment C_1, and (ii) the path C_2 that runs along the real axis to 1 and then straight up to $1 + j$. Do this for $f = z^2$ and $f = \bar{z}$.

$f = z^2$, **path (i):** $z = (1 + j)t$, $dz = (1 + j)dt$:

$$\int_{C_1} z^2 dz = \int_0^1 (1 + j)^3 t^2\,dt = \frac{(1 + j)^3}{3} = \frac{-2 + 2j}{3}.$$

$f = z^2$, **path (ii):** on $[0, 1]$, $\int_0^1 x^2 dx = \frac{1}{3}$. On the vertical leg $z = 1 + jy$, $dz = j\,dy$: $\int_0^1 (1 + jy)^2 j\,dy = j\int_0^1 (1 - y^2 + 2jy)\,dy = j\left(\frac{2}{3} + j\right) = -1 + \frac{2}{3}j$. Total $\frac{1}{3} - 1 + \frac{2}{3}j = \frac{-2+2j}{3}$ — the same.

$f = \bar{z}$, **path (i):** $\bar{z} = (1 - j)t$: $\int_0^1 (1 - j)t(1 + j)\,dt = 2 \cdot \frac{1}{2} = 1$.

$f = \bar{z}$, **path (ii):** $\int_0^1 x\,dx = \frac{1}{2}$, then $\int_0^1 (1 - jy)j\,dy = \int_0^1 (j + y)\,dy = j + \frac{1}{2}$. Total $1 + j$ — **different**.

The analytic integrand gives a path-independent answer; the non-analytic one does not. The difference, $(1 + j) - 1 = j$, equals $\oint \bar{z}\,dz$ around the closed triangle $C_2 - C_1$, and in general $\oint_C \bar{z}\,dz = 2j \times$ (area enclosed) — here the triangle has area $\frac{1}{2}$. ✓ (Around the unit circle this gives $2\pi j$, matching the direct computation $\int_0^{2\pi} e^{-j\theta} j e^{j\theta} d\theta = 2\pi j$.)

Antiderivative (fundamental theorem for contour integrals)

If f is continuous in a domain D and has an antiderivative F there ($F' = f$ throughout D), then for every contour C in D from z_1 to z_2,

$$\int_C f(z)\,dz = F(z_2) - F(z_1),$$

independent of the path. In particular $\oint_C f\,dz = 0$ for every closed contour in D.

Proof. $\frac{d}{dt}F(z(t)) = F'(z(t))z'(t) = f(z(t))z'(t)$, so the integral is $[F(z(t))]_a^b$. □

So $\int_C z^2 dz = [z^3/3]_0^{1+j}$ immediately. Conversely, Example 18.11 shows $1/(z - z_0)$ has **no** antiderivative on any domain containing a circle around z_0: its "antiderivative" $\log(z - z_0)$ is multivalued, and going once around changes it by $2\pi j$.

Worked Example 18.13 — $1/z$ and the branch of the logarithm

Compute $\int dz/z$ from $-j$ to j along (i) the right half of the unit circle and (ii) the left half.

(i) The right half lies in the cut plane $\mathbb{C} \setminus (-\infty, 0]$, where Log is an antiderivative: $\operatorname{Log} j - \operatorname{Log}(-j) = j\frac{\pi}{2} - (-j\frac{\pi}{2}) = j\pi$.

(ii) The left half crosses the negative real axis, so use a branch cut along the positive real axis instead, with $\arg z \in (0, 2\pi)$: then $\arg j = \pi/2$ and $\arg(-j) = 3\pi/2$, giving $j\pi/2 - j3\pi/2 = -j\pi$.

Directly: path (ii) is $z = e^{j\theta}$ with θ from $3\pi/2$ down to $\pi/2$, so $\int j\,d\theta = j(\pi/2 - 3\pi/2) = -j\pi$. ✓ The two paths differ by $2\pi j$: going up the right side and back down the left encircles the origin once counter-clockwise, $\oint dz/z = j\pi - (-j\pi) = 2\pi j$.

The ML inequality

Most contour arguments end by showing that some piece of the contour contributes nothing in a limit. The tool is a simple bound.

ML inequality (estimation lemma)

If $|f(z)| \le M$ for all z on a contour C of length L, then

$$\left| \int_C f(z)\,dz \right| \le ML.$$

Proof. $\left|\int_C f\,dz\right| \le \int_C |f||dz| \le M\int_C |dz| = ML$. □

To bound $|f|$ from above we need lower bounds on denominators, usually from the reverse triangle inequality $|z_1 + z_2| \ge \big||z_1| - |z_2|\big|$.

Worked Example 18.14 — bounding integrals

(a) Let C_R be the upper semicircle $|z| = R > 1$. Show $\int_{C_R} \frac{dz}{z^2+1} \to 0$ as $R \to \infty$. (b) Bound $\left|\oint_{|z|=2} \frac{e^z}{z^2+1} dz\right|$ and compare with the exact value.

(a) On C_R, $|z^2 + 1| \ge |z|^2 - 1 = R^2 - 1$, so $M = 1/(R^2-1)$; $L = \pi R$. Hence $\left|\int_{C_R}\right| \le \frac{\pi R}{R^2-1} \to 0$. For $R = 10$ the bound is 0.0317. The general rule: if $|f| \le K/R^k$ on C_R with $k > 1$, the integral over C_R vanishes as $R \to \infty$.

(b) On $|z| = 2$: $|e^z| = e^x \le e^2$ and $|z^2 + 1| \ge 4 - 1 = 3$, so $M = e^2/3$ and $L = 4\pi$: the bound is $4\pi e^2/3 = 30.95$. The exact value (Section 18.8) is $2\pi j \sin 1$, of modulus 5.287. The ML bound is crude — its job is to prove that something tends to zero, not to estimate it accurately.

Common Pitfall — forgetting $z'(t)$ or the orientation

$\int_C f\,dz$ is not $\int f\,dt$: the factor $z'(t)$ (on circles, $j\rho e^{j\theta}$) carries both the length element and the direction. A clockwise circle gives the negative of the counter-clockwise result, so $\oint dz/z = -2\pi j$ clockwise. Also, $\int_C f\,dz$ is not the same as the arc-length integral $\int_C f|dz|$; only the latter is used in bounds.

Engineering Note — contour integrals you have already met

The inverse Z-transform $x[n] = \frac{1}{2\pi j}\oint_C z^{n-1}X(z)\,dz$ (Ch. 17) is a contour integral around a circle in the ROC; on the unit circle $z = e^{j\Omega}$, $dz = jz\,d\Omega$ and it collapses to the inverse DTFT $\frac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\Omega})e^{j\Omega n}d\Omega$. The inverse Fourier transform $\frac{1}{2\pi}\int X(\omega)e^{j\omega t}d\omega$ is $\frac{1}{2\pi j}\int_{j\mathbb{R}} X(s)e^{st}ds$ along the imaginary axis. Seeing these as contour integrals is what lets us evaluate them by residues.

18.5 Cauchy's integral theorem

Motivation

Example 18.12 showed an analytic integrand giving the same answer along two different paths. Cauchy's theorem says this is always so on a domain without holes: the integral of an analytic function around any closed curve is zero. Its corollary, the Cauchy integral formula, says something even stronger — the values of an analytic function *inside* a closed curve are completely determined by its values *on* the curve. These two results convert integration problems into the bookkeeping of singular points, and they deliver, almost for free, the infinite differentiability of analytic functions, Liouville's theorem, the fundamental theorem of algebra and the maximum-modulus principle.

The theorem

Cauchy's integral theorem (Cauchy–Goursat)

Let f be analytic in a simply connected domain D. Then for every closed contour C in D,

$$\oint_C f(z)\,dz = 0.$$

Equivalently: if f is analytic inside and on a simple closed contour C, then $\oint_C f\,dz = 0$.

Proof sketch (assuming f' continuous). Let C be simple and positively oriented, enclosing a region R. Split the integral as in Section 18.4 and apply Green's theorem (Ch. 7), $\oint_C (P\,dx + Q\,dy) = \iint_R (Q_x - P_y)\,dA$:

$$\oint_C f\,dz = \oint_C (u\,dx - v\,dy) + j\oint_C (v\,dx + u\,dy) = \iint_R (-v_x - u_y)\,dA + j\iint_R (u_x - v_y)\,dA.$$

Both integrands vanish identically by the Cauchy–Riemann equations. □

Goursat's refinement removes the assumption that f' is continuous: one subdivides a triangle repeatedly, uses the fact that f is approximated by $f(z_0) + f'(z_0)(z - z_0)$ near a limit point z_0, and shows the integral is smaller than any ε. The distinction matters theoretically — it is why "analytic" alone suffices in every later theorem — but not computationally.

Consequences on a simply connected domain

If f is analytic in a simply connected domain D:

1. $\int_{z_1}^{z_2} f\,dz$ is independent of the path in D;
2. $F(z) = \int_{z_0}^{z} f(\zeta)\,d\zeta$ is analytic in D with $F' = f$ — every analytic function has an antiderivative there.

Deformation of contours

On a domain with holes, closed curves around a hole need not give zero — $\oint dz/z = 2\pi j$ around the origin. But the answer depends only on *which holes are encircled*, not on the shape of the curve.

Deformation principle

Let C and C_1 be positively oriented simple closed contours with C_1 inside C, and let f be analytic in the closed region between them (it may have singularities inside C_1). Then

$$\oint_C f\,dz = \oint_{C_1} f\,dz.$$

More generally, if C encloses disjoint contours $C_1, \dots, C_n$ and f is analytic in the region inside C and outside every C_k, then $\oint_C f\,dz = \sum_{k=1}^{n} \oint_{C_k} f\,dz$.

Proof sketch. Join C to C_1 by a cross-cut. The contour that runs around C counter-clockwise, in along the cut, around C_1 clockwise and back out along the cut bounds a simply connected region where f is analytic, so its integral is 0. The two traversals of the cut cancel, leaving $\oint_C - \oint_{C_1} = 0$. □

The practical upshot: **shrink the contour onto the singularities.** Any contour around z_0 can be replaced by a tiny circle around z_0. Combined with Example 18.11, for any positively oriented simple closed contour C,

$$\oint_C \frac{dz}{(z-a)^n} = \begin{cases} 2\pi j, & n = 1 \text{ and } a \text{ inside } C \\ 0, & \text{otherwise } (n \geq 1 \text{ integer},\ a \notin C). \end{cases}$$

Worked Example 18.15 — partial fractions plus deformation

Evaluate $\oint_C \dfrac{dz}{z^2 - 1}$ for (a) $C : |z| = 2$, (b) $C : |z - 1| = 1$, (c) $C : |z| = \tfrac{1}{2}$.

Partial fractions: $\dfrac{1}{z^2-1} = \dfrac{1}{2}\left(\dfrac{1}{z-1} - \dfrac{1}{z+1}\right)$.

(a) Both ± 1 are inside: $\tfrac{1}{2}(2\pi j - 2\pi j) = 0$. (The integral is zero even though the integrand is not analytic inside — Cauchy's theorem is sufficient, not necessary.)

(b) Only $z = 1$ is inside ($|-1 - 1| = 2 > 1$): $\tfrac{1}{2} \cdot 2\pi j = \pi j$.

(c) Neither is inside; f is analytic on and inside C: 0.

The Cauchy integral formula

Cauchy integral formula

Let f be analytic inside and on a positively oriented simple closed contour C, and let z_0 be inside C. Then

$$f(z_0) = \frac{1}{2\pi j}\oint_C \frac{f(z)}{z - z_0}\,dz.$$

Proof. The integrand $f(z)/(z - z_0)$ is analytic except at z_0, so by deformation we may replace C by a small circle $C_\rho : |z - z_0| = \rho$. Write

$$\oint_{C_\rho} \frac{f(z)}{z - z_0}dz = f(z_0)\oint_{C_\rho} \frac{dz}{z - z_0} + \oint_{C_\rho} \frac{f(z) - f(z_0)}{z - z_0}dz = 2\pi j\, f(z_0) + I_\rho.$$

By continuity, $|f(z) - f(z_0)| < \varepsilon$ on C_ρ for small ρ, so by ML, $|I_\rho| \leq (\varepsilon/\rho)(2\pi\rho) = 2\pi\varepsilon$. Since the left side does not depend on ρ, $I_\rho = 0$. □

This is astonishing from a real-variable viewpoint: boundary values determine the interior completely. Taking C to be a circle $z = z_0 + \rho e^{j\theta}$ gives the **mean-value property**

$$f(z_0) = \frac{1}{2\pi}\int_0^{2\pi} f(z_0 + \rho e^{j\theta})\,d\theta,$$

and its real part says that a harmonic function (an electrostatic potential in a charge-free region) equals its average over any circle centred at the point.

Cauchy integral formula for derivatives

Under the same hypotheses f has derivatives of all orders at z_0, and

$$f^{(n)}(z_0) = \frac{n!}{2\pi j}\oint_C \frac{f(z)}{(z-z_0)^{n+1}}\,dz, \qquad n = 0, 1, 2, \ldots$$

Proof sketch. Differentiate the integral formula with respect to z_0 under the integral sign: $\frac{d}{dz_0}(z-z_0)^{-1} = (z-z_0)^{-2}$, $\frac{d^2}{dz_0^2}(z-z_0)^{-1} = 2(z-z_0)^{-3}$, and so on. Justifying the interchange is a uniform-convergence argument on C, where $|z-z_0|$ is bounded below. $\square$

Corollary. If f is analytic in D, so are f', f'', ... Hence u and v have continuous partial derivatives of all orders — the assumption made in proving harmonicity in Section 18.3 was automatically satisfied.

Read in reverse, the derivative formula is an *integration* rule, the form in which we use it:

$$\oint_C \frac{f(z)}{(z-z_0)^{n+1}}dz = \frac{2\pi j}{n!}f^{(n)}(z_0).$$

Worked Example 18.16 — direct use of the integral formula

(a) $\displaystyle\oint_{|z|=2}\frac{e^z}{z-1}dz$. (b) $\displaystyle\oint_{|z-j|=1}\frac{dz}{z^2+1}$. (c) $\displaystyle\oint_{|z|=3}\frac{e^z}{z^2+1}dz$.

(a) $f = e^z$ is entire and $z_0 = 1$ is inside: $2\pi j\, e^1 = 17.079j$.

(b) Only $z = j$ is inside the circle $|z-j| = 1$ ($-j$ is at distance 2). Write $\dfrac{1}{z^2+1} = \dfrac{1/(z+j)}{z-j}$, with $f(z) = 1/(z+j)$ analytic inside. Result: $2\pi j \cdot \dfrac{1}{2j} = \pi$.

(c) Both $\pm j$ are inside. Surround each by a small circle (deformation principle) and apply the formula to each:

$$\oint = 2\pi j\left[\frac{e^j}{2j} + \frac{e^{-j}}{-2j}\right] = 2\pi j\cdot\frac{e^j - e^{-j}}{2j} = 2\pi j\sin 1 = 5.2871j.$$

All three values were confirmed by numerical quadrature of the parametrized integrals.

Worked Example 18.17 — higher-order formula

(a) $\displaystyle\oint_{|z|=2}\frac{e^{2z}}{(z-1)^2}dz$. (b) $\displaystyle\oint_{|z|=2}\frac{\cos z}{(z-j)^3}dz$. (c) $\displaystyle\oint_{|z|=1}\frac{\sin z}{z^4}dz$.

(a) $n = 1$, $f = e^{2z}$, $f'(1) = 2e^2$: result $2\pi j\cdot 2e^2 = 4\pi e^2 j = 92.854j$.

(b) $n = 2$, $f = \cos z$, $f''(z) = -\cos z$, $f''(j) = -\cos j = -\cosh 1$: result $\dfrac{2\pi j}{2!}(-\cosh 1) = -\pi j\cosh 1 = -4.8477j$.

(c) $n = 3$, $f = \sin z$, $f'''(0) = -\cos 0 = -1$: result $\dfrac{2\pi j}{3!}(-1) = -\dfrac{\pi j}{3} = -1.0472j$. Check with the series of Section 18.6: $\sin z/z^4 = z^{-3} - \frac{1}{6}z^{-1} + \ldots$, and only the z^{-1} term contributes, giving $2\pi j(-\frac{1}{6})$. ✓

Consequences: estimates, Liouville, and the maximum principle

Cauchy's estimate. If $|f| \le M$ on the circle $|z-z_0| = \rho$, the derivative formula and ML give

$$|f^{(n)}(z_0)| \le \frac{n!}{2\pi}\cdot\frac{M}{\rho^{n+1}}\cdot 2\pi\rho = \frac{n!\,M}{\rho^n}.$$

Liouville's theorem

A bounded entire function is constant.

Proof. If $|f| \le M$ everywhere, Cauchy's estimate with $n = 1$ gives $|f'(z_0)| \le M/\rho$ for every ρ; let $\rho \to \infty$. So $f' \equiv 0$. $\square$

That is why $\sin z$ must be unbounded in $\mathbb{C}$. It also gives a two-line proof of the **fundamental theorem of algebra**: if a non-constant polynomial P had no zero, $1/P$ would be entire and (since $|P| \to \infty$) bounded, hence constant — contradiction. So every polynomial of degree $n \ge 1$ has a root, and by induction exactly n roots counted with multiplicity. Every characteristic polynomial in this book therefore factors completely over $\mathbb{C}$.

Maximum-modulus principle

If f is analytic and non-constant in a bounded domain D and continuous on its closure, then $|f|$ attains its maximum on the boundary of D, never at an interior point.

Proof idea. By the mean-value property, $|f(z_0)| \le$ the average of $|f|$ over any small circle about z_0; if $|f(z_0)|$ were a maximum, $|f|$ would have to equal it on the whole circle, and then (by the identity theorem) everywhere. $\square$

Engineering Note — why the H_∞ norm is measured on the $j\omega$-axis

For a stable transfer function $H(s)$, analytic in the closed right half-plane and bounded at infinity, the maximum-modulus principle (applied on large half-discs) shows $\sup_{\mathrm{Re}\, s\ge 0}|H(s)| = \sup_\omega |H(j\omega)|$. The peak gain over all exponentially growing inputs equals the peak of the Bode magnitude plot. This is the H_∞ norm of robust control, and it is computable from frequency-response data alone.

Common Pitfall — hypotheses of Cauchy's theorem

$\oint_C f\,dz = 0$ requires analyticity at **every** point inside C, not just on C. $\oint_{|z|=1} e^z/z^2\,dz = 2\pi j \neq 0$ even though e^z/z^2 is perfectly well behaved on the circle. Equally, a singularity *on* the contour makes the integral improper; it must be treated as a principal value with an indentation (Section 18.8), not ignored.

18.6 Taylor and Laurent series

Motivation

Power series are how analytic functions are computed, approximated and classified. A Taylor series describes f near a point where it is analytic. A Laurent series — a power series allowed to have negative powers — describes f near, and around, its singularities, and it is valid in an **annulus** rather than a disc. Engineers already use Laurent series under another name: the Z-transform $X(z) = \sum_n x[n] z^{-n}$ *is* a Laurent series in z, and its region of convergence is the annulus of that series. The coefficient of $(z - z_0)^{-1}$ in a Laurent series is the *residue*, the quantity on which Sections 18.7–18.9 are built.

Power series

Convergence of power series

For every power series $\sum_{n=0}^{\infty} a_n (z - z_0)^n$ there is a **radius of convergence** $R \in [0, \infty]$ such that the series converges absolutely for $|z - z_0| < R$ and diverges for $|z - z_0| > R$. It is given by

$$\frac{1}{R} = \limsup_{n\to\infty} |a_n|^{1/n} \qquad \left(\text{or } R = \lim_{n\to\infty} \left|\frac{a_n}{a_{n+1}}\right| \text{ when this limit exists}\right).$$

Inside the disc of convergence the sum is analytic and may be differentiated or integrated term by term, the new series having the same radius.

The region of convergence is always a disc: there is no such thing as a power series converging on an interval but not on the corresponding disc. On the circle $|z - z_0| = R$ itself anything can happen, point by point.

Taylor's theorem

Taylor's theorem

Let f be analytic in the disc $|z - z_0| < R$. Then for every z in the disc

$$f(z) = \sum_{n=0}^{\infty} a_n (z - z_0)^n, \qquad a_n = \frac{f^{(n)}(z_0)}{n!} = \frac{1}{2\pi j} \oint_C \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta,$$

where C is any circle $|\zeta - z_0| = \rho < R$. The series converges in the **largest open disc about z_0 in which f is analytic**: its radius is the distance from z_0 to the nearest singular point of f.

Proof. Fix z with $|z - z_0| < \rho < R$ and use the Cauchy formula on the circle C of radius ρ. For ζ on C, $|(z - z_0)/(\zeta - z_0)| < 1$, so the Cauchy kernel expands as a geometric series:

$$\frac{1}{\zeta - z} = \frac{1}{(\zeta - z_0)\left(1 - \dfrac{z - z_0}{\zeta - z_0}\right)} = \sum_{n=0}^{\infty} \frac{(z - z_0)^n}{(\zeta - z_0)^{n+1}}.$$

The convergence is uniform on C, so we may integrate term by term:

$$f(z) = \frac{1}{2\pi j} \oint_C \frac{f(\zeta)}{\zeta - z} d\zeta = \sum_{n=0}^{\infty} \left[\frac{1}{2\pi j} \oint_C \frac{f(\zeta)}{(\zeta - z_0)^{n+1}} d\zeta\right] (z - z_0)^n,$$

and the bracket is $f^{(n)}(z_0)/n!$ by the derivative formula. □

This is the payoff of complex differentiability: *analytic* and *equal to a convergent power series* are the same property. Standard Maclaurin series (all valid in $\mathbb{C}$ with the stated radius):

Function	Series	Radius
$\dfrac{1}{1 - z}$	$\sum_{n\ge 0} z^n$	1
e^z	$\sum_{n\ge 0} \dfrac{z^n}{n!}$	∞
$\sin z$	$\sum_{n\ge 0} \dfrac{(-1)^n z^{2n+1}}{(2n+1)!}$	∞
$\cos z$	$\sum_{n\ge 0} \dfrac{(-1)^n z^{2n}}{(2n)!}$	∞

Function	Series	Radius
$\operatorname{Log}(1+z)$	$\sum_{n\ge1}\dfrac{(-1)^{n+1}z^n}{n}$	1
$(1+z)^\alpha$ (principal)	$\sum_{n\ge0}\binom{\alpha}{n}z^n$	1 (unless $\alpha\in\mathbb{N}$)

Worked Example 18.18 — Taylor series and their radii

(a) Expand $f(z)=1/z$ about $z_0=1+j$ and give the radius. (b) Find the first three nonzero terms of $\tan z$ about 0 and the radius. (c) Expand $g(z)=\dfrac{1}{1+z^2}$ about $z_0=1$ to second order.

(a) Write $z=z_0+(z-z_0)$: $\dfrac{1}{z}=\dfrac{1}{z_0}\cdot\dfrac{1}{1+(z-z_0)/z_0}=\sum_{n\ge0}\dfrac{(-1)^n(z-z_0)^n}{z_0^{n+1}}$, valid for $|z-z_0|<|z_0|=\sqrt{2}$. The only singularity is $z=0$, at distance $\sqrt{2}$, as the theorem predicts.

(b) Divide series: $\tan z=\dfrac{z-z^3/6+z^5/120-\cdots}{1-z^2/2+z^4/24-\cdots}$. Set $\tan z=z+bz^3+cz^5$; multiplying by the denominator and matching: z^3: $b-\tfrac12=-\tfrac16\Rightarrow b=\tfrac13$; z^5: $c-\tfrac{b}{2}+\tfrac{1}{24}=\tfrac{1}{120}\Rightarrow c=\tfrac{2}{15}$. So $\tan z=z+\tfrac13z^3+\tfrac{2}{15}z^5+\cdots$. The nearest zeros of $\cos z$ are $\pm\pi/2$, so $R=\pi/2$. Check at $z=0.3$: $0.3+0.009+0.000324=0.309324$, vs $\tan 0.3=0.309336$.

(c) $g(1)=\tfrac12$; $g'=-2z/(1+z^2)^2$, $g'(1)=-\tfrac12$; $g''=(6z^2-2)/(1+z^2)^3$, $g''(1)=\tfrac12$. So $g\approx\tfrac12-\tfrac12(z-1)+\tfrac14(z-1)^2$, with radius $|1\mp j|=\sqrt{2}$ (Example 18.7).

Zeros. If f is analytic at z_0, $f(z_0)=0$ and not all derivatives vanish there, the Taylor series begins $f=a_m(z-z_0)^m+\cdots$ with $a_m\neq0$: z_0 is a **zero of order** m, and $f(z)=(z-z_0)^m g(z)$ with g analytic and $g(z_0)\neq0$. Since $g\neq0$ near z_0, **zeros of a non-constant analytic function are isolated** — the root of the identity theorem.

Laurent series

Near a singularity a Taylor series is impossible, but an expansion in both positive and negative powers works.

Laurent's theorem

Let f be analytic in the annulus $A:\ r_1<|z-z_0|<r_2$ (with $0\le r_1<r_2\le\infty$). Then for every z in A

$$f(z)=\sum_{n=-\infty}^{\infty}a_n(z-z_0)^n=\underbrace{\sum_{n=0}^{\infty}a_n(z-z_0)^n}_{\text{analytic (regular) part}}+\underbrace{\sum_{n=1}^{\infty}\frac{a_{-n}}{(z-z_0)^n}}_{\text{principal part}},$$

with

$$a_n=\frac{1}{2\pi j}\oint_C\frac{f(\zeta)}{(\zeta-z_0)^{n+1}}d\zeta,\qquad n\in\mathbb{Z},$$

C being any positively oriented circle $|\zeta-z_0|=\rho$ with $r_1<\rho<r_2$. The expansion in a given annulus is **unique**.

Proof sketch. For z in the annulus take circles C_2 (radius just below r_2) and C_1 (just above r_1) on either side of z. Cauchy's formula on the region between them gives $f(z)=\frac{1}{2\pi j}\oint_{C_2}\frac{f(\zeta)}{\zeta-z}d\zeta-\frac{1}{2\pi j}\oint_{C_1}\frac{f(\zeta)}{\zeta-z}d\zeta$. On C_2, $|z-z_0|<|\zeta-z_0|$, and the kernel expands in nonnegative powers exactly as in Taylor's proof. On C_1, $|\zeta-z_0|<|z-z_0|$, so instead

$$-\frac{1}{\zeta-z}=\frac{1}{(z-z_0)\left(1-\dfrac{\zeta-z_0}{z-z_0}\right)}=\sum_{n=1}^{\infty}\frac{(\zeta-z_0)^{n-1}}{(z-z_0)^n},$$

which produces the negative powers. Both circles can be deformed to any circle C in the annulus. □

Note that the coefficient formula with $n=-1$ reads

$$a_{-1}=\frac{1}{2\pi j}\oint_C f(\zeta)\,d\zeta:$$

the integral of f around the annulus is $2\pi j$ times the coefficient of $(z-z_0)^{-1}$. That is the content of Example 18.11 seen from the other side, and it is the definition of the residue in Section 18.7.

In practice, nobody computes Laurent coefficients from the integral formula. Because the expansion is unique, *any* legitimate manipulation — geometric series, known Taylor series, substitution, multiplication, partial fractions — that produces a series valid in the annulus gives *the* Laurent series. The essential tool is the geometric series used in two ways:

$$\frac{1}{1-w}=\sum_{n\ge0}w^n\ \ (|w|<1),\qquad \frac{1}{1-w}=-\frac{1}{w}\cdot\frac{1}{1-1/w}=-\sum_{n\ge1}w^{-n}\ \ (|w|>1).$$

Worked Example 18.19 — one function, four expansions

Expand $f(z) = \dfrac{1}{(z-1)(z-2)}$ in (a) $|z| < 1$, (b) $1 < |z| < 2$, (c) $|z| > 2$, (d) $0 < |z-1| < 1$.

Partial fractions: $f = \dfrac{1}{z-2} - \dfrac{1}{z-1}$. The singularities 1 and 2 cut the plane about $z_0 = 0$ into three regions; in each we expand each fraction in the convergent direction.

(a) $|z| < 1$ (so also $|z/2| < 1$):

$$\frac{1}{z-2} = -\frac{1}{2}\cdot\frac{1}{1-z/2} = -\sum_{n\ge 0}\frac{z^n}{2^{n+1}}, \qquad -\frac{1}{z-1} = \frac{1}{1-z} = \sum_{n\ge 0} z^n,$$

$$f = \sum_{n\ge 0}\left(1 - 2^{-(n+1)}\right) z^n = \tfrac{1}{2} + \tfrac{3}{4}z + \tfrac{7}{8}z^2 + \cdots \quad \text{(a Taylor series)}.$$

(b) $1 < |z| < 2$: keep the first expansion; for the second use $|1/z| < 1$:

$$-\frac{1}{z-1} = -\frac{1}{z}\cdot\frac{1}{1-1/z} = -\sum_{n\ge 1} z^{-n}, \qquad f = -\sum_{n\ge 0}\frac{z^n}{2^{n+1}} - \sum_{n\ge 1}\frac{1}{z^n}.$$

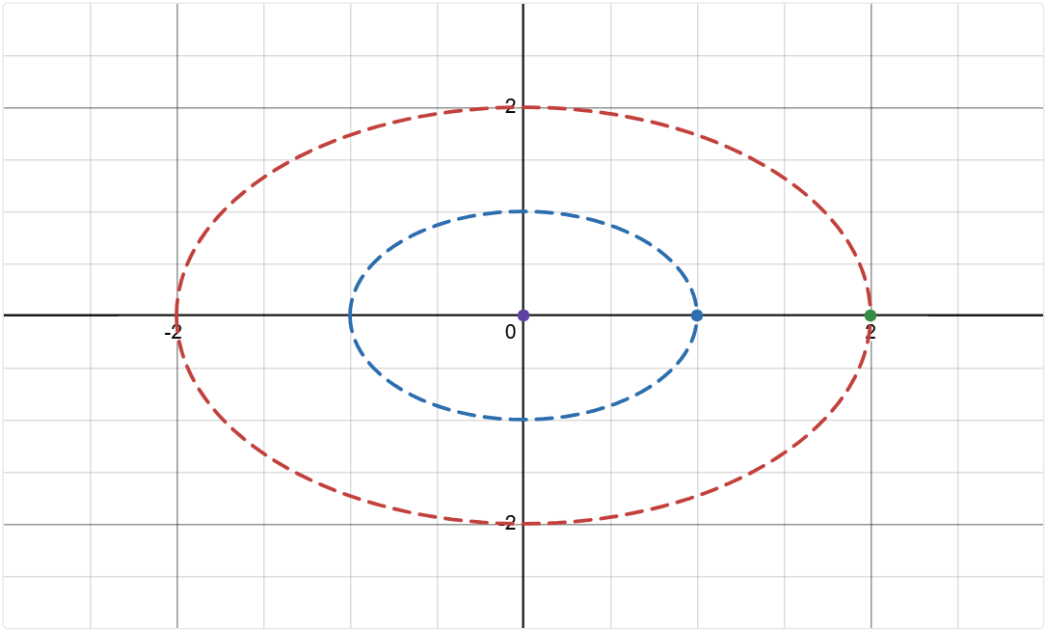
Check at $z = 1.5$: the first sum is $-\frac{1}{2}/(1-0.75) = -2$, the second $-\frac{2/3}{1-2/3} = -2$; total -4, and indeed $f(1.5) = 1/(0.5\cdot(-0.5)) = -4$. ✓

(c) $|z| > 2$: now $\dfrac{1}{z-2} = \dfrac{1}{z}\cdot\dfrac{1}{1-2/z} = \sum_{n\ge 1} 2^{n-1} z^{-n}$, so

$$f = \sum_{n\ge 1}\left(2^{n-1} - 1\right) z^{-n} = \frac{1}{z^2} + \frac{3}{z^3} + \frac{7}{z^4} + \cdots.$$

(d) About $z_0 = 1$, put $w = z - 1$: $f = \dfrac{1}{w(w-1)} = -\dfrac{1}{w}\cdot\dfrac{1}{1-w} = -\dfrac{1}{w} - 1 - w - w^2 - \cdots$ for $0 < |w| < 1$. The coefficient of $(z-1)^{-1}$ is -1.

Notice that in (c) the coefficient of z^{-1} is $2^0 - 1 = 0$: by the coefficient formula $\oint_{|z|=3} f\,dz = 0$, which agrees with Example 18.15-style reasoning ($\frac{1}{z-2}$ and $-\frac{1}{z-1}$ contribute $+2\pi j$ and $-2\pi j$). In (b) the coefficient of z^{-1} is -1, so $\oint_{|z|=1.5} f\,dz = -2\pi j$: only the pole at 1 is enclosed.



Regions of validity for the expansions of $1/((z-1)(z-2))$ about 0: a Taylor series inside the blue circle $|z| = 1$, a two-sided Laurent series in the annulus between the circles, and a series in negative powers only outside the red circle $|z| = 2$. Every boundary circle passes through a pole.

Engineering Note — the Z-transform ROC is a Laurent annulus

Put $X(z) = \sum_n x[n] z^{-n}$: the sequence values are the Laurent coefficients with $a_{-n} = x[n]$. Example 18.19 is therefore a complete catalogue of the three sequences sharing $X(z) = 1/((z-1)(z-2))$ (Ch. 17): region (c) gives a **right-sided (causal)** sequence $x[n] = 2^{n-1} - 1$ for $n \ge 1$; region (a) gives a **left-sided (anti-causal)** sequence; region (b) a **two-sided** one. The ROC is always an annulus bounded by poles, and the algebraic expression $X(z)$ alone does not determine the signal — the annulus does. A system is stable when its ROC contains the unit circle.

Isolated singularities

Classification of isolated singularities

z_0 is an **isolated singularity** of f if f is analytic in a punctured disc $0 < |z - z_0| < \rho$. Let $\sum a_n (z - z_0)^n$ be the Laurent series there. Then z_0 is

- a **removable singularity** if the principal part is zero ($a_{-n} = 0$ for all $n \geq 1$);
- a **pole of order** m if the principal part has finitely many terms with $a_{-m} \neq 0$ the last: $f = \dfrac{a_{-m}}{(z-z_0)^m} + \cdots + \dfrac{a_{-1}}{z - z_0} + \sum_{n \geq 0} a_n (z - z_0)^n$. A pole of order 1 is a **simple pole**;
- an **essential singularity** if the principal part has infinitely many nonzero terms.

Practical tests, which avoid computing series:

Type	Behaviour as $z \to z_0$	Test
removable	f bounded, has a finite limit	$\lim (z - z_0) f(z) = 0$
pole of order m	$\lvert f \rvert \to \infty$	$(z - z_0)^m f(z) \to$ finite nonzero limit
essential	no limit, finite or infinite	neither of the above

For a quotient $f = g/h$ with g, h analytic: if h has a zero of order m at z_0 and $g(z_0) \neq 0$, then z_0 is a pole of order m. More generally, if g has a zero of order k and h of order m, the result is a pole of order $m - k$ if $m > k$, otherwise a removable singularity.

Near an essential singularity the behaviour is wild: by the Casorati–Weierstrass theorem, f comes arbitrarily close to *every* complex value in every punctured neighbourhood (Picard's theorem says it actually takes every value, with at most one exception, infinitely often).

Worked Example 18.20 — classifying singularities by Laurent series

Classify the singularity at $z = 0$ and find the coefficient a_{-1} for (a) $\dfrac{\sin z}{z}$, (b) $\dfrac{1 - \cos z}{z^4}$, (c) $\dfrac{e^z}{z^3}$, (d) $e^{1/z}$, (e) $z^2 \sin(1/z)$.

(a) $\dfrac{\sin z}{z} = 1 - \dfrac{z^2}{6} + \dfrac{z^4}{120} - \cdots$: removable (define the value 1 at 0 — the sinc function is entire). $a_{-1} = 0$.

(b) $1 - \cos z = \dfrac{z^2}{2} - \dfrac{z^4}{24} + \dfrac{z^6}{720} - \cdots$, so $\dfrac{1 - \cos z}{z^4} = \dfrac{1}{2z^2} - \dfrac{1}{24} + \dfrac{z^2}{720} - \cdots$: a pole of order 2 (numerator zero of order 2, denominator of order 4). $a_{-1} = 0$.

(c) $\dfrac{e^z}{z^3} = \dfrac{1}{z^3} + \dfrac{1}{z^2} + \dfrac{1}{2z} + \dfrac{1}{6} + \cdots$: pole of order 3, $a_{-1} = \tfrac{1}{2}$.

(d) Substitute $1/z$ into the exponential series: $e^{1/z} = 1 + \dfrac{1}{z} + \dfrac{1}{2!z^2} + \dfrac{1}{3!z^3} + \cdots$, valid for $|z| > 0$. Infinitely many negative powers: essential. $a_{-1} = 1$. Along the positive real axis $e^{1/x} \to \infty$; along the negative real axis it $\to 0$; along the imaginary axis $|e^{1/(jy)}| = 1$.

(e) $z^2 \left(\dfrac{1}{z} - \dfrac{1}{6z^3} + \dfrac{1}{120 z^5} - \cdots \right) = z - \dfrac{1}{6z} + \dfrac{1}{120 z^3} - \cdots$: essential, $a_{-1} = -\tfrac{1}{6}$.

Non-isolated singularities. Branch points such as $z = 0$ for $\operatorname{Log} z$ or $z^{1/2}$ are not isolated singularities of any single-valued branch (the whole cut is singular), and have no Laurent expansion about them. The function $1/\sin(1/z)$ has poles at $z = 1/(k\pi)$ accumulating at 0, so 0 is a non-isolated singularity. Rational functions — and so every lumped-element transfer function — have only poles.

Common Pitfall — the "right" Laurent series

A function has a *different* Laurent series in each annulus. Asking for "the Laurent series of f about z_0" is meaningless until the annulus is specified. Residues are read from the series in the punctured disc $0 < |z - z_0| < \rho$ around the singularity itself — region (d) of Example 18.19, not region (b), even though both contain negative powers.

18.7 Residues

Motivation

When a function is integrated around a small circle enclosing one isolated singularity, every term of its Laurent series integrates to zero except one: the $(z - z_0)^{-1}$ term, which contributes $2\pi j \, a_{-1}$. That single coefficient is all the contour "sees" of the singularity. It deserves a name and a toolkit for computing it quickly — ideally without finding the whole Laurent series. The same numbers are, not by coincidence, the coefficients of partial-fraction expansions that you have computed by the cover-up rule in Ch. 14.

Residue

Let z_0 be an isolated singularity of f, with Laurent series $\sum_n a_n (z - z_0)^n$ in $0 < |z - z_0| < \rho$. The **residue** of f at z_0 is

$$\operatorname{Res}_{z = z_0} f(z) = a_{-1} = \frac{1}{2\pi j} \oint_C f(z)\, dz,$$

where C is any positively oriented simple closed contour around z_0 inside the punctured disc.

At a removable singularity the residue is 0. At an essential singularity it must be read from the Laurent series. At poles — the common case — there are formulas.

Computing residues at poles

Residue formulas

Simple pole.

$$\operatorname{Res}_{z=z_0} f = \lim_{z\to z_0} (z-z_0) f(z).$$

Quotient with a simple zero in the denominator. If $f = g/h$ with g, h analytic at z_0, $g(z_0) \neq 0$, $h(z_0) = 0$, $h'(z_0) \neq 0$, then

$$\operatorname{Res}_{z=z_0} \frac{g}{h} = \frac{g(z_0)}{h'(z_0)}.$$

Pole of order m.

$$\operatorname{Res}_{z=z_0} f = \frac{1}{(m-1)!} \lim_{z\to z_0} \frac{d^{m-1}}{dz^{m-1}} \Big[(z-z_0)^m f(z) \Big].$$

Derivation. At a pole of order m, $(z-z_0)^m f(z) = a_{-m} + a_{-m+1}(z-z_0) + \cdots + a_{-1}(z-z_0)^{m-1} + \ldots$ is analytic; a_{-1} is its Taylor coefficient of order $m-1$, i.e. $\frac{1}{(m-1)!}$ times its $(m-1)$-th derivative at z_0. For $m = 1$ this is the simple-pole formula. For the quotient rule, $h(z) = h'(z_0)(z-z_0) + \ldots$, so $(z-z_0)g/h \to g(z_0)/h'(z_0)$. $\square$

The quotient rule g/h' is the fastest route whenever the denominator is not already factored — for instance at the roots of z^4+1 or of $\sin z$.

Worked Example 18.21 — simple poles

(a) $f = \dfrac{ze^z}{z^2-1}$ at $z = \pm 1$. (b) $f = \dfrac{1}{z^4+1}$ at $z_1 = e^{j\pi/4}$. (c) $f = \cot z$ at $z = k\pi$. (d) $f = \dfrac{e^{jz}}{z^2+a^2}$ $(a>0)$ at $z = ja$.

(a) At $z=1$: $\lim (z-1)\dfrac{ze^z}{(z-1)(z+1)} = \dfrac{e}{2} = 1.3591$. At $z=-1$: $\dfrac{(-1)e^{-1}}{-2} = \dfrac{1}{2e} = 0.1839$.

(b) Quotient rule: $\dfrac{1}{4z_1^3} = \dfrac{z_1}{4z_1^4} = -\dfrac{z_1}{4} = -\dfrac{e^{j\pi/4}}{4} = -0.17678 - 0.17678j$ (using $z_1^4 = -1$).

(c) $\cot z = \cos z / \sin z$, $\sin(k\pi) = 0$, $(\sin z)' = \cos z$: residue $\cos(k\pi)/\cos(k\pi) = 1$ at every integer multiple of π. (This is why $\pi \cot \pi z$ is used to sum series $\sum f(n)$: it has residue 1 at every integer.)

(d) $z^2 + a^2 = (z-ja)(z+ja)$: residue $\dfrac{e^{j(ja)}}{2ja} = \dfrac{e^{-a}}{2ja}$. We will need this in Section 18.8.

Worked Example 18.22 — higher-order poles

(a) $f = \dfrac{e^{2z}}{(z-1)^2}$ at $z=1$. (b) $f = \dfrac{1}{(z^2+1)^2}$ at $z = j$. (c) $f = \dfrac{1}{z^3(z-1)}$ at $z = 0$ and $z = 1$.

(a) $m=2$: $\dfrac{d}{dz} e^{2z}\Big|_{z=1} = 2e^2 = 14.778$ — the same number as Example 18.17(a), as it must be.

(b) $(z^2+1)^2 = (z-j)^2(z+j)^2$, so $m=2$ and we differentiate $(z+j)^{-2}$: $-2(z+j)^{-3}$ at $z=j$ gives $-2/(2j)^3 = -2/(-8j) = \dfrac{1}{4j} = -\dfrac{j}{4}$.

(c) At $z=0$ $(m=3)$: $\dfrac{1}{2!}\dfrac{d^2}{dz^2}\left(\dfrac{1}{z-1}\right)\Big|_0 = \dfrac{1}{2}\cdot\dfrac{2}{(z-1)^3}\Big|_0 = -1$. Alternatively, from the series $-\dfrac{1}{z^3}\cdot\dfrac{1}{1-z} = -z^{-3} - z^{-2} - z^{-1} - \cdots$, $a_{-1} = -1$. At $z=1$ (simple): $1/1^3 = 1$. The two residues sum to 0 — see the residue at infinity below.

Residues and partial fractions

For a proper rational function $F(s) = N(s)/D(s)$ with simple poles p_k, the partial-fraction expansion $F = \sum_k A_k/(s-p_k)$ has

$$A_k = \lim_{s\to p_k} (s-p_k)F(s) = \operatorname{Res}_{s=p_k} F(s),$$

because $A_k/(s-p_k)$ is exactly the principal part of F at p_k. In general, **a proper rational function equals the sum of its principal parts at all its poles** (the difference would be an entire function tending to zero at infinity, hence zero by Liouville). The Heaviside cover-up rule is the simple-pole residue formula. At a repeated pole of order m, the coefficient of $(s-p)^{-k}$ is

$$A_k = \frac{1}{(m-k)!}\frac{d^{m-k}}{ds^{m-k}}\Big[(s-p)^m F(s)\Big]_{s=p},$$

of which the residue is the case $k=1$.

Worked Example 18.23 — partial fractions as principal parts

Expand $F(s) = \dfrac{s+3}{(s+1)(s+2)^2}$.

At $s=-1$ (simple): $A = \left.\dfrac{s+3}{(s+2)^2}\right|_{-1} = \dfrac{2}{1} = 2$.

At $s=-2$ (order 2), with $G(s) = (s+2)^2 F = \dfrac{s+3}{s+1}$: the $(s+2)^{-2}$ coefficient is $G(-2) = \dfrac{1}{-1} = -1$; the $(s+2)^{-1}$ coefficient (the residue) is $G'(-2) = \left.\dfrac{(s+1)-(s+3)}{(s+1)^2}\right|_{-2} = \dfrac{-2}{1} = -2$.

$$F(s) = \frac{2}{s+1} - \frac{2}{s+2} - \frac{1}{(s+2)^2}.$$

Check at $s=0$: $F(0) = 3/4$, and $2 - 1 - \tfrac{1}{4} = \tfrac{3}{4}$. ✓ Also, the residues 2 and -2 sum to zero, consistent with $F \sim 1/s^2$ at infinity (no $1/s$ term), as the next result explains.

The residue at infinity

Residue at infinity

If f is analytic for $|z| > R$, define

$$\operatorname{Res}_{z=\infty} f = -\frac{1}{2\pi j}\oint_{|z|=\rho} f(z)\,dz \quad (\rho > R) = -c_{-1},$$

where c_{-1} is the coefficient of $1/z$ in the Laurent expansion of f valid for $|z| > R$. Equivalently, $\operatorname{Res}_{z=\infty} f(z) = -\operatorname{Res}_{\zeta=0}\left[\dfrac{1}{\zeta^2} f\left(\dfrac{1}{\zeta}\right)\right]$.

Sum of all residues

If f has finitely many singularities in the extended plane, the sum of its residues at all of them, including ∞, is zero.

This is useful when many poles lie inside a contour and few outside: $\oint_C f\,dz = 2\pi j \sum_{\text{inside}} \operatorname{Res} = -2\pi j \left[\sum_{\text{outside}} \operatorname{Res} + \operatorname{Res}_\infty\right]$. For a rational $f = P/Q$ with $\deg Q \geq \deg P + 2$, $f = O(1/z^2)$ at infinity, the $1/z$ coefficient vanishes, and **the finite residues sum to zero** — as in Examples 18.22(c) and 18.23.

Worked Example 18.24 — many poles inside, use infinity

Evaluate $\displaystyle\oint_{|z|=2} \frac{z^{15}}{(z^2+1)^4(z^4+2)^3}dz$.

The denominator has twenty roots, all with modulus 1 or $2^{1/4} = 1.189$, all inside the contour. Computing twenty residues (with poles of orders 4 and 3!) is hopeless. Instead: the degree of the denominator is $8 + 12 = 20$, so for large $|z|$, $f = \dfrac{z^{15}}{z^{20}(1+\cdots)} = z^{-5}(1+\cdots)$ has no z^{-1} term: $c_{-1} = 0$. Hence the integral is $2\pi j\, c_{-1} = 0$.

Contrast $\displaystyle\oint_{|z|=2} \frac{z^3}{z^4+2}dz$: here $f = z^{-1}(1+2z^{-4})^{-1} = z^{-1} - 2z^{-5} + \cdots$, so $c_{-1} = 1$ and the integral is $2\pi j$ — confirming that the four simple poles each have residue $z_k^3/(4z_k^3) = \tfrac{1}{4}$.

Engineering Note — residues are the modal amplitudes

In the inverse Laplace transform of $F(s)$ with simple poles p_k, the time function is $\sum_k \operatorname{Res}_{s=p_k} F \cdot e^{p_k t}$ (Section 18.9). Each residue is the amplitude with which the natural mode $e^{p_k t}$ is excited. A small residue at a pole means that mode is weakly excited or weakly observed — the near cancellation of a pole by a nearby zero shows up as a tiny residue, which is why such a pole can be dropped in model reduction.

Common Pitfall — using the simple-pole formula at a double pole

$\lim (z - z_0) f(z)$ is infinite at a pole of order 2 or more; it is not "the residue". Determine the order first (factor the denominator, or count the order of the zero). Equally, $g(z_0)/h'(z_0)$ is valid only when h has a *simple* zero; at $z_0 = 0$ for $f = 1/(z\sin z)$, $h = z\sin z$ has a double zero and the residue is 0 (since $1/(z\sin z) = z^{-2} + \tfrac{1}{6} + \cdots$), not $1/h'(0)$, which is undefined.

18.8 Residue theorem

The theorem

Residue theorem

Let C be a positively oriented simple closed contour, and let f be analytic inside and on C except at finitely many isolated singularities $z_1, \dots, z_n$ inside C. Then

$$\oint_C f(z)\,dz = 2\pi j \sum_{k=1}^{n} \operatorname{Res}_{z=z_k} f(z).$$

Proof. Surround each z_k by a small circle C_k inside C, the circles disjoint. By the deformation principle (Section 18.5), $\oint_C = \sum_k \oint_{C_k}$. On C_k, integrate the Laurent series of f about z_k term by term: by Example 18.11 every term but $a_{-1}^{(k)}/(z-z_k)$ gives zero, and that one gives $2\pi j\, a_{-1}^{(k)}$. $\square$

Cauchy's theorem (no singularities, sum empty) and Cauchy's integral formula (one simple pole of $f(z)/(z-z_0)$ with residue $f(z_0)$) are special cases. The theorem reduces *any* contour integral of a function with isolated singularities to local algebra at the singular points.

Worked Example 18.25 — closed contour integrals

(a) $\displaystyle\oint_{|z|=2} \frac{ze^z}{z^2-1}dz$. (b) $\displaystyle\oint_{|z|=2} \tan z\,dz$. (c) $\displaystyle\oint_{|z|=1} e^{1/z}\,dz$.

(a) Both poles ± 1 are inside; by Example 18.21(a), $\oint = 2\pi j\left(\frac{e}{2}+\frac{1}{2e}\right) = 2\pi j \cosh 1 = 9.6955j$.

(b) Inside $|z|=2$, $\cos z = 0$ at $\pm\pi/2$ ($1.571 < 2$; the next, $3\pi/2$, is outside). Residues: $\sin z/(-\sin z) = -1$ at each. So $\oint = 2\pi j(-2) = -4\pi j = -12.566j$.

(c) The only singularity is the essential one at 0, with residue 1 (Example 18.20(d)): $\oint = 2\pi j$. No residue *formula* applies; the Laurent series does.

Each was confirmed by direct numerical quadrature on the parametrized circle.

The rest of this section is about the most celebrated use of the theorem: evaluating **real** definite integrals that resist real-variable methods. The strategy in every case is:

1. choose a complex function whose real or imaginary part, or whose restriction to the real axis, is the integrand;
2. choose a closed contour, part of which is the real interval of interest;
3. evaluate the closed integral by residues;
4. show that the extra parts of the contour contribute zero (or something computable) in a limit — this is where ML and Jordan's lemma come in.

Type I — trigonometric integrals over a full period

To evaluate $I = \displaystyle\int_0^{2\pi} R(\cos\theta, \sin\theta)\,d\theta$ with R rational, put $z = e^{j\theta}$. As θ runs over $[0, 2\pi]$, z runs once around the unit circle, and

$$\cos\theta = \frac{z+z^{-1}}{2}, \qquad \sin\theta = \frac{z-z^{-1}}{2j}, \qquad d\theta = \frac{dz}{jz}.$$

The integral becomes $\oint_{|z|=1} (\text{rational function of } z)\,dz$, evaluated by the residues **inside the unit circle**.

Worked Example 18.26 — $\displaystyle\int_0^{2\pi} \frac{d\theta}{2+\cos\theta}$

Substitute:

$$I = \oint_{|z|=1} \frac{1}{2+\frac{1}{2}(z+z^{-1})}\cdot\frac{dz}{jz} = \oint \frac{2\,dz}{j(z^2+4z+1)}.$$

The roots of z^2+4z+1 are $z = -2\pm\sqrt{3}$: $\alpha = -2+\sqrt{3} = -0.268$ (inside) and $\beta = -2-\sqrt{3} = -3.732$ (outside). Residue at α: $\dfrac{2}{j(\alpha-\beta)} = \dfrac{2}{j\,2\sqrt{3}} = \dfrac{1}{j\sqrt{3}}$. Hence

$$I = 2\pi j\cdot\frac{1}{j\sqrt{3}} = \frac{2\pi}{\sqrt{3}} = 3.6276.$$

Numerical quadrature: 3.62760. ✓ The same steps give the general result $\displaystyle\int_0^{2\pi}\frac{d\theta}{a+b\cos\theta} = \frac{2\pi}{\sqrt{a^2-b^2}}$ for $a > |b|$, and the same with $\sin\theta$ in place of $\cos\theta$ (e.g. $\int_0^{2\pi} d\theta/(5-4\sin\theta) = 2\pi/3$).

Worked Example 18.27 — a cosine-weighted integral

Evaluate $I = \displaystyle\int_0^{2\pi} \frac{\cos 2\theta}{5 - 4\cos\theta}\,d\theta$.

It is easier to compute $J = \int_0^{2\pi} \frac{e^{j2\theta}}{5-4\cos\theta}\,d\theta$ and take $I = \operatorname{Re} J$ (the denominator is real). With $e^{j2\theta} = z^2$ and $5 - 4\cos\theta = 5 - 2(z + z^{-1}) = -\dfrac{2z^2 - 5z + 2}{z} = -\dfrac{(2z-1)(z-2)}{z}$:

$$J = \oint_{|z|=1} \frac{z^2 \cdot z}{-(2z-1)(z-2)} \cdot \frac{dz}{jz} = \oint \frac{z^2\,dz}{-j(2z-1)(z-2)}.$$

Only $z = \frac{1}{2}$ is inside. Writing $2z - 1 = 2(z - \frac{1}{2})$, the residue is $\dfrac{(1/2)^2}{-j \cdot 2 \cdot (\frac{1}{2} - 2)} = \dfrac{1/4}{3j} = \dfrac{1}{12j}$. So $J = 2\pi j/(12j) = \pi/6$, real, and $I = \pi/6 = 0.5236$. ✓ (numerically 0.523599).

Generalization: $\displaystyle\int_0^{2\pi} \frac{\cos n\theta}{1 - 2a\cos\theta + a^2}\,d\theta = \frac{2\pi a^n}{1 - a^2}$ for $|a| < 1$. This is the Fourier-coefficient formula for the Poisson kernel, and in DSP terms it is the statement that $|1 - ae^{-j\Omega}|^{-2}$ has inverse DTFT $a^{|n|}/(1 - a^2)$.

Worked Example 18.28 — a double pole at the origin

Evaluate $I = \displaystyle\int_0^{2\pi} \frac{\sin^2\theta}{5 + 4\cos\theta}\,d\theta$.

Now $\sin^2\theta = -\dfrac{(z - z^{-1})^2}{4} = -\dfrac{(z^2-1)^2}{4z^2}$ and $5 + 4\cos\theta = \dfrac{(2z+1)(z+2)}{z}$, so

$$I = \oint_{|z|=1} f(z)\,dz, \qquad f(z) = -\frac{(z^2-1)^2}{4j\,z^2(2z+1)(z+2)}.$$

Inside the unit circle: a double pole at $z = 0$ and a simple pole at $z = -\frac{1}{2}$.

At $z = -\frac{1}{2}$: $\text{Res} = -\dfrac{(1/4 - 1)^2}{4j \cdot \frac{1}{4} \cdot 2 \cdot \frac{3}{2}} = -\dfrac{9/16}{3j} = -\dfrac{3}{16j}$.

At $z = 0$: let $g(z) = z^2 f(z) = -\dfrac{1}{4j} \cdot \dfrac{(z^2-1)^2}{2z^2 + 5z + 2}$. With $N = (z^2-1)^2$ ($N(0) = 1$, $N'(0) = 0$) and $D = 2z^2 + 5z + 2$ ($D(0) = 2$, $D'(0) = 5$): $(N/D)'(0) = \dfrac{0 \cdot 2 - 1 \cdot 5}{4} = -\dfrac{5}{4}$, so $\text{Res} = g'(0) = \dfrac{5}{16j}$.

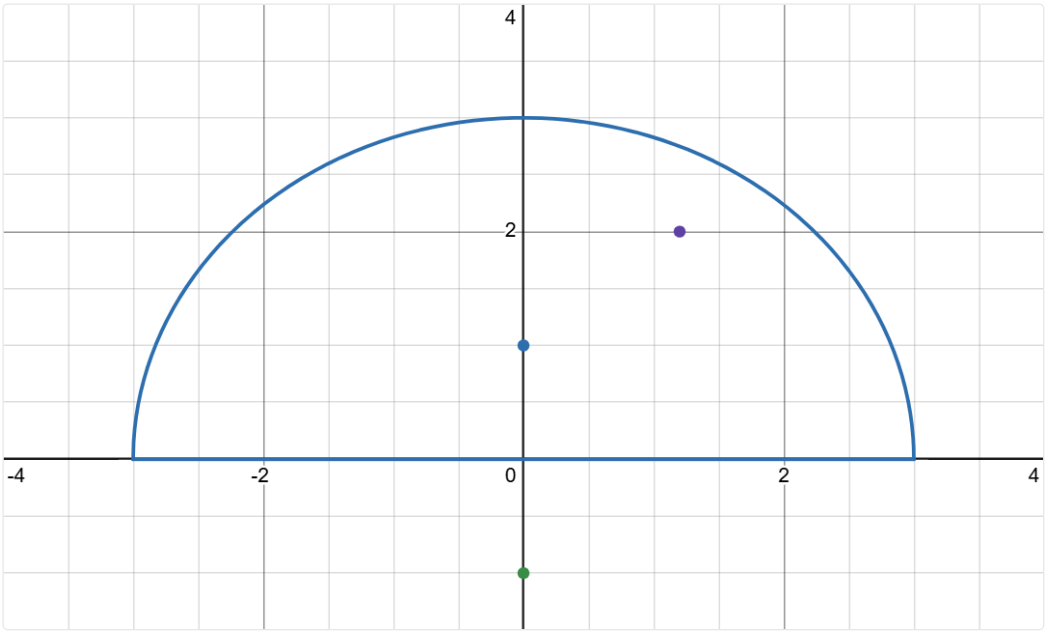
Sum $= \dfrac{2}{16j} = \dfrac{1}{8j}$, and $I = 2\pi j \cdot \dfrac{1}{8j} = \dfrac{\pi}{4} = 0.7854$. ✓

Common Pitfall — the pole on the wrong side

Only poles **inside** $|z| = 1$ count. For a denominator $a + b\cos\theta$ the two roots are reciprocals of each other (their product is 1), so exactly one is inside when $a > |b|$. If you find both inside or both outside, there is an algebra error. If $a \le |b|$ a root lies *on* the circle and the real integral diverges.

Type II — improper integrals of rational functions

To evaluate $\displaystyle\int_{-\infty}^{\infty} \frac{P(x)}{Q(x)}\,dx$, close the real segment $[-R, R]$ with the upper semicircle $C_R:\ z = Re^{j\theta}, 0 \le \theta \le \pi$.



The standard contour for Type II and III integrals: the real segment $[-R, R]$ closed by the upper semicircle C_R (here $R = 3$). As $R \to \infty$ it encloses every upper-half-plane pole; lower-half-plane poles never count.

Rational integrals over the real line

Let P and Q be polynomials with $\deg Q \geq \deg P + 2$ and $Q(x) \neq 0$ for real x. Then

$$\int_{-\infty}^{\infty} \frac{P(x)}{Q(x)} dx = 2\pi j \sum_{\operatorname{Im} z_k > 0} \operatorname{Res}_{z=z_k} \frac{P(z)}{Q(z)}.$$

Proof. For R large enough, the closed contour $[-R, R] + C_R$ encloses all upper-half-plane poles, so $\int_{-R}^{R} P/Q\,dx + \int_{C_R} P/Q\,dz = 2\pi j \sum \operatorname{Res}$. The degree condition gives $|P/Q| \leq K/R^2$ on C_R, so by ML $\left|\int_{C_R}\right| \leq \pi R \cdot K/R^2 \to 0$. (The degree condition also guarantees the improper integral converges, so the symmetric limit $\int_{-R}^{R}$ is the genuine integral.) $\square$

One could equally close in the lower half-plane, traversed clockwise, giving $-2\pi j \sum_{\operatorname{Im} z_k < 0} \operatorname{Res}$; for rational functions both give the same answer.

Worked Example 18.29 — three rational integrals

(a) $\displaystyle\int_{-\infty}^{\infty} \frac{dx}{(x^2+1)^2}$. (b) $\displaystyle\int_{-\infty}^{\infty} \frac{x^2\,dx}{(x^2+1)(x^2+4)}$. (c) $\displaystyle\int_{-\infty}^{\infty} \frac{dx}{x^4+1}$.

(a) The only upper-half-plane pole is $z = j$, of order 2, with residue $-j/4$ (Example 18.22(b)). Integral $= 2\pi j(-j/4) = \pi/2 = 1.5708$. ✓

(b) Degree condition: $4 \geq 2 + 2$. ✓ Upper poles j and $2j$, both simple:

$$\operatorname{Res}_j = \frac{j^2}{2j\,(j^2+4)} = \frac{-1}{6j}, \qquad \operatorname{Res}_{2j} = \frac{(2j)^2}{((2j)^2+1)\,4j} = \frac{-4}{-12j} = \frac{1}{3j}.$$

Sum $= \dfrac{1}{6j}$; integral $= 2\pi j/(6j) = \pi/3 = 1.0472$. ✓

(c) The roots of $z^4 = -1$ are $e^{j\pi/4}, e^{j3\pi/4}, e^{j5\pi/4}, e^{j7\pi/4}$; the upper two are $z_1 = e^{j\pi/4}$ and $z_2 = e^{j3\pi/4}$. By the quotient rule (Example 18.21(b)) the residues are $-z_k/4$:

$$\int = 2\pi j \cdot \left(-\frac{z_1 + z_2}{4}\right) = -\frac{\pi j}{2} \cdot j\sqrt{2} = \frac{\pi}{\sqrt{2}} = 2.2214,$$

using $z_1 + z_2 = \frac{1+j}{\sqrt{2}} + \frac{-1+j}{\sqrt{2}} = j\sqrt{2}$. ✓ (The same method gives $\int dx/(x^6+1) = 2\pi/3$.)

Type III — Fourier-type integrals and Jordan's lemma

Integrals such as $\displaystyle\int_{-\infty}^{\infty} \frac{\cos \omega x}{x^2 + a^2} dx$ are Fourier transforms of rational functions (Ch. 16). The trick is to integrate $R(z)e^{j\omega z}$ instead of $R(z)\cos \omega z$: on the upper half-plane, $|e^{j\omega z}| = e^{-\omega y} \leq 1$ for $\omega > 0$, whereas $\cos \omega z$ grows exponentially there. Then take real or imaginary parts.

Here the degree condition can be relaxed by one: the oscillation of $e^{j\omega z}$ is enough to kill the semicircle when $R(z)$ merely tends to zero.

Jordan's lemma

Let $\omega > 0$, and suppose $|R(z)| \leq M_R$ on the upper semicircle C_R with $M_R \to 0$ as $R \to \infty$. Then

$$\lim_{R \to \infty} \int_{C_R} R(z)\, e^{j\omega z}\, dz = 0.$$

Proof. On C_R, $z = Re^{j\theta}$ and $|e^{j\omega z}| = e^{-\omega R \sin\theta}$, so

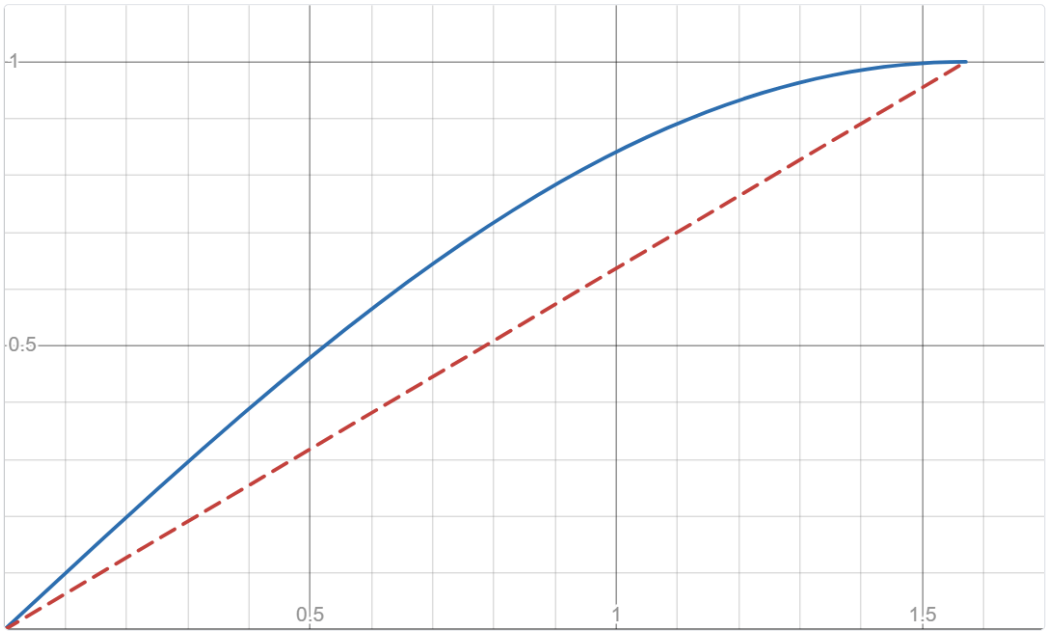
$$\left|\int_{C_R} R\, e^{j\omega z} dz\right| \leq M_R R \int_0^{\pi} e^{-\omega R \sin\theta} d\theta = 2M_R R \int_0^{\pi/2} e^{-\omega R \sin\theta} d\theta.$$

On $[0, \pi/2]$ the concave function $\sin\theta$ lies above its chord: $\sin\theta \geq 2\theta/\pi$ (**Jordan's inequality**). Therefore

$$\int_0^{\pi/2} e^{-\omega R \sin\theta} d\theta \leq \int_0^{\pi/2} e^{-2\omega R\theta/\pi} d\theta = \frac{\pi}{2\omega R}\left(1 - e^{-\omega R}\right) < \frac{\pi}{2\omega R},$$

and the whole bound is $< \pi M_R/\omega \to 0$. $\square$

The ML inequality alone would give only $\pi R M_R$, which need not vanish if $M_R \sim 1/R$; Jordan's lemma recovers the missing factor of R by noting that $e^{-\omega R \sin\theta}$ is tiny except near $\theta = 0$ and $\theta = \pi$.



Jordan's inequality: on $0 \le \theta \le \pi/2$ the sine curve (blue) lies above its chord $2\theta/\pi$ (red, dashed), so $e^{-\omega R \sin\theta} \le e^{-2\omega R\theta/\pi}$ — the bound that makes the semicircle vanish.

Fourier-type integrals

If $R = P/Q$ with $\deg Q \ge \deg P + 1$, no real poles, and $\omega > 0$, then

$$\int_{-\infty}^{\infty} R(x)\, e^{j\omega x} dx = 2\pi j \sum_{\operatorname{Im} z_k > 0} \operatorname{Res}_{z=z_k} \left[R(z) e^{j\omega z} \right],$$

and $\int R\cos\omega x\,dx$, $\int R\sin\omega x\,dx$ are its real and imaginary parts when R is real on the real axis. For $\omega < 0$ close in the **lower** half-plane, clockwise: $-2\pi j \sum_{\operatorname{Im} z_k < 0} \operatorname{Res}$.

Worked Example 18.30 — the Lorentzian and its Fourier transform

Evaluate $\displaystyle\int_{-\infty}^{\infty} \frac{\cos\omega x}{x^2 + a^2} dx$ for $a > 0$ and all real ω; then give the numerical value for $a = 1$, $\omega = 3$.

For $\omega > 0$: the only upper pole of $e^{j\omega z}/(z^2 + a^2)$ is ja, with residue $e^{-\omega a}/(2ja)$ (Example 18.21(d)). So

$$\int_{-\infty}^{\infty} \frac{e^{j\omega x}}{x^2 + a^2} dx = 2\pi j \cdot \frac{e^{-a\omega}}{2ja} = \frac{\pi}{a} e^{-a\omega}.$$

This is real, so the cosine integral equals it and the sine integral is zero (as oddness requires). The integrand is even in ω, so for all ω:

$$\int_{-\infty}^{\infty} \frac{\cos\omega x}{x^2 + a^2} dx = \frac{\pi}{a} e^{-a|\omega|}.$$

With $a = 1, \omega = 3$: $\pi e^{-3} = 0.15641$; numerical quadrature gives 0.156411. ✓ In transform language this is the pair $\dfrac{1}{t^2 + a^2} \leftrightarrow \dfrac{\pi}{a} e^{-a|\omega|}$, the dual of $e^{-a|t|} \leftrightarrow \dfrac{2a}{\omega^2 + a^2}$ in Ch. 16. The kink at $\omega = 0$ in the answer is the residue method's way of switching half-planes.

Worked Example 18.31 — a case needing Jordan's lemma

Evaluate $\displaystyle\int_{-\infty}^{\infty} \frac{x \sin x}{x^2 + 4} dx$.

Here $R(z) = z/(z^2 + 4)$ decays only like $1/R$, so ML fails and Jordan's lemma is essential. Consider $\displaystyle\int \frac{z e^{jz}}{z^2 + 4} dz$. Upper pole $2j$, residue $\dfrac{2j\, e^{j(2j)}}{2 \cdot 2j} = \dfrac{e^{-2}}{2}$. So

$$\int_{-\infty}^{\infty} \frac{x e^{jx}}{x^2 + 4} dx = 2\pi j \cdot \frac{e^{-2}}{2} = j\pi e^{-2}.$$

The imaginary part is the required integral: $\pi e^{-2} = 0.42517$ (numerically 0.425168 ✓). The real part, $\int x\cos x/(x^2 + 4)\,dx = 0$, is consistent with odd symmetry. (Strictly, this integral converges only conditionally; the contour argument produces it as $\lim_{R\to\infty} \int_{-R}^{R}$.)

Worked Example 18.32 — double pole, Fourier type

Evaluate $\displaystyle\int_{-\infty}^{\infty} \frac{\cos 2x}{(x^2+1)^2}\,dx$.

Take $f = e^{j2z}/(z^2+1)^2$, double pole at j. With $g = e^{j2z}/(z+j)^2$:

$$g'(z) = e^{j2z}\left[\frac{2j}{(z+j)^2} - \frac{2}{(z+j)^3}\right], \qquad g'(j) = e^{-2}\left[\frac{2j}{-4} - \frac{2}{-8j}\right] = e^{-2}\left[-\frac{j}{2} - \frac{j}{4}\right] = -\frac{3j}{4}e^{-2}.$$

Integral $= 2\pi j \cdot (-\frac{3j}{4}e^{-2}) = \dfrac{3\pi}{2e^2} = 0.63775$. ✓ (quadrature 0.637752).

Type IV — poles on the real axis: indentation and principal values

If the integrand has a simple pole on the real axis, the real integral does not exist in the ordinary sense, but its **Cauchy principal value** may:

$$\mathrm{PV}\int_{-\infty}^{\infty} f(x)\,dx = \lim_{\varepsilon\to 0^+}\left[\int_{-\infty}^{x_0-\varepsilon} + \int_{x_0+\varepsilon}^{\infty}\right] f(x)\,dx.$$

To compute it, detour around x_0 on a small semicircle γ_ε of radius ε in the upper half-plane.

Indentation (half-residue) lemma

If f has a simple pole at x_0 and γ_ε is the upper semicircle $z = x_0 + \varepsilon e^{j\theta}$ traversed clockwise (θ from π to 0), then

$$\lim_{\varepsilon\to 0}\int_{\gamma_\varepsilon} f(z)\,dz = -\pi j\,\mathrm{Res}_{z=x_0} f.$$

More generally an arc of angle α contributes αj times the residue, with sign set by the direction.

Proof. Near x_0, $f = \dfrac{a_{-1}}{z-x_0} + g(z)$ with g analytic. The g part is bounded and the arc length $\pi\varepsilon \to 0$. The principal-part integral is $a_{-1}\int_{\pi}^{0} \frac{j\varepsilon e^{j\theta}}{\varepsilon e^{j\theta}}\,d\theta = -\pi j\,a_{-1}$ exactly. □

Consequently, with the upper semicircle closed as before, a simple real-axis pole counts as **half** a residue:

$$\mathrm{PV}\int_{-\infty}^{\infty} f\,dx = 2\pi j \sum_{\mathrm{Im}\,z_k>0} \mathrm{Res}\,f + \pi j \sum_{\text{real simple poles}} \mathrm{Res}\,f.$$

Worked Example 18.33 — the Dirichlet integral $\int_0^\infty \frac{\sin x}{x}dx$

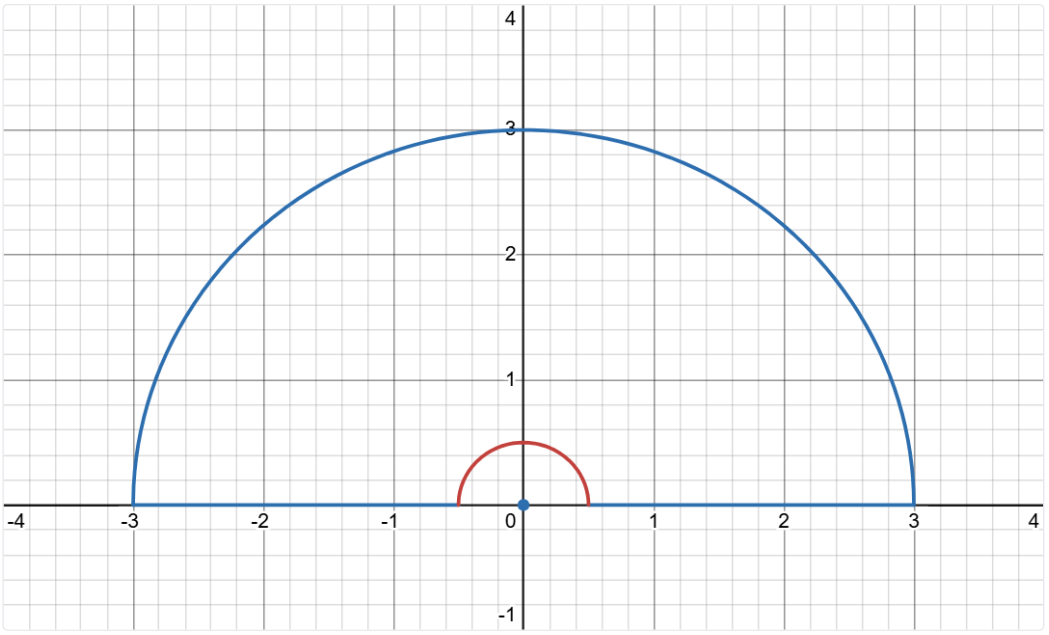
Consider $f(z) = e^{jz}/z$, which has a simple pole at 0 with residue 1 and no other singularities. Use the indented contour: $[-R, -\varepsilon]$, the small clockwise semicircle γ_ε, $[\varepsilon, R]$, and the large semicircle C_R. Nothing is enclosed, so the total is 0:

$$\left[\int_{-R}^{-\varepsilon} + \int_{\varepsilon}^{R}\right]\frac{e^{jx}}{x}dx + \int_{\gamma_\varepsilon} f\,dz + \int_{C_R} f\,dz = 0.$$

By Jordan's lemma ($M_R = 1/R$), $\int_{C_R} \to 0$. By the indentation lemma, $\int_{\gamma_\varepsilon} \to -\pi j$. Hence $\mathrm{PV}\int_{-\infty}^{\infty}\frac{e^{jx}}{x}dx = \pi j$. The real part, $\mathrm{PV}\int \cos x/x\,dx$, is 0 (odd integrand); the imaginary part is an ordinary convergent integral (the singularity of $\sin x/x$ is removable):

$$\int_{-\infty}^{\infty}\frac{\sin x}{x}dx = \pi, \qquad \int_0^{\infty}\frac{\sin x}{x}dx = \frac{\pi}{2}.$$

This is the area under the unnormalized sinc — the integral behind the Fourier transform of the rectangular pulse, and the limiting value $\mathrm{Si}(\infty) = \pi/2$ of the sine integral that governs the Gibbs overshoot in Ch. 15. The answer π agrees with numerical quadrature to all printed digits.



The indented contour for Example 18.33: the small red semicircle detours above the pole at the origin, so the pole lies outside the closed contour, and in the limit the detour contributes $-\pi j$ times the residue.

Branch cuts (keyhole contours), briefly. Integrals such as $\int_0^\infty \frac{x^{a-1}}{1+x}dx$ $(0<a<1)$ use a multivalued integrand z^{a-1} with its cut along the positive real axis. The *keyhole* contour runs out along the top of the cut, around a large circle, back along the bottom of the cut (where z^{a-1} has gained a factor $e^{j2\pi(a-1)}$) and around a small circle at the origin. The two cut integrals combine to $(1-e^{j2\pi a})I$; the residue at $z=-1=e^{j\pi}$ is $e^{j\pi(a-1)}$; solving gives

$$\int_0^\infty \frac{x^{a-1}}{1+x}dx = \frac{\pi}{\sin \pi a}.$$

For $a=\frac{1}{2}$ this is π; for $a=\frac{2}{3}$ it is $2\pi/\sqrt{3}=3.6276$, as numerical quadrature confirms.

Common Pitfall — closing on the wrong side

For $e^{j\omega z}$ with $\omega>0$, close in the **upper** half-plane, where $|e^{j\omega z}|=e^{-\omega y}$ decays. Closing in the lower half-plane makes the arc integral blow up and gives a wrong (often complex) answer. In inverse-transform applications this is exactly the choice that produces causality, as the next section shows. And never integrate $\cos \omega z$ directly over a semicircle: it contains both $e^{j\omega z}$ and $e^{-j\omega z}$, one of which grows on each side.

Engineering Note — why these integrals matter

Type I integrals are averages over one period of a periodic quantity (mean power in a phase-modulated signal, the response of a ring resonator over a revolution). Type II integrals give the total noise power at a filter output: for white noise into $H(s)$, the output variance is proportional to $\frac{1}{2\pi}\int |H(j\omega)|^2 d\omega$, a rational integral solved by residues (the basis of tabulated "I_n" integrals in control texts). Type III integrals are inverse Fourier transforms; Type IV, with its half-residues, reappears as the $\pi\delta(\omega)$ terms in the transforms of the step and the signum.

18.9 Applications to engineering analysis

This section collects the places where the machinery of Sections 18.5–18.8 underpins the transform methods of Part V. The theme is the same throughout: an engineering quantity is a contour integral, the contour can be closed or deformed, and the answer is a sum of residues or a count of zeros and poles.

The Bromwich inversion integral for the Laplace transform

Ch. 14 inverted Laplace transforms with tables and partial fractions. The general inversion formula is a contour integral.

Bromwich (complex inversion) integral

Let $F(s)=\mathcal{L}\{f(t)\}$ converge for $\operatorname{Re} s>\sigma_0$, and let $\gamma>\sigma_0$. Then, at points where f is continuous,

$$f(t)=\frac{1}{2\pi j}\int_{\gamma-j\infty}^{\gamma+j\infty} F(s)\,e^{st}\,ds = \frac{1}{2\pi j}\lim_{W\to\infty}\int_{\gamma-jW}^{\gamma+jW} F(s)e^{st}ds,$$

the path being the vertical line $\operatorname{Re} s=\gamma$ (the **Bromwich contour**), which lies to the right of every singularity of F. At a jump of f the integral gives the midpoint value.

Derivation from Fourier inversion. For fixed γ in the region of convergence, $g(t)=f(t)e^{-\gamma t}u(t)$ is absolutely integrable, and its Fourier transform is $G(\omega)=\int_0^\infty f(t)e^{-(\gamma+j\omega)t}dt = F(\gamma+j\omega)$. The Fourier inversion formula of Ch. 16 gives

$$f(t)e^{-\gamma t}=\frac{1}{2\pi}\int_{-\infty}^{\infty} F(\gamma+j\omega)e^{j\omega t}d\omega.$$

Multiply by $e^{\gamma t}$ and substitute $s = \gamma + j\omega$, $ds = j\,d\omega$: the result is the Bromwich integral. □ So the Laplace inversion formula is nothing more than Fourier inversion along a line shifted into the region of convergence. The value of γ does not matter, as long as the line stays right of all singularities — by Cauchy's theorem the integrand is analytic between any two such lines.

Evaluation by residues. Suppose F is rational and strictly proper (or, more generally, $|F(s)| \to 0$ uniformly as $|s| \to \infty$ in the left region). Close the line with a large arc Γ_R to the left.

- For $t > 0$: $|e^{st}| = e^{t\,\mathrm{Re}\,s}$ is small where $\mathrm{Re}\,s$ is very negative. A rotated form of Jordan's lemma (substitute $s = jz$; the left half-plane becomes the upper half-plane and $e^{st} = e^{jtz}$) shows $\int_{\Gamma_R} F(s)e^{st}ds \to 0$. The closed contour encloses **all** the poles of F.
- For $t < 0$: close to the **right** instead, where e^{st} now decays. No singularities lie right of the Bromwich line, so $f(t) = 0$ — **causality emerges from analyticity in the right half-plane**.

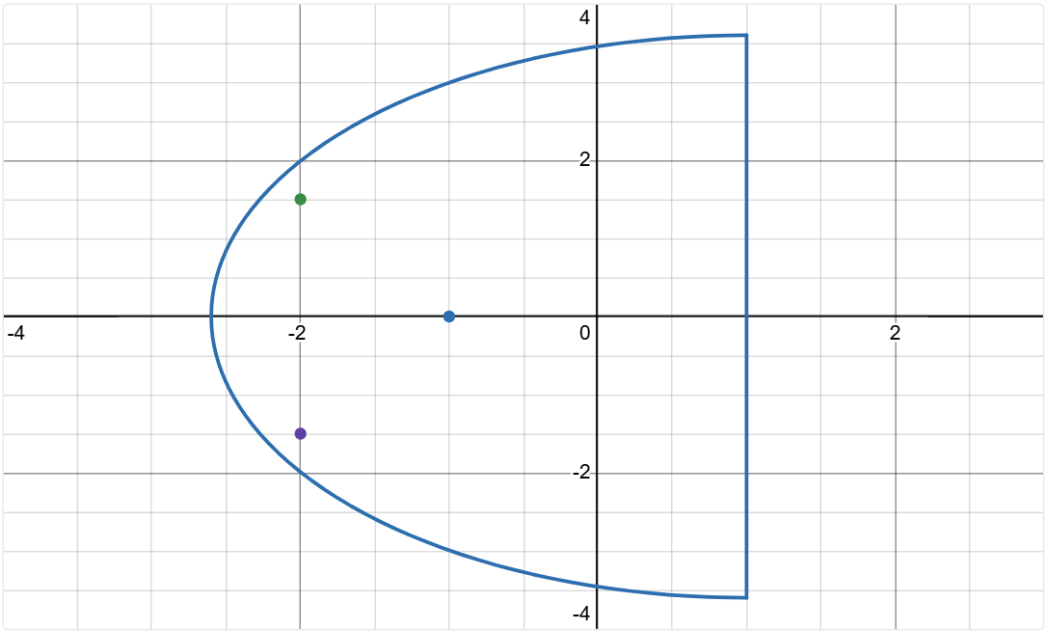
Inversion by residues

If $F(s)$ is rational and strictly proper, with poles $p_1, \dots, p_n$, then

$$f(t) = \sum_{k=1}^{n} \mathrm{Res}_{s=p_k}\left[F(s)e^{st}\right], \qquad t > 0,$$

and $f(t) = 0$ for $t < 0$. At a simple pole p the term is $\left[(s-p)F(s)\right]_{s=p} e^{pt}$; at a pole of order m it is $\dfrac{1}{(m-1)!}\dfrac{d^{m-1}}{ds^{m-1}}\left[(s-p)^m F(s)e^{st}\right]_{s=p}$, which produces the $t^k e^{pt}$ terms automatically.

This one formula replaces the table look-up and the partial-fraction step together: the derivative of e^{st} with respect to s is te^{st}, which is where the polynomial-times-exponential terms of repeated poles come from.



The Bromwich contour: the vertical line $\mathrm{Re}\,s = \gamma$ (here $\gamma = 1$) to the right of all poles, closed for $t > 0$ by a large arc to the left, which by Jordan's lemma contributes nothing as its radius grows; the enclosed residues of $F(s)e^{st}$ give $f(t)$.

Worked Example 18.34 — simple and repeated real poles

Invert (a) $F(s) = \dfrac{1}{s(s+1)^2}$ and (b) $F(s) = \dfrac{s+3}{(s+1)(s+2)^2}$.

(a) At $s = 0$ (simple): $\left[\dfrac{e^{st}}{(s+1)^2}\right]_{s=0} = 1$. At $s = -1$ (order 2):

$$\frac{d}{ds}\left[\frac{e^{st}}{s}\right]_{s=-1} = \left[\frac{te^{st}}{s} - \frac{e^{st}}{s^2}\right]_{s=-1} = -te^{-t} - e^{-t}.$$

So $f(t) = 1 - e^{-t} - te^{-t}$ for $t \geq 0$. Checks: $f(0) = 0$ (consistent with the initial-value theorem, $\lim sF = 0$); $f(\infty) = 1 = \lim_{s\to 0} sF$; at $t = 2$, $f = 1 - 3e^{-2} = 0.59399$, matching a numerical Bromwich inversion. ✓

(b) At $s = -1$: $\left[\dfrac{(s+3)e^{st}}{(s+2)^2}\right]_{-1} = 2e^{-t}$. At $s = -2$ (order 2), with $G(s) = \dfrac{(s+3)e^{st}}{s+1}$:

$$G'(s) = \frac{\left[e^{st} + t(s+3)e^{st}\right](s+1) - (s+3)e^{st}}{(s+1)^2}, \qquad G'(-2) = \frac{(1+t)e^{-2t}(-1) - e^{-2t}}{1} = -(2+t)e^{-2t}.$$

So $f(t) = 2e^{-t} - 2e^{-2t} - te^{-2t}$ — the time-domain image of the partial fractions of Example 18.23. At $t = 1.3$: 0.29996, matching numerical inversion. ✓

Worked Example 18.35 — a complex-conjugate pair

Invert $F(s) = \dfrac{1}{s^2 + 2s + 5}$.

Poles $p, \bar{p} = -1 \pm 2j$. At $p = -1 + 2j$: $\dfrac{e^{pt}}{p - \bar{p}} = \dfrac{e^{(-1+2j)t}}{4j}$. The residue at $\bar{p}$ is the conjugate (because F is real on the real axis), so

$$f(t) = 2\,\mathrm{Re}\left\{\frac{e^{(-1+2j)t}}{4j}\right\} = \frac{e^{-t}}{2}\,\mathrm{Re}\{-je^{j2t}\} = \frac{1}{2}e^{-t}\sin 2t.$$

In general a conjugate pair contributes $2\,\mathrm{Re}\{\mathrm{Res}_p\}$ — a damped sinusoid whose amplitude and phase are the modulus and angle of the residue. At $t = 1.3$: 0.070245. ✓

Common Pitfall — when the arc does not vanish

The residue-sum formula needs $F(s) \to 0$ on the left arc. It fails for an improper F (e.g. $F = s/(s+1) = 1 - 1/(s+1)$, whose constant part is the impulse $\delta(t)$ and must be split off first), and it must be adapted for a delay $e^{-sT}F(s)$: then $e^{s(t-T)}$ decays on the left arc only for $t > T$, so the residues give $f(t-T)$ for $t > T$ and closing right gives 0 for $t < T$ — the shift theorem recovered. Functions with branch points, such as $F = 1/\sqrt{s}$ (inverse $1/\sqrt{\pi t}$), need a contour that wraps around the branch cut on the negative real axis rather than a residue sum.

Inverse Z-transform by residues

The same idea inverts Z-transforms (Ch. 17). Since $X(z) = \sum_n x[n]z^{-n}$ is a Laurent series converging in the ROC annulus, the Laurent coefficient formula gives

$$x[n] = \frac{1}{2\pi j}\oint_C X(z)\,z^{n-1}\,dz = \sum_{\text{poles inside } C} \mathrm{Res}\left[X(z)z^{n-1}\right],$$

where C is a counter-clockwise circle in the ROC. For a causal sequence (ROC outside the outermost pole) C encloses all poles of X — but watch for an extra pole of z^{n-1} at $z = 0$ when n is small.

Worked Example 18.36 — causal inverse Z-transform

Find $x[n]$ for $X(z) = \dfrac{z}{(z - 0.5)(z - 1)}$, $|z| > 1$.

$X(z)z^{n-1} = \dfrac{z^n}{(z-0.5)(z-1)}$, which has no pole at $z = 0$ for $n \geq 0$. Residues: at $z = 1$, $\dfrac{1}{0.5} = 2$; at $z = 0.5$, $\dfrac{0.5^n}{-0.5} = -2(0.5)^n$. So

$$x[n] = \big(2 - 2(0.5)^n\big)u[n] = 0,\ 1,\ 1.5,\ 1.75,\ 1.875, \ldots$$

Check: $\sum_n x[n]z^{-n}$ at $z = 2$ sums to 1.3333, equal to $X(2) = 2/(1.5 \cdot 1)$. ✓ For $n < 0$ the integrand acquires a pole at $z = 0$ of order $-n$ whose residue cancels the others exactly, giving $x[n] = 0$ — causality again, provable more easily via the residue at infinity.

The argument principle

The final group of applications counts zeros and poles without finding them.

Argument principle

Let f be analytic inside and on a positively oriented simple closed contour C except for finitely many poles inside C, and let f have no zeros or poles on C. Then

$$\frac{1}{2\pi j}\oint_C \frac{f'(z)}{f(z)}dz = Z - P,$$

where Z and P are the numbers of zeros and poles of f inside C, each counted with multiplicity. Equivalently, $Z - P = \dfrac{1}{2\pi}\Delta_C \arg f(z)$: the net number of times the image curve $f(C)$ winds counter-clockwise around the origin.

Proof. The logarithmic derivative f'/f is analytic except at zeros and poles of f. Near a zero of order m, $f = (z - z_0)^m g$ with $g(z_0) \neq 0$, so $f'/f = \dfrac{m}{z - z_0} + \dfrac{g'}{g}$: a simple pole with residue m. Near a pole of order m, $f = (z - z_0)^{-m} g$, and the residue of f'/f is $-m$. The residue theorem gives $Z - P$. For the second form, note $f'/f = \frac{d}{dz}\log f$, so $\oint_C f'/f\,dz$ is the change of $\log f = \ln|f| + j\arg f$ around C; $\ln|f|$ returns to its starting value and $\arg f$ changes by $2\pi(Z - P)$. □

The second form is the useful one: **draw the image of C under f and count how many times it encircles the origin.** That is a graphical computation — and exactly what a Nyquist plot is.

Rouché's theorem

If f and g are analytic inside and on C and $|g(z)| < |f(z)|$ on C, then f and $f + g$ have the same number of zeros inside C.

(Intuition: on C, $f + g = f(1 + g/f)$ with $|g/f| < 1$, so $1 + g/f$ stays in the disc $|w - 1| < 1$ and cannot wind around 0; the winding of $f + g$ equals that of f. This is the "dog on a leash" argument.)

Worked Example 18.37 — locating polynomial roots

How many roots of $p(z) = z^5 + 3z + 1$ lie in $|z| < 1$, and how many in $1 < |z| < 2$?

On $|z| = 1$: take $f = 3z$, $g = z^5 + 1$. Then $|g| \le 2 < 3 = |f|$, so p has as many zeros in the unit disc as $3z$: **one**.

On $|z| = 2$: take $f = z^5$, $g = 3z + 1$. Then $|g| \le 7 < 32 = |f|$, so p has five zeros in $|z| < 2$.

Hence four roots lie in the annulus $1 < |z| < 2$. Numerically the roots have moduli 0.332, 1.263 (twice) and 1.374 (twice). ✓ The integral $\frac{1}{2\pi j}\oint_{|z|=1} p'/p\,dz$ evaluated by quadrature gives 1.0000. ✓ For a discrete-time characteristic polynomial, the same count on the unit circle decides stability: all roots must lie inside.

The Nyquist stability criterion — the idea

A feedback loop with loop transfer function $L(s)$ (forward path times feedback path) has closed-loop transfer function $T(s) = \dfrac{G(s)}{1 + L(s)}$. Its poles are the **zeros of** $1 + L(s)$. The closed loop is stable when $1 + L$ has no zeros in the closed right half-plane. Computing those zeros means factoring a polynomial; Nyquist's insight is to *count* them with the argument principle using only the frequency response $L(j\omega)$, which can be measured.

1. **The contour.** Take the *Nyquist contour* D: up the imaginary axis from $-jR$ to jR, then around the large semicircle $Re^{j\theta}$ from $\theta = \pi/2$ to $-\pi/2$. It encloses the right half-plane and is traversed **clockwise**. (If L has poles on the $j\omega$-axis, indent around them with small semicircles into the left half-plane.)
2. **Apply the argument principle to $F(s) = 1 + L(s)$.** Inside D, let Z = number of zeros of $1 + L$ (closed-loop RHP poles, unknown) and P = number of poles of $1 + L$, which are the poles of L (open-loop RHP poles, known from the model). Because D is clockwise, the image $F(D)$ encircles the origin $N = Z - P$ times **clockwise**.
3. **Shift the origin.** $F(D)$ encircling 0 is the same as $L(D) = F(D) - 1$ encircling -1. For strictly proper L, the large semicircle maps to the single point $L(\infty) = 0$, so $L(D)$ is just the Nyquist plot $L(j\omega)$, $-\infty < \omega < \infty$.

Nyquist criterion

Let N be the number of clockwise encirclements of the point -1 by the Nyquist plot $L(j\omega)$, $-\infty < \omega < \infty$, and P the number of open-loop poles of L in the right half-plane. The number of closed-loop poles in the right half-plane is

$$Z = N + P.$$

The closed loop is stable if and only if $Z = 0$, i.e. the plot encircles -1 exactly P times **counter-clockwise**. If L is open-loop stable ($P = 0$), stability requires no encirclement of -1.

Worked Example 18.38 — critical gain from the Nyquist plot

Let $L(s) = \dfrac{K}{(s+1)^3}$ with $K > 0$. Find the range of K for closed-loop stability.

All open-loop poles are at -1, so $P = 0$ and we need no encirclement of -1. On the imaginary axis,

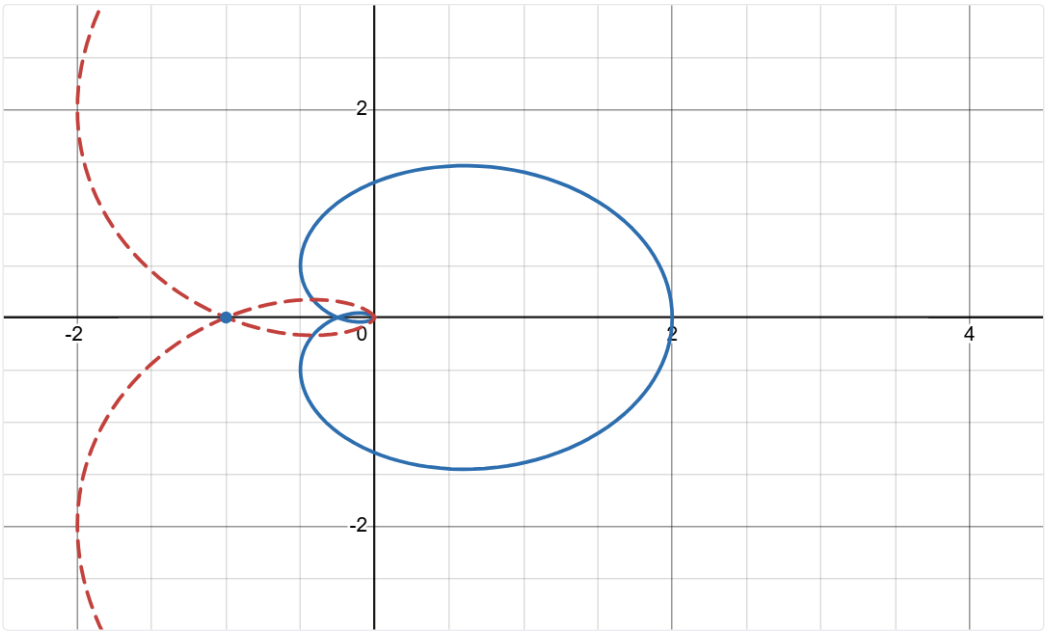
$$L(j\omega) = \frac{K}{(1 + j\omega)^3} = \frac{K}{(1+\omega^2)^{3/2}} e^{-j3\arctan\omega}.$$

At $\omega = 0$ the plot starts at K on the positive real axis; as $\omega \to \infty$ the phase tends to $-3\pi/2$ and the magnitude to 0. It crosses the negative real axis when the phase is $-\pi$: $3\arctan\omega = \pi$, $\omega_{180} = \tan(\pi/3) = \sqrt{3}$. There $|L| = K/(1+3)^{3/2} = K/8$, so the crossing point is $-K/8$.

- If $K < 8$, the crossing lies between -1 and 0: no encirclement, $Z = 0$, **stable**. The gain margin is $8/K$.
- If $K > 8$, the crossing lies left of -1; the plot (with its mirror image for $\omega < 0$) encircles -1 twice clockwise, so $Z = 2$: two closed-loop poles in the right half-plane.
- At $K = 8$ the plot passes through -1: closed-loop poles on the $j\omega$-axis at $\pm j\sqrt{3}$.

Check by algebra: the closed-loop characteristic polynomial is $(s+1)^3 + K = s^3 + 3s^2 + 3s + 1 + K$, and the Routh condition $3 \cdot 3 > 1 + K$ gives $K < 8$. With $K = 8$ its roots are -3 and $\pm j\sqrt{3} = \pm 1.732j$. ✓

Writing $L(j\omega)$ in polar form, $r = |L|$ and $\theta = \angle L = -3\arctan\omega$, we have $1/\sqrt{1+\omega^2} = \cos(\theta/3)$, so the whole Nyquist plot is the polar curve $r = K\cos^3(\theta/3)$, $|\theta| \le 3\pi/2$.



Nyquist plots of $L(s) = K/(s+1)^3$: for $K = 2$ (blue) the curve crosses the negative real axis at -0.25 and does not encircle -1 (stable); for $K = 8$ (red, dashed; only the part near the origin is visible) the crossing is exactly at -1, the edge of instability. Larger K scales the curve outward until it encircles -1.

Engineering Note — why Nyquist beats root-finding

The criterion needs only $L(j\omega)$, which can be **measured** with a network analyser on real hardware, including pure delays e^{-sT} (which make $1 + L$ non-polynomial and defeat Routh's test). Gain and phase margins are read directly as distances of the plot from -1. The mathematics underneath is entirely the argument principle: closed-loop poles are counted by winding numbers.

Common Pitfall — orientation and the open-loop count

Two sign conventions collide here: the Nyquist contour is traversed clockwise, and textbooks count encirclements clockwise as positive, giving $Z = N + P$. If you count counter-clockwise encirclements as positive the formula becomes $Z = P - N_{\text{ccw}}$. Also, P counts **open-loop RHP poles**, not zeros; forgetting an unstable open-loop pole (e.g. an inverted pendulum or a magnetic levitator) leads to the wrong conclusion even when the plot is drawn correctly.

Gain–phase relations (Kramers–Kronig), briefly

Let $H(\omega)$ be the frequency response of a causal, stable system, considered as a function of complex ω; causality makes it analytic in the lower half ω-plane for the $e^{j\omega t}$ convention ($s = j\omega$ in the right half s-plane), and suppose $H \to 0$ as $|\omega| \to \infty$. Integrate $H(\zeta)/(\zeta - \omega)$ around the real axis indented at $\zeta = \omega$ and closed in the half-plane of analyticity. There are no enclosed singularities, the large arc vanishes, and the indentation contributes πj times the residue $H(\omega)$ — exactly the Type IV computation of Example 18.33. The result is

$$H(\omega) = \frac{j}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty}\frac{H(\zeta)}{\zeta-\omega}d\zeta \quad\Longrightarrow\quad \operatorname{Re}H(\omega) = -\frac{1}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty}\frac{\operatorname{Im}H(\zeta)}{\zeta-\omega}d\zeta.$$

(The closed contour runs clockwise, and the small indentation passes below $\zeta = \omega$, so it turns counter-clockwise about the pole and contributes $+\pi j H(\omega)$; the PV integral plus this term is zero.) Check with $H = 1/(1 + j\omega)$: $\operatorname{Im}H = -\zeta/(1+\zeta^2)$, and the right side at $\omega = 0$ is $\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{d\zeta}{1+\zeta^2} = 1 = \operatorname{Re}H(0)$. ✓ The real and imaginary parts of a causal frequency response are **Hilbert transforms** of each other: specifying one determines the other. Applied to $\log H = \ln|H| + j\angle H$ for minimum-phase systems (no RHP zeros, so $\log H$ is analytic too), this is Bode's gain–phase relation, the reason a slope of -20 dB/decade goes with about -90° of phase.

Summary

Topic	Key formula or statement
Complex function	$f(z) = u(x,y) + jv(x,y)$
Exponential, logarithm	$e^z = e^x(\cos y + j\sin y)$; $\operatorname{Log} z = \ln\lvert z\rvert + j\operatorname{Arg} z$, $\operatorname{Arg}\in(-\pi,\pi]$
Complex power	$z^\alpha = e^{\alpha \log z}$ (principal value uses Log)
Derivative	$f'(z_0) = \lim_{\Delta z\to 0}[f(z_0+\Delta z) - f(z_0)]/\Delta z$, direction-independent
Cauchy–Riemann	$u_x = v_y,\ u_y = -v_x$; $f' = u_x + jv_x$
Polar C–R	$u_r = v_\theta/r,\ v_r = -u_\theta/r$
Harmonic parts	$\nabla^2 u = \nabla^2 v = 0$; level curves of u, v orthogonal
Conformality	angles preserved where $f' \neq 0$; local scale $\lvert f'\rvert$, area scale $\lvert f'\rvert^2$
Contour integral	$\int_C f\,dz = \int_a^b f(z(t))z'(t)\,dt$
Fundamental integral	$\oint_{\lvert z-z_0\rvert=\rho}(z-z_0)^n dz = 2\pi j$ if $n=-1$, else 0

Topic	Key formula or statement
ML inequality	$\left\vert\int_C f\,dz\right\vert \le ML$
Cauchy's theorem	$\oint_C f\,dz = 0$ for f analytic inside and on C
Cauchy integral formula	$f^{(n)}(z_0) = \dfrac{n!}{2\pi j}\oint_C \dfrac{f(z)}{(z-z_0)^{n+1}}dz$
Cauchy estimate, Liouville	$\vert f^{(n)}(z_0)\vert \le n!M/\rho^n$; bounded entire $\Rightarrow$ constant
Taylor series	$a_n = f^{(n)}(z_0)/n!$; radius = distance to nearest singularity
Laurent series	$f = \sum_{n=-\infty}^{\infty} a_n (z-z_0)^n$ in $r_1 < \vert z-z_0\vert < r_2$; $a_n = \frac{1}{2\pi j}\oint \frac{f}{(z-z_0)^{n+1}}dz$
Singularities	removable / pole of order m / essential, by the principal part
Residue, simple pole	$\lim_{z\to z_0}(z-z_0)f(z) = g(z_0)/h'(z_0)$
Residue, order m	$\frac{1}{(m-1)!}\lim \frac{d^{m-1}}{dz^{m-1}}[(z-z_0)^m f]$
Residue theorem	$\oint_C f\,dz = 2\pi j \sum_{\text{inside}} \operatorname{Res} f$
Trig integrals	$z = e^{j\theta}$, $\cos\theta = \frac{z+z^{-1}}{2}$, $\sin\theta = \frac{z-z^{-1}}{2j}$, $d\theta = \frac{dz}{jz}$; residues in $\vert z\vert < 1$
Rational integrals	$\int_{-\infty}^{\infty} \frac{P}{Q}dx = 2\pi j \sum_{\operatorname{Im} z_k>0} \operatorname{Res}$, $\deg Q \ge \deg P + 2$
Jordan's lemma	$\int_{C_R} R(z)e^{j\omega z}dz \to 0$ ($\omega > 0$, $R\to 0$ on C_R)
Fourier-type integrals	$\int_{-\infty}^{\infty} R(x)e^{j\omega x}dx = 2\pi j \sum_{\operatorname{Im} z_k>0} \operatorname{Res}[Re^{j\omega z}]$, $\omega > 0$
Indentation	simple real pole contributes πj Res to the PV
Bromwich integral	$f(t) = \frac{1}{2\pi j}\int_{\gamma-j\infty}^{\gamma+j\infty} F(s)e^{st}ds = \sum \operatorname{Res}[F(s)e^{st}]$, $t > 0$
Inverse Z-transform	$x[n] = \frac{1}{2\pi j}\oint_C X(z)z^{n-1}dz = \sum_{\text{inside}} \operatorname{Res}[X(z)z^{n-1}]$
Argument principle	$\frac{1}{2\pi j}\oint_C \frac{f'}{f}dz = Z - P = \frac{1}{2\pi}\Delta_C \arg f$
Nyquist criterion	$Z = N + P$ (clockwise encirclements of -1); stable iff $Z = 0$

Chapter 19 — Probability

> **Prerequisites:** Ch. 1 (sets, functions, sums), Ch. 5 (integral calculus), Ch. 6 (multiple integrals), Ch. 16 (Fourier transforms, for the characteristic function)
> **Learning outcomes:** After this chapter you can …
>
> - build a probability model — sample space, events, probability measure — from the axioms, and count outcomes with permutations and combinations;
> - compute conditional probabilities, apply the law of total probability, and invert conditioning with Bayes' theorem (binary channels, fault detectors, MAP decisions);
> - decide whether events are independent and compute the reliability of series, parallel, k-out-of-n and bridge systems;
> - describe discrete, continuous and mixed random variables by their PMF, PDF and CDF, and derive the distribution of a function of a random variable;
> - compute expectations, variances and higher moments, use the Markov and Chebyshev bounds, and obtain moments from the moment-generating and characteristic functions;
> - set up a joint distribution of two random variables, find marginals and conditionals, and compute the distribution of a sum of independent random variables.

Every measurement an engineer makes is uncertain. The voltage across a resistor fluctuates because electrons are in thermal motion; a bit sent over a wireless link is sometimes received in error; a batch of capacitors has values scattered around the nominal; a power-supply component fails after an unpredictable number of hours; packets arrive at a router at irregular instants. None of these can be predicted exactly, but all of them are *regular in the aggregate*: the fraction of bits in error over a long run settles to a stable number, the histogram of capacitor values has a repeatable shape, the average lifetime of a large population of components is well defined. **Probability theory** is the mathematics of that aggregate regularity. It lets us replace "we cannot know" by quantitative statements — "the bit-error rate is 10^{-6}", "the system survives five years with probability 0.98", "the noise exceeds the threshold 0.3 % of the time" — on which designs can be based.

This chapter builds the theory from the ground up. Sections 19.1–19.4 work with *events*: the axioms, counting, conditioning, Bayes' theorem and independence. Sections 19.5–19.8 introduce *random variables* — numerical outcomes — and the three functions that describe them (PMF, PDF, CDF), together with the most important families of distributions and the first ideas of joint distributions. Section 19.9 condenses a distribution into a few numbers: the mean, the variance, the higher moments, and the transforms (moment-generating and characteristic functions) that generate them. Ch. 20 turns the theory around — from a model to data, and from data back to a model — and catalogues the common distributions in more depth; Ch. 21 lets the random variable depend on time.

Throughout, outcomes are denoted ζ, events by capital letters $A, B, \ldots$, random variables by capital letters $X, Y, \ldots$ and their values by the corresponding lowercase letters $x, y, \ldots$.

19.1 Sample spaces and events

Motivation

Before we can attach numbers to uncertainty we must say precisely *what* is uncertain. "The probability that the receiver makes an error" is meaningless until we specify the experiment (one bit? one packet? one hour of operation?), list what can happen, and agree which collections of outcomes we want to talk about. This bookkeeping is the sample space and its events. Getting it right removes most of the paradoxes and wrong answers that plague informal probability arguments.

Experiments, outcomes and sample spaces

Random experiment, outcome, sample space

A **random experiment** is a procedure whose result cannot be predicted with certainty but whose set of possible results is known in advance. Each possible result is an **outcome** ζ. The set of all outcomes is the **sample space** Ω (some texts write S).

The outcomes must be **mutually exclusive** (exactly one occurs on each trial) and **collectively exhaustive** (one of them always occurs). How finely to describe the outcomes is a modelling choice: for a single coin toss $\Omega = \{H, T\}$ suffices, but if you care about where the coin lands you need a richer description.

Sample spaces come in three kinds:

Kind	Example experiment	Sample space
Finite	Send a 3-bit word and record which bits are in error	$\Omega = \{000, 001, \ldots, 111\}$, 8 outcomes (1 = bit in error)
Countably infinite	Retransmit a packet until it is received correctly; record the number of attempts	$\Omega = \{1, 2, 3, \ldots\}$
Uncountable (continuum)	Measure the lifetime of a capacitor in hours	$\Omega = [0, \infty)$
Uncountable, multidimensional	Sample the in-phase and quadrature noise voltages of a receiver	$\Omega = \mathbb{R}^2$

Events and set operations

Event

An **event** is a subset $A \subseteq \Omega$ of outcomes. We say the event A **occurs** on a trial if the outcome ζ of that trial satisfies $\zeta \in A$. The whole space Ω is the **certain event**; the empty set $\varnothing$ is the **impossible event**; a single outcome $\{\zeta\}$ is an **elementary event**.

Because events are sets, the algebra of sets (Ch. 1) becomes the logic of events:

Set notation	Read as	Event occurs when …
$A \cup B$	A or B (union)	at least one of A, B occurs
$A \cap B$ (also AB)	A and B (intersection)	both occur
A^c (also $\bar{A}$)	not A (complement)	A does not occur
$A \setminus B = A \cap B^c$	A but not B	A occurs and B does not
$A \subseteq B$	A implies B	whenever A occurs, B occurs
$A \cap B = \varnothing$	A, B mutually exclusive (disjoint)	they never occur together

The rules that matter most in calculation are the **distributive laws** and **De Morgan's laws**:

$$A \cap (B \cup C) = (A \cap B) \cup (A \cap C), \qquad (A \cup B)^c = A^c \cap B^c, \qquad (A \cap B)^c = A^c \cup B^c.$$

De Morgan's laws extend to any number of events: "not (at least one occurs)" is "none occurs", $\left(\bigcup_i A_i\right)^c = \bigcap_i A_i^c$. This is the single most useful identity in reliability and error analysis, because "at least one component fails" is usually hard to compute directly while "no component fails" is easy.

A collection of events $B_1, B_2, \dots, B_n$ is a **partition** of Ω if the events are pairwise disjoint and their union is Ω. Exactly one event of a partition occurs on each trial. Partitions are the scaffolding of the law of total probability (Section 19.2).

Worked Example 19.1 — Events in a 3-bit word

A 3-bit word is transmitted; outcome $\zeta = b_1 b_2 b_3$ with $b_i = 1$ if bit i is received in error. Let A = "bit 1 is in error", B = "exactly one bit is in error", C = "the word is received correctly".

Step 1 — list the sets. $A = \{100, 101, 110, 111\}$, $B = \{100, 010, 001\}$, $C = \{000\}$.

Step 2 — combine. $A \cap B = \{100\}$ ("only bit 1 is wrong"); $A \cup B = \{100, 101, 110, 111, 010, 001\}$; C^c = "at least one error" $= \Omega \setminus \{000\}$, which contains 7 outcomes.

Step 3 — check disjointness. $B \cap C = \varnothing$: a word cannot have exactly one error and no error. $A \cap C = \varnothing$ as well. The events "0 errors", "1 error", "2 errors", "3 errors" form a partition of Ω into sets of sizes $1, 3, 3, 1$.

Which subsets are events? (σ-algebras)

For finite and countable Ω every subset can be an event. For a continuum such as $\Omega = [0, 1]$ it turns out to be impossible to assign a probability to *every* subset consistently with the axioms below (a classical result of measure theory). We therefore restrict attention to a family $\mathcal{F}$ of subsets, the **events**, that is closed under the operations we need.

σ-algebra (event field)

A family $\mathcal{F}$ of subsets of Ω is a **σ-algebra** if

1. $\Omega \in \mathcal{F}$;
2. $A \in \mathcal{F} \Rightarrow A^c \in \mathcal{F}$;
3. $A_1, A_2, \dots \in \mathcal{F} \Rightarrow \bigcup_{i=1}^{\infty} A_i \in \mathcal{F}$.

By De Morgan's laws it is then also closed under countable intersections. On $\mathbb{R}$ the standard choice is the **Borel** σ-algebra, the smallest one containing all intervals; it contains every set an engineer will ever write down.

For practical work you may treat "event" as "any subset you can describe". The σ-algebra is there to guarantee that limits of events — "the error count *eventually* stays below 5", "the voltage *ever* exceeds 1 V" — are themselves events.

The axioms of probability

Probability was put on a rigorous footing by Kolmogorov (1933), who took the following three properties as axioms and derived everything else from them.

Probability space (Kolmogorov axioms)

A **probability space** is a triple $(\Omega, \mathcal{F}, P)$ where P assigns to every event $A \in \mathcal{F}$ a real number $P(A)$ such that

1. **Non-negativity:** $P(A) \geq 0$;
2. **Normalization:** $P(\Omega) = 1$;
3. **Countable additivity:** if $A_1, A_2, \dots$ are pairwise disjoint, then

$$P\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i).$$

The axioms do not say *what* number to assign to an event; they only constrain the assignment to be internally consistent. The numbers come from modelling: symmetry ("all 36 outcomes of two dice are equally likely"), physics (Boltzmann statistics of thermal noise), or measurement (a long-run relative frequency of failures). The **relative-frequency interpretation** — if the experiment is repeated N times and A occurs N_A times, then $N_A/N \to P(A)$ as $N \to \infty$ — is what connects the axioms to the laboratory, and it is a *theorem* of the theory (the law of large numbers, Section 19.9 and Ch. 20) rather than a definition.

Consequences of the axioms

Every rule of probability you will use follows from the three axioms by short arguments.

Elementary properties

For events A, B in a probability space:

1. $P(\varnothing) = 0$.
2. $P(A^c) = 1 - P(A)$.
3. If $A \subseteq B$ then $P(A) \le P(B)$ (monotonicity); in particular $0 \le P(A) \le 1$.
4. $P(A \cup B) = P(A) + P(B) - P(A \cap B)$ (addition rule).
5. $P(A \cup B) \le P(A) + P(B)$, and more generally $P\left(\bigcup_i A_i\right) \le \sum_i P(A_i)$ (union, or Boole, bound).

Proof sketch. (1) Take $A_1 = \Omega$ and $A_i = \varnothing$ for $i \ge 2$; additivity gives $P(\Omega) = P(\Omega) + \sum_{i \ge 2} P(\varnothing)$, forcing $P(\varnothing) = 0$. (2) A and A^c are disjoint with union Ω, so $P(A) + P(A^c) = 1$. (3) Write $B = A \cup (B \setminus A)$, a disjoint union, so $P(B) = P(A) + P(B \setminus A) \ge P(A)$. (4) Split $A \cup B$ into the three disjoint pieces $A \setminus B$, $A \cap B$, $B \setminus A$; also $P(A) = P(A \setminus B) + P(A \cap B)$ and similarly for B. Adding the last two and subtracting gives the result: the intersection has been counted twice. (5) follows from (4) because $P(A \cap B) \ge 0$, and by induction for finitely many events. $\square$

The addition rule generalizes to the **inclusion–exclusion principle**:

$$P\left(\bigcup_{i=1}^{n} A_i\right) = \sum_i P(A_i) - \sum_{i<j} P(A_i A_j) + \sum_{i<j<k} P(A_i A_j A_k) - \cdots + (-1)^{n+1} P(A_1 A_2 \cdots A_n).$$

For three events, $P(A \cup B \cup C) = P(A) + P(B) + P(C) - P(AB) - P(AC) - P(BC) + P(ABC)$. Truncating the series after the first sum gives the union bound (an upper bound); truncating after the second sum gives a lower bound (the **Bonferroni inequalities** alternate in this way).

A final consequence is **continuity of probability**: if $A_1 \subseteq A_2 \subseteq \cdots$ then $P\left(\bigcup_n A_n\right) = \lim_n P(A_n)$, and if $A_1 \supseteq A_2 \supseteq \cdots$ then $P\left(\bigcap_n A_n\right) = \lim_n P(A_n)$. This is what will make the CDF right-continuous in Section 19.8.

Worked Example 19.2 — Two test stations (addition rule)

Boards from a production line pass through an in-circuit test (ICT) and a functional test (FT). Records show $P(\text{fails ICT}) = 0.05$, $P(\text{fails FT}) = 0.04$ and $P(\text{fails both}) = 0.01$. Find the probability that a board fails at least one test, fails exactly one test, and passes both.

Step 1 — at least one. Let I and F be the failure events. By the addition rule,

$$P(I \cup F) = 0.05 + 0.04 - 0.01 = 0.08.$$

Step 2 — exactly one. "Exactly one" is $(I \cup F) \setminus (I \cap F)$, so its probability is $0.08 - 0.01 = 0.07$. Check: $P(I \setminus F) = 0.05 - 0.01 = 0.04$ and $P(F \setminus I) = 0.04 - 0.01 = 0.03$; total 0.07. ✓

Step 3 — passes both. By De Morgan, "passes both" is $I^c \cap F^c = (I \cup F)^c$, probability $1 - 0.08 = 0.92$.

The union bound would have given $P(I \cup F) \le 0.09$: close, because the overlap is small. When failures are rare, the union bound is nearly exact — the basis of many quick error-rate estimates.

Equally likely outcomes and counting

When Ω is finite with N outcomes and symmetry makes them equally likely, additivity forces each outcome to have probability $1/N$, and

$$P(A) = \frac{|A|}{|\Omega|} = \frac{\text{number of outcomes in } A}{\text{total number of outcomes}}.$$

Probability then reduces to **counting**, and counting large sets needs a few systematic tools — the subject of combinatorics.

Multiplication (product) principle

If a procedure consists of k stages, and stage i can be carried out in n_i ways regardless of how the earlier stages were done, then the whole procedure can be carried out in $n_1 n_2 \cdots n_k$ ways.

The four basic counts follow by choosing k items from n distinct items, distinguishing whether order matters and whether repetition is allowed:

	Order matters	Order does not matter
With replacement	n^k	$\binom{n+k-1}{k}$
Without replacement	$P(n,k) = \dfrac{n!}{(n-k)!}$	$\binom{n}{k} = \dfrac{n!}{k!\,(n-k)!}$

Derivations. Ordered with replacement: k stages, n choices each, giving n^k (the number of k-symbol words over an n-letter alphabet; 2^k binary words of length k). Ordered without replacement: n choices for the first item, $n-1$ for the second, ..., $n-k+1$ for the k-th, product $n!/(n-k)!$; with $k = n$ this is $n!$, the number of **permutations** of n items. Unordered without replacement: each unordered set of k items corresponds to exactly $k!$ ordered lists, so the number of **combinations** is $P(n,k)/k! = \binom{n}{k}$. Unordered with replacement ("stars and bars"): a multiset of size k from n types is a row of k stars separated into n bins by $n-1$ bars; choosing the positions of the k stars among $n+k-1$ symbols gives $\binom{n+k-1}{k}$.

The binomial coefficient obeys $\binom{n}{k} = \binom{n}{n-k}$, Pascal's rule $\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}$, and the **binomial theorem** $(a+b)^n = \sum_{k=0}^{n} \binom{n}{k} a^k b^{n-k}$, which will normalize the binomial distribution in Section 19.6.

Multinomial coefficient

The number of ways to split n distinct items into groups of sizes $k_1, \dots, k_r$ with $k_1 + \cdots + k_r = n$ (equivalently, the number of distinct arrangements of a word with k_i copies of letter i) is

$$\binom{n}{k_1, k_2, \dots, k_r} = \frac{n!}{k_1!\, k_2! \cdots k_r!}.$$

For example, the number of distinct orders in which 4 identical resistors, 3 identical capacitors and 2 identical inductors can be placed in 9 slots is $9!/(4!\,3!\,2!) = 1260$.

For large n, factorials are evaluated with **Stirling's approximation** $n! \approx \sqrt{2\pi n}\,(n/e)^n$, which is already within $1\,\%$ for $n = 10$.

Worked Example 19.3 — Two dice

Two fair dice are rolled. Find the probability that the sum is 7, and the probability that at least one die shows a 6.

Step 1 — sample space. Ordered pairs (d_1, d_2), $|\Omega| = 6^2 = 36$, all equally likely. (Using *unordered* pairs, 21 outcomes, would be wrong: $\{3,4\}$ can occur in two ways but $\{3,3\}$ in only one, so unordered outcomes are not equally likely.)

Step 2 — sum 7. $A = \{(1,6), (2,5), (3,4), (4,3), (5,2), (6,1)\}$, so $P(A) = 6/36 = 1/6$.

Step 3 — at least one 6. The complement is "no 6", which has $5 \times 5 = 25$ outcomes. Hence $P = 1 - 25/36 = 11/36 \approx 0.306$. Inclusion–exclusion agrees: $1/6 + 1/6 - 1/36 = 11/36$. ✓

Worked Example 19.4 — Sampling inspection (hypergeometric counting)

A reel of 50 integrated circuits contains 5 defective ones. An inspector draws 4 at random without replacement. Find the probability that (a) none is defective, (b) exactly one is defective, (c) at least one is defective.

Step 1 — sample space. Unordered samples of 4 from 50: $\binom{50}{4} = 230\,300$, all equally likely.

Step 2 — none defective. All 4 must come from the 45 good parts: $\binom{45}{4} = 148\,995$. So

$$P(\text{none}) = \frac{\binom{45}{4}}{\binom{50}{4}} = \frac{148\,995}{230\,300} \approx 0.6470.$$

Step 3 — exactly one. Choose 1 of the 5 defectives and 3 of the 45 good parts (product principle):

$$P(\text{one}) = \frac{\binom{5}{1}\binom{45}{3}}{\binom{50}{4}} = \frac{5 \times 14\,190}{230\,300} \approx 0.3081.$$

Step 4 — at least one. $1 - 0.6470 = 0.3530$.

In general, drawing n from a population of N containing K "marked" items, the probability of exactly k marked items is $\binom{K}{k}\binom{N-K}{n-k}/\binom{N}{n}$ — the **hypergeometric** distribution. Sampling inspection plans in quality control are designed with it (Ch. 20).

Worked Example 19.5 — Address collisions (the birthday problem)

Each of n wireless sensor nodes picks a 16-bit address uniformly at random ($M = 2^{16} = 65\,536$ possibilities), independently of the others. What is the probability that at least two nodes pick the same address, for $n = 100$ and $n = 300$?

Step 1 — complement. "No collision" means the n addresses are all different. The number of ordered assignments with no repeat is $M(M-1)\cdots(M-n+1)$ out of M^n equally likely assignments. So

$$P(\text{no collision}) = \prod_{k=0}^{n-1} \left(1 - \frac{k}{M}\right).$$

Step 2 — approximation. For $k \ll M$, $1 - k/M \approx e^{-k/M}$, so the product is approximately $\exp\!\left(-\sum_{k=0}^{n-1} k/M\right) = \exp\!\left(-\dfrac{n(n-1)}{2M}\right)$.

Step 3 — numbers. For $n = 100$: exact $P(\text{collision}) = 0.0728$, approximation $1 - e^{-9900/131072} = 0.0727$. For $n = 300$: exact 0.4961, approximation 0.4956.

With only 300 nodes — less than half a percent of the address space — a collision is a coin flip. The same calculation with $M = 365$ gives the famous result that 23 people share a birthday with probability 0.507. Collisions become likely once $n \approx \sqrt{M}$, which is why hash functions and random identifiers need about twice as many bits as one would naively expect.

Common Pitfall — "equally likely" must be justified

The formula $P(A) = |A|/|\Omega|$ is valid only when the outcomes really are equally likely. Choosing a description in which they are not (unordered dice, "number of errors" as the outcome of a 3-bit word, "sum of the dice" as the outcome) and then counting gives wrong answers. When in doubt, describe outcomes at the finest level the physics makes symmetric — ordered tuples of individual trials — and count there.

Engineering Note — modelling first

Almost every probability error in engineering reports is a modelling error, not an arithmetic one. Before computing, write down (1) the experiment, (2) the sample space, (3) the events of interest as subsets, (4) the source of the probability numbers (symmetry, data sheet, measurement). The axioms then do the rest mechanically.

19.2 Conditional probability

Motivation

Information changes probabilities. The probability that a bit was received in error is 10^{-3} on average, but if the automatic gain control has just flagged a deep fade it may be 10^{-1}. The probability that a power module fails in the next month is small, but much larger if it has already run hot for a year. Engineering decisions are almost always made *after* some partial information has arrived — a sensor reading, a test result, a received symbol — and conditional probability is the tool that updates the model accordingly.

Definition

Suppose we learn that event B has occurred. Outcomes outside B are now impossible, and the outcomes inside B should keep their *relative* likelihoods. The natural rule is therefore to restrict to B and rescale so that B has total probability 1.

Conditional probability

For events A, B with $P(B) > 0$, the **conditional probability of A given B** is

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)}.$$

In the relative-frequency picture: among the N_B trials in which B occurred, the fraction in which A also occurred is $N_{AB}/N_B = (N_{AB}/N)/(N_B/N) \to P(AB)/P(B)$. For equally likely outcomes, $P(A \mid B) = |A \cap B|/|B|$: count inside the **reduced sample space** B.

Conditional probability is a probability

For fixed B with $P(B) > 0$, the map $A \mapsto P(A \mid B)$ satisfies all three Kolmogorov axioms on $(\Omega, \mathcal{F})$. Consequently every rule of Section 19.1 holds conditionally: $P(A^c \mid B) = 1 - P(A \mid B)$, $P(A_1 \cup A_2 \mid B) = P(A_1 \mid B) + P(A_2 \mid B) - P(A_1 A_2 \mid B)$, and so on.

Proof. Non-negativity is clear. $P(\Omega \mid B) = P(B)/P(B) = 1$. If the A_i are disjoint, so are the $A_i \cap B$, and $P\left(\bigcup A_i \mid B\right) = P\left(\bigcup (A_i \cap B)\right)/P(B) = \sum P(A_i \cap B)/P(B) = \sum P(A_i \mid B)$. $\square$

Worked Example 19.6 — Reduced sample space

Two fair dice are rolled. Given that the first die shows 6, what is the probability that the sum is at least 10? Compare with the unconditional probability.

Step 1 — condition. $B = \{(6,1), \dots, (6,6)\}$, six equally likely outcomes.

Step 2 — count inside B. The sum is at least 10 for $(6,4), (6,5), (6,6)$: $P(A \mid B) = 3/6 = 1/2$.

Step 3 — unconditional. Sums 10, 11, 12 occur in $3 + 2 + 1 = 6$ of 36 outcomes: $P(A) = 1/6$.

Knowing the first die is a 6 triples the probability. Check with the formula: $P(A \cap B) = 3/36$, $P(B) = 6/36$, ratio $1/2$. ✓

The multiplication rule and the chain rule

Rearranging the definition gives the **multiplication rule**

$$P(A \cap B) = P(A \mid B)\, P(B) = P(B \mid A)\, P(A),$$

which is how joint probabilities are usually *computed* in sequential experiments: the probability of the first stage times the conditional probability of the second stage given the first. Applying it repeatedly yields the chain rule.

Chain rule

If $P(A_1 A_2 \cdots A_{n-1}) > 0$,

$$P(A_1 A_2 \cdots A_n) = P(A_1)\, P(A_2 \mid A_1)\, P(A_3 \mid A_1 A_2) \cdots P(A_n \mid A_1 \cdots A_{n-1}).$$

Proof. Write each conditional probability as a ratio; the product telescopes: $P(A_1) \cdot \frac{P(A_1 A_2)}{P(A_1)} \cdot \frac{P(A_1 A_2 A_3)}{P(A_1 A_2)} \cdots = P(A_1 \cdots A_n)$. $\square$

Sequential experiments are conveniently drawn as **probability trees**: each branch is labelled with a conditional probability given the path so far, and the probability of a complete path is the product of its branch labels. The labels on the branches leaving any node sum to 1, and the probabilities of all complete paths sum to 1 — two checks worth making every time.

Worked Example 19.7 — Drawing without replacement (chain rule)

A tray holds 10 MOSFETs, 3 of which are counterfeit. Parts are drawn one at a time without replacement. Find (a) the probability that the first two drawn are both counterfeit, and (b) the probability that the first counterfeit appears on the third draw.

(a) Let C_i = "draw i is counterfeit". Then

$$P(C_1 C_2) = P(C_1)P(C_2 \mid C_1) = \frac{3}{10}\cdot\frac{2}{9} = \frac{1}{15} \approx 0.0667.$$

Counting check: $\binom{3}{2}/\binom{10}{2} = 3/45 = 1/15$. ✓

(b) The event is $C_1^c C_2^c C_3$. By the chain rule,

$$P(C_1^c C_2^c C_3) = \frac{7}{10}\cdot\frac{6}{9}\cdot\frac{3}{8} = \frac{126}{720} = 0.175.$$

Each factor is a conditional probability computed in the *current* tray: after two genuine parts are removed, 8 parts remain, 3 of them counterfeit.

The law of total probability

Often $P(A)$ is hard to find directly but easy once we know which of several mutually exclusive "situations" holds. The law of total probability averages the conditional answers, weighting each situation by its probability.

Law of total probability

If $B_1, \dots, B_n$ is a partition of Ω with $P(B_i) > 0$ for all i, then for any event A

$$P(A) = \sum_{i=1}^{n} P(A \mid B_i)\,P(B_i).$$

The same holds for a countably infinite partition.

Proof. Because the B_i partition Ω, the sets $A \cap B_i$ are disjoint and their union is A. By additivity $P(A) = \sum_i P(A \cap B_i)$, and each term equals $P(A \mid B_i)P(B_i)$ by the multiplication rule. □

The simplest and most used case is the two-set partition $\{B, B^c\}$:

$$P(A) = P(A \mid B)P(B) + P(A \mid B^c)\big(1 - P(B)\big).$$

Geometrically, $P(A)$ is a weighted average of the conditional probabilities $P(A \mid B_i)$, so it always lies between the smallest and the largest of them.

Worked Example 19.8 — Three production lines

A plant makes the same voltage regulator on three lines. Line 1 produces 50 % of the output with a defect rate of 1 %, line 2 produces 30 % with 2 % defective, and line 3 produces 20 % with 3 % defective. What fraction of all regulators is defective?

Step 1 — partition. L_1, L_2, L_3 (which line made the part), with $P(L_1) = 0.5$, $P(L_2) = 0.3$, $P(L_3) = 0.2$; these sum to 1. ✓

Step 2 — conditionals. $P(D \mid L_1) = 0.01$, $P(D \mid L_2) = 0.02$, $P(D \mid L_3) = 0.03$.

Step 3 — total probability.

$$P(D) = 0.01(0.5) + 0.02(0.3) + 0.03(0.2) = 0.005 + 0.006 + 0.006 = 0.017.$$

So 1.7 % of regulators are defective — between the best line's 1 % and the worst's 3 %, as it must be. Section 19.3 asks the reverse question: given a defective part, which line made it?

Worked Example 19.9 — A channel with fades (Gilbert–Elliott model)

A radio link is in a "good" state 90 % of the time, with bit-error probability 10^{-3}, and in a "bad" (faded) state 10 % of the time, with bit-error probability 10^{-1}. Find the average bit-error probability, and the probability that two consecutive bits (sent within the same state, the state lasting much longer than a bit) are both in error. Assume errors are independent *given the state*.

Step 1 — average error probability. With E = "bit in error", G and G^c the states:

$$P(E) = 10^{-3}(0.9) + 10^{-1}(0.1) = 0.0009 + 0.01 = 0.0109.$$

The bad state, present only 10 % of the time, contributes over 90 % of the errors.

Step 2 — two errors. Conditionally on the state, two errors have probability p^2:

$$P(E_1E_2) = (10^{-3})^2(0.9) + (10^{-1})^2(0.1) = 9\times10^{-7} + 10^{-3} \approx 1.0009\times10^{-3}.$$

Step 3 — compare with a memoryless channel. If bits were independent with the average error rate, $P(E_1E_2)$ would be $0.0109^2 = 1.19\times10^{-4}$ — more than eight times too small. Moreover $P(E_2 \mid E_1) = 1.0009\times10^{-3}/0.0109 \approx 0.092$: once one error is seen, the next bit is almost 10 times more likely than average to be wrong. Errors on fading channels come in **bursts**, which is why such links use interleaving before the error-correcting code.

Common Pitfall — the conditioning bar is not symmetric

$P(A \mid B)$ and $P(B \mid A)$ are different numbers, related by $P(A \mid B)P(B) = P(B \mid A)P(A)$. "Most failed units had overheated" ($P(\text{hot} \mid \text{fail})$ large) does not mean "most units that overheat fail" ($P(\text{fail} \mid \text{hot})$ may be small). Confusing the two — sometimes called the *prosecutor's fallacy* — is the most common reasoning error in fault analysis. Bayes' theorem (Section 19.3) converts one into the other.

Common Pitfall — averaging conditionals with the wrong weights

The law of total probability weights $P(A \mid B_i)$ by $P(B_i)$, not equally. Averaging the three defect rates in Example 19.8 without weights gives 2 %, not the correct 1.7 %. And the partition must be genuinely exhaustive and disjoint; overlapping "situations" double-count.

Engineering Note — conditioning as a design tool

The law of total probability is the formal version of "divide into cases". It appears as the averaging of error rates over fading states, of failure rates over operating temperatures, of delay over network loads. When a direct calculation looks hard, ask: *which unknown, if I knew it, would make the problem easy?* Condition on it, then average.

19.3 Bayes' theorem

Motivation

Physical models usually run from cause to effect. A data sheet tells us the probability that a detector raises an alarm *given* that a fault is present; a channel model tells us the probability of receiving a 1 *given* that a 0 was sent. But the engineer's question runs the other way: the alarm has sounded — is there a fault? A 1 has been received — what was sent? Bayes' theorem inverts the conditioning, turning cause-to-effect models into effect-to-cause inferences. It is the mathematical core of detection, diagnosis, classification and estimation.

Statement and derivation

Bayes' theorem

Let $B_1, \dots, B_n$ be a partition of Ω with $P(B_i) > 0$, and let A be an event with $P(A) > 0$. Then

$$P(B_k \mid A) = \frac{P(A \mid B_k)\,P(B_k)}{\displaystyle\sum_{i=1}^{n} P(A \mid B_i)\,P(B_i)}.$$

For a two-set partition $\{B, B^c\}$:

$$P(B \mid A) = \frac{P(A \mid B)P(B)}{P(A \mid B)P(B) + P(A \mid B^c)P(B^c)}.$$

Derivation. The multiplication rule gives $P(B_k \cap A)$ in two ways: $P(B_k \mid A)P(A) = P(A \mid B_k)P(B_k)$. Divide by $P(A)$ and expand $P(A)$ with the law of total probability. □

The terms have standard names, which carry over unchanged to estimation theory (Ch. 20):

Term	Name	Meaning
$P(B_k)$	**prior**	belief in hypothesis B_k before the observation
$P(A \mid B_k)$	**likelihood**	how probable the observation is if B_k is true
$P(A)$	**evidence** (normalizer)	total probability of the observation
$P(B_k \mid A)$	**posterior**	updated belief after observing A

In words: *posterior is proportional to likelihood times prior*, and the denominator merely makes the posteriors sum to 1. This suggests a practical recipe: compute the products $P(A \mid B_i)P(B_i)$ for every hypothesis, then divide each by their sum.

Worked Example 19.10 — Which line made the defective part?

Continue Example 19.8. A regulator selected at random is found defective. Find the probability that it came from each line.

Step 1 — joint products. $P(D \mid L_i)P(L_i)$: line 1, 0.005; line 2, 0.006; line 3, 0.006. Sum $= P(D) = 0.017$.

Step 2 — normalize.

$$P(L_1 \mid D) = \frac{0.005}{0.017} = 0.294, \qquad P(L_2 \mid D) = \frac{0.006}{0.017} = 0.353, \qquad P(L_3 \mid D) = \frac{0.006}{0.017} = 0.353.$$

Check: the posteriors sum to 1. ✓

Line 1 makes half the parts but only 29 % of the defectives; line 3 makes a fifth of the parts but 35 % of the defectives. The prior (production share) and the likelihood (defect rate) pull in opposite directions, and Bayes' theorem weighs them exactly.

The binary channel

The simplest communication model has a binary input $X \in \{0, 1\}$ and a binary output $Y \in \{0, 1\}$. It is specified by the **prior** probabilities $P(X = 0) = p_0$, $P(X = 1) = p_1 = 1 - p_0$, and the **transition probabilities** $P(Y = y \mid X = x)$. In the **binary symmetric channel** (BSC) both kinds of error have the same probability ε: $P(Y = 1 \mid X = 0) = P(Y = 0 \mid X = 1) = \varepsilon$. In an asymmetric channel (optical on–off keying, where a "1" can be lost but noise rarely creates one, is a typical example) the two error probabilities differ.

Worked Example 19.11 — Binary asymmetric channel

A source sends 0 with probability 0.6 and 1 with probability 0.4. The channel has $P(Y = 1 \mid X = 0) = 0.05$ and $P(Y = 0 \mid X = 1) = 0.10$. Find (a) the output probabilities, (b) the posterior probabilities of the input given each output, (c) the error probability if the receiver simply decides $\hat{X} = Y$.

(a) Total probability.

$$P(Y = 1) = 0.05(0.6) + 0.90(0.4) = 0.03 + 0.36 = 0.39, \qquad P(Y = 0) = 0.95(0.6) + 0.10(0.4) = 0.57 + 0.04 = 0.61.$$

(b) Bayes.

$$P(X = 1 \mid Y = 1) = \frac{0.36}{0.39} = 0.923, \qquad P(X = 0 \mid Y = 0) = \frac{0.57}{0.61} = 0.934.$$

So a received 1 is wrong with probability 0.077 and a received 0 with probability 0.066.

(c) Error probability. An error occurs when $(X, Y) = (0, 1)$ or $(1, 0)$:

$$P_e = P(Y = 1 \mid X = 0)p_0 + P(Y = 0 \mid X = 1)p_1 = 0.05(0.6) + 0.10(0.4) = 0.07.$$

Check: $P_e = P(Y = 1)(1 - 0.923) + P(Y = 0)(1 - 0.934) = 0.39(0.0769) + 0.61(0.0656) = 0.030 + 0.040 = 0.070$. ✓

MAP and ML decisions

A receiver that observes $Y = y$ must decide which input was sent. The decision that minimizes the probability of error is the one that picks the input with the **largest posterior**.

MAP decision rule

Given an observation A and hypotheses $B_1, \dots, B_n$, the rule "decide B_k where k maximizes $P(B_k \mid A)$" — equivalently, maximizes $P(A \mid B_k)P(B_k)$ — minimizes the probability of a wrong decision. It is called the **maximum a posteriori (MAP)** rule. When all priors are equal, it reduces to the **maximum-likelihood (ML)** rule: maximize $P(A \mid B_k)$.

Proof sketch. For any decision rule, the probability of a *correct* decision is $\sum_{\text{observations } a} P(\text{decided hypothesis is true} \mid a)P(a)$. Each term is maximized separately by choosing, for each a, the hypothesis with the largest posterior. Since the denominators $P(a)$ are common to all hypotheses, comparing posteriors is the same as comparing the products likelihood $\times$ prior. □

For two hypotheses the MAP rule is a **likelihood-ratio test**:

$$\Lambda(a) = \frac{P(a \mid B_1)}{P(a \mid B_0)} \underset{B_0}{\overset{B_1}{\gtrless}} \frac{P(B_0)}{P(B_1)},$$

i.e. decide B_1 if the likelihood ratio exceeds the prior odds against it. Section 19.7 applies exactly this test to a signal in Gaussian noise.

Worked Example 19.12 — When MAP ignores the channel

In the channel of Example 19.11, MAP gives: for $Y=0$, compare $0.95(0.6)=0.57$ with $0.10(0.4)=0.04$ — decide 0; for $Y=1$, compare $0.05(0.6)=0.03$ with $0.90(0.4)=0.36$ — decide 1. So $\hat{X}=Y$ is already MAP, and $P_e=0.07$ is the minimum possible.

Now suppose 1s are rare: $p_1=0.03$, $p_0=0.97$, same channel.

Step 1 — $Y=1$ received. Compare $P(Y=1\mid 0)p_0=0.05(0.97)=0.0485$ with $P(Y=1\mid 1)p_1=0.90(0.03)=0.027$. The first is larger: **decide 0 even though 1 was received.**

Step 2 — $Y=0$ received. $0.95(0.97)$ vastly exceeds $0.10(0.03)$: decide 0.

Step 3 — error probabilities. The MAP receiver always outputs 0 and is wrong only when a 1 was sent: $P_e=0.03$. The "trust the channel" receiver $\hat{X}=Y$ has $P_e=0.05(0.97)+0.10(0.03)=0.0515$.

With strongly unequal priors, a noisy observation may carry less information than the prior. In practice one would not build such a receiver — it never detects a 1 — which shows that "minimum error probability" is not always the right criterion. Detection theory therefore also uses rules that weight the two errors by different *costs* (Bayes risk) or fix the false-alarm rate (Neyman–Pearson).

Base rates and fault detection

Bayes' theorem explains why detectors for rare events produce mostly false alarms, a fact that surprises almost everyone the first time.

Worked Example 19.13 — Insulation fault detector

An online partial-discharge monitor is fitted to a population of cable joints, of which $0.2\,\%$ have an incipient insulation fault. The monitor detects a real fault with probability 0.99 (sensitivity) and raises a false alarm on a healthy joint with probability 0.02. (a) An alarm is raised on a joint. What is the probability that it is faulty? (b) A second, independent monitor of the same specification also alarms on that joint. What now?

Step 1 — set up. F = faulty, A = alarm. Prior $P(F)=0.002$. Likelihoods $P(A\mid F)=0.99$, $P(A\mid F^c)=0.02$.

Step 2 — Bayes.

$$P(F\mid A)=\frac{0.99(0.002)}{0.99(0.002)+0.02(0.998)}=\frac{0.00198}{0.00198+0.01996}=0.0902.$$

Despite a "99 % accurate" detector, only about **9 %** of alarms are real. Out of 100 000 joints, 200 are faulty and 198 of those alarm; but 2% of the 99 800 healthy joints — 1996 — also alarm.

Step 3 — odds form for the second alarm. Write Bayes in odds: posterior odds = likelihood ratio $\times$ prior odds, where the likelihood ratio of an alarm is $\Lambda=0.99/0.02=49.5$. After the first alarm the odds are $0.0902/0.9098=0.0992$. A second alarm, conditionally independent given the joint's state, multiplies the odds again by 49.5:

$$\text{odds}=0.0992\times 49.5=4.91,\qquad P(F\mid A_1A_2)=\frac{4.91}{1+4.91}=0.831.$$

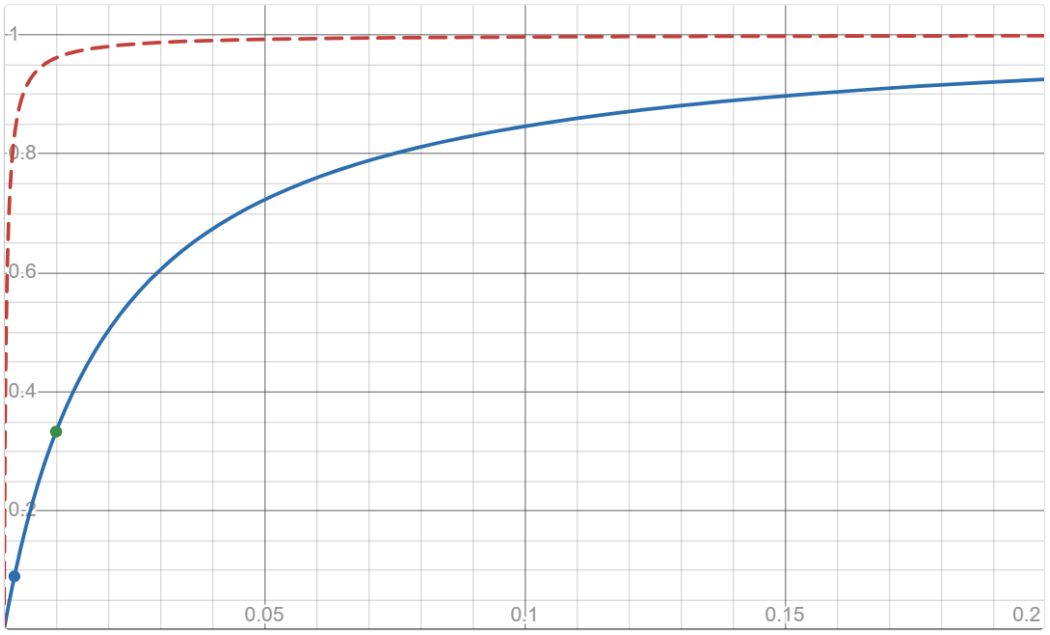
Two independent alarms move the probability from $0.2\,\%$ to $83\,\%$. Confirmation by an independent test is the standard engineering cure for the base-rate problem.

The **odds form** used in Step 3 is worth stating separately because it makes sequential updating trivial:

$$\underbrace{\frac{P(B\mid A)}{P(B^c\mid A)}}_{\text{posterior odds}}=\underbrace{\frac{P(A\mid B)}{P(A\mid B^c)}}_{\text{likelihood ratio}}\times\underbrace{\frac{P(B)}{P(B^c)}}_{\text{prior odds}}.$$

With independent observations the likelihood ratios multiply; taking logarithms, the evidence *adds*, which is why practical detectors accumulate **log-likelihood ratios**.

The dependence of the posterior on the prior is shown below for the detector of Example 19.13.



Posterior probability of a fault after one alarm (blue) and after two independent alarms (red, dashed) as a function of the prior fault probability x, for sensitivity 0.99 and false-alarm rate 0.02. For rare faults the single-alarm posterior collapses towards zero; a second alarm restores confidence.

Common Pitfall — base-rate neglect

A test's sensitivity $P(A \mid F)$ and specificity $1 - P(A \mid F^c)$ describe the *test*; the probability that an alarm is real, $P(F \mid A)$, depends also on the *population* through the prior $P(F)$. Quoting "99 % accurate" without the base rate says almost nothing about how alarms should be treated. The same detector deployed on a population with $10\,\%$ faulty units has $P(F \mid A) = 0.85$.

Engineering Note — Bayes everywhere

The binary channel and the fault detector are the same mathematics. So are spam filters, radar target detection, built-in self-test diagnostics, and the decoding of error-correcting codes (where the "hypotheses" are the possible codewords). In every case: write the prior, write the likelihood of the observation under each hypothesis, multiply, normalize, and decide by the largest posterior or by a cost-weighted threshold.

19.4 Independence

Motivation

Most probability models of real systems are built from parts: the bits of a word, the components of a circuit, the successive packets on a link, the samples of a noise waveform. The model becomes tractable when the parts do not influence each other, because then the probability of a compound event is simply the product of the probabilities of its pieces. Independence is that "no influence" assumption made precise. It is the most powerful simplification in applied probability — and the most frequently abused one, so knowing exactly what it means, and when it fails, matters as much as using it.

Independence of two events

Intuitively, A and B are independent if learning that B occurred does not change the probability of A: $P(A \mid B) = P(A)$. Multiplying by $P(B)$ gives a symmetric form that also makes sense when $P(B) = 0$, and this is taken as the definition.

Independent events

Events A and B are **independent** if

$$P(A \cap B) = P(A)\,P(B).$$

If $P(B) > 0$ this is equivalent to $P(A \mid B) = P(A)$; if $P(A) > 0$, to $P(B \mid A) = P(B)$.

Complements of independent events

If A and B are independent, so are A and B^c, A^c and B, and A^c and B^c.

Proof. $P(A \cap B^c) = P(A) - P(A \cap B) = P(A) - P(A)P(B) = P(A)\big(1 - P(B)\big) = P(A)P(B^c)$. The other cases follow by applying this twice. □

Common Pitfall — independent is not the same as disjoint

Disjoint events with non-zero probabilities are never independent: if $A \cap B = \varnothing$ then $P(AB) = 0 \neq P(A)P(B)$. Indeed, disjoint events are strongly *dependent* — knowing that A occurred tells you for certain that B did not. "Mutually exclusive" is a property of the sets; "independent" is a property of the probability measure.

Independence of several events

For three or more events, pairwise independence is not enough.

Mutual independence

Events $A_1, \dots, A_n$ are **(mutually) independent** if for *every* subcollection $A_{i_1}, \dots, A_{i_k}$ with $2 \le k \le n$ and distinct indices,

$$P(A_{i_1} \cap A_{i_2} \cap \cdots \cap A_{i_k}) = P(A_{i_1})P(A_{i_2}) \cdots P(A_{i_k}).$$

For n events this is $2^n - n - 1$ conditions. An infinite family is independent if every finite subfamily is.

Worked Example 19.14 — Pairwise but not mutually independent (parity bit)

Two fair, independent data bits b_1, b_2 are sent with an even-parity bit $b_3 = b_1 \oplus b_2$. Let A_i = "$b_i = 1$". Are A_1, A_2, A_3 independent?

Step 1 — marginals. The four equally likely words are $000, 011, 101, 110$. Each bit equals 1 in exactly two of them: $P(A_i) = 1/2$.

Step 2 — pairs. $A_1 \cap A_2 = \{110\}$, $A_1 \cap A_3 = \{101\}$, $A_2 \cap A_3 = \{011\}$, each with probability $1/4 = P(A_i)P(A_j)$. So the events are **pairwise independent**.

Step 3 — triple. $A_1 \cap A_2 \cap A_3 = \varnothing$ (no valid word is 111), so $P = 0 \neq 1/8$. The events are **not mutually independent**: any two bits determine the third.

This is exactly why a parity bit detects errors: the three bits are not free.

Conditional independence

Events A and B are **conditionally independent given** C if $P(AB \mid C) = P(A \mid C)P(B \mid C)$. Conditional independence neither implies nor is implied by independence. The fading channel of Example 19.9 is the standard illustration: given the channel state, bit errors are independent; *unconditionally* they are strongly dependent, because an error is evidence that the channel is in the bad state, which makes the next error more likely. The second alarm in Example 19.13 was assumed conditionally independent given the joint's state — not independent outright, since both alarms respond to the same fault.

Repeated independent trials

The most important use of independence is to build the probability law of n repeated, independent trials of the same experiment. Suppose each trial results in "success" with probability p and "failure" with probability $q = 1 - p$ (a **Bernoulli trial**). By independence, any particular sequence with k successes and $n - k$ failures has probability $p^k q^{n-k}$, and there are $\binom{n}{k}$ such sequences (choose the positions of the successes). Therefore:

Binomial probability law

In n independent Bernoulli trials with success probability p, the probability of exactly k successes is

$$P(k \text{ successes}) = \binom{n}{k} p^k (1-p)^{n-k}, \qquad k = 0, 1, \dots, n.$$

These probabilities sum to $(p + q)^n = 1$ by the binomial theorem.

Worked Example 19.15 — Bit errors and a Hamming code

A binary channel has independent bit errors with probability $p = 0.01$. (a) What is the probability that an uncoded 4-bit data word is received correctly? (b) The 4 data bits are instead sent as a 7-bit Hamming codeword, which corrects any single error. What is the probability that the decoded word is wrong?

(a) All 4 bits correct: $(0.99)^4 = 0.9606$; word error probability $1 - 0.9606 = 0.0394$.

(b) The decoder fails only if 2 or more of the 7 bits are wrong:

$$P(\text{fail}) = 1 - \left[\binom{7}{0}(0.99)^7 + \binom{7}{1}(0.01)(0.99)^6\right] = 1 - [0.93207 + 0.06590] = 0.00203.$$

The code reduces the word-error probability by a factor of about 19, at the price of sending 7 bits instead of 4. The dominant failure term is $\binom{7}{2}p^2q^5 \approx 0.00199$, so $P(\text{fail}) \approx 21p^2$: a single-error-correcting code turns an error rate proportional to p into one proportional to p^2. This scaling argument is the essence of coding gain.

Reliability of systems

Reliability R is the probability that a component or system performs its function (over a stated time under stated conditions). If components fail independently, the reliability of a system follows from its structure by the rules of this section. Let component i work with probability p_i and fail with probability $q_i = 1 - p_i$.

Series system. The system works only if *every* component works (a chain: fuse, converter, regulator, load). By independence,

$$R_{\text{series}} = p_1 p_2 \cdots p_n = \prod_{i=1}^{n} p_i.$$

A series system is less reliable than its weakest component, and reliability decays geometrically with the number of parts: 100 parts of reliability 0.999 give only 0.905.

Parallel (redundant) system. The system works if *at least one* component works. By De Morgan, it fails only if all fail:

$$R_{\text{parallel}} = 1 - q_1 q_2 \cdots q_n = 1 - \prod_{i=1}^{n} (1 - p_i).$$

A parallel system is more reliable than its best component. Two units of 0.9 in parallel give 0.99; three give 0.999 — each additional unit adds "one nine".

k-out-of-n system. The system works if at least k of n identical, independent components work. By the binomial law,

$$R_{k/n} = \sum_{i=k}^{n} \binom{n}{i} p^i (1-p)^{n-i}.$$

Series is n-out-of-n, parallel is 1-out-of-n. The important special case 2-out-of-3 is **triple modular redundancy (TMR)** with a majority voter: $R_{\text{TMR}} = 3p^2 - 2p^3$ (for a perfect voter).

Series–parallel networks are reduced step by step: replace each parallel group by an equivalent component with the parallel formula, each series chain by the series formula, and repeat — much as series and parallel resistors are combined. Networks that cannot be reduced this way (the **bridge** is the classic one) are handled by **conditioning on a key component** with the law of total probability:

$$R = R(\text{system} \mid \text{component } k \text{ works})\, p_k + R(\text{system} \mid \text{component } k \text{ fails})\, q_k,$$

where in each case the network simplifies: a working component is replaced by a short circuit, a failed one by an open circuit.

Worked Example 19.16 — A redundant power path

A board is powered through an input fuse ($p = 0.999$), then two identical DC–DC converters in parallel (each $p = 0.95$), then a supervisory controller ($p = 0.99$). Find the system reliability, and compare with a single converter.

Step 1 — reduce the parallel pair. $R_{\text{conv}} = 1 - (0.05)^2 = 0.9975$.

Step 2 — series chain. $R = 0.999 \times 0.9975 \times 0.99 = 0.98654$.

Step 3 — without redundancy. $R = 0.999 \times 0.95 \times 0.99 = 0.93955$.

The second converter cuts the failure probability from $6.0\,\%$ to $1.35\,\%$. The fuse and controller now dominate: the remaining unreliability is about $0.1\,\% + 0.25\,\% + 1\,\%$. Further redundancy should go where the largest series term is — here the controller.

Worked Example 19.17 — 2-out-of-3 voting

Three channels of a safety sensor each work with probability 0.95, independently; a perfect voter outputs the majority. Find the system reliability.

Step 1 — binomial. At least 2 of 3 must work:

$$R = \binom{3}{2}(0.95)^2(0.05) + \binom{3}{3}(0.95)^3 = 0.135375 + 0.857375 = 0.99275.$$

Step 2 — check with the formula. $3p^2 - 2p^3 = 3(0.9025) - 2(0.857375) = 2.7075 - 1.71475 = 0.99275$. ✓

TMR improves on a single channel (0.95) — but only because $p > 1/2$. Solving $3p^2 - 2p^3 = p$ gives $p = 1/2$: if each channel is more likely to fail than to work, majority voting makes things *worse*.

Worked Example 19.18 — The bridge network

Five links connect a source S to a terminal T: link 1 from S to node u, link 2 from u to T, link 3 from S to node v, link 4 from v to T, and a bridging link 5 between u and v. Each works independently with probability $p = 0.9$. Find the probability that S and T are connected.

Step 1 — condition on link 5 working. Nodes u and v merge. The network becomes $(1 \parallel 3)$ in series with $(2 \parallel 4)$:

$$R_1 = \left[1 - (0.1)^2\right]^2 = 0.99^2 = 0.9801.$$

Step 2 — condition on link 5 failed. The network is two series paths in parallel, (1–2) ∥ (3–4):

$$R_0 = 1 - (1 - 0.81)^2 = 1 - 0.0361 = 0.9639.$$

Step 3 — total probability.

$$R = 0.9(0.9801) + 0.1(0.9639) = 0.88209 + 0.09639 = 0.97848.$$

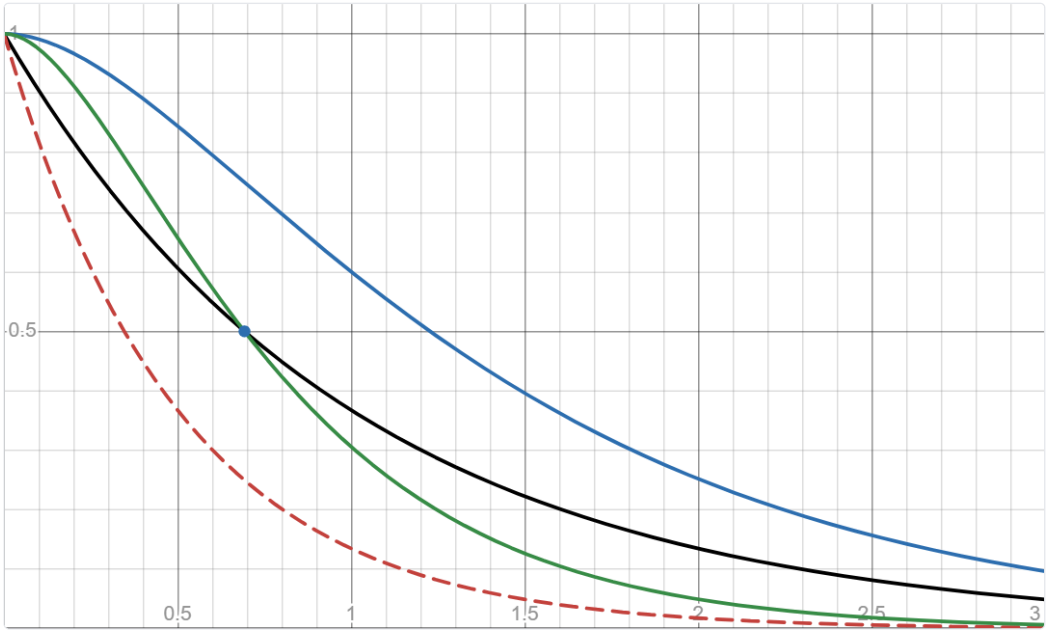
A brute-force check — summing the probabilities of all $2^5 = 32$ working/failed patterns for which a path exists — gives the same 0.97848. Conditioning reduced 32 cases to 2.

Reliability as a function of time

If a component's lifetime T has the exponential distribution (Section 19.6) with constant failure rate λ, its reliability at time t is $R(t) = P(T > t) = e^{-\lambda t}$. Substituting $p = e^{-\lambda t}$ into the structure formulas gives the reliability of a system as a function of time:

$$R_{\text{series}}(t) = e^{-n\lambda t}, \qquad R_{\text{par},2}(t) = 2e^{-\lambda t} - e^{-2\lambda t}, \qquad R_{\text{TMR}}(t) = 3e^{-2\lambda t} - 2e^{-3\lambda t}.$$

A series system of exponential components is again exponential, with failure rate equal to the sum of the component rates — the basis of the "parts count" reliability prediction method.



Reliability versus normalized time λt for a single unit (black), two units in series (red, dashed), two in parallel (blue) and 2-out-of-3 TMR (green). TMR is better than a single unit early in life but worse after $\lambda t = \ln 2$, when each channel's reliability drops below $1/2$; it suits short missions with repair or reset.

Common Pitfall — common-cause failures

The product formulas assume *independent* failures. Two "redundant" converters fed from the same overheated enclosure, two sensors calibrated with the same faulty reference, or three TMR channels running the same buggy software are not independent. A common cause that fails all channels at once with probability 10^{-3} caps the system reliability at about 0.999 no matter how much redundancy is added. Reliability engineers model this explicitly (the β-factor model) or diversify the redundant channels.

Engineering Note — where independence comes from

Independence is a *physical* assumption, justified by separation of mechanisms: different thermal noise sources in different resistors, bits separated by more than the channel's coherence time, components that share no stress. Write down why you believe it before using the product rule, and check it against data when you can — Ch. 20 gives tests for exactly this.

19.5 Random variables

Motivation

Outcomes of experiments are often not numbers: a received word, the state of a network, a sequence of heads and tails. Engineering questions, however, are almost always numerical — *how many* bits are wrong, *what* voltage was measured, *how long* until failure, *how much* power is in the noise. A random variable is the device that attaches a number to each outcome. Once we have numbers we can add, average, threshold and filter them, and the full machinery of calculus becomes available. From here on, almost all of probability is phrased in terms of random variables, and the underlying sample space fades into the background.

Definition

Random variable

A **random variable** (RV) on a probability space $(\Omega, \mathcal{F}, P)$ is a function $X : \Omega \to \mathbb{R}$ that assigns a real number $X(\zeta)$ to each outcome ζ, such that for every real x the set

$$\{X \le x\} = \{\zeta \in \Omega : X(\zeta) \le x\}$$

is an event (belongs to $\mathcal{F}$). The set of values X can take is its **range** S_X.

The technical condition (called *measurability*) guarantees that we can ask for $P(X \le x)$; it is automatically satisfied by every function an engineer writes down, and we shall not mention it again. Note the language: a random variable is neither random nor a variable — it is a deterministic *function*. The randomness lives in which outcome ζ occurs.

Once $\{X \le x\}$ is an event for every x, so are all the sets built from them by countable unions, intersections and complements, for instance

$$\{a < X \le b\} = \{X \le b\} \setminus \{X \le a\}, \qquad \{X = a\} = \bigcap_{n=1}^{\infty} \{a - 1/n < X \le a\}, \qquad \{X > a\} = \{X \le a\}^c.$$

So every question of the form "does X fall in the set B?" has a probability $P(X \in B)$. The assignment $B \mapsto P(X \in B)$ is itself a probability measure on the real line, called the **distribution** (or **law**) of X. Two random variables defined on completely different sample spaces can have the same distribution; for most purposes they are then interchangeable.

Worked Example 19.19 — Number of bit errors

A 3-bit word is sent over a channel with independent bit errors of probability $p = 0.1$. Let X = number of bits in error. Find the probability of each value of X.

Step 1 — the function. $\Omega = \{000, 001, \dots, 111\}$ (1 = error) and $X(\zeta)$ is the number of 1s in ζ: $X(000) = 0$, $X(010) = 1$, $X(111) = 3$, and so on. $S_X = \{0, 1, 2, 3\}$.

Step 2 — outcome probabilities. By independence, an outcome with k ones has probability $0.1^k\, 0.9^{3-k}$.

Step 3 — collect outcomes with the same value of X.

$$P(X=0) = 0.9^3 = 0.729, \qquad P(X=1) = 3(0.1)(0.9)^2 = 0.243,$$
$$P(X=2) = 3(0.1)^2(0.9) = 0.027, \quad P(X=3) = 0.1^3 = 0.001.$$

The probabilities sum to 1. ✓ Eight outcomes have been condensed into four numbers — the information relevant to the question "how many errors?".

Types of random variable

Discrete, continuous and mixed random variables

- X is **discrete** if its range S_X is finite or countably infinite: X takes isolated values $x_1, x_2, \dots$ with probabilities $P(X = x_k) > 0$ that sum to 1. (Counts, symbols, bits, quantizer outputs.)
- X is **continuous** if $P(X = x) = 0$ for every single value x and probabilities of intervals are given by integrals of a density: $P(a < X \le b) = \int_a^b f_X(x)\, dx$. (Voltages, times, phases, positions.)
- X is **mixed** if it has both: some isolated values with positive probability, and a continuous part spread over intervals. (A clipped voltage, the waiting time of a packet that is either sent at once or queued.)

Every random variable is completely described by its **cumulative distribution function** $F_X(x) = P(X \le x)$ (Section 19.8). For discrete RVs it is more convenient to list the probabilities of the individual values, the **probability mass function** (PMF); for continuous RVs, the derivative of the CDF, the **probability density function** (PDF). Both are developed in Section 19.7.

Common Pitfall — "probability zero" is not "impossible"

For a continuous RV every individual value has probability zero: the thermal-noise voltage is exactly $1.000\ldots$ mV with probability 0, yet some value always occurs. Zero-probability events can happen; they are just too "thin" to carry probability. Consequently, for a continuous RV, $P(a < X < b) = P(a \le X \le b)$ — endpoints do not matter. For discrete and mixed RVs they matter a great deal.

Indicator random variables

The simplest random variable takes only the values 0 and 1.

Indicator random variable

For an event A, the **indicator** of A is

$$I_A(\zeta) = \begin{cases} 1, & \zeta \in A \\ 0, & \zeta \notin A. \end{cases}$$

It satisfies $P(I_A = 1) = P(A)$, $I_{A^c} = 1 - I_A$, $I_{A \cap B} = I_A I_B$, and $I_{A \cup B} = I_A + I_B - I_A I_B$.

Indicators turn events into numbers and set operations into arithmetic. Their great use is in **counting**: the number of events among $A_1, \dots, A_n$ that occur is $X = I_{A_1} + \cdots + I_{A_n}$. In Example 19.19, X is the sum of three indicators "bit i is wrong". Section 19.9 shows that this decomposition makes the mean of X trivial to compute even when the events are dependent.

Functions of a random variable

If X is a random variable and g is an ordinary real function, then $Y = g(X)$ — the function $\zeta \mapsto g(X(\zeta))$ — is again a random variable. This is the probabilistic version of passing a signal through a memoryless system: a diode, a square-law detector, a limiter, a quantizer, an amplifier. The central question is: **given the distribution of X, what is the distribution of Y?**

The principle is always the same: an event about Y is an event about X,

$$P(Y \in B) = P\big(g(X) \in B\big) = P\big(X \in g^{-1}(B)\big), \qquad g^{-1}(B) = \{x : g(x) \in B\}.$$

For a discrete X this simply means collecting probability: every value y of Y gets the total probability of the x-values that map to it,

$$P(Y = y) = \sum_{x:\, g(x)=y} P(X = x).$$

For continuous X the same principle leads to the CDF method and the density-transformation formula of Sections 19.7 and 19.8.

Worked Example 19.20 — A squarer acting on a discrete signal

A 5-level signal X takes the values $-2, -1, 0, 1, 2$ V with probabilities $0.1, 0.2, 0.4, 0.2, 0.1$. It drives a square-law power detector whose output is $Y = X^2$ (in V^2). Find the PMF of Y.

Step 1 — range of Y. $g(x) = x^2$ maps $\{-2, -1, 0, 1, 2\}$ onto $\{0, 1, 4\}$.

Step 2 — collect preimages.

$$P(Y = 0) = P(X = 0) = 0.4, \qquad P(Y = 1) = P(X = -1) + P(X = 1) = 0.4, \qquad P(Y = 4) = P(X = -2) + P(X = 2) = 0.2.$$

Step 3 — check. $0.4 + 0.4 + 0.2 = 1$. ✓ Because g is not one-to-one, information is lost: from $Y = 1$ we cannot tell whether X was $+1$ or -1.

Worked Example 19.21 — A limiter produces a mixed random variable

A voltage X is equally likely to be anywhere in $(-2, 2)$ V, i.e. $P(a < X < b) = (b - a)/4$ for $-2 \le a < b \le 2$. It passes through an ideal limiter with output $Y = X$ for $|X| \le 1$, $Y = +1$ for $X > 1$ and $Y = -1$ for $X < -1$. Describe the distribution of Y.

Step 1 — clipped values. $P(Y = 1) = P(X > 1) = (2 - 1)/4 = 0.25$; likewise $P(Y = -1) = 0.25$. These are point masses.

Step 2 — the linear region. For $-1 < a < b < 1$, $P(a < Y < b) = P(a < X < b) = (b - a)/4$: probability is spread uniformly over $(-1, 1)$ with density $1/4$ per volt, total 0.5.

Step 3 — check. $0.25 + 0.25 + 0.5 = 1$. ✓

Y is **mixed**: it is neither discrete (it takes a continuum of values) nor continuous ($P(Y = 1) > 0$). Saturating amplifiers, ADCs driven beyond full scale, and rectifiers all produce mixed outputs; Section 19.8 draws their staircase-plus-ramp CDFs, and Section 19.7 represents the point masses with Dirac impulses.

Engineering Note — random variables are measurements

A good habit is to read "random variable" as "the reading on an instrument attached to the experiment". Different instruments on the same experiment give different RVs on the same sample space (X = number of errors, Y = position of the first error, Z = parity of the received word); their joint behaviour is the subject of the joint distributions introduced in Section 19.6. And a memoryless circuit applied to a reading gives a new reading, $Y = g(X)$, whose distribution is fixed by that of X.

19.6 Probability distributions

Motivation

A handful of distributions account for the overwhelming majority of probability models in electrical engineering. Each arises from a simple mechanism: counting successes in independent trials (binomial), waiting for the first success (geometric), counting rare events in a long interval (Poisson), complete ignorance over an interval (uniform), memoryless lifetimes (exponential), the sum of many small effects (Gaussian), the envelope of a two-dimensional Gaussian (Rayleigh). Recognizing the mechanism lets you write down the distribution without collecting data. This section introduces these key families and the first ideas of **joint** distributions of two random variables; Ch. 20 extends the catalogue (chi-square, Student t, lognormal, Weibull, ...) and shows how to fit and test distributions against data.

Distribution of a random variable

The **distribution** of X is the rule that gives $P(X \in B)$ for every event $B \subseteq \mathbb{R}$. In practice it is specified by a PMF $p_X(x_k) = P(X = x_k)$ for a discrete RV, by a PDF $f_X(x)$ with $P(X \in B) = \int_B f_X(x)\,dx$ for a continuous RV, or in all cases by the CDF $F_X(x) = P(X \le x)$. A **family** of distributions is a formula with adjustable **parameters** (n, p for the binomial; μ, σ for the Gaussian).

Discrete families

Bernoulli distribution

$X \sim \text{Bernoulli}(p)$: $P(X = 1) = p$, $P(X = 0) = 1 - p$. The indicator of any event with probability p; a single bit with error probability p.

Binomial distribution

$X \sim \text{Bin}(n, p)$: the number of successes in n independent Bernoulli(p) trials,

$$p_X(k) = \binom{n}{k} p^k (1 - p)^{n-k}, \qquad k = 0, 1, \ldots, n.$$

This is the law derived in Section 19.4; Example 19.19 was $\text{Bin}(3, 0.1)$. The PMF rises to a peak near $k \approx np$ and then falls; the ratio of successive terms, $p_X(k+1)/p_X(k) = \frac{(n-k)p}{(k+1)(1-p)}$, exceeds 1 exactly when $k < (n+1)p - 1$, which locates the mode at $\lfloor (n+1)p \rfloor$.

Geometric distribution

$N \sim \text{Geom}(p)$: the number of independent trials up to and including the first success,

$$p_N(k) = (1-p)^{k-1}p, \qquad k = 1, 2, 3, \ldots$$

with tail $P(N > k) = (1-p)^k$ (the first k trials all fail).

The geometric distribution is the only **memoryless** discrete distribution: $P(N > m + k \mid N > m) = (1-p)^{m+k}/(1-p)^m = P(N > k)$. Having already failed m times does not make success any closer.

Poisson distribution

$X \sim \text{Poisson}(\lambda)$, $\lambda > 0$:

$$p_X(k) = e^{-\lambda}\frac{\lambda^k}{k!}, \qquad k = 0, 1, 2, \ldots$$

The probabilities sum to $e^{-\lambda}e^{\lambda} = 1$ by the exponential series.

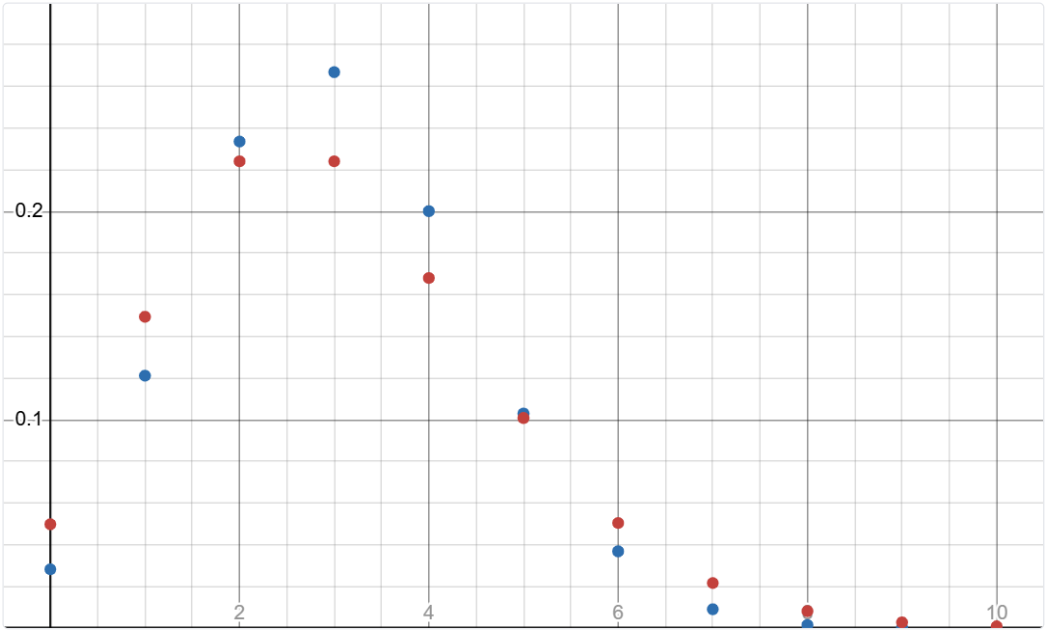
Poisson limit of the binomial

If $n \to \infty$ and $p \to 0$ with $np = \lambda$ fixed, then $\binom{n}{k}p^k(1-p)^{n-k} \to e^{-\lambda}\lambda^k/k!$ for each fixed k.

Proof. Write $p = \lambda/n$:

$$\binom{n}{k}\left(\frac{\lambda}{n}\right)^k\left(1-\frac{\lambda}{n}\right)^{n-k} = \frac{\lambda^k}{k!}\cdot\underbrace{\frac{n(n-1)\cdots(n-k+1)}{n^k}}_{\to 1}\cdot\underbrace{\left(1-\frac{\lambda}{n}\right)^{n}}_{\to e^{-\lambda}}\cdot\underbrace{\left(1-\frac{\lambda}{n}\right)^{-k}}_{\to 1}. \qquad \square$$

This is the **law of rare events**: whenever a large number of independent opportunities each produce an event with small probability, the count is approximately Poisson with λ = expected number of events. Photon arrivals at a photodiode, electrons crossing a barrier (shot noise), packet arrivals from many independent users, defects on a wafer, and bit errors in a long frame all follow this pattern. If events occur "at random" at an average **rate** r per second, the count in an interval of length τ is $\text{Poisson}(r\tau)$ — the **Poisson process** of Ch. 21.



PMFs of $\text{Bin}(10, 0.3)$ *(blue) and* $\text{Poisson}(3)$ *(red), both with mean 3. The Poisson PMF is slightly wider and has a tail beyond* $k = 10$*; with only* $n = 10$ *trials and* $p = 0.3$ *the Poisson approximation is rough, but it becomes excellent as* n *grows with* np *fixed.*

Worked Example 19.22 — Errors in a frame (Poisson approximation)

A 1000-bit frame is sent over a channel with independent bit errors, $p = 0.002$. Find the probability that the frame is error-free and the probability that it has 3 or more errors (more than a double-error-correcting code can handle).

Step 1 — exact model. $X \sim \text{Bin}(1000, 0.002)$. $P(X = 0) = 0.998^{1000} = 0.13506$.

Step 2 — Poisson model. $\lambda = np = 2$. $P(X = 0) \approx e^{-2} = 0.13534$ — within $0.2\,\%$.

Step 3 — three or more errors.

$$P(X \geq 3) = 1 - e^{-2}\left(1 + 2 + \frac{2^2}{2!}\right) = 1 - 5e^{-2} = 0.32332.$$

The exact binomial value is 0.32332 to five decimals. ✓

One frame in three would be uncorrectable; the design must lower p, shorten the frame or use a stronger code.

Worked Example 19.23 — Retransmissions (geometric)

An ARQ protocol resends a packet until it is acknowledged; each attempt succeeds independently with probability 0.8. Find the probability that more than 3 attempts are needed, and the probability that exactly 2 attempts are needed given that the first failed.

Step 1 — tail. $P(N > 3) = (0.2)^3 = 0.008$.

Step 2 — memorylessness. $P(N = 2 \mid N > 1) = P(N = 1) = 0.8$ by the memoryless property. Directly: $P(N = 2)/P(N > 1) = (0.2)(0.8)/0.2 = 0.8$. ✓

Continuous families

Uniform distribution

$X \sim \mathcal{U}(a, b)$: $f_X(x) = \dfrac{1}{b - a}$ for $a < x < b$ and 0 otherwise. Probability is proportional to length: $P(c < X < d) = (d - c)/(b - a)$ for $a \leq c < d \leq b$.

The uniform distribution models the phase of an oscillator that is not synchronized to anything ($\Theta \sim \mathcal{U}(0, 2\pi)$), and the rounding error of a fine quantizer with step Δ ($e \sim \mathcal{U}(-\Delta/2, \Delta/2)$, Section 19.9).

Exponential distribution

$T \sim \text{Exp}(\lambda)$, rate $\lambda > 0$:

$$f_T(t) = \lambda e^{-\lambda t}\ (t \geq 0), \qquad P(T > t) = e^{-\lambda t}\ (t \geq 0).$$

Memoryless property

$T \sim \text{Exp}(\lambda)$ satisfies $P(T > s + t \mid T > s) = P(T > t)$ for all $s, t \geq 0$, and it is the only continuous distribution on $[0, \infty)$ with this property.

Proof of the property. $P(T > s + t \mid T > s) = e^{-\lambda(s+t)}/e^{-\lambda s} = e^{-\lambda t}$. (Uniqueness: $G(t) = P(T > t)$ must satisfy $G(s + t) = G(s)G(t)$, whose only monotone solutions are exponentials.) □

A component with exponential lifetime does not age: a unit that has survived 10 000 hours is as good as new. This is realistic for electronic parts during their "useful life" — after infant mortality and before wear-out — where failures are caused by random external stresses rather than accumulated damage. The exponential is also the distribution of the time between events of a Poisson process: if events occur at rate r, the waiting time T to the first one satisfies $P(T > t) = P(\text{no events in } [0, t]) = e^{-rt}$.

Gaussian (normal) distribution

$X \sim \mathcal{N}(\mu, \sigma^2)$, with $\mu \in \mathbb{R}$, $\sigma > 0$:

$$f_X(x) = \frac{1}{\sqrt{2\pi}\,\sigma} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right), \qquad -\infty < x < \infty.$$

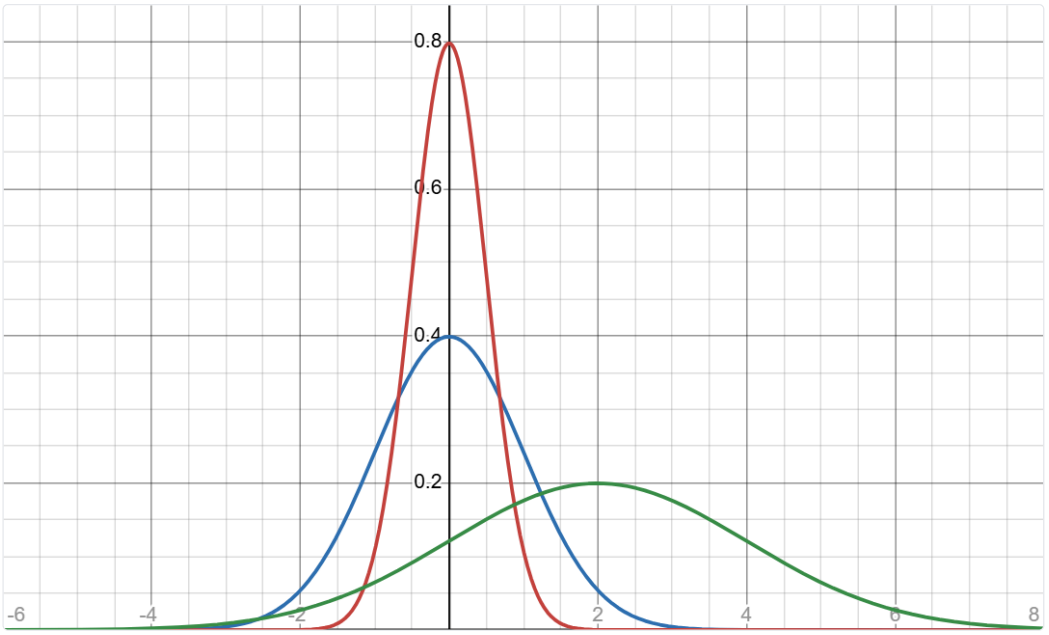
The **standard** Gaussian is $Z \sim \mathcal{N}(0, 1)$, with PDF $\varphi(z) = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}$, CDF $\Phi(z)$ and tail $Q(z) = 1 - \Phi(z)$.

Normalization. With $I = \int_{-\infty}^{\infty} e^{-z^2/2} dz$, convert I^2 to a double integral over the plane and use polar coordinates (Ch. 6):

$$I^2 = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{-(u^2+v^2)/2}\, du\, dv = \int_0^{2\pi}\int_0^{\infty} e^{-r^2/2}\, r\, dr\, d\phi = 2\pi,$$

so $I = \sqrt{2\pi}$, and the substitution $z = (x - \mu)/\sigma$ handles general μ, σ.

The Gaussian is symmetric about μ, has its inflection points at $\mu \pm \sigma$, and its tails fall off faster than any exponential. Its pre-eminence comes from the **central limit theorem** (Ch. 20): the sum of many small independent contributions is approximately Gaussian whatever the individual distributions. Thermal noise (the sum of the effects of enormous numbers of electrons), aggregate interference, and manufacturing tolerances that result from many small process variations are all modelled as Gaussian. Gaussian probabilities are computed from tables of Φ or Q (Section 19.8).



Gaussian PDFs: $\mathcal{N}(0,1)$ (blue), $\mathcal{N}(0,0.25)$ (red) and $\mathcal{N}(2,4)$ (green). The mean μ shifts the curve; the standard deviation σ scales its width by σ and its height by $1/\sigma$, keeping the area equal to 1.

Rayleigh distribution

$R \sim \text{Rayleigh}(\sigma)$:

$$f_R(r) = \frac{r}{\sigma^2} e^{-r^2/(2\sigma^2)} \ (r \ge 0), \qquad P(R > r) = e^{-r^2/(2\sigma^2)}.$$

It is the distribution of the envelope $R = \sqrt{X^2 + Y^2}$ when X, Y are independent $\mathcal{N}(0, \sigma^2)$ — the amplitude of narrowband Gaussian noise, or of a radio signal arriving over many scattered paths with no direct line of sight. Its mean-square value is $E[R^2] = 2\sigma^2$.

Worked Example 19.24 — Component lifetime and deep fades

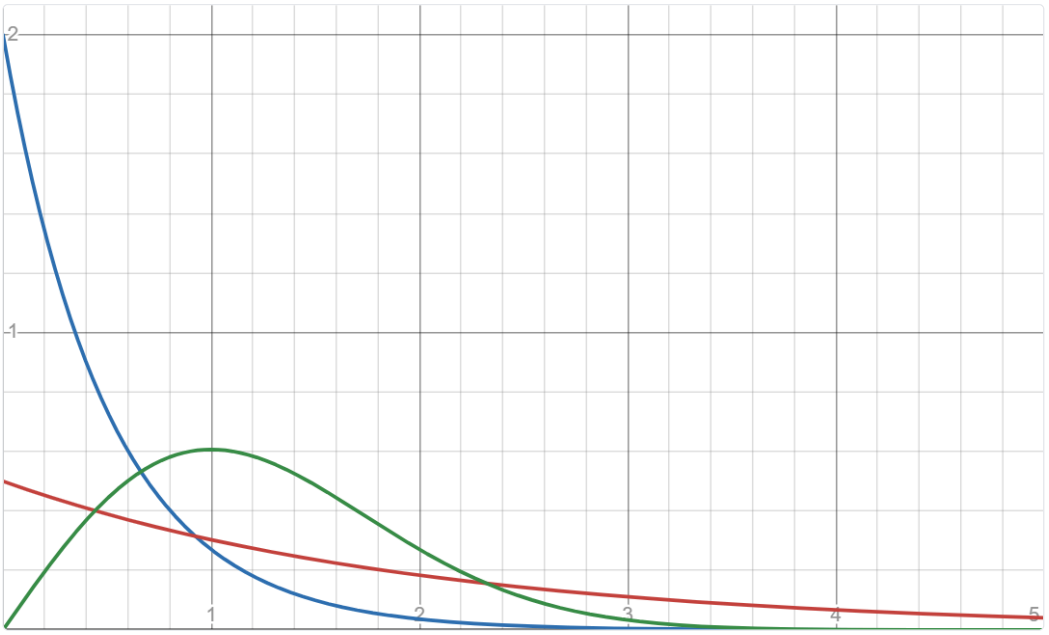
(a) A power MOSFET has an exponential lifetime with failure rate $\lambda = 2 \times 10^{-5}$ per hour. Find the probability that it survives one year of continuous operation (8760 h), and the probability that it survives a second year given that it survived the first. (b) A Rayleigh-fading signal has mean-square amplitude $E[R^2] = 2\sigma^2$. Find the probability that the amplitude is more than 20 dB below its RMS value.

(a) $P(T > 8760) = e^{-2\times10^{-5}\times 8760} = e^{-0.1752} = 0.839$. By memorylessness, the conditional probability of surviving the second year is also 0.839, and of surviving both years $0.839^2 = 0.704$.

(b) 20 dB below RMS in amplitude means $R < 0.1\sqrt{2\sigma^2}$, i.e. $R^2 < 0.01 \times 2\sigma^2$:

$$P(R < 0.1\,R_{\text{rms}}) = 1 - e^{-0.02\sigma^2/(2\sigma^2)} = 1 - e^{-0.01} = 0.00995.$$

About 1 % of the time the signal is in a 20 dB fade; by the same formula, 10 % of the time it is in a 10 dB fade ($1 - e^{-0.1} = 0.095$). Each extra 10 dB of fade margin buys a factor of 10 in outage probability — the classic Rayleigh rule of thumb.



Exponential PDFs with $\lambda = 2$ (blue) and $\lambda = 0.5$ (red), both maximal at $t = 0$: the most likely lifetime is "immediately", though the median is $\ln 2/\lambda$. The Rayleigh PDF with $\sigma = 1$ (green) vanishes at 0, peaks at $r = \sigma$ and has a Gaussian-like tail.

Joint distributions: a first look

Engineering problems usually involve several random quantities at once: the transmitted and received bits, the in-phase and quadrature noise components, the lifetimes of two redundant units. Their *individual* distributions do not say how they interact; that information is in the **joint distribution**. We introduce the essentials for two random variables; correlation and covariance as data-analysis tools are developed in Ch. 20, and families of RVs indexed by time in Ch. 21.

Joint PMF, joint PDF, joint CDF

For two random variables X, Y on the same probability space:

- the **joint CDF** is $F_{XY}(x, y) = P(X \le x,\ Y \le y)$;
- if both are discrete, the **joint PMF** is $p_{XY}(x_i, y_k) = P(X = x_i,\ Y = y_k)$, with $\sum_i \sum_k p_{XY}(x_i, y_k) = 1$;
- they are **jointly continuous** with **joint PDF** $f_{XY}(x, y) \ge 0$ if, for every region D of the plane,

$$P\big((X, Y) \in D\big) = \iint_D f_{XY}(x, y)\, dx\, dy, \qquad \iint_{\mathbb{R}^2} f_{XY}\, dx\, dy = 1.$$

Then $f_{XY}(x, y) = \dfrac{\partial^2 F_{XY}}{\partial x\, \partial y}$.

From the joint distribution we recover each variable alone — the **marginal** distributions — by summing or integrating out the other variable (law of total probability):

$$p_X(x_i) = \sum_k p_{XY}(x_i, y_k), \qquad f_X(x) = \int_{-\infty}^{\infty} f_{XY}(x, y)\, dy.$$

The **conditional** distribution of Y given $X = x$ is the joint divided by the marginal, exactly as in Section 19.2:

$$p_{Y|X}(y_k \mid x_i) = \frac{p_{XY}(x_i, y_k)}{p_X(x_i)}, \qquad f_{Y|X}(y \mid x) = \frac{f_{XY}(x, y)}{f_X(x)} \quad (f_X(x) > 0).$$

Independent random variables

X and Y are **independent** if $P(X \in A,\ Y \in B) = P(X \in A)P(Y \in B)$ for all events A, B. Equivalently, the joint CDF (or joint PMF, or joint PDF) factors into the product of the marginals:

$$F_{XY}(x, y) = F_X(x) F_Y(y) \quad \text{for all } x, y, \qquad \text{or} \qquad f_{XY}(x, y) = f_X(x) f_Y(y).$$

The marginals determine the joint distribution only in the independent case; in general, many different joint distributions share the same marginals.

Worked Example 19.25 — Joint PMF of a binary channel

For the channel of Example 19.11 ($p_0 = 0.6$, $P(Y=1 \mid X=0) = 0.05$, $P(Y=0 \mid X=1) = 0.10$), tabulate the joint PMF of input X and output Y, find the marginals, and decide whether X and Y are independent.

Step 1 — joint PMF by the multiplication rule $p_{XY}(x,y) = P(Y=y \mid X=x)P(X=x)$:

	$Y=0$	$Y=1$	p_X
$X=0$	0.57	0.03	0.60
$X=1$	0.04	0.36	0.40
p_Y	0.61	0.39	1

Step 2 — marginals are the row and column sums (written in the margins — hence the name).

Step 3 — independence test. $p_X(0)p_Y(0) = 0.6 \times 0.61 = 0.366 \neq 0.57$. Not independent — fortunately, since a channel whose output is independent of its input carries no information.

Worked Example 19.26 — A joint PDF on a triangle

X and Y have joint PDF $f_{XY}(x,y) = 2$ on the triangle $0 < y < x < 1$ and 0 elsewhere. (For example, X and Y could be the larger and smaller of two independent $\mathcal{U}(0,1)$ readings.) Find the marginals, the conditional PDF of Y given $X = x$, and $P(X + Y < 1)$.

Step 1 — check normalization. The triangle has area $1/2$; $2 \times \frac{1}{2} = 1$. ✓

Step 2 — marginals.

$$f_X(x) = \int_0^x 2\,dy = 2x \quad (0 < x < 1), \qquad f_Y(y) = \int_y^1 2\,dx = 2(1-y) \quad (0 < y < 1).$$

Step 3 — conditional. $f_{Y|X}(y \mid x) = 2/(2x) = 1/x$ for $0 < y < x$: given $X = x$, Y is uniform on $(0, x)$.

Step 4 — a probability. The region $\{y < x,\ x + y < 1,\ y > 0\}$ is the triangle with vertices $(0,0)$, $(1,0)$, $(\frac{1}{2}, \frac{1}{2})$, of area $\frac{1}{4}$. So $P(X+Y<1) = 2 \times \frac{1}{4} = \frac{1}{2}$.

X and Y are not independent: $f_X(x)f_Y(y) = 4x(1-y)$ is not equal to 2, and in any case the support (a triangle, not a rectangle) already rules out independence.

Sums of independent random variables

The distribution of a sum $Z = X + Y$ arises constantly: signal plus noise, total delay of two stages, combined tolerance of two resistors in series, total lifetime of a unit and its cold spare. For independent X, Y, the event $\{Z \le z\}$ is the region $x + y \le z$, and

$$F_Z(z) = \int_{-\infty}^{\infty} \int_{-\infty}^{z-x} f_X(x) f_Y(y)\,dy\,dx.$$

Differentiating with respect to z gives the central result.

Distribution of a sum of independent RVs

If X and Y are independent with PDFs f_X, f_Y, then $Z = X + Y$ has PDF

$$f_Z(z) = \int_{-\infty}^{\infty} f_X(x)\, f_Y(z-x)\,dx = (f_X * f_Y)(z),$$

the **convolution** of the two densities. For independent integer-valued RVs, $p_Z(n) = \sum_k p_X(k)\, p_Y(n-k)$, the discrete convolution.

This is the same convolution that gives the output of an LTI system (Ch. 16, Ch. 17), and it can be computed the same way — by transforms. The transform of a density is its characteristic function (Section 19.9), and convolution becomes multiplication.

Worked Example 19.27 — Sums of uniform and exponential RVs

(a) Two independent errors $X, Y \sim \mathcal{U}(0,1)$ add. Find the PDF of $Z = X + Y$. (b) A unit with $\text{Exp}(\lambda)$ lifetime T_1 has a cold spare, switched in perfectly on failure, with independent $\text{Exp}(\lambda)$ lifetime T_2. Find the reliability of the pair, and evaluate it for $\lambda = 2 \times 10^{-5}\ \text{h}^{-1}$ at one year.

(a) $f_X(x) f_Y(z-x) = 1$ when $0 < x < 1$ and $0 < z - x < 1$, i.e. $\max(0, z-1) < x < \min(1, z)$. The length of that interval is z for $0 < z \le 1$ and $2 - z$ for $1 < z < 2$:

$$f_Z(z) = \begin{cases} z, & 0 < z \le 1 \\ 2 - z, & 1 < z < 2 \\ 0, & \text{otherwise} \end{cases}$$

— a **triangle**, the convolution of two rectangles. Adding more uniforms smooths the shape further towards a Gaussian (central limit theorem).

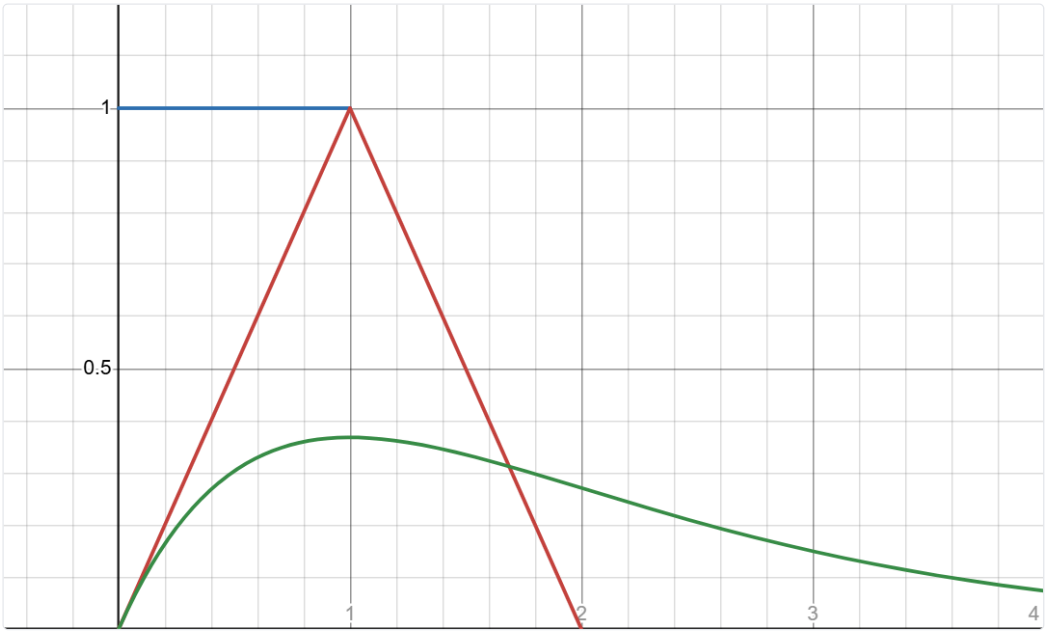
(b) For $z > 0$,

$$f_Z(z) = \int_0^z \lambda e^{-\lambda x}\, \lambda e^{-\lambda(z-x)}\, dx = \lambda^2 e^{-\lambda z} \int_0^z dx = \lambda^2 z e^{-\lambda z},$$

the **Erlang-2** (gamma) density. The reliability is

$$R(t) = P(Z > t) = \int_t^\infty \lambda^2 z e^{-\lambda z} dz = (1 + \lambda t) e^{-\lambda t}.$$

With $\lambda t = 0.1752$: $R = 1.1752\, e^{-0.1752} = 0.9863$, against 0.8393 for a single unit and $1 - (1 - 0.8393)^2 = 0.9742$ for two units running in *active* parallel. A cold spare beats a hot one because it does not age while waiting (assuming a perfect switch).



Convolution in action: the $\mathcal{U}(0,1)$ density (blue) convolved with itself gives the triangle (red); two independent $\text{Exp}(1)$ lifetimes add to the Erlang-2 density ze^{-z} (green), which, unlike the exponential, is zero at the origin — two failures rarely happen in quick succession.

Common Pitfall — marginals do not determine the joint

Knowing that X and Y are each $\mathcal{N}(0,1)$ does not determine $P(X + Y > 2)$: if $Y = X$ the answer is $Q(1) = 0.159$; if $Y = -X$ it is 0; if they are independent it is $Q(\sqrt{2}) = 0.079$. Any computation involving two random variables needs their joint distribution, and assuming independence is a modelling decision that must be justified.

Engineering Note — independence makes joint models cheap

Specifying a general joint PMF of n binary variables needs $2^n - 1$ numbers; under independence, n numbers suffice. This exponential saving is why independence (or conditional independence given a few hidden variables, as in the fading channel) underlies almost every tractable model of noise, errors and failures.

19.7 Probability density and mass functions

Motivation

The PMF and PDF are the working descriptions of a random variable: they are what you sketch, fit to histograms, multiply by likelihoods and integrate against. The PMF is simple — a list of probabilities. The PDF needs more care, because its values are *not* probabilities, it can exceed 1, it can contain impulses, and it transforms in a non-obvious way when the variable is passed through a nonlinearity. This section states the properties precisely, shows how to treat discrete,

continuous and mixed variables in one notation, and derives the transformation rule that gives the density at the output of a memoryless system.

The probability mass function

PMF

The **probability mass function** of a discrete random variable X with range $S_X = \{x_1, x_2, \dots\}$ is

$$p_X(x) = P(X = x).$$

It satisfies $p_X(x) \geq 0$, $p_X(x) = 0$ for $x \notin S_X$, and $\sum_k p_X(x_k) = 1$. For any set B, $P(X \in B) = \sum_{x_k \in B} p_X(x_k)$.

Any non-negative sequence summing to 1 is a valid PMF, and constructing a model often means choosing such a sequence from a family and fixing its parameters.

The probability density function

PDF

A random variable X is **continuous** with **probability density function** f_X if $f_X(x) \geq 0$, $\int_{-\infty}^{\infty} f_X(x)\,dx = 1$, and for all $a < b$

$$P(a < X \leq b) = \int_a^b f_X(x)\,dx.$$

The name "density" is literal. For a small interval of width Δx around a point where f_X is continuous,

$$P(x < X \leq x + \Delta x) \approx f_X(x)\,\Delta x,$$

so $f_X(x)$ is probability *per unit of* x. If X is a voltage, f_X has units of V^{-1}. This has three consequences that trip up newcomers:

1. $f_X(x)$ **is not a probability.** It can exceed 1: the $\mathcal{U}(0, 0.1)$ density equals 10 on its support.
2. **Only areas are probabilities.** $P(X = x) = \int_x^x f_X = 0$ for every x.
3. **Densities change under a change of units.** If $Y = 1000X$ (the same voltage in mV), then $f_Y(y) = f_X(y/1000)/1000$, so that $f_Y(y)\,dy = f_X(x)\,dx$ (see the transformation rule below).

A histogram of measured values, scaled so that its total area is 1 (bar height = fraction of samples in the bin divided by bin width), approximates the PDF; that is how densities are estimated from data in Ch. 20.

Useful single-number descriptions read off a PDF or PMF are the **mode** (the location of the maximum — the "most likely" value), the **median** m (with $P(X \leq m) = 1/2$, Section 19.8), and the **mean** (the balance point, Section 19.9). For a symmetric unimodal density like the Gaussian, all three coincide; for a skewed one like the exponential they differ (mode 0, median $\ln 2/\lambda$, mean $1/\lambda$).

Worked Example 19.28 — Normalizing a density

The normalized position X of a laser spot on a detector has PDF $f_X(x) = c\,x(1 - x)$ for $0 < x < 1$ and 0 otherwise. Find c, $P(X > 0.5)$ and $P(0.25 < X < 0.75)$.

Step 1 — normalize. $\int_0^1 x(1-x)\,dx = \frac{1}{2} - \frac{1}{3} = \frac{1}{6}$, so $c = 6$.

Step 2 — by symmetry about $x = \frac{1}{2}$, $P(X > 0.5) = 0.5$.

Step 3 — integrate. With antiderivative $G(x) = 3x^2 - 2x^3$,

$$P(0.25 < X < 0.75) = G(0.75) - G(0.25) = (1.6875 - 0.84375) - (0.1875 - 0.03125) = 0.84375 - 0.15625 = 0.6875.$$

The maximum value of the density is $f_X(0.5) = 1.5$ — larger than 1, which is perfectly legitimate.

Discrete and mixed variables as densities: Dirac impulses

Using the Dirac delta $\delta(x)$ (Ch. 16), a discrete random variable can be given a *generalized* density

$$f_X(x) = \sum_k p_X(x_k)\,\delta(x - x_k),$$

because $\int_a^b f_X(x)\,dx$ then picks up exactly the masses $p_X(x_k)$ with $a < x_k \leq b$. A mixed random variable has a density that is the sum of an ordinary part and impulses. The limiter output of Example 19.21, for instance, has

$$f_Y(y) = 0.25\,\delta(y + 1) + 0.25\,\delta(y - 1) + 0.25\ \mathrm{rect}(y/2),$$

where $\mathrm{rect}(y/2) = 1$ for $|y| < 1$. This unified notation lets every formula of this chapter — expectations, transformations, convolutions — be written once for all three types. The CDF (Section 19.8) achieves the same unification without generalized functions.

Conditional densities given an event

If B is an event with $P(B) > 0$, the **conditional PDF** of X given B is the derivative of the conditional CDF $P(X \leq x \mid B)$. When $B = \{X \in D\}$ is itself defined by X, the result is the original density restricted to D and renormalized:

$$f_{X|B}(x) = \begin{cases} \dfrac{f_X(x)}{P(X \in D)}, & x \in D \\ 0, & x \notin D. \end{cases}$$

For an exponential lifetime and $B = \{T > s\}$ this gives $f_{T|B}(t) = \lambda e^{-\lambda(t-s)}$ for $t > s$: the same exponential shape shifted to start at s — memorylessness again.

Bayes' theorem with densities

When the observation is continuous, the event $\{X = x\}$ has probability zero and Section 19.3's formula cannot be applied literally. Conditioning on the small interval $\{x < X \le x + \Delta x\}$ and letting $\Delta x \to 0$, the factors Δx cancel, leaving

$$P(H_i \mid X = x) = \frac{f_{X|H_i}(x)\,P(H_i)}{\sum_j f_{X|H_j}(x)\,P(H_j)},$$

i.e. Bayes' theorem with *conditional densities* playing the role of likelihoods. The MAP rule compares $f_{X|H_i}(x)P(H_i)$.

Worked Example 19.29 — MAP threshold for a binary signal in Gaussian noise

A receiver observes $X = s + N$, where $s = -A$ (symbol 0) with probability p_0 or $s = +A$ (symbol 1) with probability p_1, and $N \sim \mathcal{N}(0, \sigma^2)$ is independent noise. Find the MAP decision threshold, and evaluate it and the error probability for $A = 1$ V, $\sigma = 0.5$ V, $p_0 = 0.75$, $p_1 = 0.25$.

Step 1 — likelihoods. Given symbol 1, $X \sim \mathcal{N}(A, \sigma^2)$; given symbol 0, $X \sim \mathcal{N}(-A, \sigma^2)$.

Step 2 — likelihood-ratio test. Decide 1 when $p_1 f_{X|1}(x) > p_0 f_{X|0}(x)$:

$$\frac{f_{X|1}(x)}{f_{X|0}(x)} = \exp\!\left(\frac{(x+A)^2 - (x-A)^2}{2\sigma^2}\right) = \exp\!\left(\frac{2Ax}{\sigma^2}\right) > \frac{p_0}{p_1}.$$

Taking logarithms: decide 1 when $x > x_{\text{th}}$, with

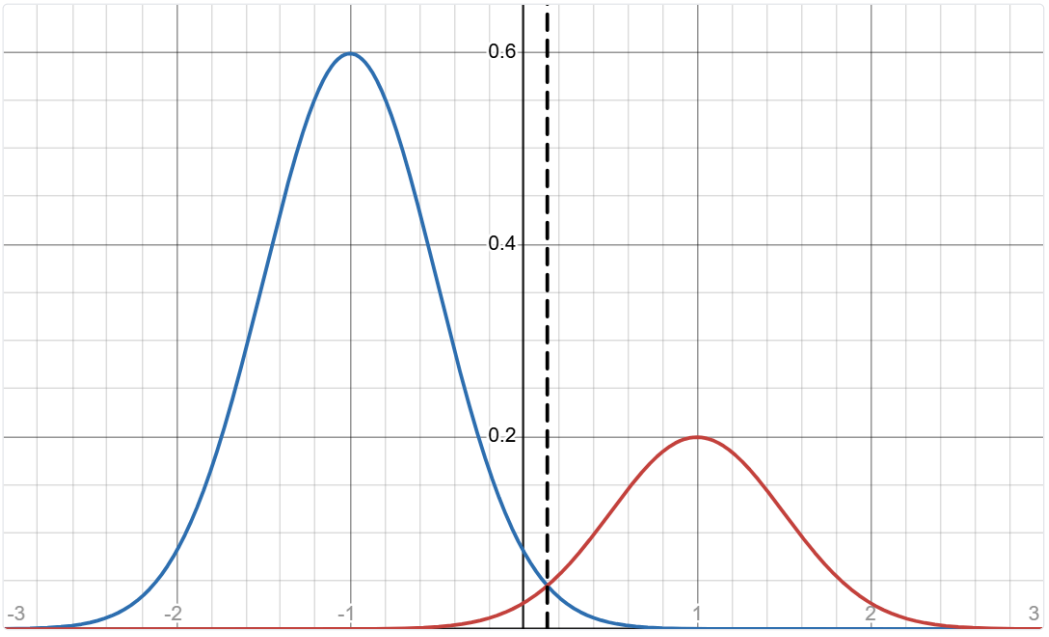
$$x_{\text{th}} = \frac{\sigma^2}{2A}\ln\frac{p_0}{p_1}.$$

Step 3 — numbers. $x_{\text{th}} = \dfrac{0.25}{2}\ln 3 = 0.1373$ V. The threshold moves *towards the less likely symbol*, so that more ambiguous observations are attributed to the more likely one.

Step 4 — error probability. An error occurs if symbol 0 is sent and $X > x_{\text{th}}$, or symbol 1 is sent and $X < x_{\text{th}}$:

$$P_e = p_0\,Q\!\left(\frac{x_{\text{th}} + A}{\sigma}\right) + p_1\,Q\!\left(\frac{A - x_{\text{th}}}{\sigma}\right) = 0.75\,Q(2.275) + 0.25\,Q(1.725) = 0.01916.$$

With the "natural" threshold 0 (the ML rule), $P_e = Q(A/\sigma) = Q(2) = 0.02275$. The MAP threshold reduces the error probability by about 16 %. With equal priors, $\ln(p_0/p_1) = 0$ and the two rules coincide.



Prior-weighted likelihoods $p_0 f_{X|0}(x)$ (blue) and $p_1 f_{X|1}(x)$ (red) for Example 19.29. The MAP threshold (dashed) is where the two curves cross, at $x = 0.137$ V rather than midway at 0; the error probability is the area under the lower curve on each side of the threshold.

Functions of a random variable: the density transformation

We now find the PDF of $Y = g(X)$ when X is continuous. Start with the simplest case.

Transformation by a monotone function

Let X have PDF f_X and let g be differentiable and strictly monotone (increasing or decreasing) on the range of X, with inverse $x = g^{-1}(y)$. Then $Y = g(X)$ has PDF

$$f_Y(y) = f_X\big(g^{-1}(y)\big)\left|\frac{dx}{dy}\right| = \left.\frac{f_X(x)}{|g'(x)|}\right|_{x=g^{-1}(y)}.$$

Derivation. For increasing g, $\{Y \le y\} = \{X \le g^{-1}(y)\}$, so $F_Y(y) = F_X(g^{-1}(y))$; differentiate by the chain rule to get $f_X(g^{-1}(y))\,\frac{d}{dy}g^{-1}(y)$. For decreasing g, $\{Y \le y\} = \{X \ge g^{-1}(y)\}$, so $F_Y(y) = 1 - F_X(g^{-1}(y))$, whose derivative carries a minus sign that the absolute value absorbs. Physically: probability is conserved, $f_Y(y)|dy| = f_X(x)|dx|$ — a steep part of g stretches a small dx into a large dy and thins the density. □

Transformation by a general function

If the equation $y = g(x)$ has finitely many real roots $x_1(y), \dots, x_m(y)$, at each of which $g'(x_i) \neq 0$, then

$$f_Y(y) = \sum_{i=1}^{m} \frac{f_X(x_i)}{|g'(x_i)|},$$

and $f_Y(y) = 0$ if there are no roots. Intervals on which g is constant produce point masses (impulses) in f_Y, as in the limiter.

Reason. The event $\{y < Y \le y + dy\}$ is the union of disjoint small intervals of x, one around each root, of widths $dy/|g'(x_i)|$; add their probabilities.

Worked Example 19.30 — Linear transformation of a Gaussian

A sensor output $X \sim \mathcal{N}(\mu, \sigma^2)$ is amplified and offset: $Y = aX + b$ with $a \neq 0$. Find the distribution of Y, and the density at the output of a gain-10, offset $+0.5$ V stage when $X \sim \mathcal{N}(0.1,\ 0.02^2)$ V.

Step 1 — inverse. $x = (y - b)/a$, $|dx/dy| = 1/|a|$.

Step 2 — substitute.

$$f_Y(y) = \frac{1}{|a|}\cdot\frac{1}{\sqrt{2\pi}\sigma}\exp\left(-\frac{\left(\frac{y-b}{a} - \mu\right)^2}{2\sigma^2}\right) = \frac{1}{\sqrt{2\pi}\,|a|\sigma}\exp\left(-\frac{(y - a\mu - b)^2}{2a^2\sigma^2}\right).$$

So $Y \sim \mathcal{N}(a\mu + b,\ a^2\sigma^2)$: **a linear function of a Gaussian is Gaussian.**

Step 3 — numbers. $Y \sim \mathcal{N}(10(0.1) + 0.5,\ (10 \times 0.02)^2) = \mathcal{N}(1.5,\ 0.2^2)$ V. In particular $Z = (X - \mu)/\sigma$ is $\mathcal{N}(0, 1)$ — **standardization**, which reduces every Gaussian probability to the standard tables.

Worked Example 19.31 — Square-law detector

Gaussian noise $X \sim \mathcal{N}(0, \sigma^2)$ drives a square-law detector, $Y = X^2$. Find f_Y and the probability that the detector output exceeds $4\sigma^2$.

Step 1 — roots. For $y > 0$, $x^2 = y$ has roots $x_{1,2} = \pm\sqrt{y}$, with $|g'(x)| = 2|x| = 2\sqrt{y}$. For $y < 0$ there are no roots.

Step 2 — add contributions.

$$f_Y(y) = \frac{f_X(\sqrt{y}) + f_X(-\sqrt{y})}{2\sqrt{y}} = \frac{1}{\sqrt{2\pi y}\,\sigma}\,e^{-y/(2\sigma^2)}, \qquad y > 0.$$

This is the **chi-square distribution with one degree of freedom** (scaled by σ^2). It is infinite at $y = 0$ — yet integrable, since $y^{-1/2}$ has a finite integral near 0.

Step 3 — tail probability. Easier through X than through f_Y: $P(Y > 4\sigma^2) = P(|X| > 2\sigma) = 2Q(2) = 0.0455$.

Worked Example 19.32 — A sinusoid with random phase

An oscillator's output sampled at a random instant is $Y = A\cos\Theta$, with $\Theta \sim \mathcal{U}(0, 2\pi)$. Find the PDF of Y and the fraction of time the sinusoid spends within half its amplitude of zero.

Step 1 — roots. For $|y| < A$, $A\cos\theta = y$ has two roots in $(0, 2\pi)$, $\theta_1 = \arccos(y/A)$ and $\theta_2 = 2\pi - \theta_1$. At each, $|g'(\theta)| = A|\sin\theta| = \sqrt{A^2 - y^2}$.

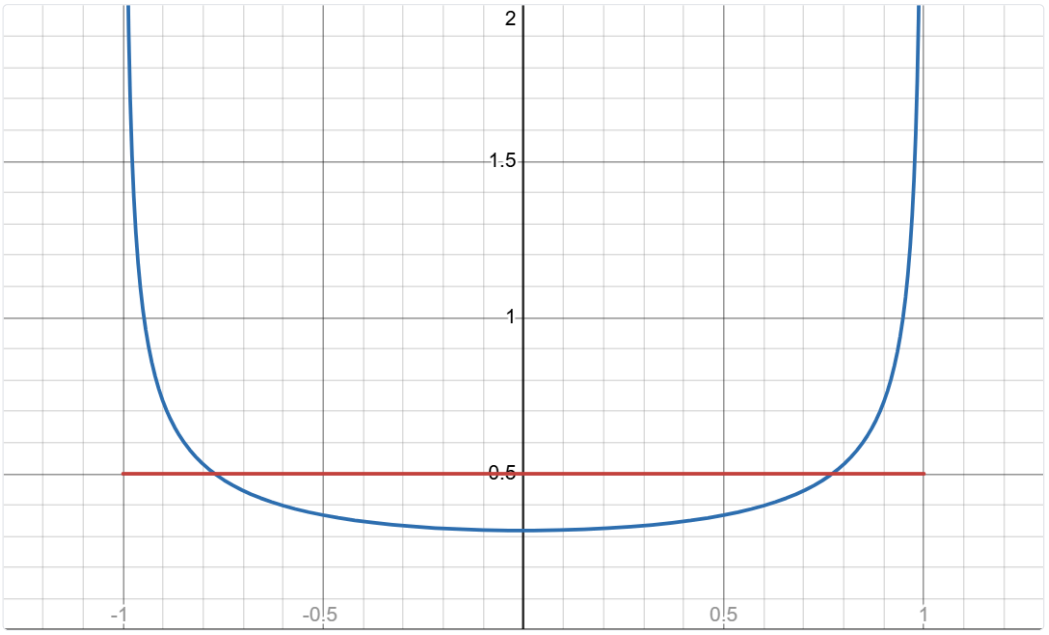
Step 2 — transform. $f_\Theta = 1/(2\pi)$ on $(0, 2\pi)$, so

$$f_Y(y) = 2\cdot\frac{1/(2\pi)}{\sqrt{A^2 - y^2}} = \frac{1}{\pi\sqrt{A^2 - y^2}}, \qquad |y| < A.$$

This is the **arcsine** density. It is smallest at $y = 0$ and infinite (but integrable) at $y = \pm A$: a sinusoid moves fastest through zero and lingers near its peaks.

Step 3 — probability. $P(|Y| < A/2) = \int_{-A/2}^{A/2} \frac{dy}{\pi\sqrt{A^2 - y^2}} = \frac{2}{\pi}\arcsin\frac{1}{2} = \frac{1}{3}$.

Only a third of the time is spent in the middle half of the range. This is why a histogram of ADC codes for a full-scale sine input (the "code density test") is bathtub-shaped, and why departures from the arcsine shape reveal the converter's non-linearity.



Arcsine density of $\cos\Theta$ with uniform phase (blue), compared with the uniform density on $(-1,1)$ (red). The sinusoid spends most of its time near its extremes; a triangle wave of the same amplitude would give the flat red density.

Common Pitfall — forgetting the Jacobian

The most common error in transforming densities is to substitute $x = g^{-1}(y)$ into f_X and stop, omitting the factor $|dx/dy|$. The result is not even normalized. A quick check: integrate your f_Y — it must give 1. A second check: the units of f_Y must be the reciprocal of the units of Y.

Engineering Note — memoryless nonlinearities

The transformation rule is the probabilistic counterpart of a transfer characteristic. Diodes, square-law and envelope detectors, logarithmic amplifiers, companders, limiters and quantizers all map an input distribution into an output distribution by exactly this rule. Designers use it in reverse, too: a compander is chosen so that the output of a speech signal with a peaked (Laplacian-like) amplitude distribution is spread more evenly across the quantizer levels.

19.8 Cumulative distributions

Motivation

The PMF works only for discrete variables and the PDF only for continuous ones (unless we admit impulses). The **cumulative distribution function** works for every random variable, discrete, continuous or mixed, without any generalized functions. It is also the function that answers the questions engineers most often ask — "what fraction of resistors are below 990 Ω?", "what is the probability that the component has failed by time t?", "what threshold is exceeded only 0.1 % of the time?" — and it is the natural tool for deriving distributions of functions of random variables, extremes of several variables, and for generating random numbers in simulation.

Definition and properties

Cumulative distribution function (CDF)

The **CDF** of a random variable X is

$$F_X(x) = P(X \le x), \qquad -\infty < x < \infty.$$

Properties of the CDF

Every CDF satisfies:

1. $0 \le F_X(x) \le 1$;
2. F_X is **non-decreasing**: $a < b \Rightarrow F_X(a) \le F_X(b)$;
3. $\lim_{x\to-\infty} F_X(x) = 0$ and $\lim_{x\to+\infty} F_X(x) = 1$;
4. F_X is **right-continuous**: $\lim_{h\downarrow 0} F_X(x+h) = F_X(x)$;
5. $P(a < X \le b) = F_X(b) - F_X(a)$;
6. $P(X = a) = F_X(a) - F_X(a^-)$, the size of the jump at a, where $F_X(a^-) = \lim_{h\downarrow 0} F_X(a-h)$.

Conversely, any function with properties 2–4 is the CDF of some random variable.

Proof sketch. (2) $\{X \le a\} \subseteq \{X \le b\}$, then monotonicity of P. (5) $\{X \le b\}$ is the disjoint union of $\{X \le a\}$ and $\{a < X \le b\}$. (3) and (4) follow from continuity of probability (Section 19.1): the events $\{X \le -n\}$ decrease to $\varnothing$, the events $\{X \le n\}$ increase to Ω, and $\{X \le x + 1/n\}$ decrease to $\{X \le x\}$. (6) The events $\{a - 1/n < X \le a\}$ decrease to $\{X = a\}$, and their probabilities are $F_X(a) - F_X(a - 1/n)$. $\square$

Property 6 is the key to reading a CDF. Wherever F_X is continuous, $P(X = x) = 0$; wherever it jumps, the jump is a point mass. Hence:

Type of RV	Shape of the CDF	Link to PMF/PDF
Discrete	staircase, flat between jumps	$F_X(x) = \sum_{x_k \le x} p_X(x_k)$; jumps $= p_X(x_k)$
Continuous	continuous (no jumps)	$F_X(x) = \int_{-\infty}^{x} f_X(u)\,du$, $f_X(x) = F_X'(x)$
Mixed	ramps plus jumps	jumps = point masses; slope = continuous density

For a continuous RV the relation $f_X = F_X'$ holds wherever F_X is differentiable; for a discrete or mixed RV it holds in the generalized sense, the derivative of a jump of height p being $p\,\delta(x - x_k)$.

Common Pitfall — $<$ versus $\le$

With the convention $F_X(x) = P(X \le x)$, the probability of an interval depends on whether its endpoints are included when X has point masses there: $P(a \le X \le b) = F_X(b) - F_X(a^-)$, $P(a < X < b) = F_X(b^-) - F_X(a)$. For a discrete count, $P(X < 3) = F_X(2)$, not $F_X(3)$. For continuous variables the distinction disappears.

Worked Example 19.33 — Staircase CDF of an error count

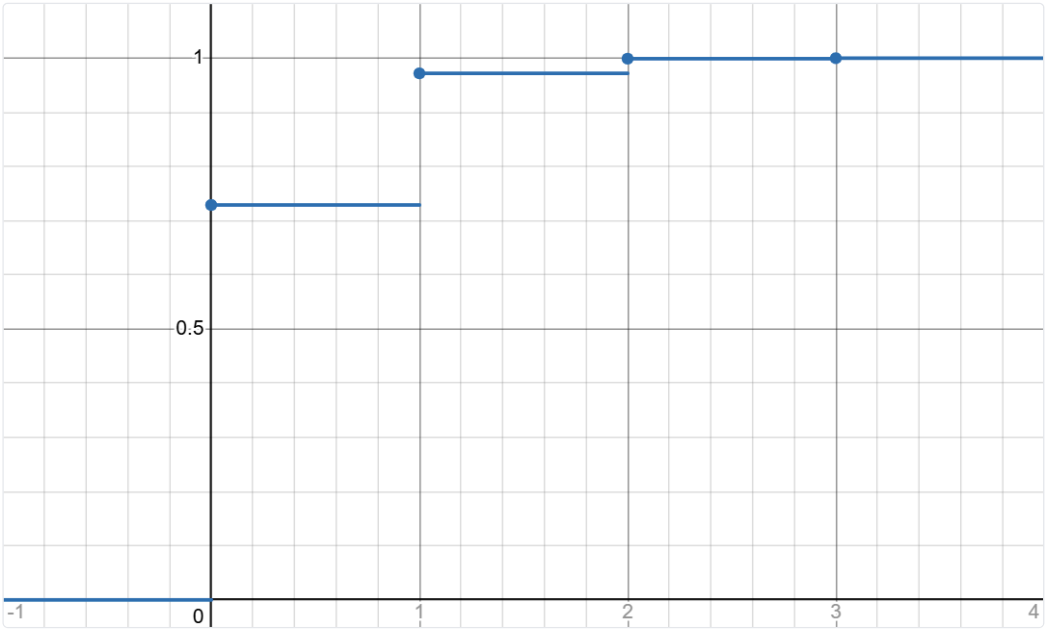
For the number of errors $X \sim \text{Bin}(3, 0.1)$ of Example 19.19, write $F_X(x)$, and use it to find $P(1 \le X \le 2)$ and $P(X > 1)$.

Step 1 — accumulate the PMF $(0.729, 0.243, 0.027, 0.001)$:

$$F_X(x) = \begin{cases} 0, & x < 0 \\ 0.729, & 0 \le x < 1 \\ 0.972, & 1 \le x < 2 \\ 0.999, & 2 \le x < 3 \\ 1, & x \ge 3. \end{cases}$$

Step 2 — interval with point masses. $P(1 \le X \le 2) = F_X(2) - F_X(1^-) = 0.999 - 0.729 = 0.270$. Check: $0.243 + 0.027 = 0.270$. ✓

Step 3 — tail. $P(X > 1) = 1 - F_X(1) = 1 - 0.972 = 0.028$.



Staircase CDF of $\text{Bin}(3, 0.1)$. *Each jump equals the PMF value at that point; the filled dots mark the right-continuity convention — the CDF takes the upper value at each jump.*

The Gaussian CDF and the Q-function

The Gaussian CDF has no closed form; it is tabulated, or computed from the **error function** $\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$, available in every numerical library:

$$\Phi(z) = \int_{-\infty}^{z} \frac{1}{\sqrt{2\pi}} e^{-u^2/2}\,du = \frac{1}{2}\left[1 + \text{erf}\left(\frac{z}{\sqrt{2}}\right)\right], \qquad Q(z) = 1 - \Phi(z) = \frac{1}{2}\,\text{erfc}\left(\frac{z}{\sqrt{2}}\right).$$

By symmetry $\Phi(-z) = 1 - \Phi(z)$ and $Q(-z) = 1 - Q(z)$. For $X \sim \mathcal{N}(\mu, \sigma^2)$, standardization (Example 19.30) gives

$$F_X(x) = \Phi\left(\frac{x - \mu}{\sigma}\right), \qquad P(X > x) = Q\left(\frac{x - \mu}{\sigma}\right).$$

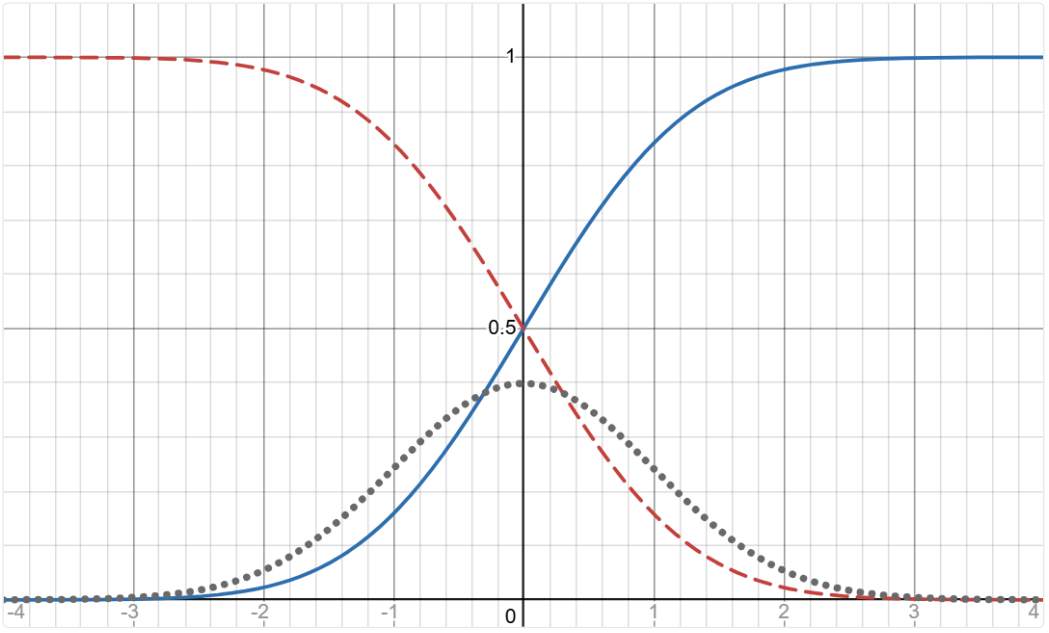
Communications engineers use Q because error probabilities are tail probabilities; statisticians tabulate Φ. A short table covers most needs:

z	$\Phi(z)$	$Q(z)$
0	0.5000	0.5000
1	0.8413	0.1587
1.645	0.9500	0.0500
1.960	0.9750	0.0250
2	0.9772	0.02275
2.326	0.9900	0.0100
2.576	0.9950	0.0050
3	0.99865	1.350×10^{-3}
4	—	3.167×10^{-5}
5	—	2.867×10^{-7}
6	—	9.866×10^{-10}

The probabilities of falling within 1, 2, 3 standard deviations of the mean are 0.6827, 0.9545 and 0.9973 — the "68–95–99.7 rule". For large z the bound

$$\frac{z}{1+z^2}\,\frac{e^{-z^2/2}}{\sqrt{2\pi}} < Q(z) < \frac{1}{z}\,\frac{e^{-z^2/2}}{\sqrt{2\pi}} \qquad (z>0)$$

shows that Q falls off essentially like $e^{-z^2/2}$; the simpler Chernoff bound $Q(z) \le \tfrac12 e^{-z^2/2}$ is often enough for design estimates.



Standard Gaussian CDF $\Phi(z)$ (blue), Q-function $1-\Phi(z)$ (red, dashed) and the PDF $\varphi(z)$ (grey, dotted). The CDF's slope is the PDF: steepest at $z=0$, where the density is largest.

Worked Example 19.34 — Resistor tolerance

A batch of nominal 1 kΩ resistors has values $R \sim \mathcal{N}(1000,\ 10^2)$ Ω. (a) What fraction lies between 990 and 1020 Ω? (b) What fraction lies outside a $\pm 2\,\%$ tolerance band? (c) What symmetric band contains 99.9 % of the batch?

(a) Standardize: $z_1 = (990-1000)/10 = -1$, $z_2 = (1020-1000)/10 = 2$.

$$P(990<R<1020) = \Phi(2) - \Phi(-1) = 0.97725 - 0.15866 = 0.8186.$$

(b) $\pm 2\,\%$ is $\pm 20\ \Omega = \pm 2\sigma$: $P(|R-1000|>20) = 2Q(2) = 0.0455$, i.e. 4.55 % of parts fail a 2 % specification.

(c) We need $2Q(z) = 0.001$, $Q(z) = 0.0005$, $z = 3.291$: the band is $1000 \pm 32.9\ \Omega$, i.e. about $\pm 3.3\,\%$.

Quantiles

Quantile, median, percentile

For $0<u<1$, the **u-quantile** of X is

$$x_u = F_X^{-1}(u) = \inf\{x : F_X(x) \ge u\},$$

the smallest x at which the CDF reaches u. The **median** is $x_{0.5}$; the **quartiles** are $x_{0.25}, x_{0.75}$; the $100u$-th **percentile** is x_u.

For a continuous, strictly increasing CDF, F_X^{-1} is the ordinary inverse. The "inf" in the definition handles flat parts and jumps. Quantiles are how specifications are written: "the 99th-percentile latency is 4 ms", "the B_{10} life of a bearing (10 % failed)", "the 1 % outage fade depth". For the exponential distribution, solving $1 - e^{-\lambda t} = u$ gives $t_u = -\ln(1-u)/\lambda$; the median life is $\ln 2/\lambda$, about 69 % of the mean life $1/\lambda$.

Reliability function and hazard rate

For a lifetime $T \geq 0$, the complement of the CDF is the **reliability** (or **survival**) function, and its relative rate of decrease is the **hazard rate**:

$$R(t) = P(T > t) = 1 - F_T(t), \qquad h(t) = \frac{f_T(t)}{R(t)} = -\frac{d}{dt}\ln R(t).$$

The hazard rate is the conditional failure density of a unit that has survived to t: $P(t < T \leq t + dt \mid T > t) \approx h(t)\,dt$. Integrating, $R(t) = \exp\!\left(-\int_0^t h(u)\,du\right)$. A constant hazard $h(t) = \lambda$ gives the exponential distribution — the mathematical statement of memorylessness. An increasing hazard means wear-out (electrolytic capacitors, fans, electromigration); a decreasing hazard means infant mortality (latent manufacturing defects, removed by burn-in). The sequence decreasing–constant–increasing over a product's life is the well-known **bathtub curve**; the Weibull family that models each phase is covered in Ch. 20.

The CDF method for functions of random variables

The most reliable way to find the distribution of $Y = g(X)$ — always valid, including for non-monotone g, flat regions, and mixed outputs — is to compute its CDF directly from the definition:

$$F_Y(y) = P(g(X) \leq y) = P\big(X \in \{x : g(x) \leq y\}\big),$$

and then differentiate if a density is wanted. The density-transformation formulas of Section 19.7 are shortcuts derived this way.

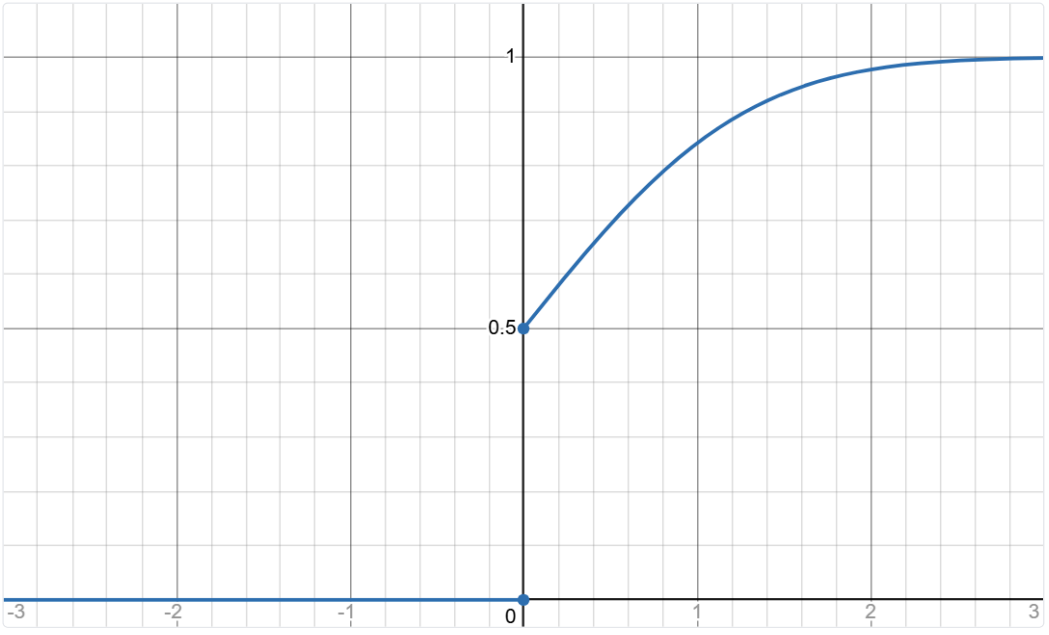
Worked Example 19.35 — Half-wave rectified noise (a mixed CDF)

Noise $X \sim \mathcal{N}(0,1)$ V passes through an ideal half-wave rectifier, $Y = \max(X, 0)$. Find F_Y and describe the distribution.

Step 1 — $y < 0$. $Y \geq 0$ always, so $F_Y(y) = 0$.

Step 2 — $y \geq 0$. $\{Y \leq y\} = \{X \leq y\}$ (if $X \leq 0$ then $Y = 0 \leq y$; if $X > 0$ then $Y = X$). So $F_Y(y) = \Phi(y)$.

Step 3 — interpret. F_Y jumps from 0 to $\Phi(0) = \tfrac{1}{2}$ at $y = 0$: a point mass $P(Y = 0) = \tfrac{1}{2}$ (all negative inputs map to 0). For $y > 0$ the CDF follows Φ, with density $\varphi(y)$. In generalized-density form, $f_Y(y) = \tfrac{1}{2}\delta(y) + \varphi(y)u(y)$.



CDF of half-wave rectified Gaussian noise: zero for $y < 0$, a jump of $1/2$ at $y = 0$ (the point mass of all clipped negative inputs), then the Gaussian CDF. A mixed random variable needs no impulses in this description.

Extremes: the minimum and the maximum

The CDF method is particularly efficient for the largest and smallest of several independent random variables, which appear as the lifetimes of parallel and series systems and as peak values of noise.

Distribution of the maximum and minimum

Let $X_1, \ldots, X_n$ be independent with CDFs $F_1, \ldots, F_n$. Then

$$F_{\max}(x) = P(\max_i X_i \leq x) = \prod_{i=1}^{n} F_i(x), \qquad P(\min_i X_i > x) = \prod_{i=1}^{n} \big(1 - F_i(x)\big).$$

Proof. The maximum is at most x exactly when every $X_i \le x$; the minimum exceeds x exactly when every $X_i > x$. Independence turns the intersections into products. □

For lifetimes these are the reliability formulas of Section 19.4 in CDF language: a series system fails at the *first* component failure, $T_{\text{sys}} = \min_i T_i$, so $R_{\text{sys}}(t) = \prod R_i(t)$; a parallel system fails at the *last*, $T_{\text{sys}} = \max_i T_i$, so $F_{\text{sys}}(t) = \prod F_i(t)$. With exponential components, $\min_i T_i \sim \text{Exp}(\lambda_1 + \cdots + \lambda_n)$.

Worked Example 19.36 — Peaks of noise

A comparator sees 1000 independent samples of Gaussian noise $X_i \sim \mathcal{N}(0, \sigma^2)$ per frame. Its threshold is set at 3σ, "because noise exceeds 3σ only 0.13 % of the time". Find the probability of at least one false trigger per frame, and the threshold needed to make it 1 %.

Step 1 — maximum. $P(\max_i X_i \le 3\sigma) = \Phi(3)^{1000} = 0.998650^{1000} = 0.2590$.

Step 2 — false trigger. $P(\text{at least one}) = 1 - 0.2590 = 0.741$. Almost three frames in four trigger falsely!

Step 3 — redesign. We need $\Phi(z)^{1000} = 0.99$, i.e. $\Phi(z) = 0.99^{1/1000} = 0.99998995$, so $Q(z) = 1.005 \times 10^{-5}$ and $z \approx 4.26$. The threshold must be about 4.3σ.

When many independent chances are taken, a rare event per trial becomes a likely event per frame (compare the union bound $1000 \times 0.00135 = 1.35$, which is useless here because it exceeds 1). This is the "look-elsewhere" effect that governs radar CFAR thresholds and test-limit settings on automatic test equipment.

Generating random variables: the inverse-transform method

The quantile function also runs the other way. If $U \sim \mathcal{U}(0,1)$ and F is any CDF, then

$$X = F^{-1}(U) \quad \text{has CDF } F,$$

because $P(F^{-1}(U) \le x) = P(U \le F(x)) = F(x)$. Conversely, if X is continuous then $F_X(X) \sim \mathcal{U}(0,1)$ (the **probability integral transform**). This is how simulations turn a uniform random-number generator into samples from any distribution: for $\text{Exp}(\lambda)$, $X = -\ln(1-U)/\lambda$; for Rayleigh(σ), $X = \sigma\sqrt{-2\ln(1-U)}$; for a discrete distribution, choose the smallest x_k with $F(x_k) \ge U$. Monte Carlo methods built on this idea are developed in Ch. 24.

Worked Example 19.37 — Simulating component lifetimes

A reliability simulation needs lifetimes with $\text{Exp}(\lambda)$, $\lambda = 2 \times 10^{-5}\ \text{h}^{-1}$. The uniform generator returns $u = 0.5$ and $u = 0.95$. What lifetimes are produced, and what do they mean?

Step 1 — formula. $t = -\ln(1-u)/\lambda$.

Step 2 — numbers. $u = 0.5$: $t = \ln 2/(2\times10^{-5}) = 34\,657$ h, the median life. $u = 0.95$: $t = -\ln(0.05)/(2\times10^{-5}) = 149\,787$ h, the 95th-percentile life.

Step 3 — check. $F(34\,657) = 1 - e^{-0.6931} = 0.5$. ✓ Each uniform sample is mapped to the lifetime with that cumulative probability.

Engineering Note — read specifications as CDF points

Nearly every probabilistic specification is a point on a CDF or its complement: a bit-error rate is $P(\text{error})$, an outage probability is $F_{\text{SNR}}(\text{threshold})$, a "six-sigma" process puts the specification limit where $Q(z)$ is tiny, an MTTF is a mean but a warranty period is a quantile. Plotting the empirical CDF of measured data (Ch. 20) is the quickest way to compare a batch against such a specification.

19.9 Expectation and variance

Motivation

A full distribution is often more information than a design needs. An engineer wants to know the DC level of a noisy signal, its RMS fluctuation, the average number of retransmissions, the mean time to failure, the noise power at the output of an ADC. These are all **expectations** — probability-weighted averages — of the random variable or of a function of it. The mean locates the distribution, the variance measures its spread, higher moments describe its shape, and the moment-generating and characteristic functions package all the moments into a single transform that turns the convolution of densities into multiplication. This section develops these tools and the inequalities that make them useful even when the distribution itself is unknown.

Expected value

Expectation (mean)

The **expected value** (mean) of X is

$$E[X] = \mu_X = \begin{cases} \displaystyle\sum_k x_k\, p_X(x_k), & X \text{ discrete}, \\[2mm] \displaystyle\int_{-\infty}^{\infty} x\, f_X(x)\, dx, & X \text{ continuous}, \end{cases}$$

provided the sum or integral converges absolutely ($\sum |x_k| p_X(x_k) < \infty$ or $\int |x| f_X\, dx < \infty$). Otherwise the mean does not exist.

The mean is the **centre of mass** of the probability distribution: if unit mass is distributed along the x-axis according to f_X, $E[X]$ is the balance point. Its link with experiment is the **law of large numbers**: the average $\frac{1}{N}\sum_{i=1}^{N} X_i$ of N independent repetitions converges to $E[X]$ as $N \to \infty$ (Ch. 20). Using the generalized density of Section 19.7, the two formulas are one: $E[X] = \int x f_X(x)\,dx$ with impulses turning the integral into a sum.

Common Pitfall — the mean need not exist

The **Cauchy** density $f_X(x) = \dfrac{1}{\pi(1+x^2)}$ — the distribution of $\tan\Theta$ for uniform Θ, and of the ratio of two independent zero-mean Gaussians — is symmetric about 0, yet $\int |x| f_X\,dx = \infty$, so $E[X]$ does not exist. Averages of Cauchy samples do not settle down as N grows: the average of N independent Cauchy variables is again standard Cauchy. Heavy-tailed quantities (ratios of noisy measurements, impulsive interference) can defeat averaging; always check that the mean exists before relying on it.

Expectation of a function of a random variable

To find $E[g(X)]$ we could first find the distribution of $Y = g(X)$ (Sections 19.7–19.8) and then its mean. Fortunately that is unnecessary.

Expectation of a function (law of the unconscious statistician)

$$E[g(X)] = \sum_{k} g(x_k)\,p_X(x_k) \qquad \text{or} \qquad E[g(X)] = \int_{-\infty}^{\infty} g(x)\,f_X(x)\,dx.$$

For two random variables, $E[g(X,Y)] = \iint g(x,y) f_{XY}(x,y)\,dx\,dy$ (or the double sum).

Proof (discrete case). $E[Y] = \sum_y y\,P(Y=y) = \sum_y y \sum_{x:g(x)=y} p_X(x) = \sum_x g(x) p_X(x)$, by regrouping the terms of an absolutely convergent sum. The continuous case follows by approximating with discrete variables, or directly from the transformation formula for monotone g. □

In Example 19.20, $E[Y] = E[X^2] = 4(0.1) + 1(0.2) + 0 + 1(0.2) + 4(0.1) = 1.2$, the same as from the PMF of Y: $0(0.4) + 1(0.4) + 4(0.2) = 1.2$. ✓

Linearity

Linearity of expectation

For any random variables X, Y (on the same space, with finite means) and constants a, b, c:

$$E[aX + bY + c] = a\,E[X] + b\,E[Y] + c.$$

By induction, $E\left[\sum_i X_i\right] = \sum_i E[X_i]$. **No independence is required.**

Proof. By the two-variable form of the previous theorem, $E[aX+bY] = \iint (ax+by) f_{XY}\,dx\,dy = a\int x f_X\,dx + b\int y f_Y\,dy$, using the marginal formulas of Section 19.6. □

Linearity combined with indicator variables is one of the most effective tricks in applied probability. Since $E[I_A] = 1\cdot P(A) + 0\cdot P(A^c) = P(A)$, the expected number of events that occur among $A_1, \dots, A_n$ is

$$E\left[\sum_i I_{A_i}\right] = \sum_i P(A_i),$$

however the events depend on each other.

Worked Example 19.38 — Means by indicators

(a) Find the mean of $X \sim \text{Bin}(n,p)$. (b) In Example 19.5, find the expected number of *pairs* of nodes that share an address, for $n = 300$ nodes and $M = 65\,536$ addresses.

(a) Write $X = I_1 + \cdots + I_n$, I_i the indicator of success on trial i. Then $E[X] = \sum_i P(\text{success on } i) = np$. (The direct route, $\sum_k k\binom{n}{k}p^k q^{n-k}$, needs an index shift and the binomial theorem — and gives the same answer.)

(b) For each of the $\binom{300}{2} = 44\,850$ pairs, let I_{ij} indicate that nodes i and j collide; $P(I_{ij}=1) = 1/M$. The indicators are dependent, but linearity does not care:

$$E[\text{number of colliding pairs}] = \binom{300}{2}\frac{1}{65\,536} = 0.684.$$

Compare: $P(\text{at least one collision}) = 0.496$. Since $P(N \ge 1) \le E[N]$ for any count N (Markov's inequality below), the expected number of collisions is a quick upper bound on the collision probability, and an accurate one when collisions are rare.

Mean of a non-negative variable and mean time to failure

For a non-negative random variable there is a useful alternative formula in terms of the tail of the distribution.

Tail formula

If $T \geq 0$, then

$$E[T] = \int_0^\infty P(T > t)\,dt = \int_0^\infty \big(1 - F_T(t)\big)\,dt.$$

For a non-negative integer-valued N, $E[N] = \sum_{k=0}^{\infty} P(N > k)$.

Proof. Write $T = \int_0^\infty I_{\{T>t\}}\,dt$ (the integrand is 1 for $t < T$ and 0 afterwards) and take expectations inside the integral: $E[T] = \int_0^\infty P(T > t)\,dt$. □

In reliability this is the **mean time to failure** $\mathrm{MTTF} = \int_0^\infty R(t)\,dt$ — the area under the reliability curve.

Worked Example 19.39 — MTTF of redundant configurations

Components have exponential lifetimes with $\lambda = 2 \times 10^{-5}\ \mathrm{h}^{-1}$. Find the MTTF of a single unit, two units in active parallel, TMR (2-out-of-3), and a unit with a perfectly switched cold spare.

Step 1 — single unit. $\int_0^\infty e^{-\lambda t}dt = 1/\lambda = 50\,000$ h.

Step 2 — active parallel. $\int_0^\infty (2e^{-\lambda t} - e^{-2\lambda t})\,dt = \frac{2}{\lambda} - \frac{1}{2\lambda} = \frac{3}{2\lambda} = 75\,000$ h.

Step 3 — TMR. $\int_0^\infty (3e^{-2\lambda t} - 2e^{-3\lambda t})\,dt = \frac{3}{2\lambda} - \frac{2}{3\lambda} = \frac{5}{6\lambda} = 41\,667$ h.

Step 4 — cold standby. $\int_0^\infty (1+\lambda t)e^{-\lambda t}\,dt = \frac{1}{\lambda} + \frac{1}{\lambda} = \frac{2}{\lambda} = 100\,000$ h. (Directly: $E[T_1 + T_2] = E[T_1] + E[T_2]$ by linearity.)

TMR has a *shorter* mean life than a single unit, although it is more reliable for $\lambda t < \ln 2$ (graph in Section 19.4). The MTTF is a poor figure of merit for systems intended for short missions; quote $R(t_{\text{mission}})$ instead.

Variance and standard deviation

Variance, standard deviation

The **variance** of X is the mean-square deviation from the mean,

$$\mathrm{Var}(X) = \sigma_X^2 = E\big[(X - \mu_X)^2\big],$$

and the **standard deviation** is $\sigma_X = \sqrt{\mathrm{Var}(X)}$, which has the same units as X.

Expanding the square and using linearity gives the computational form

$$\mathrm{Var}(X) = E[X^2] - 2\mu_X E[X] + \mu_X^2 = E[X^2] - \mu_X^2.$$

Properties of variance

1. $\mathrm{Var}(X) \geq 0$, with equality if and only if X is constant with probability 1.
2. $\mathrm{Var}(aX + b) = a^2\,\mathrm{Var}(X)$: a shift does not change spread; a scale multiplies the standard deviation by $|a|$.
3. If X, Y are independent, $\mathrm{Var}(X + Y) = \mathrm{Var}(X) + \mathrm{Var}(Y)$; more generally (below) a covariance term appears.

Proof of 2. $aX + b - E[aX + b] = a(X - \mu_X)$, so $\mathrm{Var}(aX + b) = E[a^2(X - \mu_X)^2] = a^2\,\mathrm{Var}(X)$. □

The decomposition $E[X^2] = \mu_X^2 + \sigma_X^2$ has a direct electrical meaning. If X is a voltage across 1 Ω, $E[X^2]$ is the average (total) power, μ_X^2 is the power of the DC component and σ_X^2 is the power of the fluctuating (AC) component; σ_X is the AC RMS value read by a true-RMS meter with AC coupling.

Worked Example 19.40 — Quantization noise

An N-bit ADC with full-scale range $\pm V_{\mathrm{FS}}$ has step $\Delta = 2V_{\mathrm{FS}}/2^N$. For a busy input, the rounding error is modelled as $e \sim \mathcal{U}(-\Delta/2, \Delta/2)$. Find the mean and variance of e, and the signal-to-quantization-noise ratio (SQNR) for a full-scale sine wave, evaluated for $N = 8$, $V_{\mathrm{FS}} = 1$ V.

Step 1 — mean. By symmetry $E[e] = 0$.

Step 2 — variance.

$$\mathrm{Var}(e) = E[e^2] = \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2} x^2\,dx = \frac{1}{\Delta}\cdot\frac{2}{3}\left(\frac{\Delta}{2}\right)^3 = \frac{\Delta^2}{12}.$$

The RMS quantization noise is $\Delta/\sqrt{12} \approx 0.289\Delta$.

Step 3 — SQNR. A full-scale sine has power $V_{\mathrm{FS}}^2/2$. With $\Delta = 2V_{\mathrm{FS}}/2^N$,

$$\mathrm{SQNR} = \frac{V_{\mathrm{FS}}^2/2}{\Delta^2/12} = \frac{3}{2}\,2^{2N}, \qquad 10\log_{10}\mathrm{SQNR} = 6.02N + 1.76\ \mathrm{dB}.$$

Step 4 — numbers. $\Delta = 2/256 = 7.8125$ mV, $\mathrm{Var}(e) = 5.086 \times 10^{-6}\ \mathrm{V}^2$, RMS noise 2.255 mV, $\mathrm{SQNR} = 10\log_{10}(0.5/5.086 \times 10^{-6}) = 49.93$ dB, matching $6.02(8) + 1.76 = 49.92$ dB. Every extra bit buys about 6 dB.

Means and variances of the key distributions

Distribution	Mean	Variance	Derivation hint
Bernoulli(p)	p	$p(1-p)$	$E[X^2]=E[X]=p$
Bin(n,p)	np	$np(1-p)$	sum of n independent Bernoullis
Geom(p)	$1/p$	$(1-p)/p^2$	tail formula: $\sum_k (1-p)^k = 1/p$
Poisson(λ)	λ	λ	MGF below, or $E[X(X-1)]=\lambda^2$
$\mathcal{U}(a,b)$	$(a+b)/2$	$(b-a)^2/12$	Example 19.40 shifted and scaled
Exp(λ)	$1/\lambda$	$1/\lambda^2$	$E[T^n]=n!/\lambda^n$
$\mathcal{N}(\mu,\sigma^2)$	μ	σ^2	standardize; $E[Z^2]=1$ by parts
Rayleigh(σ)	$\sigma\sqrt{\pi/2}$	$(2-\pi/2)\sigma^2$	$E[R^2]=2\sigma^2$

Two derivations. For $Z\sim\mathcal{N}(0,1)$, $E[Z]=0$ by symmetry and, integrating by parts with $u=z$, $dv=z\varphi(z)\,dz$ (so $v=-\varphi(z)$): $E[Z^2]=\int z^2\varphi(z)\,dz = [-z\varphi(z)]_{-\infty}^{\infty}+\int\varphi(z)\,dz = 1$. Then $X=\mu+\sigma Z$ has mean μ and variance σ^2, which justifies the names of the parameters. For $T\sim\text{Exp}(\lambda)$, repeated integration by parts gives $E[T^n]=\int_0^\infty t^n\lambda e^{-\lambda t}dt = n!/\lambda^n$, so $E[T]=1/\lambda$, $E[T^2]=2/\lambda^2$ and $\text{Var}(T)=1/\lambda^2$: the standard deviation of an exponential lifetime equals its mean.

Sums, covariance and independence

For two random variables, expanding $E[(X+Y-\mu_X-\mu_Y)^2]$ gives

$$\text{Var}(X+Y)=\text{Var}(X)+\text{Var}(Y)+2\,\text{Cov}(X,Y),\qquad \text{Cov}(X,Y)=E[(X-\mu_X)(Y-\mu_Y)]=E[XY]-\mu_X\mu_Y.$$

Expectation of a product of independent RVs

If X and Y are independent, then $E[XY]=E[X]E[Y]$, more generally $E[g(X)h(Y)]=E[g(X)]E[h(Y)]$. Hence $\text{Cov}(X,Y)=0$ and variances of independent RVs add:

$$\text{Var}\left(\sum_{i=1}^{n}X_i\right)=\sum_{i=1}^{n}\text{Var}(X_i)\qquad (X_i \text{ independent}).$$

Proof. $E[g(X)h(Y)]=\iint g(x)h(y)f_X(x)f_Y(y)\,dx\,dy=\int g f_X\,dx\int h f_Y\,dy$, the double integral factoring because the joint density does. □

The converse is false: zero covariance (**uncorrelated**) does not imply independence. For $X\sim\mathcal{N}(0,1)$ and $Y=X^2$, $\text{Cov}(X,Y)=E[X^3]=0$, yet Y is a function of X. Covariance, the correlation coefficient and their estimation from data are developed in Ch. 20; autocorrelation of signals in Ch. 21.

Two consequences are used constantly. First, the **variance of an average**: if $X_1,\dots,X_N$ are independent with common variance σ^2, then $\bar X=\frac{1}{N}\sum X_i$ has $\text{Var}(\bar X)=\sigma^2/N$, so averaging N independent readings reduces the RMS noise by $\sqrt{N}$ (signal averaging gives 3 dB of SNR per doubling of N). Second, **tolerance stack-up**: independent tolerances add in quadrature, not linearly.

Worked Example 19.41 — DC plus noise, and resistors in series

(a) A sensor output is $V=2+N$ V with $N\sim\mathcal{N}(0,0.5^2)$. Find the mean, variance and mean-square value of V, and the average power it delivers to 1 Ω. (b) Two independent resistors, each with mean 1000 Ω and standard deviation 10 Ω, are connected in series. Find the mean and standard deviation of the total, absolute and relative.

(a) $E[V]=2$ V, $\text{Var}(V)=0.25$ V^2, $E[V^2]=2^2+0.25=4.25$ V^2. Power into 1 Ω: 4.25 W, of which 4 W is DC and 0.25 W is noise.

(b) Mean 2000 Ω; variance $10^2+10^2=200$ Ω^2; standard deviation $\sqrt{200}=14.14$ Ω. Relative spread: $14.14/2000=0.71\,\%$, compared with $1\,\%$ for each resistor. Independent errors partially cancel; a worst-case (linear) stack-up of ±20 Ω would be pessimistic.

Conditional expectation and the law of total expectation

Conditioning works for expectations exactly as for probabilities. For an event B, $E[X\mid B]$ is the mean computed from the conditional distribution of X given B. If $B_1,\dots,B_n$ partition Ω,

$$E[X]=\sum_{i=1}^{n}E[X\mid B_i]\,P(B_i),$$

the **law of total expectation**, proved by applying total probability inside the sum or integral that defines $E[X]$.

Worked Example 19.42 — Mean number of transmissions by conditioning

In the ARQ protocol of Example 19.23, each attempt succeeds with probability p. Find $E[N]$ without summing a series.

Step 1 — condition on the first attempt. If it succeeds (probability p), $N = 1$. If it fails (probability $1-p$), one attempt has been used and, by independence, the situation restarts: $E[N \mid \text{fail}] = 1 + E[N]$.

Step 2 — solve. $E[N] = p \cdot 1 + (1-p)(1 + E[N])$, so $pE[N] = 1$ and $E[N] = 1/p$.

Step 3 — numbers. With $p = 0.8$, $E[N] = 1.25$ attempts: the throughput of the link is 80 % of its raw rate. Check by the tail formula: $\sum_{k \ge 0} (0.2)^k = 1/0.8 = 1.25$. ✓

Inequalities: Markov and Chebyshev

Means and variances bound tail probabilities even when the distribution is unknown.

Markov and Chebyshev inequalities

Markov: if $X \ge 0$ and $a > 0$, then $P(X \ge a) \le \dfrac{E[X]}{a}$.

Chebyshev: for any X with mean μ and variance σ^2, and any $k > 0$,

$$P(|X - \mu| \ge k\sigma) \le \frac{1}{k^2}.$$

Proof. Markov: $X \ge a\, I_{\{X \ge a\}}$ for $X \ge 0$; take expectations, $E[X] \ge aP(X \ge a)$. Chebyshev: apply Markov to the non-negative variable $(X-\mu)^2$ with $a = k^2\sigma^2$. □

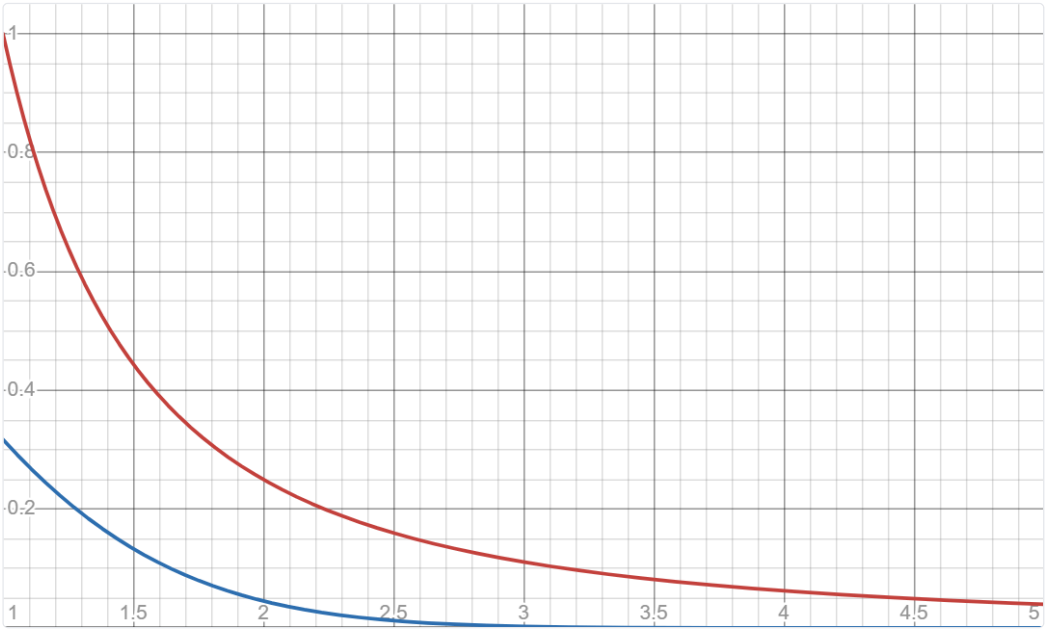
Worked Example 19.43 — Guaranteed yield without a distribution

A supplier guarantees only that a batch of resistors has mean 1000 Ω and standard deviation 10 Ω. What fraction can lie outside 1000 ± 30 Ω? Compare with the Gaussian model.

Step 1 — Chebyshev with $k = 3$. $P(|R - 1000| \ge 30) \le 1/9 = 0.111$.

Step 2 — Gaussian. $2Q(3) = 0.0027$.

Chebyshev's bound is distribution-free and therefore very conservative — about 40 times the Gaussian value here — but it is a *guarantee*. It is attained only by a three-point distribution, which real batches rarely resemble. Chebyshev's inequality also proves the weak law of large numbers in one line: $P(|\bar{X} - \mu| \ge \epsilon) \le \sigma^2/(N\epsilon^2) \to 0$.



Chebyshev bound $1/k^2$ (red) on $P(|X-\mu| \ge k\sigma)$, and the exact value $2Q(k)$ for a Gaussian (blue). The distribution-free bound decays only polynomially; Gaussian tails decay like $e^{-k^2/2}$.

Moments and the shape of a distribution

Moments

The n**-th moment** of X is $m_n = E[X^n]$ and the n**-th central moment** is $\mu_n = E[(X-\mu)^n]$. Thus $m_1 = \mu$, $\mu_2 = \sigma^2$. The normalized third and fourth central moments are the **skewness** and **kurtosis**:

$$\gamma_1 = \frac{\mu_3}{\sigma^3}, \qquad \beta_2 = \frac{\mu_4}{\sigma^4} \quad (\text{excess kurtosis } \beta_2 - 3).$$

Skewness measures asymmetry (positive when the right tail is longer); kurtosis measures the weight of the tails relative to a Gaussian, for which $\gamma_1 = 0$ and $\beta_2 = 3$. Central moments are found from ordinary moments by expanding the binomial: for instance $\mu_3 = m_3 - 3\mu m_2 + 2\mu^3$. For the exponential distribution, with $m_n = n!/\lambda^n$, this gives $\mu_3 = (6 - 6 + 2)/\lambda^3 = 2/\lambda^3$ and $\gamma_1 = 2$; similarly $\beta_2 = 9$ (excess kurtosis 6). Impulsive noise in power-line communications and switching transients is characterized by large excess kurtosis — its tails are much heavier than Gaussian, so Gaussian-based error-rate predictions are optimistic.

Knowing all the moments usually determines the distribution (it does, for example, whenever the moment-generating function below exists near 0). The transforms in the rest of the section encode the whole sequence of moments in one function.

The moment-generating function

Moment-generating function (MGF)

$$M_X(s) = E\left[e^{sX}\right] = \int_{-\infty}^{\infty} e^{sx} f_X(x)\,dx \quad \Big(\text{or } \sum_k e^{sx_k} p_X(x_k)\Big),$$

defined for the real s for which the expectation is finite. It always exists at $s = 0$, where $M_X(0) = 1$.

The MGF of a continuous RV is the two-sided Laplace transform (Ch. 14) of f_X evaluated at $-s$. Its name comes from the following property.

Properties of the MGF

If $M_X(s)$ is finite in an open interval around $s = 0$, then:

1. **Moments:** $E[X^n] = M_X^{(n)}(0) = \dfrac{d^n M_X}{ds^n}\Big|_{s=0}$, and $M_X(s) = \sum_{n=0}^{\infty} \dfrac{E[X^n]}{n!} s^n$.
2. **Uniqueness:** M_X determines the distribution of X.
3. **Linear transformation:** $M_{aX+b}(s) = e^{bs} M_X(as)$.
4. **Sums:** if X, Y are independent, $M_{X+Y}(s) = M_X(s) M_Y(s)$.

Proof of 1 and 4. Expand $e^{sX} = \sum_n (sX)^n/n!$ and take expectations term by term (justified by the finiteness of M_X near 0); the coefficient of $s^n/n!$ is $E[X^n]$. For 4, $E[e^{s(X+Y)}] = E[e^{sX}e^{sY}] = E[e^{sX}]E[e^{sY}]$ by the product theorem for independent variables. □

A related convenience is the **cumulant** function $\ln M_X(s)$: its first two derivatives at 0 are the mean and the variance directly, $(\ln M_X)'(0) = \mu$, $(\ln M_X)''(0) = \sigma^2$.

Worked Example 19.44 — MGFs of the exponential, Poisson and Gaussian

Find the MGFs and use them to obtain the means and variances.

Exponential. For $s < \lambda$: $M_T(s) = \int_0^\infty e^{st}\lambda e^{-\lambda t}dt = \dfrac{\lambda}{\lambda - s}$. Then $M'(s) = \lambda/(\lambda - s)^2$, $M''(s) = 2\lambda/(\lambda - s)^3$, so $E[T] = 1/\lambda$, $E[T^2] = 2/\lambda^2$, $\mathrm{Var}(T) = 1/\lambda^2$. ✓ (The MGF does not exist for $s \ge \lambda$ — the exponential tail is not light enough.)

Poisson. $M_X(s) = \sum_k e^{sk} e^{-\lambda}\lambda^k/k! = e^{-\lambda}\sum_k (\lambda e^s)^k/k! = \exp\big(\lambda(e^s - 1)\big)$. Its logarithm is $\lambda(e^s - 1)$, whose first and second derivatives at 0 are both λ: **mean = variance =** λ.

Gaussian. For $Z \sim \mathcal{N}(0,1)$, complete the square: $sz - z^2/2 = -\frac{1}{2}(z - s)^2 + \frac{s^2}{2}$, so $M_Z(s) = e^{s^2/2}\int \varphi(z - s)\,dz = e^{s^2/2}$. By property 3, $X = \mu + \sigma Z$ has

$$M_X(s) = \exp\big(\mu s + \tfrac{1}{2}\sigma^2 s^2\big)\,.$$

$\ln M_X = \mu s + \frac{1}{2}\sigma^2 s^2$, giving mean μ and variance σ^2 at once. Expanding $e^{s^2/2} = \sum s^{2k}/(2^k k!)$ also gives all the moments of Z: odd moments vanish and $E[Z^{2k}] = (2k)!/(2^k k!) = 1 \cdot 3 \cdot 5 \cdots (2k-1)$, so $E[Z^4] = 3$ (kurtosis 3).

Worked Example 19.45 — Closure of Poisson and Gaussian families under addition

(a) Packets from two independent sources arrive as Poisson(λ_1) and Poisson(λ_2) counts per slot. What is the distribution of the total? (b) A receiver input has independent thermal noise $N_1 \sim \mathcal{N}(0,1)$ and interference $N_2 \sim \mathcal{N}(0,4)$ (in $\mu\mathrm{V}^2$). What is the distribution of $N_1 + N_2$, and the probability that it exceeds 5 μV?

(a) $M(s) = e^{\lambda_1(e^s-1)}e^{\lambda_2(e^s-1)} = e^{(\lambda_1+\lambda_2)(e^s-1)}$, the MGF of Poisson($\lambda_1 + \lambda_2$). By uniqueness, merged independent Poisson streams are Poisson with the summed rate. (Doing this by discrete convolution requires the binomial theorem; the MGF makes it a one-liner.)

(b) $M(s) = e^{s^2/2}e^{4s^2/2} = e^{5s^2/2}$, so $N_1 + N_2 \sim \mathcal{N}(0,5)$. Then $P(N_1 + N_2 > 5) = Q(5/\sqrt{5}) = Q(2.236) = 0.0127$. Independent Gaussian noises add in *power* (variance), and the sum stays Gaussian — the property that makes Gaussian noise analysis of linear systems so clean (Ch. 21).

The characteristic function

The MGF may fail to exist (for the Cauchy distribution it is infinite for every $s \neq 0$). Replacing the real s by an imaginary $j\omega$ cures this, because $|e^{j\omega X}| = 1$.

Characteristic function

$$\Phi_X(\omega) = E\big[e^{j\omega X}\big] = \int_{-\infty}^{\infty} f_X(x)\, e^{j\omega x}\, dx, \qquad \omega \in \mathbb{R}.$$

It exists for every random variable, with $|\Phi_X(\omega)| \le \Phi_X(0) = 1$.

Comparing with the Fourier transform of Ch. 16, $\Phi_X(\omega)$ is the Fourier transform of the density with the sign of the exponent reversed: $\Phi_X(\omega) = \mathcal{F}\{f_X\}(-\omega)$. Every Fourier result transfers immediately:

- **Inversion:** $f_X(x) = \dfrac{1}{2\pi}\displaystyle\int_{-\infty}^{\infty} \Phi_X(\omega) e^{-j\omega x}\, d\omega$, so Φ_X determines the distribution.
- **Convolution theorem:** for independent X, Y, $\Phi_{X+Y}(\omega) = \Phi_X(\omega)\Phi_Y(\omega)$ — the transform-domain version of $f_{X+Y} = f_X * f_Y$ (Section 19.6).
- **Moments:** if $E[|X|^n] < \infty$, $E[X^n] = j^{-n}\Phi_X^{(n)}(0)$; smoothness of Φ_X at the origin reflects how many moments exist, just as smoothness of a signal reflects the decay of its spectrum.
- **Symmetry:** $\Phi_X(-\omega) = \Phi_X(\omega)^*$; Φ_X is real and even exactly when f_X is even.

Standard pairs: $\mathcal{N}(\mu,\sigma^2) \mapsto e^{j\mu\omega - \sigma^2\omega^2/2}$; $\mathrm{Exp}(\lambda) \mapsto \lambda/(\lambda - j\omega)$; $\mathcal{U}(-a,a) \mapsto \sin(a\omega)/(a\omega)$; Cauchy $\mapsto e^{-|\omega|}$ (not differentiable at 0, matching the non-existent mean); $\mathrm{Poisson}(\lambda) \mapsto \exp(\lambda(e^{j\omega} - 1))$.

For integer-valued random variables one also uses the **probability generating function** $G_N(z) = E[z^N] = \sum_k p_N(k) z^k$, which is the Z-transform of the PMF (Ch. 17) evaluated at z^{-1}; $G_N'(1) = E[N]$ and the PGF of a sum of independent counts is the product of the PGFs.

Worked Example 19.46 — Sum of independent uniform errors via characteristic functions

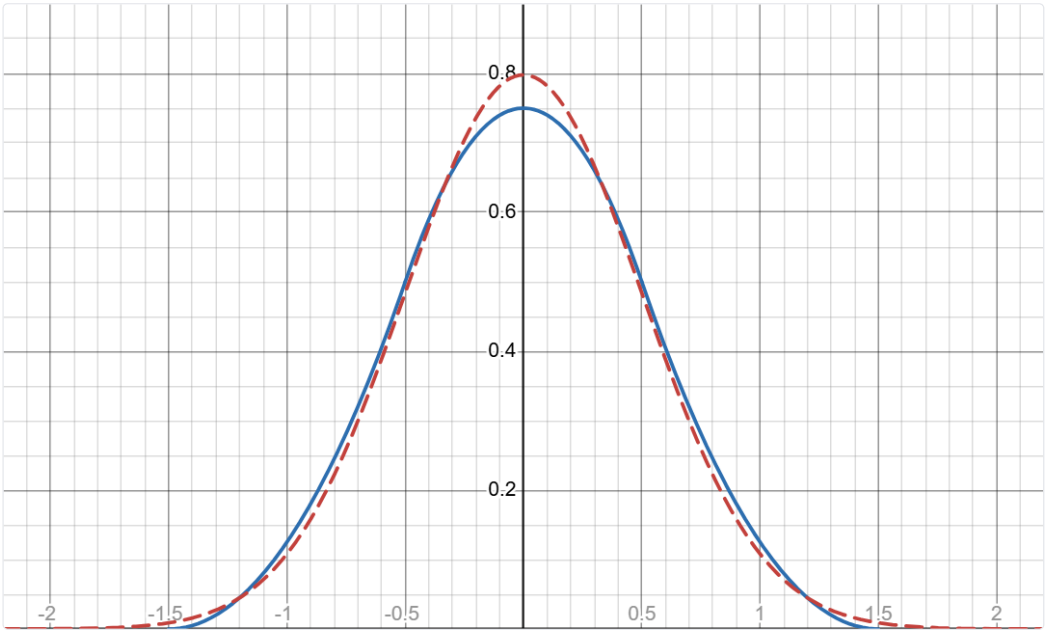
A measurement accumulates n independent rounding errors $e_i \sim \mathcal{U}(-\tfrac12, \tfrac12)$ (in units of one LSB). Find the characteristic function, mean and variance of the total error $S_n = e_1 + \cdots + e_n$, and compare its distribution with a Gaussian for $n = 3$.

Step 1 — one error. $\Phi_e(\omega) = \int_{-1/2}^{1/2} e^{j\omega x} dx = \dfrac{\sin(\omega/2)}{\omega/2}$.

Step 2 — the sum. By independence, $\Phi_{S_n}(\omega) = \left(\dfrac{\sin(\omega/2)}{\omega/2}\right)^n$ — the n-fold product, corresponding to the n-fold convolution of rectangles (the triangle of Example 19.27 for $n = 2$).

Step 3 — moments. Expand near $\omega = 0$: $\frac{\sin u}{u} = 1 - \frac{u^2}{6} + \cdots$ with $u = \omega/2$, so $\Phi_e(\omega) = 1 - \frac{\omega^2}{24} + \cdots$. Matching with $\Phi(\omega) = 1 + j\omega E[e] - \frac{\omega^2}{2}E[e^2] + \cdots$ gives $E[e] = 0$, $E[e^2] = 1/12$ (as in Example 19.40). Then $\Phi_{S_n}(\omega) = 1 - \frac{n\omega^2}{24} + \cdots$, so $\mathrm{Var}(S_n) = n/12$.

Step 4 — Gaussian comparison. For $n = 3$, $\mathrm{Var}(S_3) = 1/4$, $\sigma = 1/2$. The exact density (three convolved rectangles, a piecewise quadratic) has $f_{S_3}(0) = 3/4$; the Gaussian $\mathcal{N}(0, 1/4)$ has $f(0) = 1/(\sqrt{2\pi}\cdot\tfrac12) = 0.798$ — already within 6 %. Since $\left(\frac{\sin(\omega/2)}{\omega/2}\right)^n \approx \left(1 - \frac{\omega^2}{24}\right)^n \to$ a Gaussian shape after rescaling by $\sqrt{n}$, the characteristic function makes the central limit theorem plausible in a single line; Ch. 20 states it precisely.



Density of the sum of three independent $\mathcal{U}(-\frac12, \frac12)$ errors (blue, piecewise quadratic) and the Gaussian with the same variance $1/4$ (red, dashed). Three uniform terms are already nearly Gaussian; the difference lies mainly in the tails, which the uniform sum truncates at ± 1.5.

Common Pitfall — sign conventions for transforms

The characteristic function uses $e^{+j\omega x}$, the Fourier transform of this book uses $e^{-j\omega t}$, and the MGF uses the real exponent e^{sx}. Mixing conventions flips the sign of odd moments (and of the phase). When borrowing a Fourier pair for a characteristic function, replace ω by $-\omega$; for even densities nothing changes.

Engineering Note — moments as the designer's summary

Mean (DC level, bias), variance (AC power, noise power, tolerance), and the shape parameters (skewness, kurtosis) are the quantities that appear in specifications and link budgets. Second-order reasoning — means and variances, which add for independent contributions — handles the bulk of noise and tolerance analysis; the full distribution, usually Gaussian by the central limit theorem, is needed only at the final step, when the variance is converted into an error probability with $Q(\cdot)$.

Summary

Concept	Key formula
Axioms	$P(A) \geq 0$, $P(\Omega) = 1$, $P(\bigcup A_i) = \sum P(A_i)$ for disjoint A_i
Complement, addition rule	$P(A^c) = 1 - P(A)$, $P(A \cup B) = P(A) + P(B) - P(AB)$
Union bound	$P(\bigcup A_i) \leq \sum P(A_i)$
Counting	n^k, $n!/(n-k)!$, $\binom{n}{k} = \dfrac{n!}{k!(n-k)!}$, $\binom{n+k-1}{k}$
Conditional probability	$P(A \mid B) = P(AB)/P(B)$
Chain rule	$P(A_1 \cdots A_n) = P(A_1)P(A_2 \mid A_1) \cdots P(A_n \mid A_1 \cdots A_{n-1})$
Total probability	$P(A) = \sum_i P(A \mid B_i)P(B_i)$
Bayes' theorem	$P(B_k \mid A) = P(A \mid B_k)P(B_k) / \sum_i P(A \mid B_i)P(B_i)$
Odds form	posterior odds = likelihood ratio $\times$ prior odds
MAP threshold, $\pm A$ in $\mathcal{N}(0, \sigma^2)$	$x_{\text{th}} = \dfrac{\sigma^2}{2A} \ln \dfrac{p_0}{p_1}$
Independence	$P(AB) = P(A)P(B)$; for RVs $f_{XY} = f_X f_Y$
Series / parallel reliability	$\prod p_i$ / $1 - \prod(1 - p_i)$
k-out-of-n, TMR	$\sum_{i \geq k} \binom{n}{i} p^i (1-p)^{n-i}$; $3p^2 - 2p^3$
Binomial, geometric, Poisson	$\binom{n}{k} p^k q^{n-k}$; $q^{k-1}p$; $e^{-\lambda}\lambda^k/k!$
Uniform, exponential	$1/(b-a)$; $\lambda e^{-\lambda t}$, $P(T > t) = e^{-\lambda t}$
Gaussian	$\dfrac{1}{\sqrt{2\pi}\sigma} e^{-(x-\mu)^2/2\sigma^2}$, $P(X > x) = Q\big((x-\mu)/\sigma\big)$
Rayleigh	$\dfrac{r}{\sigma^2} e^{-r^2/2\sigma^2}$, $P(R > r) = e^{-r^2/2\sigma^2}$
CDF	$F_X(x) = P(X \leq x)$, $P(a < X \leq b) = F_X(b) - F_X(a)$, $f_X = F_X'$
Marginal, conditional	$f_X = \int f_{XY}\, dy$, $f_{Y\mid X} = f_{XY}/f_X$
Sum of independent RVs	$f_{X+Y} = f_X * f_Y$
Density transformation	$f_Y(y) = \sum_i f_X(x_i)/\lvert g'(x_i)\rvert$, $g(x_i) = y$
Max / min of independent RVs	$F_{\max} = \prod F_i$, $P(\min > x) = \prod(1 - F_i)$
Hazard rate	$h(t) = f_T(t)/R(t)$, $R(t) = \exp\left(-\int_0^t h\right)$
Expectation, LOTUS	$E[g(X)] = \int g(x) f_X(x)\, dx$; $E[aX + bY] = aE[X] + bE[Y]$
Tail formula, MTTF	$E[T] = \int_0^\infty P(T > t)\, dt$
Variance	$\operatorname{Var}(X) = E[X^2] - \mu^2$, $\operatorname{Var}(aX + b) = a^2 \operatorname{Var}(X)$
Sum of variances	$\operatorname{Var}(X + Y) = \operatorname{Var} X + \operatorname{Var} Y + 2 \operatorname{Cov}(X, Y)$
Quantization noise	$\Delta^2/12$; SQNR $= 6.02N + 1.76$ dB
Markov, Chebyshev	$P(X \geq a) \leq E[X]/a$; $P(\lvert X - \mu\rvert \geq k\sigma) \leq 1/k^2$
MGF	$M_X(s) = E[e^{sX}]$, $E[X^n] = M_X^{(n)}(0)$, $M_{X+Y} = M_X M_Y$
Characteristic function	$\Phi_X(\omega) = E[e^{j\omega X}]$, $\Phi_{X+Y} = \Phi_X \Phi_Y$
Gaussian MGF	$\exp(\mu s + \sigma^2 s^2/2)$

Chapter 20 — Statistical Analysis

> **Prerequisites:** Ch. 5 (Integral Calculus), Ch. 6 (Multivariable Calculus), Ch. 8 (Matrices and Linear Systems), Ch. 19 (Probability) **Learning outcomes:** After this chapter you can …
>
> - summarise a data set with location, spread and shape statistics, and choose robust statistics when outliers are present;
> - compute covariance, correlation coefficients and covariance matrices, and interpret them correctly;
> - recognise the standard distributions (Bernoulli, binomial, Poisson, uniform, exponential, Gaussian, Rayleigh, chi-square, t, F), their moments and the relations between them;
> - derive sampling distributions, apply the central limit theorem, and build estimators by the method of moments and maximum likelihood;
> - construct confidence intervals and carry out z, t, chi-square and F tests with correct interpretation of p-values and error probabilities;
> - fit and diagnose a linear regression, and evaluate and report measurement uncertainty in the GUM framework.

Probability theory (Ch. 19) starts from a model — a distribution with known parameters — and deduces what data should look like. **Statistics** runs the argument backwards: it starts from data and infers something about the model that produced them. An engineer who measures the noise floor of a receiver, calibrates a temperature sensor, qualifies a batch of capacitors or reports "4.702 kΩ ± 0.012 kΩ" is doing statistics, whether or not the word is used.

The chapter follows the natural order of a data analysis. We first describe data (Sections 20.1–20.3), then recall the distributions used as models (20.4). Sections 20.5–20.8 form the core of *inference*: how statistics computed from a sample are themselves random (sampling distributions), how to estimate parameters, how to attach intervals, and how to test claims. Section 20.9 fits relations between variables by regression, and Section 20.10 assembles everything into the internationally agreed method for evaluating measurement uncertainty (the *GUM*).

Throughout, $X_1, \dots, X_n$ denotes a random sample (random variables, uppercase) and $x_1, \dots, x_n$ the observed numbers (lowercase), following the notation of Ch. 19.

20.1 Descriptive statistics

Why describe before inferring

Before any model is fitted, a data set should be *looked at*. A single miswired channel, a saturated ADC, a unit error between millivolts and volts, or a bimodal population (two suppliers mixed in one reel) will invalidate every later calculation, and each is obvious from a summary or a plot but invisible in a single average. Descriptive statistics compress n numbers into a handful of meaningful ones and are the first defence against garbage-in, garbage-out.

Data, population and sample

A **population** is the complete set of items or outcomes about which we want to draw conclusions (all resistors produced by a process, all possible readings of a voltmeter on a fixed source). A **sample** is the finite subset $x_1, \dots, x_n$ actually observed; n is the **sample size**. A **statistic** is any function of the sample, $t = g(x_1, \dots, x_n)$, that does not depend on unknown parameters.

Data come in several types, and the type dictates the admissible summaries:

Type	Example	Meaningful operations
Nominal (categorical)	failure mode: open / short / drift	counting, mode
Ordinal	inspection grade A/B/C	ordering, median, ranks
Interval	temperature in °C	differences, mean, standard deviation
Ratio	resistance in Ω, time to failure	all of the above plus ratios, coefficient of variation

Averaging category codes ("open = 1, short = 2") is meaningless; quoting a coefficient of variation for a temperature in °C is meaningless because the zero is arbitrary.

Order statistics and the five-number summary

Sorting the sample gives the **order statistics** $x_{(1)} \le x_{(2)} \le \dots \le x_{(n)}$. Many robust summaries are built from them.

Quantiles, quartiles and the five-number summary

For $0 < p < 1$, a **p-quantile** q_p is a value with (approximately) a fraction p of the data below it and $1 - p$ above. The **median** is $q_{0.5}$; the **lower and upper quartiles** are $Q_1 = q_{0.25}$ and $Q_3 = q_{0.75}$. The **interquartile range** is $\mathrm{IQR} = Q_3 - Q_1$. The **five-number summary** is $\left(x_{(1)},\, Q_1,\, \tilde{x},\, Q_3,\, x_{(n)}\right)$, where $\tilde{x}$ is the median.

Several conventions exist for quartiles of a finite sample (software packages offer up to nine); for hand work we use the *median of halves*: Q_1 is the median of the lower half of the sorted data and Q_3 the median of the upper half (excluding the overall median when n is odd). Differences between conventions shrink as n grows and do not matter for the decisions quartiles are used for.

The **box plot** draws a box from Q_1 to Q_3 with a line at the median and whiskers to the most extreme points within the **fences**

$$Q_1 - 1.5\,\mathrm{IQR}, \qquad Q_3 + 1.5\,\mathrm{IQR}.$$

Points beyond the fences are flagged as potential outliers. For Gaussian data, about 0.7% of points fall outside the fences, so a flagged point is a reason to *investigate*, not automatically to delete.

Frequency tables and histograms

For larger n the data are grouped into K class intervals (bins) of width h, with **frequencies** f_k (counts), **relative frequencies** f_k/n and **frequency density** $f_k/(nh)$. A histogram plotted with frequency density has unit total area and is directly comparable with a probability density function $f_X(x)$ from Ch. 19 — this is the bridge between data and model.

The choice of bin width matters: too wide hides structure, too narrow shows noise. Two common rules are

$$K \approx 1 + \log_2 n \quad \text{(Sturges)}, \qquad h \approx 2\,\mathrm{IQR}\,n^{-1/3} \quad \text{(Freedman–Diaconis)}.$$

Sturges' rule assumes near-Gaussian data and undersmooths large samples; Freedman–Diaconis uses the IQR and is robust to outliers. The **empirical cumulative distribution function**

$$\hat{F}_n(x) = \frac{1}{n}\,\#\{i : x_i \le x\}$$

needs no binning at all: it is a staircase rising by $1/n$ at each data point, and by the Glivenko–Cantelli theorem it converges uniformly to the true CDF $F_X(x)$ as $n \to \infty$.

Shape: skewness and kurtosis

Location and spread (Section 20.2) are not the whole story. The *shape* of a distribution is summarised by standardised third and fourth moments. With $m_k = \frac{1}{n}\sum_i (x_i - \bar{x})^k$ the kth sample central moment,

$$g_1 = \frac{m_3}{m_2^{3/2}} \quad \text{(sample skewness)}, \qquad g_2 = \frac{m_4}{m_2^2} - 3 \quad \text{(sample excess kurtosis)}.$$

Skewness is zero for symmetric data, positive when the right tail is long (time-to-failure, power of noise, lognormal component values) and negative when the left tail is long. Excess kurtosis is zero for a Gaussian, positive for heavy-tailed data with more extreme values (impulsive noise, interference), and negative for flat, light-tailed data (a uniform distribution has $g_2 = -1.2$). Because they involve high powers of deviations, g_1 and g_2 are very sensitive to outliers and need n of at least several tens to be informative.

Worked Example 20.1 — Summarising a batch of resistors

Twelve resistors of nominal value 1 kΩ are measured (in Ω):

$$998,\ 1003,\ 1001,\ 995,\ 1007,\ 1002,\ 999,\ 1004,\ 1000,\ 1012,\ 997,\ 1001.$$

Find the five-number summary, the IQR, the fences, and comment on the shape.

Step 1 — sort. $995,\ 997,\ 998,\ 999,\ 1000,\ 1001,\ 1001,\ 1002,\ 1003,\ 1004,\ 1007,\ 1012$.

Step 2 — median. With $n = 12$ (even) the median is the average of the 6th and 7th values: $\tilde{x} = (1001 + 1001)/2 = 1001\ \Omega$.

Step 3 — quartiles (median of halves). Lower half $995, \dots, 1001$: $Q_1 = (998 + 999)/2 = 998.5\ \Omega$. Upper half $1001, \dots, 1012$: $Q_3 = (1003 + 1004)/2 = 1003.5\ \Omega$. Hence $\mathrm{IQR} = 5\ \Omega$.

Step 4 — five-number summary. $(995,\ 998.5,\ 1001,\ 1003.5,\ 1012)\ \Omega$; range $= 17\ \Omega$.

Step 5 — fences. $Q_1 - 1.5\,\mathrm{IQR} = 991\ \Omega$, $Q_3 + 1.5\,\mathrm{IQR} = 1011\ \Omega$. The value $1012\ \Omega$ lies beyond the upper fence and is flagged.

Step 6 — shape. Working with deviations $d_i = x_i - 1000$ keeps the arithmetic small: $\sum d_i = 19$, so $\bar{x} = 1001.583\ \Omega$. The central moments are $m_2 = 19.41\ \Omega^2$, $m_3 = 71.42\ \Omega^3$, $m_4 = 1267\ \Omega^4$, giving $g_1 = 71.42/19.41^{1.5} = 0.84$ and $g_2 = 1267/19.41^2 - 3 = 0.36$. The positive skewness is driven almost entirely by the flagged point. Before reporting statistics, one should check whether the $1012\ \Omega$ reading is a genuine part (perhaps from a different reel) or a contact-resistance error in the fixture.

Worked Example 20.2 — Statistics from a frequency table

The rise times of 40 logic buffers are grouped into 1 ns classes:

Class (ns)	4–5	5–6	6–7	7–8	8–9
Frequency f_k	3	9	15	10	3

Estimate the mean and standard deviation.

Step 1 — class marks. Represent each class by its midpoint $c_k = 4.5,\ 5.5,\ 6.5,\ 7.5,\ 8.5$ ns.

Step 2 — mean. $\bar{x} \approx \frac{1}{n}\sum_k f_k c_k = \frac{3(4.5)+9(5.5)+15(6.5)+10(7.5)+3(8.5)}{40} = \frac{261}{40} = 6.525$ ns.

Step 3 — variance. $s^2 \approx \frac{1}{n-1}\sum_k f_k (c_k - \bar{x})^2 = \frac{42.975}{39} = 1.102\ \mathrm{ns}^2$, so $s \approx 1.05$ ns.

Step 4 — grouping error. Replacing every value by its class mark adds an error that is roughly uniform over a class of width h; Sheppard's correction subtracts $h^2/12 = 0.083\ \mathrm{ns}^2$ from the variance, giving $s \approx 1.01$ ns. The correction is small when $h \ll s$ and is often ignored, but it shows why grouped statistics are approximate.

Engineering Note — Look at the raw data first

Production test logs routinely contain sentinel values (-999, 9.9×10^{37} "overload" from a DMM, zero for "no reading"). A five-number summary exposes them instantly because they appear as $x_{(1)}$ or $x_{(n)}$. Make computing the minimum and maximum the reflex first step of every analysis.

Common Pitfall — Deleting outliers to improve the statistics

Removing points only because they are inconvenient biases every later result (spread is underestimated, confidence intervals become too narrow). Delete a point only with a documented physical cause (fixture fault, logging error). Otherwise keep it and, if needed, use robust statistics (Section 20.2) whose value it cannot dominate.

20.2 Mean, median, variance, and standard deviation

Measures of location

Three numbers compete to describe "the typical value".

Sample mean, median and mode

- **Sample mean:** $\bar{x} = \dfrac{1}{n}\sum_{i=1}^{n} x_i$.
- **Sample median:** $\tilde{x} = x_{((n+1)/2)}$ for n odd, $\tilde{x} = \tfrac{1}{2}\big(x_{(n/2)} + x_{(n/2+1)}\big)$ for n even.
- **Mode:** the most frequent value (or, for continuous grouped data, the class with the highest density).

Each is the solution of a minimisation problem, which explains its behaviour:

$$\bar{x} = \arg\min_{c} \sum_{i=1}^{n} (x_i - c)^2, \qquad \tilde{x} = \arg\min_{c} \sum_{i=1}^{n} |x_i - c|.$$

Proof sketch. Differentiating $\sum (x_i - c)^2$ gives $-2\sum (x_i - c) = 0$, i.e. $c = \bar{x}$; the second derivative $2n > 0$ confirms a minimum. For $\sum |x_i - c|$ the derivative (where it exists) is $\#\{x_i < c\} - \#\{x_i > c\}$, which changes sign exactly when half the points lie on each side — at the median. $\square$

Squared loss punishes large deviations heavily, so a single wild point drags the mean; absolute loss treats all deviations linearly, so the median moves at most to the next data point. This is formalised by the **breakdown point**, the fraction of data that can be made arbitrarily bad before the statistic becomes arbitrarily bad: 0 (strictly $1/n$) for the mean, 50% for the median.

The mean has compensating virtues: it is linear ($\overline{ax + b} = a\bar{x} + b$), easy to update, and for Gaussian data it is the most efficient estimator of the centre (Section 20.6) — the median needs about $\pi/2 \approx 1.57$ times as many samples to achieve the same variance.

A useful compromise is the **trimmed mean**, which discards a fixed fraction (say 10%) from each end before averaging. It is common in sensor fusion and in reading-averaging routines in instrument firmware.

Weighted mean

When observations have different reliabilities, they should not count equally. If x_i has standard uncertainty u_i, the **inverse-variance weighted mean** is

$$\bar{x}_w = \frac{\sum_i w_i x_i}{\sum_i w_i}, \qquad w_i = \frac{1}{u_i^2}, \qquad u(\bar{x}_w) = \Big(\sum_i w_i\Big)^{-1/2}.$$

It is the minimum-variance unbiased linear combination of independent measurements of the same quantity: minimising $\operatorname{Var}\big(\sum a_i x_i\big) = \sum a_i^2 u_i^2$ subject to $\sum a_i = 1$ with a Lagrange multiplier (Ch. 6) gives $a_i \propto 1/u_i^2$.

Measures of spread

Sample variance and standard deviation

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n} (x_i - \bar{x})^2, \qquad s = \sqrt{s^2}.$$

The **range** is $x_{(n)} - x_{(1)}$; the **mean absolute deviation** is $\frac{1}{n}\sum |x_i - \bar{x}|$; the **median absolute deviation** is $\mathrm{MAD} = \operatorname{median}_i |x_i - \tilde{x}|$. The **coefficient of variation** (ratio data only) is $\mathrm{CV} = s/\bar{x}$.

The standard deviation s carries the units of the data and is the usual measure of spread. For Gaussian data, $1.4826\,\mathrm{MAD}$ and $\mathrm{IQR}/1.349$ are consistent estimates of σ that are robust to outliers.

Why divide by $n - 1$?

The divisor $n - 1$ (Bessel's correction) makes s^2 an *unbiased* estimator of the population variance σ^2. The derivation is short and worth knowing.

Unbiasedness of the sample variance

If $X_1, \dots, X_n$ are independent with common mean μ and variance σ^2, then $E[S^2] = \sigma^2$, where $S^2 = \frac{1}{n-1}\sum (X_i - \bar{X})^2$.

Proof. Write $X_i - \bar X = (X_i - \mu) - (\bar X - \mu)$ and expand:

$$\sum_{i=1}^{n}(X_i - \bar X)^2 = \sum_{i=1}^{n}(X_i - \mu)^2 - n(\bar X - \mu)^2,$$

because the cross term is $-2(\bar X - \mu)\sum(X_i - \mu) = -2n(\bar X - \mu)^2$. Taking expectations, $E[(X_i - \mu)^2] = \sigma^2$ and $E[(\bar X - \mu)^2] = \operatorname{Var}(\bar X) = \sigma^2/n$ (Ch. 19, variance of a sum of independent variables). Hence

$$E\Big[\sum (X_i - \bar X)^2\Big] = n\sigma^2 - n\cdot\frac{\sigma^2}{n} = (n-1)\sigma^2. \qquad \square$$

The intuition: deviations are measured from $\bar x$, which is itself fitted to the data and therefore sits closer to the points than the true μ does. One "degree of freedom" is used up in estimating μ — the n deviations satisfy one linear constraint $\sum(x_i - \bar x) = 0$, so only $n-1$ are free. The same counting gives the divisor $n - p$ when p parameters are fitted in regression (Section 20.9).

Note that s itself is *not* unbiased for σ: by Jensen's inequality $E[S] < \sigma$. For Gaussian data $E[S] = c_4\sigma$ with $c_4 = \sqrt{2/(n-1)}\,\Gamma(n/2)/\Gamma((n-1)/2)$, e.g. $c_4 = 0.798$ for $n = 2$ and 0.973 for $n = 10$. The bias is usually ignored except in quality-control charts.

Computational formulas and numerical stability

Expanding the square gives the "computational" formula

$$s^2 = \frac{1}{n-1}\Big(\sum x_i^2 - n\bar x^2\Big) = \frac{1}{n-1}\Big(\sum x_i^2 - \frac{(\sum x_i)^2}{n}\Big),$$

which needs only running sums. It is exact in real arithmetic but disastrous in floating point when $|\bar x| \gg s$: two large, nearly equal numbers are subtracted, and the relative rounding error of each (about 10^{-16} in double precision) is multiplied by $\bar x^2/s^2$ (catastrophic cancellation, Ch. 22).

The stable alternatives are (i) the **two-pass** algorithm (compute $\bar x$ first, then $\sum(x_i - \bar x)^2$), (ii) **shifting** the data by any value close to the mean before using the one-pass formula, or (iii) **Welford's online algorithm**, which updates mean and sum of squared deviations sample by sample:

$$\begin{aligned} \delta &= x_k - \bar x_{k-1}, \qquad \bar x_k = \bar x_{k-1} + \frac{\delta}{k},\\ M_k &= M_{k-1} + \delta\,(x_k - \bar x_k), \qquad s_k^2 = \frac{M_k}{k-1}. \end{aligned}$$

Welford's recursion is what a well-written DMM "statistics" mode or a streaming data logger should use.

Variance, RMS and power

For an electrical signal sampled as $v_1, \dots, v_n$, the mean is the DC component and the (population-divisor) variance is the AC power in a 1 Ω reference. Since

$$\frac{1}{n}\sum v_i^2 = \bar v^{\,2} + \frac{1}{n}\sum (v_i - \bar v)^2,$$

the squared RMS value equals the squared DC value plus the squared standard deviation:

$$V_{\text{rms}}^2 = V_{\text{DC}}^2 + \sigma_v^2.$$

A "true-RMS AC" meter that blocks DC reports σ_v; a DC-coupled true-RMS meter reports $\sqrt{V_{\text{DC}}^2 + \sigma_v^2}$. This identity is the statistical form of Parseval's theorem (Ch. 15) restricted to the zero-frequency term.

> **Worked Example 20.3 — Mean and standard deviation of ADC readings**
>
> Eight readings of a nominal 2.5 V reference are $2.47,\ 2.53,\ 2.51,\ 2.49,\ 2.55,\ 2.45,\ 2.50,\ 2.52$ V. Find $\bar x$, s, and the RMS value.
>
> **Step 1 — mean.** $\sum x_i = 20.02$, so $\bar x = 2.5025$ V.
>
> **Step 2 — deviations.** $x_i - \bar x = -0.0325,\ 0.0275,\ 0.0075,\ -0.0125,\ 0.0475,\ -0.0525,\ -0.0025,\ 0.0175$ (they sum to zero — a free arithmetic check).
>
> **Step 3 — sum of squares.** $\sum(x_i - \bar x)^2 = 0.00735$ V^2.
>
> **Step 4 — variance and standard deviation.** $s^2 = 0.00735/7 = 1.05 \times 10^{-3}$ V^2, $s = 32.4$ mV. (With divisor n one would get 30.3 mV; the difference is $\sqrt{8/7}$, i.e. about 7% for $n = 8$.)
>
> **Step 5 — RMS.** $\frac{1}{n}\sum x_i^2 = 50.1074/8 = 6.263425$ V^2, and indeed $\bar x^2 + \frac{1}{n}\sum(x_i - \bar x)^2 = 6.26250625 + 0.00091875 = 6.263425$. So $V_{\text{rms}} = 2.50268$ V, dominated by the DC value as expected.

> **Worked Example 20.4 — When the computational formula fails**
>
> A frequency counter logs four readings $10^9 + 4,\ 10^9 + 7,\ 10^9 + 13,\ 10^9 + 16$ (in Hz). The true sample variance is that of $4, 7, 13, 16$: $\bar d = 10$, $\sum(d_i - \bar d)^2 = 36 + 9 + 9 + 36 = 90$, $s^2 = 30$ Hz^2.
>
> Evaluating $\big(\sum x_i^2 - (\sum x_i)^2/n\big)/(n-1)$ in IEEE double precision returns -170.7 Hz^2 — a *negative* variance. Each $x_i^2 \approx 10^{18}$ is stored with an absolute rounding error of about $10^{18} \times 1.1 \times 10^{-16} \approx 100$, comparable to the 90 we are trying to recover. Subtracting 10^9 first (or using the two-pass or Welford algorithm) returns exactly 30 Hz^2.

Worked Example 20.5 — Combining three calibrations

Three laboratories report the value of a standard resistor as 10.12 ± 0.02, 10.05 ± 0.05 and $10.09 \pm 0.03\ \Omega$ (standard uncertainties). Find the weighted mean and its uncertainty.

Step 1 — weights. $w_i = 1/u_i^2 = 2500,\ 400,\ 1111.1\ \Omega^{-2}$; $\sum w_i = 4011.1$.

Step 2 — weighted mean. $\bar{x}_w = (2500 \times 10.12 + 400 \times 10.05 + 1111.1 \times 10.09)/4011.1 = 10.1047\ \Omega$.

Step 3 — uncertainty. $u(\bar{x}_w) = 1/\sqrt{4011.1} = 0.0158\ \Omega$ — smaller than the best single uncertainty, as it should be.

Step 4 — consistency check. $\chi^2 = \sum w_i (x_i - \bar{x}_w)^2 = 0.585 + 1.197 + 0.240 = 2.02$ with $n - 1 = 2$ degrees of freedom. A value near the degrees of freedom indicates the three results agree within their stated uncertainties (Section 20.8); a value much larger would suggest an unrecognised error in at least one laboratory.

Common Pitfall — Quoting s when you mean the uncertainty of the mean

The standard deviation s describes the scatter of *individual* readings. The uncertainty of their *average* is the standard error $s/\sqrt{n}$ (Section 20.5). In Example 20.3, the readings scatter by 32 mV but the mean is known to about $32/\sqrt{8} \approx 11$ mV. Confusing the two either overstates or understates the result by a factor $\sqrt{n}$.

Engineering Note — Robust statistics in firmware

Embedded systems reading noisy sensors often use a *median-of-k* filter (typically $k = 3$ or 5) to reject single-sample glitches from ESD or relay switching, followed by an averaging filter to reduce Gaussian noise. The median removes impulses that would corrupt a mean; the subsequent mean recovers the efficiency the median loses.

20.3 Covariance and correlation

Motivation

Engineering data are rarely one-dimensional. A sensor's output depends on temperature; two receiver channels share a local oscillator and therefore share its phase noise; the gain and offset of an ADC drift together with supply voltage. Quantifying how two variables vary *together* is needed to decide whether one predicts the other, to propagate uncertainties correctly when inputs are not independent (Section 20.10), and to design systems that cancel common-mode effects.

Population and sample covariance

Recall from Ch. 19 that for random variables X and Y with means μ_X, μ_Y,

$$\operatorname{Cov}(X,Y) = E\big[(X-\mu_X)(Y-\mu_Y)\big] = E[XY] - \mu_X\mu_Y, \qquad \rho_{XY} = \frac{\operatorname{Cov}(X,Y)}{\sigma_X \sigma_Y}.$$

Sample covariance and Pearson correlation coefficient

For paired data (x_i, y_i), $i = 1, \dots, n$, define the sums of squares and products

$$S_{xx} = \sum (x_i - \bar{x})^2, \qquad S_{yy} = \sum (y_i - \bar{y})^2, \qquad S_{xy} = \sum (x_i - \bar{x})(y_i - \bar{y}).$$

The **sample covariance** is $s_{xy} = S_{xy}/(n-1)$ and the **sample (Pearson) correlation coefficient** is

$$r = \frac{s_{xy}}{s_x s_y} = \frac{S_{xy}}{\sqrt{S_{xx} S_{yy}}}.$$

The sign of s_{xy} says whether large x tends to go with large y (positive) or small y (negative). Its magnitude depends on units (Ω·°C, say), which is why the dimensionless r is preferred for describing the *strength* of association.

Bounds on the correlation coefficient

$-1 \le r \le 1$, with $|r| = 1$ if and only if all points lie exactly on a straight line $y = a + bx$ with $b \neq 0$ (sign of r = sign of b). The same holds for ρ_{XY}, with "exactly" replaced by "with probability one".

Proof. Let $\mathbf{u} = (x_i - \bar{x})_i$ and $\mathbf{v} = (y_i - \bar{y})_i$ be the centred data vectors in $\mathbb{R}^n$. Then $r = \langle \mathbf{u}, \mathbf{v} \rangle / (\|\mathbf{u}\|\|\mathbf{v}\|)$ is the cosine of the angle between them. The Cauchy–Schwarz inequality (Ch. 9) gives $|\langle \mathbf{u}, \mathbf{v} \rangle| \le \|\mathbf{u}\|\|\mathbf{v}\|$, with equality iff $\mathbf{v} = b\mathbf{u}$, i.e. $y_i - \bar{y} = b(x_i - \bar{x})$ for all i. $\square$

This geometric picture — **correlation is the cosine of the angle between centred data vectors** — is worth remembering: $r = 0$ means the centred vectors are orthogonal, and r^2 is the squared cosine, the fraction of $\|\mathbf{v}\|^2$ captured by projecting $\mathbf{v}$ onto $\mathbf{u}$. This is exactly the r^2 of simple linear regression (Section 20.9).

Further properties follow directly from the bilinearity of covariance:

- $\operatorname{Cov}(aX + b,\ cY + d) = ac \operatorname{Cov}(X,Y)$, so ρ is invariant to changes of units and origin (up to sign if $ac < 0$).
- $\operatorname{Var}(X \pm Y) = \operatorname{Var} X + \operatorname{Var} Y \pm 2 \operatorname{Cov}(X,Y)$.
- Independent $\Rightarrow$ uncorrelated; the converse fails in general but holds for jointly Gaussian variables (Ch. 19).

What correlation does not measure

Pearson's r measures **linear** association only. If X is symmetric about zero and $Y = X^2$, then Y is a deterministic function of X, yet $\operatorname{Cov}(X, Y) = E[X^3] - E[X]E[X^2] = 0$, so $\rho = 0$. Conversely, a strong r can be produced by a single extreme point, by mixing two groups with different means, or by a common cause (both x and y rise with ambient temperature). The four data sets of *Anscombe's quartet* share identical means, variances, $r = 0.816$ and regression lines while looking completely different when plotted. The rule is simple: never interpret r without a scatter plot.

Common Pitfall — Correlation is not causation, and not agreement

A correlation between solder-joint failures and production day of week may reflect a third variable (which operator was on shift). Separately, two instruments measuring the same voltage can have $r = 0.999$ while one reads consistently 2% high: correlation measures association, not agreement. For method comparison, analyse the *differences* $y_i - x_i$ (mean bias and its spread) instead.

Rank correlation

When the relation is monotonic but not linear, or the data contain outliers or are ordinal, replace values by their ranks.

Spearman's rank correlation

Let R_i and Q_i be the ranks of x_i among the x's and of y_i among the y's (average ranks for ties). **Spearman's** r_s is the Pearson correlation of the ranks. With no ties it simplifies to

$$r_s = 1 - \frac{6\sum_i d_i^2}{n(n^2-1)}, \qquad d_i = R_i - Q_i.$$

The shortcut follows from $\sum R_i = \sum Q_i = n(n+1)/2$ and $\sum R_i^2 = \sum Q_i^2 = n(n+1)(2n+1)/6$, which fix the means and variances of the ranks; expanding $\sum d_i^2 = \sum R_i^2 + \sum Q_i^2 - 2\sum R_i Q_i$ and substituting gives the formula. $r_s = \pm 1$ for any strictly monotonic relation, linear or not.

The covariance matrix

For a random vector $\mathbf{X} = (X_1, \dots, X_p)^{\mathsf{T}}$ with mean $\boldsymbol{\mu}$, the **covariance matrix** is

$$\boldsymbol{\Sigma} = E\big[(\mathbf{X} - \boldsymbol{\mu})(\mathbf{X} - \boldsymbol{\mu})^{\mathsf{T}}\big], \qquad \Sigma_{ij} = \operatorname{Cov}(X_i, X_j).$$

Its sample counterpart, from n observation vectors $\mathbf{x}_k$, is $\mathbf{S} = \frac{1}{n-1}\sum_k (\mathbf{x}_k - \bar{\mathbf{x}})(\mathbf{x}_k - \bar{\mathbf{x}})^{\mathsf{T}}$.

Properties of the covariance matrix

1. $\boldsymbol{\Sigma}$ is symmetric and positive semidefinite: $\mathbf{a}^{\mathsf{T}}\boldsymbol{\Sigma}\mathbf{a} = \operatorname{Var}(\mathbf{a}^{\mathsf{T}}\mathbf{X}) \geq 0$ for every $\mathbf{a}$.
2. For a linear map $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{b}$: $\boldsymbol{\Sigma}_Y = \mathbf{A}\boldsymbol{\Sigma}_X\mathbf{A}^{\mathsf{T}}$.
3. Its eigenvectors (Ch. 10) are orthogonal **principal axes**; the eigenvalues are the variances along those axes, and $\operatorname{tr}\boldsymbol{\Sigma} = \sum_i \sigma_i^2$ is the total variance.

Proof of 1 and 2. $\mathbf{a}^{\mathsf{T}}\mathbf{X}$ is a scalar random variable with mean $\mathbf{a}^{\mathsf{T}}\boldsymbol{\mu}$, so its variance is $E[(\mathbf{a}^{\mathsf{T}}(\mathbf{X} - \boldsymbol{\mu}))^2] = \mathbf{a}^{\mathsf{T}}E[(\mathbf{X} - \boldsymbol{\mu})(\mathbf{X} - \boldsymbol{\mu})^{\mathsf{T}}]\mathbf{a}$, which is non-negative because it is a variance. For 2, $\mathbf{Y} - E\mathbf{Y} = \mathbf{A}(\mathbf{X} - \boldsymbol{\mu})$, and substituting into the definition gives $\mathbf{A}\boldsymbol{\Sigma}_X\mathbf{A}^{\mathsf{T}}$. Property 3 is the spectral theorem for real symmetric matrices. $\square$

Property 2 is the matrix form of uncertainty propagation used in Section 20.10. Property 3 underlies principal component analysis: rotating to the eigenvector basis produces *uncorrelated* components, and discarding those with small eigenvalues compresses the data with minimal loss of variance. The **correlation matrix** is $\mathbf{R} = \mathbf{D}^{-1}\boldsymbol{\Sigma}\mathbf{D}^{-1}$ with $\mathbf{D} = \operatorname{diag}(\sigma_1, \dots, \sigma_p)$; it has ones on the diagonal.

Worked Example 20.6 — Correlation of an RTD calibration

A platinum RTD is calibrated at six temperatures:

T (°C)	0	20	40	60	80	100
R (Ω)	100.0	107.9	115.5	123.2	130.9	138.5

Find s_{TR} and r.

Step 1 — means. $\bar{T} = 50\ ^\circ\text{C}$, $\bar{R} = 716/6 = 119.333\ \Omega$.

Step 2 — sums of squares. $S_{TT} = 2(50^2 + 30^2 + 10^2) = 7000\ (^\circ\text{C})^2$; $S_{RR} = 1035.29\ \Omega^2$.

Step 3 — sum of products. Because $\sum(T_i - \bar{T}) = 0$, $S_{TR} = \sum(T_i - \bar{T})R_i = -50(100.0) - 30(107.9) - 10(115.5) + 10(123.2) + 30(130.9) + 50(138.5) = 2692\ \Omega\,^\circ\text{C}$.

Step 4 — covariance and correlation. $s_{TR} = 2692/5 = 538.4\ \Omega\,^\circ\text{C}$; $r = 2692/\sqrt{7000 \times 1035.29} = 0.99999$.

Interpretation. r is so close to 1 that it no longer discriminates between "linear" and "slightly curved". The physically known curvature of platinum (Callendar–Van Dusen equation) is invisible in r; it shows up only in the residuals of a fit (Section 20.9). A high r is necessary but not sufficient for a good linear model.

Worked Example 20.7 — Rank correlation of capacitor ageing

Six electrolytic capacitors have equivalent series resistance (ESR, in mΩ) and measured remaining life (kh):

ESR	3.1	2.4	4.8	1.9	3.6	5.2
Life	12	15	7	18	9	8

Step 1 — rank each variable. ESR ranks: $3, 2, 5, 1, 4, 6$. Life ranks: $4, 5, 1, 6, 3, 2$.

Step 2 — rank differences. $d_i = -1, -3, 4, -5, 1, 4$; $\sum d_i^2 = 1 + 9 + 16 + 25 + 1 + 16 = 68$.

Step 3 — Spearman. $r_s = 1 - 6(68)/(6 \cdot 35) = 1 - 408/210 = -0.943$.

Step 4 — compare. Pearson's r on the raw values is -0.939. The two agree here because the relation is roughly linear; had one capacitor failed early with a huge ESR, r would be pulled strongly while r_s would change by at most one rank.

Worked Example 20.8 — Sum and difference of correlated noise

Two amplifier channels have output noise with $\sigma_1 = 2$ mV, $\sigma_2 = 3$ mV and correlation $\rho = 0.5$ (shared supply ripple). Find the noise of the sum and of the difference, and the principal axes.

Step 1 — covariance matrix. $\mathrm{Cov} = \rho\sigma_1\sigma_2 = 3\ \mathrm{mV}^2$, so

$$\boldsymbol{\Sigma} = \begin{pmatrix} 4 & 3 \\ 3 & 9 \end{pmatrix}\ \mathrm{mV}^2.$$

Step 2 — sum. $\mathbf{a} = (1, 1)^{\mathsf{T}}$: $\mathrm{Var} = \mathbf{a}^{\mathsf{T}}\boldsymbol{\Sigma}\mathbf{a} = 4 + 9 + 2(3) = 19\ \mathrm{mV}^2$, $\sigma_{1+2} = 4.36$ mV.

Step 3 — difference. $\mathbf{a} = (1, -1)^{\mathsf{T}}$: $\mathrm{Var} = 4 + 9 - 6 = 7\ \mathrm{mV}^2$, $\sigma_{1-2} = 2.65$ mV. A differential measurement partially cancels the common component — the statistical basis of common-mode rejection.

Step 4 — principal axes. The eigenvalues solve $\lambda^2 - 13\lambda + 27 = 0$: $\lambda = (13 \pm \sqrt{61})/2 = 10.41,\ 2.59\ \mathrm{mV}^2$. The unit-norm combination with the least variance is the eigenvector of $\lambda = 2.59$, approximately $(0.91, -0.42)^{\mathsf{T}}$, with $\sigma = 1.61$ mV. (For comparison, the normalised plain difference $(1, -1)^{\mathsf{T}}/\sqrt{2}$ has variance $3.5\ \mathrm{mV}^2$.) Weighting the quieter channel more heavily cancels more of the shared ripple.

Engineering Note — Covariance in multi-channel systems

In antenna arrays, the sample covariance matrix of the element signals is the starting point of adaptive beamforming and direction-of-arrival estimation: its large eigenvalues correspond to signals and its small ones to noise. In instrumentation, the off-diagonal terms decide whether averaging two channels helps (uncorrelated noise, $\sigma/\sqrt{2}$) or barely helps (strongly correlated noise).

20.4 Common distributions

Why a catalogue

Statistical inference needs models, and a surprisingly small set of distributions covers most engineering situations. Each arises from a specific mechanism — counting successes, counting rare events, waiting for the next event, adding many small effects, taking the magnitude of a 2-D Gaussian vector, summing squared Gaussian errors — and recognising the mechanism tells you which model to use. The last three entries (χ^2, t, F) are less physical models of data than *sampling distributions*: they describe statistics computed from Gaussian samples and are the workhorses of Sections 20.7–20.8.

General definitions (pmf, pdf, CDF, expectation, moment generating function $M_X(s) = E[e^{sX}]$) are in Ch. 19. For each distribution below we give the mechanism, the pmf or pdf, the mean and variance, and where it appears in EE.

Bernoulli distribution

Bernoulli(p)

$X \in \{0, 1\}$ with $P(X = 1) = p$, $P(X = 0) = 1 - p$. Then $E[X] = p$, $\mathrm{Var}(X) = p(1 - p)$, $M_X(s) = 1 - p + pe^s$.

The variance follows from $X^2 = X$: $E[X^2] = p$, so $\mathrm{Var}\,X = p - p^2$. It is maximal, $1/4$, at $p = 1/2$ — the worst case used for sample-size planning of proportions (Section 20.7). Models: one transmitted bit is in error or not; one device passes or fails test; one photon is detected or not.

Binomial distribution

Binomial(n, p)

The number of successes in n independent Bernoulli(p) trials:

$$P(X = k) = \binom{n}{k} p^k (1 - p)^{n-k}, \qquad k = 0, 1, \ldots, n,$$

with $E[X] = np$, $\mathrm{Var}(X) = np(1 - p)$, $M_X(s) = (1 - p + pe^s)^n$.

Derivation. Any particular sequence with k successes has probability $p^k(1-p)^{n-k}$, and there are $\binom{n}{k}$ such sequences. Writing $X = \sum_{i=1}^{n} B_i$ with independent Bernoulli B_i, linearity gives $E[X] = np$ and independence gives $\operatorname{Var} X = np(1-p)$; the MGF is the nth power of the Bernoulli MGF because MGFs of independent sums multiply. The pmf is unimodal with mode at $\lfloor (n+1)p \rfloor$.

Poisson distribution

Poisson(λ)

$$P(X = k) = \frac{\lambda^k e^{-\lambda}}{k!}, \qquad k = 0, 1, 2, \ldots,$$

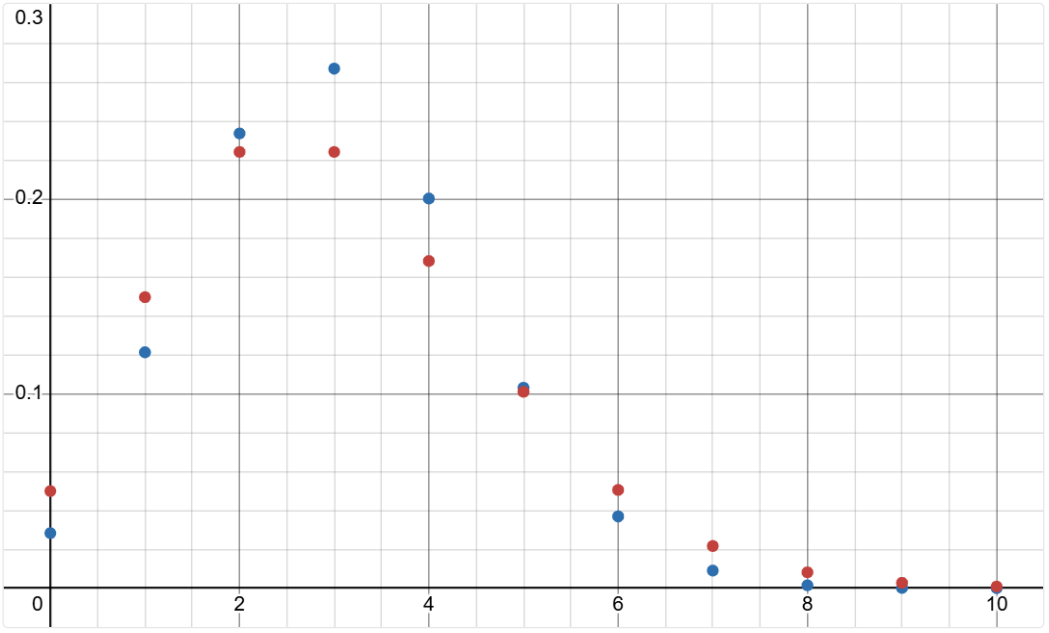
with $E[X] = \operatorname{Var}(X) = \lambda$ and $M_X(s) = \exp\big(\lambda(e^s - 1)\big)$.

Poisson limit of the binomial

If $n \to \infty$ and $p \to 0$ with $np = \lambda$ fixed, then $\binom{n}{k} p^k (1-p)^{n-k} \to \lambda^k e^{-\lambda}/k!$.

Proof sketch. $\binom{n}{k} p^k = \frac{n(n-1)\cdots(n-k+1)}{n^k} \frac{\lambda^k}{k!} \to \frac{\lambda^k}{k!}$, and $(1-\lambda/n)^{n-k} \to e^{-\lambda}$. Equivalently, the binomial MGF $(1 + p(e^s - 1))^n = (1 + \lambda(e^s - 1)/n)^n \to e^{\lambda(e^s - 1)}$. $\square$

So the Poisson law describes the count of *rare, independent* events in a fixed interval: electrons crossing a junction (shot noise), photons on a detector, radioactive decays, packet arrivals on a lightly loaded link, soft errors in a memory over a day. The equality of mean and variance is a useful diagnostic: count data whose variance greatly exceeds the mean are *overdispersed* (clustered events), and a plain Poisson model will underestimate their variability.



Binomial$(10, 0.3)$ pmf (blue) and Poisson(3) pmf (red): equal means, but the Poisson has variance 3 against the binomial's 2.1, so it is flatter with a longer right tail.

Uniform distribution

Uniform(a, b)

$$f_X(x) = \frac{1}{b-a} \quad (a \le x \le b), \qquad E[X] = \frac{a+b}{2}, \qquad \operatorname{Var}(X) = \frac{(b-a)^2}{12}.$$

Derivation of the variance. Centre at zero with half-width $c = (b-a)/2$: $\operatorname{Var} X = \frac{1}{2c}\int_{-c}^{c} x^2\,dx = \frac{c^2}{3} = \frac{(b-a)^2}{12}$.

The uniform law models complete ignorance within known bounds. Two cases matter enormously in EE. **Quantisation error** of an ideal ADC with step Δ is (under mild conditions) uniform on $[-\Delta/2, \Delta/2]$, with variance $\Delta^2/12$ — the source of the familiar $6.02N + 1.76$ dB SNR formula. **Type B uncertainty** from a manufacturer's "$\pm a$" specification is modelled as uniform on $[-a, a]$, giving standard uncertainty $a/\sqrt{3}$ (Section 20.10). The random phase of an unsynchronised oscillator is uniform on $[0, 2\pi)$.

Exponential distribution

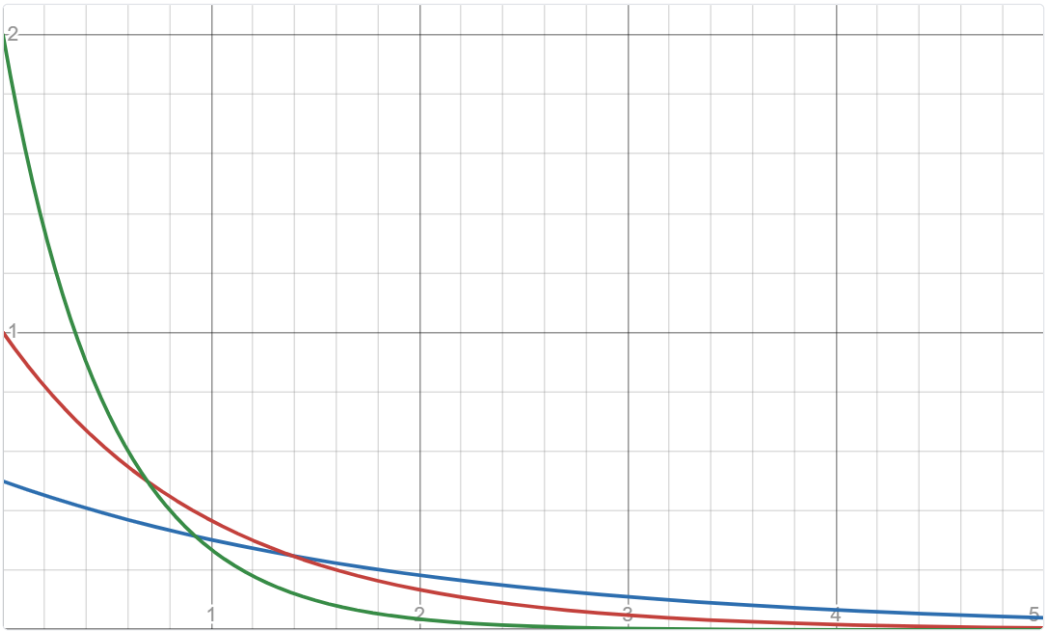
Exponential(λ)

$$f_X(x) = \lambda e^{-\lambda x} \ (x \ge 0), \qquad F_X(x) = 1 - e^{-\lambda x}, \qquad E[X] = \frac{1}{\lambda}, \qquad \operatorname{Var}(X) = \frac{1}{\lambda^2}.$$

It is the waiting time to the first event of a Poisson process of rate λ: $P(X > x) = P(\text{no events in } [0, x]) = e^{-\lambda x}$. It is the only continuous distribution with the **memoryless property**

$$P(X > s+t \mid X > s) = \frac{e^{-\lambda(s+t)}}{e^{-\lambda s}} = e^{-\lambda t} = P(X > t).$$

In reliability engineering, λ is a constant **failure rate** (failures per hour, or FIT = failures per 10^9 device-hours) and $1/\lambda$ is the **MTBF** (mean time between failures). Memorylessness means a working part is "as good as new" — appropriate for the flat bottom of the bathtub curve (random failures), wrong for wear-out (electrolytic capacitors, fans, relays), which is modelled by the Weibull distribution instead.



Exponential pdfs for $\lambda = 0.5$ (blue), 1 (red) and 2 (green). The pdf starts at λ and decays with time constant $1/\lambda$ — the same shape as an RC discharge.

Gaussian (normal) distribution

Gaussian $\mathcal{N}(\mu, \sigma^2)$

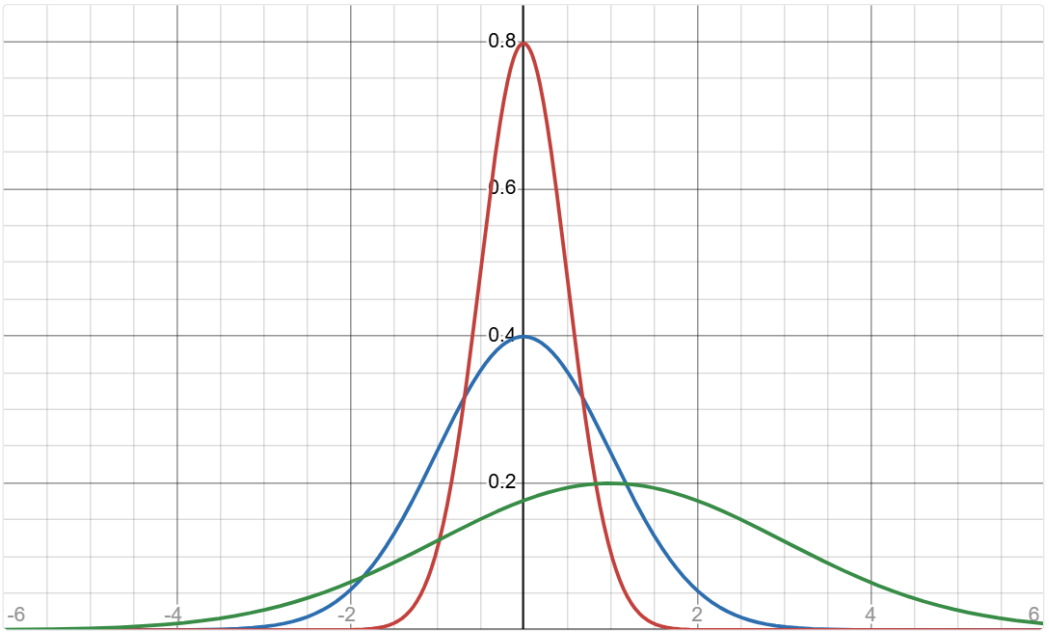
$$f_X(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\!\left(-\frac{(x-\mu)^2}{2\sigma^2}\right), \qquad E[X] = \mu, \quad \operatorname{Var}(X) = \sigma^2, \quad M_X(s) = e^{\mu s + \sigma^2 s^2/2}.$$

The **standard** Gaussian $Z \sim \mathcal{N}(0,1)$ has CDF $\Phi(z)$; engineers usually use the tail function $Q(z) = 1 - \Phi(z) = P(Z > z)$.

Any Gaussian is standardised by $Z = (X-\mu)/\sigma$, so $P(X > x) = Q\big((x-\mu)/\sigma\big)$. Key values: $P(|Z| \le 1) = 0.6827$, $P(|Z| \le 2) = 0.9545$, $P(|Z| \le 3) = 0.9973$ (the "68–95–99.7 rule"); $Q(1.645) = 0.05$, $Q(1.960) = 0.025$, $Q(2.576) = 0.005$, $Q(3) = 1.35 \times 10^{-3}$. For large z, $Q(z) \approx \frac{1}{z\sqrt{2\pi}} e^{-z^2/2}$.

Three facts make the Gaussian central:

1. **Closure under linear operations.** Any linear combination of jointly Gaussian variables is Gaussian; the output of an LTI system driven by Gaussian noise is Gaussian (Ch. 21).
2. **The central limit theorem** (Section 20.5): sums of many small independent effects are approximately Gaussian, which is why thermal noise, aggregate manufacturing variation and many measurement errors are Gaussian.
3. **Maximum entropy.** Among all distributions with given mean and variance, the Gaussian has the largest entropy — it is the "least committal" model consistent with knowing only two moments.



Gaussian pdfs: $\mathcal{N}(0,1)$ (blue), $\mathcal{N}(0,0.25)$ (red) and $\mathcal{N}(1,4)$ (green). Halving σ doubles the peak height; the area stays 1.

Rayleigh distribution

Rayleigh(σ)

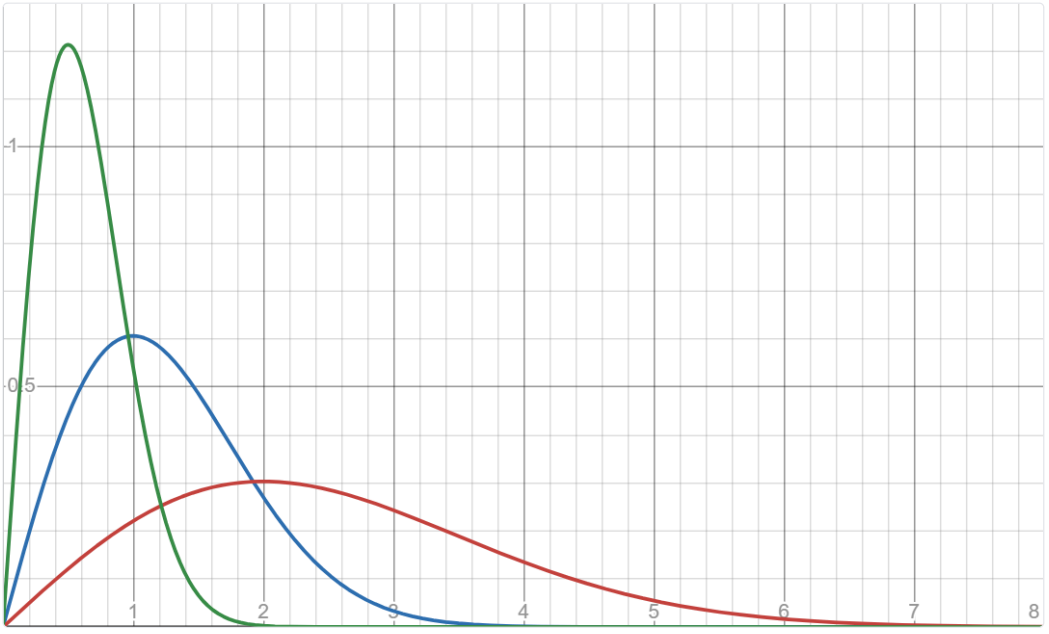
If X, Y are independent $\mathcal{N}(0,\sigma^2)$, then $R = \sqrt{X^2+Y^2}$ has

$$f_R(r) = \frac{r}{\sigma^2} e^{-r^2/(2\sigma^2)} \ (r \geq 0), \qquad P(R > r) = e^{-r^2/(2\sigma^2)},$$

$$E[R] = \sigma\sqrt{\pi/2} \approx 1.253\sigma, \qquad E[R^2] = 2\sigma^2, \qquad \mathrm{Var}(R) = \left(2 - \frac{\pi}{2}\right)\sigma^2 \approx 0.429\sigma^2.$$

Derivation. In polar coordinates (r,ϕ) the joint pdf $\frac{1}{2\pi\sigma^2} e^{-(x^2+y^2)/(2\sigma^2)}$ becomes, with the Jacobian r (Ch. 6), $\frac{r}{2\pi\sigma^2} e^{-r^2/(2\sigma^2)}$. Integrating out $\phi \in [0, 2\pi)$ gives f_R; the phase is uniform and independent of R. The moments follow from $\int_0^\infty r^2 e^{-r^2/(2\sigma^2)} dr = \sigma^3\sqrt{\pi/2}$.

The Rayleigh law is the **envelope of narrowband Gaussian noise** (in-phase and quadrature components are independent Gaussians) and the amplitude of a **multipath-faded** radio signal with no line-of-sight path. R^2 is exponential with mean $2\sigma^2$, so the *power* of a Rayleigh-faded signal is exponentially distributed. Adding a deterministic component gives the Rician distribution.



Rayleigh pdfs for $\sigma = 1$ (blue), $\sigma = 2$ (red) and $\sigma = 0.5$ (green). The mode is at $r = \sigma$; the long right tail is the occasional noise peak that triggers a false alarm.

Chi-square distribution

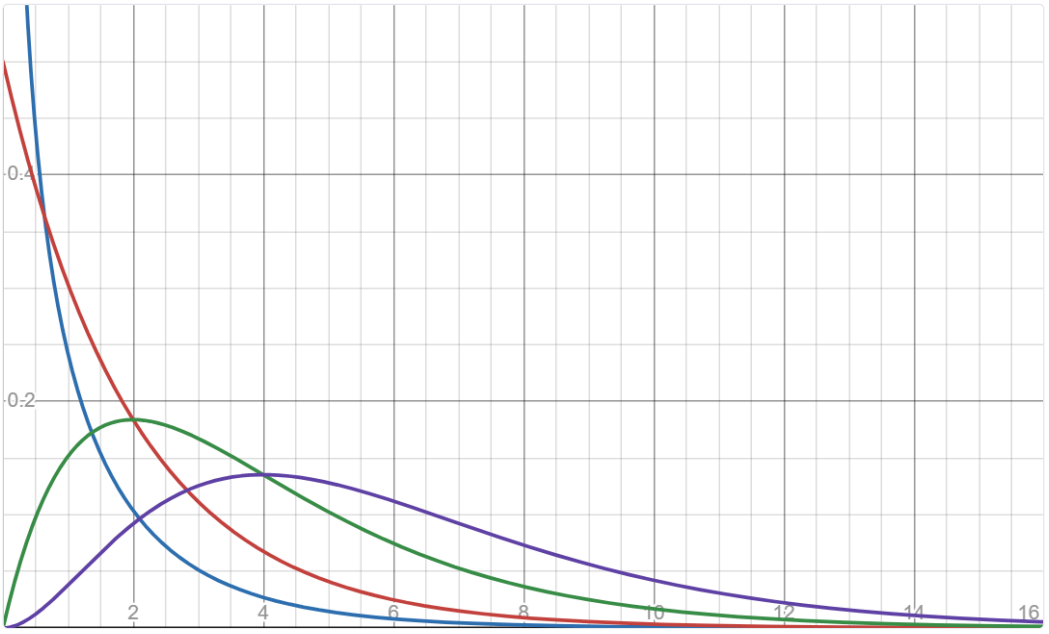
Chi-square χ^2_k

If $Z_1, \dots, Z_k$ are independent $\mathcal{N}(0,1)$, then $Q = \sum_{i=1}^{k} Z_i^2$ has the chi-square distribution with k **degrees of freedom**:

$$f_Q(q) = \frac{q^{k/2-1} e^{-q/2}}{2^{k/2}\Gamma(k/2)} \ (q > 0), \qquad E[Q] = k, \qquad \mathrm{Var}(Q) = 2k, \qquad M_Q(s) = (1-2s)^{-k/2}.$$

Derivation of the moments. For one term, $E[Z^2] = 1$ and $E[Z^4] = 3$, so $\mathrm{Var}(Z^2) = 2$; adding k independent terms gives mean k and variance $2k$. The MGF of Z^2 is $\int \frac{1}{\sqrt{2\pi}} e^{sz^2 - z^2/2} dz = (1-2s)^{-1/2}$, and the kth power gives M_Q, which is the MGF of a gamma distribution with shape $k/2$ and scale 2 — hence the pdf.

Special cases tie the catalogue together: χ^2_2 is exponential with mean 2, and $\sqrt{\chi^2_2} \cdot \sigma$ is Rayleigh. χ^2_k is skewed right for small k and approaches $\mathcal{N}(k, 2k)$ as $k \to \infty$ (CLT). In EE it describes **noise power estimates** (a sum of squared Gaussian samples), **energy detectors** in spectrum sensing, and, most importantly for this chapter, the sample variance of Gaussian data (Section 20.5) and goodness-of-fit statistics (Section 20.8).



Chi-square pdfs for $k = 1$ (blue), 2 (red), 4 (green) and 6 (purple). For $k \geq 3$ the mode is at $k - 2$; the distributions spread and become more symmetric as k grows.

Student's t distribution

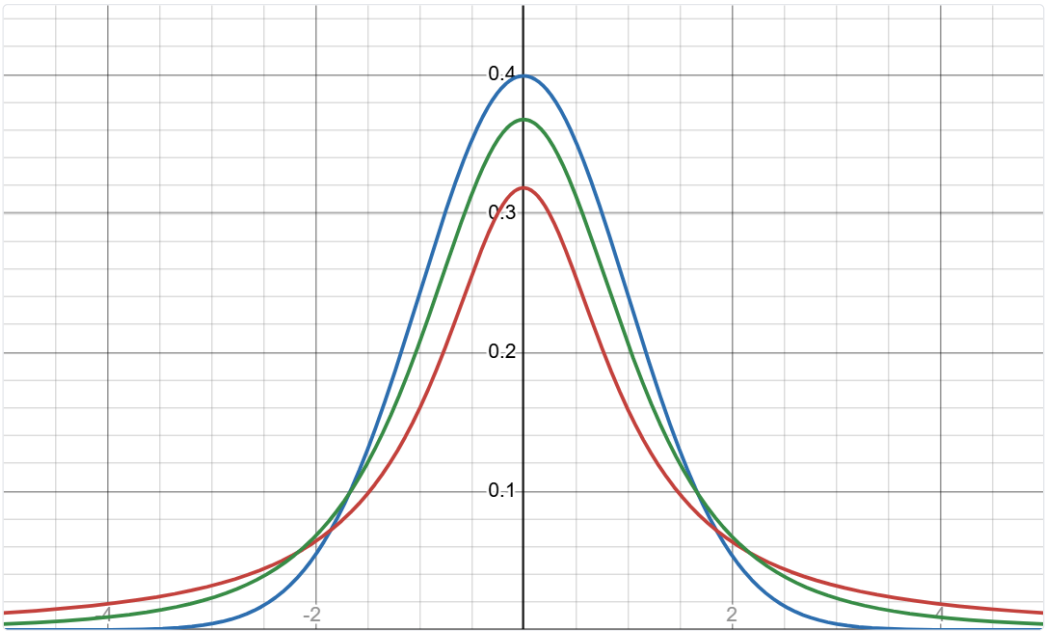
Student's t_ν

If $Z \sim \mathcal{N}(0,1)$ and $V \sim \chi^2_\nu$ are independent, then $T = Z / \sqrt{V/\nu}$ has the t distribution with ν degrees of freedom:

$$f_T(t) = \frac{\Gamma\left(\frac{\nu+1}{2}\right)}{\sqrt{\nu\pi}\,\Gamma\left(\frac{\nu}{2}\right)} \left(1 + \frac{t^2}{\nu}\right)^{-(\nu+1)/2},$$

with $E[T] = 0$ ($\nu > 1$) and $\mathrm{Var}(T) = \nu/(\nu-2)$ ($\nu > 2$).

The t distribution is what a standardised Gaussian becomes when the unknown σ is replaced by an estimate from ν degrees of freedom. The extra randomness of the estimate fattens the tails: with $\nu = 3$, $P(|T| > 3) = 0.058$, versus 0.0027 for the Gaussian — a factor of 21. As $\nu \to \infty$, $V/\nu \to 1$ and $t_\nu \to \mathcal{N}(0,1)$. The two-sided 95% critical value $t_{0.025,\nu}$ is 12.71 for $\nu = 1$, 3.18 for $\nu = 3$, 2.57 for $\nu = 5$, 2.23 for $\nu = 10$ and 2.04 for $\nu = 30$, against 1.96 for the Gaussian. The case $\nu = 1$ is the Cauchy distribution, which has no mean at all: averaging Cauchy samples does not reduce their spread.



Student t pdfs for $\nu = 1$ (red, Cauchy) and $\nu = 3$ (green) against $\mathcal{N}(0,1)$ (blue). Lower peaks, heavier tails: small samples must use wider intervals.

The F distribution

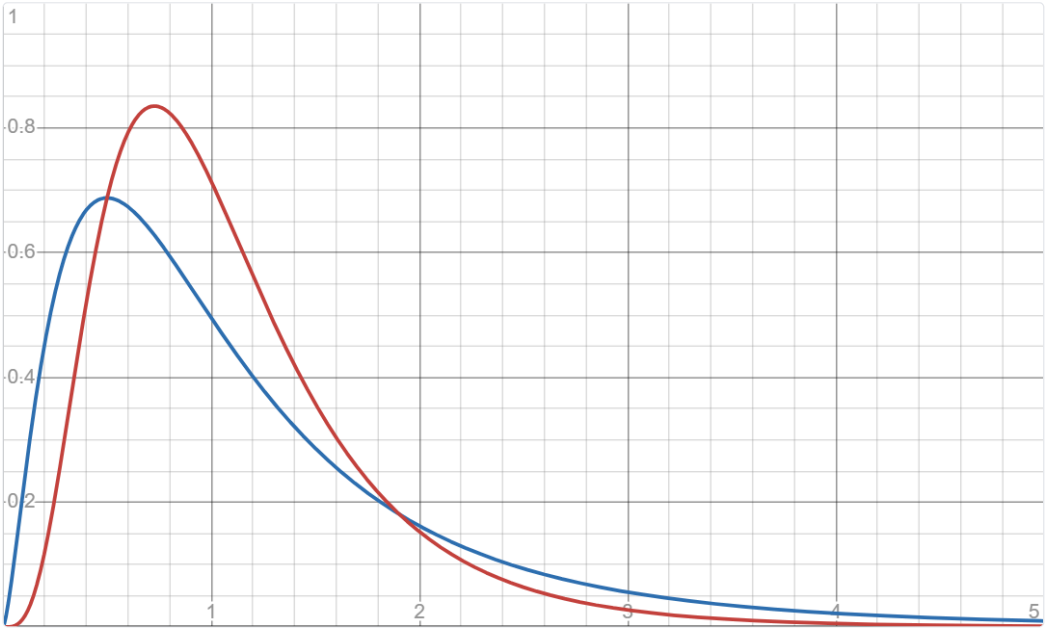
Fisher–Snedecor F_{d_1,d_2}

If $U \sim \chi^2_{d_1}$ and $V \sim \chi^2_{d_2}$ are independent, $F = \dfrac{U/d_1}{V/d_2}$ has pdf

$$f(x) = \frac{(d_1/d_2)^{d_1/2}}{B(d_1/2, d_2/2)}\, x^{d_1/2-1}\left(1 + \frac{d_1}{d_2}x\right)^{-(d_1+d_2)/2} \qquad (x > 0),$$

with $E[F] = d_2/(d_2 - 2)$ for $d_2 > 2$; B is the beta function.

F is the distribution of a **ratio of two independent variance estimates** from Gaussian data, normalised by their degrees of freedom; it is used to compare the noise of two instruments (Section 20.8) and to test the significance of regression models (Section 20.9). Useful identities: $1/F_{d_1,d_2} \sim F_{d_2,d_1}$, so lower critical values follow from upper ones, and $t_\nu^2 \sim F_{1,\nu}$.



F pdfs for $(d_1, d_2) = (5, 10)$ (blue) and $(10, 20)$ (red). Both concentrate near 1 — the value expected when two variance estimates agree — and tighten as the degrees of freedom grow.

Relations between the distributions

From	Operation	Gives
n independent Bernoulli(p)	sum	Binomial(n, p)

From	Operation	Gives
Binomial(n,p)	$n\to\infty$, $np=\lambda$	Poisson(λ)
Binomial, Poisson	large $np(1-p)$, large λ	Gaussian (CLT)
Poisson process rate λ	time to first event	Exponential(λ)
Two independent $\mathcal{N}(0,\sigma^2)$	magnitude $\sqrt{X^2+Y^2}$	Rayleigh(σ)
k independent $\mathcal{N}(0,1)$	sum of squares	χ^2_k
$\chi^2_2/2$	—	Exponential(1)
$\mathcal{N}(0,1)$ and χ^2_ν	$Z/\sqrt{V/\nu}$	t_ν
$\chi^2_{d_1}$ and $\chi^2_{d_2}$	ratio of normalised	F_{d_1,d_2}
Uniform$(0,1)$	$-\ln(U)/\lambda$	Exponential(λ)

The last line is the **inverse-transform method** for generating random numbers (Ch. 24): if F is a continuous CDF and U is uniform, $F^{-1}(U)$ has CDF F.

Worked Example 20.9 — Packet errors: binomial versus Poisson

A 100-bit packet is sent over a channel with independent bit errors of probability $p=0.01$. The error-correcting code fixes up to 2 bit errors. Find the probability that a packet is lost.

Step 1 — model. The number of bit errors is $X\sim\text{Binomial}(100,0.01)$; a packet is lost if $X\ge 3$.

Step 2 — exact. $P(X=0)=0.99^{100}=0.36603$; $P(X=1)=100(0.01)(0.99)^{99}=0.36973$; $P(X=2)=\binom{100}{2}(0.01)^2(0.99)^{98}=0.18486$. So $P(X\ge 3)=1-0.92063=0.0794$.

Step 3 — Poisson approximation. $\lambda=np=1$: $P(X\ge 3)\approx 1-e^{-1}(1+1+\tfrac12)=1-2.5e^{-1}=0.0803$.

Step 4 — comment. The approximation is within 1.2% (relative). Without the code, a packet would be lost whenever $X\ge 1$, with probability 0.634; the code reduces the loss rate by a factor of 8.

Worked Example 20.10 — Photon counting

A photodetector registers on average $\lambda=4$ photons per 1 ms gate. Find (a) the probability of an empty gate, (b) the probability of 8 or more counts, (c) the signal-to-noise ratio of a count.

(a) $P(X=0)=e^{-4}=0.0183$.

(b) $P(X\ge 8)=1-\sum_{k=0}^{7}e^{-4}4^k/k!=0.0511$. Doubling the mean count happens in 5% of gates purely by chance — the irreducible **shot noise** of light.

(c) Mean 4, standard deviation $\sqrt{4}=2$, so SNR $=\lambda/\sqrt{\lambda}=\sqrt{\lambda}=2$. To improve SNR by a factor of 10 one must collect 100 times more photons (longer gate or larger aperture): shot-noise-limited SNR grows only as the square root of signal.

Worked Example 20.11 — Reliability with exponential lifetimes

A power module has constant failure rate $\lambda=2\times10^{-5}\ \text{h}^{-1}$ (MTBF $=50\,000$ h).

(a) One-year survival. $P(T>8760\ \text{h})=e^{-8760/50000}=e^{-0.1752}=0.839$.

(b) Survival to the MTBF. $P(T>50\,000)=e^{-1}=0.368$: only 37% of units reach the MTBF — the MTBF is a mean, not a typical life.

(c) Memorylessness. Given a module has already run 3 years, the probability it survives one more year is still 0.839. Burn-in therefore does nothing for exponential lifetimes; it helps only when early failures (decreasing hazard rate) are present.

(d) Series system. Ten independent modules, all required: the system lifetime is the minimum of ten exponentials, which is exponential with rate 10λ, so $\text{MTBF}_{\text{sys}}=5000$ h.

Worked Example 20.12 — Gaussian yield and Rayleigh false alarms

(a) Yield. Resistor values are $\mathcal{N}(1000\ \Omega,\ (4\ \Omega)^2)$. The fraction inside a $\pm1\%$ tolerance band (990–1010 Ω) is $P(|Z|\le 10/4)=1-2Q(2.5)=1-2(0.00621)=0.9876$, i.e. 1.24% rejects.

(b) False alarms. A radar detector compares the envelope of receiver noise with a threshold. The I and Q noise components are each $\mathcal{N}(0,\sigma^2)$ with $\sigma=1$ mV, so the envelope is Rayleigh(1 mV). For a threshold of 3 mV, $P_{\text{FA}}=e^{-9/2}=0.0111$. To achieve $P_{\text{FA}}=10^{-6}$ the threshold must be $\sigma\sqrt{2\ln 10^6}=5.26$ mV. Note how slowly the threshold grows: a millionfold reduction in false alarms costs less than a doubling of threshold.

Common Pitfall — Assuming Gaussian tails far from the mean

Real component distributions are often truncated (parts outside tolerance were screened out) or have heavier tails than Gaussian. Predicting a 10^{-9} failure rate from a Gaussian fitted to 50 samples extrapolates far beyond the data; at 6σ the answer depends entirely on the assumed tail shape. Tail probabilities should be supported by data or by physics, not by the convenience of the Gaussian formula.

Engineering Note — Matching mechanism to model

Ask what generates the data. Counting events in a fixed window: binomial (fixed n) or Poisson (no natural n). Time between events: exponential (no ageing) or Weibull (ageing). Sum of many small effects: Gaussian. Magnitude of a 2-D Gaussian: Rayleigh. Product of many small factors (component values after several process steps): lognormal, since the logarithm is a sum.

20.5 Sampling

Statistics are random variables

A sample mean computed today from 16 readings will differ from one computed tomorrow from another 16. Before the data are taken, every statistic $T = g(X_1, \dots, X_n)$ is a random variable, and its distribution — the **sampling distribution** — tells us how far T is likely to be from the quantity it is meant to estimate. All of inference rests on this idea: a confidence interval is a statement about the sampling distribution of an estimator, and a hypothesis test compares an observed statistic with its sampling distribution under a hypothesis.

Random sample

$X_1, \dots, X_n$ is a **random sample** (i.i.d. sample) from a distribution F if the X_i are independent and each has CDF F. The **standard error** of a statistic is the standard deviation of its sampling distribution.

Independence is a physical assumption, not a mathematical gift. Readings taken faster than the correlation time of the noise (Ch. 21), units taken consecutively from one reel, or repeated measurements without re-seating a probe are *not* independent, and the formulas below then understate the true variability.

Sampling distribution of the mean

Mean and variance of the sample mean

If $X_1, \dots, X_n$ is a random sample from a distribution with mean μ and variance σ^2, then

$$E[\bar{X}] = \mu, \qquad \operatorname{Var}(\bar{X}) = \frac{\sigma^2}{n}, \qquad \operatorname{SE}(\bar{X}) = \frac{\sigma}{\sqrt{n}}.$$

If the sample is from $\mathcal{N}(\mu, \sigma^2)$, then $\bar{X} \sim \mathcal{N}(\mu, \sigma^2/n)$ exactly.

Proof. Linearity of expectation gives $E[\bar{X}] = \frac{1}{n}\sum E[X_i] = \mu$. Independence lets variances add: $\operatorname{Var}(\sum X_i) = n\sigma^2$, and dividing by n^2 gives σ^2/n. A linear combination of independent Gaussians is Gaussian. □

The $1/\sqrt{n}$ **law** is the most important scaling in measurement: averaging four readings halves the noise, averaging a hundred reduces it tenfold. It is the statistical reason a lock-in amplifier, a signal averager on an oscilloscope, or a long integration time on a DMM improves resolution — and the reason improvement becomes expensive: each extra decimal digit costs a factor of 100 in measurement time.

If the readings are correlated with correlation coefficient ρ_k between samples k apart, the variance of the mean becomes

$$\operatorname{Var}(\bar{X}) = \frac{\sigma^2}{n}\left[1 + 2\sum_{k=1}^{n-1}\left(1 - \frac{k}{n}\right)\rho_k\right],$$

so positive correlation inflates the standard error. The ratio $n_{\text{eff}} = n/[\,\cdot\,]$ is the **effective number of independent samples**. For first-order (exponentially correlated) noise with $\rho_k = a^k$ and large n, $n_{\text{eff}} \approx n(1-a)/(1+a)$.

Finite populations. When sampling *without replacement* n items from a finite lot of N, the variance of the mean is multiplied by the finite-population correction $(N-n)/(N-1)$. It matters only when the sample is a sizeable fraction of the lot (more than about 5%).

The central limit theorem

The Gaussian result above needs Gaussian data. The CLT says that for *any* distribution with finite variance, the mean of a large sample is approximately Gaussian anyway.

Central limit theorem (Lindeberg–Lévy)

Let $X_1, X_2, \dots$ be i.i.d. with mean μ and finite variance $\sigma^2 > 0$. Then the standardised mean

$$Z_n = \frac{\bar{X}_n - \mu}{\sigma/\sqrt{n}} = \frac{\sum_{i=1}^{n} X_i - n\mu}{\sigma\sqrt{n}}$$

converges in distribution to $\mathcal{N}(0,1)$: $P(Z_n \le z) \to \Phi(z)$ for every z.

Proof sketch (via characteristic functions). Let $Y_i = (X_i - \mu)/\sigma$, so $E[Y_i] = 0$, $E[Y_i^2] = 1$, and let $\varphi(\omega) = E[e^{j\omega Y}]$ be their common characteristic function (the Fourier transform of the pdf, Ch. 16). A Taylor expansion about $\omega = 0$ gives

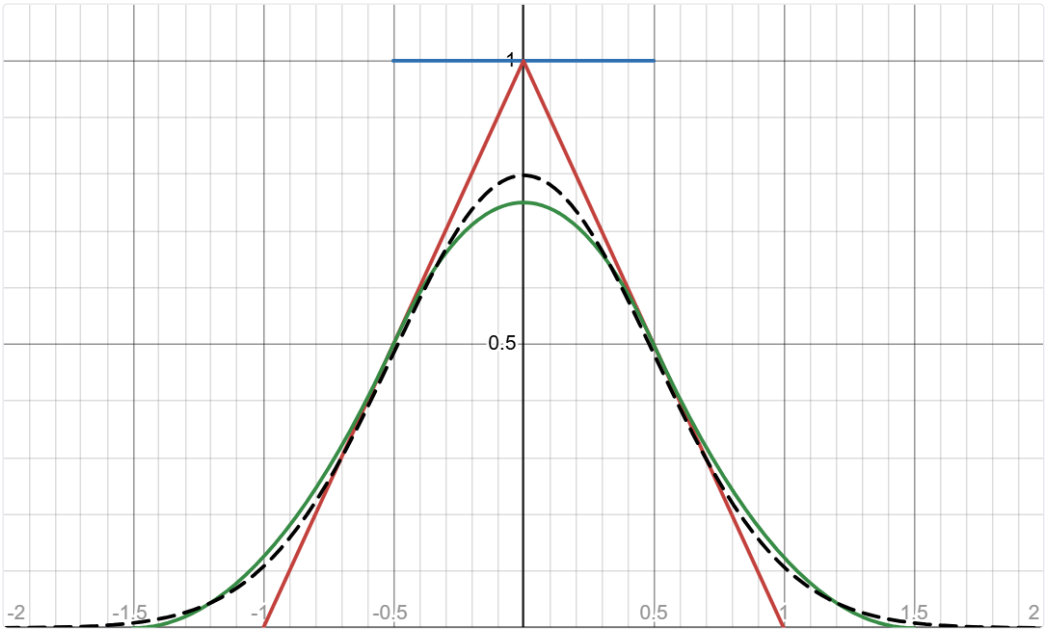
$$\varphi(\omega) = 1 + j\omega E[Y] - \frac{\omega^2}{2}E[Y^2] + o(\omega^2) = 1 - \frac{\omega^2}{2} + o(\omega^2).$$

Since $Z_n = \frac{1}{\sqrt{n}}\sum Y_i$ and characteristic functions of independent sums multiply,

$$\varphi_{Z_n}(\omega) = \Big[\varphi\Big(\frac{\omega}{\sqrt{n}}\Big)\Big]^n = \Big[1 - \frac{\omega^2}{2n} + o\Big(\frac{1}{n}\Big)\Big]^n \longrightarrow e^{-\omega^2/2},$$

which is the characteristic function of $\mathcal{N}(0,1)$. Lévy's continuity theorem converts convergence of characteristic functions into convergence of CDFs. □

In signal terms: the pdf of a sum is the *convolution* of the individual pdfs (Ch. 19), and repeated convolution of any reasonable pulse with itself tends to a Gaussian shape. The figure shows this for uniform pdfs, whose repeated convolutions (the Irwin–Hall densities) are piecewise polynomials.



Pdf of the centred sum of n independent Uniform$(0,1)$ variables: $n=1$ (blue), $n=2$ (red, triangle), $n=3$ (green, piecewise quadratic), against the Gaussian with the $n=3$ variance $3/12 = 0.25$ (dashed). Three uniforms are already close to Gaussian.

How large must n be? The **Berry–Esseen theorem** bounds the error: $\sup_z |P(Z_n \le z) - \Phi(z)| \le C\rho/(\sigma^3\sqrt{n})$ with $\rho = E|X-\mu|^3$ and $C < 0.48$. The convergence is fast for symmetric, light-tailed data (uniform: $n \approx 3$–5 suffices for the centre of the distribution), slow for skewed data (exponential, lognormal: n of 30–50), and fails for distributions without finite variance (Cauchy). The approximation is always worst in the far tails — the CLT is a statement about the *bulk* of the distribution.

The CLT also explains the **normal approximation to the binomial and Poisson**: a Binomial(n,p) count is a sum of n Bernoullis, so it is approximately $\mathcal{N}(np, np(1-p))$ when $np(1-p) \gtrsim 10$; a Poisson(λ) count is approximately $\mathcal{N}(\lambda,\lambda)$ for $\lambda \gtrsim 10$. A **continuity correction** (evaluating at $k \pm \tfrac{1}{2}$) improves the approximation for integer counts.

Sampling distribution of the variance

For Gaussian samples the sample variance has an exact distribution, and it is independent of the sample mean.

Sampling theorem for Gaussian samples

If $X_1, \dots, X_n$ is a random sample from $\mathcal{N}(\mu, \sigma^2)$, then

1. $\bar{X}$ and S^2 are independent;
2. $\dfrac{(n-1)S^2}{\sigma^2} \sim \chi^2_{n-1}$;
3. $T = \dfrac{\bar{X} - \mu}{S/\sqrt{n}} \sim t_{n-1}$.

Proof sketch. Choose an orthogonal matrix $\mathbf{Q}$ (Ch. 9) whose first row is $(1,\dots,1)/\sqrt{n}$, and set $\mathbf{Y} = \mathbf{Q}(\mathbf{X} - \mu\mathbf{1})/\sigma$. Because $\mathbf{Q}$ is orthogonal and the $(X_i-\mu)/\sigma$ are i.i.d. $\mathcal{N}(0,1)$, the Y_i are again i.i.d. $\mathcal{N}(0,1)$ (the covariance $\mathbf{QIQ}^{\mathsf{T}} = \mathbf{I}$). Now $Y_1 = \sqrt{n}(\bar{X}-\mu)/\sigma$, and since $\|\mathbf{Y}\|^2 = \|(\mathbf{X}-\mu\mathbf{1})/\sigma\|^2$,

$$\sum_{i=2}^{n} Y_i^2 = \frac{1}{\sigma^2}\Big[\sum_i (X_i-\mu)^2 - n(\bar{X}-\mu)^2\Big] = \frac{(n-1)S^2}{\sigma^2}.$$

So $\bar{X}$ depends only on Y_1 and S^2 only on $Y_2, \dots, Y_n$, giving independence (1), and $(n-1)S^2/\sigma^2$ is a sum of $n-1$ squared standard Gaussians, giving (2). Then $T = Y_1 / \sqrt{\chi^2_{n-1}/(n-1)}$, which is t_{n-1} by definition (3). □

The rotation argument shows geometrically where the "lost" degree of freedom goes: one dimension of the n-dimensional data space (the direction of $\mathbf{1}$) is used by the mean.

Consequences: $\operatorname{Var}(S^2) = 2\sigma^4/(n-1)$, so the relative standard uncertainty of S^2 is $\sqrt{2/(n-1)}$ and that of S is about $1/\sqrt{2(n-1)}$. With $n=10$ readings, s is uncertain by about 24%; with $n=50$, by 10%. Standard deviations estimated from a handful of readings are themselves very uncertain — which is precisely why the t distribution, rather than the Gaussian, is used for small samples.

Common Pitfall — Point 2 needs Gaussian data

The χ^2 result for S^2 is *not* protected by the CLT. For heavy-tailed data the variance of S^2 is $\sigma^4\left(\frac{2}{n-1}+\frac{\kappa}{n}\right)$ with κ the excess kurtosis, which can be much larger than the Gaussian value. Intervals and tests for variances (Sections 20.7–20.8) are therefore far less robust than those for means.

Two-sample statistics

For independent Gaussian samples of sizes n_1, n_2 with variances σ_1^2, σ_2^2:

$$\bar{X}_1 - \bar{X}_2 \sim \mathcal{N}\left(\mu_1-\mu_2,\ \frac{\sigma_1^2}{n_1}+\frac{\sigma_2^2}{n_2}\right), \qquad \frac{S_1^2/\sigma_1^2}{S_2^2/\sigma_2^2} \sim F_{n_1-1,\,n_2-1}.$$

The second result follows directly from the definition of F as a ratio of independent normalised chi-squares.

Sample proportions

If $X \sim \text{Binomial}(n,p)$ counts defectives in a sample, the sample proportion $\hat{p} = X/n$ has $E[\hat{p}] = p$ and $\text{SE}(\hat{p}) = \sqrt{p(1-p)/n}$, and is approximately Gaussian for $np(1-p) \gtrsim 10$.

Worked Example 20.13 — How much averaging is enough?

An ADC channel has Gaussian reading noise with $\sigma = 5$ mV.

(a) For a 16-reading average, $\text{SE} = 5/\sqrt{16} = 1.25$ mV, and $P(|\bar{X}-\mu| > 2\text{ mV}) = 2Q(2/1.25) = 2Q(1.6) = 0.110$.

(b) To make the standard error at most 0.5 mV we need $\sigma/\sqrt{n} \le 0.5$, i.e. $n \ge (5/0.5)^2 = 100$ readings.

(c) If the readings are correlated with $\rho_k = 0.6^k$ (the noise is lowpass-filtered before sampling), the effective sample size is only $n_{\text{eff}} \approx n(0.4/1.6) = n/4$. One then needs about 400 readings — or, better, should sample more slowly so that successive readings become independent.

Worked Example 20.14 — CLT for skewed lifetimes

Component lifetimes are exponential with mean 1000 h (so $\sigma = 1000$ h). A life test runs 40 parts. Find the probability that the sample mean lifetime is below 800 h.

Step 1 — CLT. $\text{SE} = 1000/\sqrt{40} = 158.1$ h. $P(\bar{X} < 800) \approx \Phi\big((800-1000)/158.1\big) = \Phi(-1.265) = 0.103$.

Step 2 — exact. A sum of 40 independent exponentials is gamma distributed (shape 40, scale 1000), so $\bar{X}$ is gamma with shape 40 and scale 25; its CDF at 800 gives 0.0956.

Step 3 — comment. The CLT answer is about 8% high in relative terms because the exponential is strongly skewed; the true distribution of $\bar{X}$ is still slightly right-skewed at $n = 40$. For a quick engineering estimate the CLT is adequate; for an acceptance test with contractual consequences, use the exact distribution.

Worked Example 20.15 — Distribution of a noise-variance estimate

A noise generator is specified as $\sigma^2 = 4\ \text{mV}^2$. From $n = 10$ Gaussian samples, what is the probability that the estimate s^2 exceeds $6\ \text{mV}^2$, even though the generator meets specification?

Step 1 — pivot. $(n-1)S^2/\sigma^2 = 9S^2/4 \sim \chi^2_9$.

Step 2 — translate. $S^2 > 6$ is equivalent to $\chi^2_9 > 9(6)/4 = 13.5$.

Step 3 — evaluate. From chi-square tables or software, $P(\chi^2_9 > 13.5) = 0.141$.

Comment. In one test out of seven, a perfectly good generator would appear to be 50% noisier than specified. The central 95% range of χ^2_9 is $[2.70,\ 19.02]$, so s^2 ranges over $[1.20,\ 8.45]\ \text{mV}^2$ — a factor of seven. Ten samples are far too few to verify a variance.

Worked Example 20.16 — Sampling a production lot

A process has defect rate $p = 2\%$. In a sample of $n = 500$ parts, what is the probability that the observed defect rate is 3% or more (15 or more defectives)?

Step 1 — mean and SE. $E[X] = np = 10$, $\text{Var}\,X = np(1-p) = 9.8$, $\text{SD} = 3.13$.

Step 2 — normal approximation with continuity correction. $P(X \ge 15) \approx Q\big((14.5-10)/3.13\big) = Q(1.44) = 0.075$.

Step 3 — exact. The binomial tail $P(X \ge 15) = 0.081$. The approximation is serviceable; the remaining discrepancy reflects the right skew of a binomial with small p. (Without the continuity correction one would get $Q(1.60) = 0.055$, noticeably worse.)

Engineering Note — Dithering and the CLT

Adding a small random dither before quantisation and then averaging many readings lets an ADC resolve DC levels far finer than one LSB: the dither makes the quantisation errors of successive readings independent and zero-mean, so their average converges at the $1/\sqrt{n}$ rate. Without dither, a constant input always produces the same code and averaging gains nothing.

20.6 Estimation

The estimation task

A model has unknown parameters θ — the mean and standard deviation of a noise source, the failure rate of a component, the Rayleigh parameter of a fading channel, the slope of a sensor. An **estimator** $\hat\theta = g(X_1, \dots, X_n)$ is a rule that turns data into a value for θ; the number it produces for a particular data set is an **estimate**. Because $\hat\theta$ is a statistic, it has a sampling distribution, and "good" estimators are those whose sampling distribution is concentrated near the true θ.

Properties of estimators

Bias, variance, MSE, consistency, efficiency

- **Bias:** $b(\hat\theta) = E[\hat\theta] - \theta$. $\hat\theta$ is **unbiased** if $b = 0$ for all θ.
- **Mean squared error:** $\operatorname{MSE}(\hat\theta) = E\big[(\hat\theta - \theta)^2\big]$.
- **Consistency:** $\hat\theta_n \to \theta$ in probability as $n \to \infty$.
- **Efficiency:** among unbiased estimators, one with smaller variance is more efficient; the relative efficiency of $\hat\theta_1$ to $\hat\theta_2$ is $\operatorname{Var}\hat\theta_2 / \operatorname{Var}\hat\theta_1$.

Bias–variance decomposition

$$\operatorname{MSE}(\hat\theta) = \operatorname{Var}(\hat\theta) + b(\hat\theta)^2.$$

Proof. Add and subtract $E\hat\theta$: $E[(\hat\theta - E\hat\theta + E\hat\theta - \theta)^2] = E[(\hat\theta - E\hat\theta)^2] + 2(E\hat\theta - \theta)E[\hat\theta - E\hat\theta] + (E\hat\theta - \theta)^2$, and the middle expectation is zero. □

Unbiasedness is not sacred. A slightly biased estimator with much smaller variance can have lower MSE — for Gaussian data, the variance estimator with divisor $n+1$ has the smallest MSE of all estimators of the form $c\sum(X_i - \bar X)^2$, even though it is biased. A sufficient condition for consistency is that both bias and variance tend to zero; $\bar X$ is consistent for μ (by the law of large numbers, Ch. 19) and S^2 is consistent for σ^2.

The Cramér–Rao lower bound

How good can an unbiased estimator possibly be? For a model with pdf $f(x;\theta)$ that is smooth in θ, define the **score** $\partial_\theta \ln f(X;\theta)$ and the **Fisher information** per observation

$$I(\theta) = E\Big[\Big(\frac{\partial}{\partial\theta}\ln f(X;\theta)\Big)^2\Big] = -E\Big[\frac{\partial^2}{\partial\theta^2}\ln f(X;\theta)\Big].$$

Cramér–Rao lower bound (CRLB)

Under regularity conditions (support independent of θ, differentiation under the integral allowed), every unbiased estimator from an i.i.d. sample of size n satisfies

$$\operatorname{Var}(\hat\theta) \ge \frac{1}{n\,I(\theta)}.$$

An unbiased estimator attaining the bound is called **efficient**.

Proof sketch. Let $L(\theta) = \prod f(x_i;\theta)$ be the joint pdf and $U = \partial_\theta \ln L$ the total score. Differentiating $\int L\,d\mathbf{x} = 1$ gives $E[U] = 0$; differentiating $\int \hat\theta L\,d\mathbf{x} = \theta$ gives $E[\hat\theta U] = 1$, so $\operatorname{Cov}(\hat\theta, U) = 1$. The Cauchy–Schwarz inequality for covariances gives $1 \le \operatorname{Var}(\hat\theta)\operatorname{Var}(U)$, and $\operatorname{Var}(U) = nI(\theta)$ by independence. □

For a DC level θ in white Gaussian noise of variance σ^2, $\ln f = -\frac{(x-\theta)^2}{2\sigma^2} + \text{const}$, so $I = 1/\sigma^2$ and the bound is σ^2/n — exactly the variance of $\bar X$. The sample mean is efficient: no unbiased processing of the samples can do better. The CRLB is the standard benchmark in estimation theory for radar, communications and sensor arrays.

Method of moments

The oldest general recipe: equate sample moments to population moments and solve.

Method of moments (MoM)

If the model has p parameters and its first p moments are known functions $\mu'_k(\theta) = E[X^k]$, the MoM estimator solves

$$\frac{1}{n}\sum_{i=1}^{n} x_i^k = \mu'_k(\hat\theta), \qquad k = 1, \dots, p.$$

(Central moments may be used instead of raw moments.)

MoM is simple, needs only moment formulas, and gives consistent estimators (sample moments converge to population moments, and continuous functions preserve convergence). It is often a good *starting value* for an iterative maximum-likelihood search. Its weakness is that it can be inefficient and can produce impossible values (outside the parameter space or the data range).

Maximum likelihood

Likelihood and maximum likelihood estimator (MLE)

For observed data $x_1, \dots, x_n$, the **likelihood** is the joint pdf (or pmf) viewed as a function of the parameter:

$$L(\theta) = \prod_{i=1}^{n} f(x_i;\theta), \qquad \ell(\theta) = \ln L(\theta) = \sum_{i=1}^{n} \ln f(x_i;\theta).$$

The **MLE** $\hat\theta$ maximises L (equivalently ℓ). When the maximum is interior and ℓ is smooth, it solves the **likelihood equation** $\partial \ell / \partial \theta = 0$.

The MLE chooses the parameter value under which the observed data were most probable. It is the dominant estimation method in engineering because of its large-sample properties:

Asymptotic properties of the MLE

Under regularity conditions, as $n \to \infty$,

1. $\hat\theta$ is **consistent**;
2. $\hat\theta$ is **asymptotically Gaussian and efficient**: $\hat\theta \approx \mathcal{N}\big(\theta,\, 1/(n I(\theta))\big)$;
3. **invariance:** the MLE of $g(\theta)$ is $g(\hat\theta)$.

Point 2 provides standard errors almost for free: $\mathrm{SE}(\hat\theta) \approx 1/\sqrt{-\ell''(\hat\theta)}$, the inverse square root of the curvature of the log-likelihood at its peak (the **observed information**). A sharply peaked log-likelihood means the data pin θ down well. With several parameters, the inverse of the matrix of second derivatives (the negative Hessian of ℓ) approximates the covariance matrix of $\hat{\boldsymbol\theta}$. Point 3 means, for example, that the MLE of a standard deviation is the square root of the MLE of the variance, and the MLE of an MTBF is the reciprocal of the MLE of the failure rate.

MLE in Gaussian noise is least squares

If $x_i = s_i(\boldsymbol\theta) + w_i$ with w_i i.i.d. $\mathcal{N}(0,\sigma^2)$, then

$$\ell(\boldsymbol\theta) = -\frac{n}{2}\ln(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum_{i=1}^{n}\big(x_i - s_i(\boldsymbol\theta)\big)^2,$$

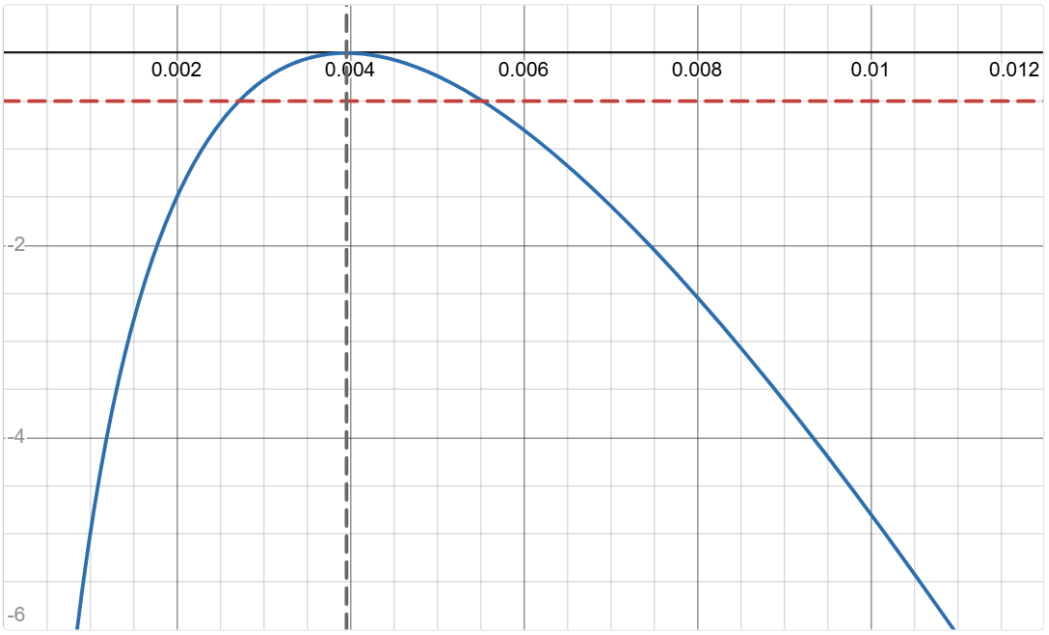
so maximising the likelihood over $\boldsymbol\theta$ is the same as minimising the sum of squared residuals.

This single observation justifies least-squares curve fitting (Section 20.9, Ch. 23) whenever the noise is Gaussian, and suggests weighted least squares (weights $1/\sigma_i^2$) when the noise variances differ.

Standard MLEs

Model	MLE	Notes
Bernoulli(p)	$\hat p = \bar x$ (proportion of successes)	unbiased
Poisson(λ)	$\hat\lambda = \bar x$	unbiased, efficient
Exponential(λ)	$\hat\lambda = 1/\bar x$	biased: $E\hat\lambda = n\lambda/(n-1)$
$\mathcal{N}(\mu,\sigma^2)$	$\hat\mu = \bar x$, $\hat\sigma^2 = \frac{1}{n}\sum(x_i-\bar x)^2$	$\hat\sigma^2$ biased by factor $(n-1)/n$
Uniform$(0,\theta)$	$\hat\theta = x_{(n)}$	biased low; support depends on θ
Rayleigh(σ)	$\hat\sigma^2 = \frac{1}{2n}\sum r_i^2$	unbiased for σ^2

Derivation for the Gaussian. $\ell(\mu,\sigma^2) = -\frac{n}{2}\ln(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum(x_i-\mu)^2$. Setting $\partial\ell/\partial\mu = \frac{1}{\sigma^2}\sum(x_i-\mu) = 0$ gives $\hat\mu = \bar x$; setting $\partial\ell/\partial\sigma^2 = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4}\sum(x_i-\hat\mu)^2 = 0$ gives $\hat\sigma^2 = \frac{1}{n}\sum(x_i-\bar x)^2$. The MLE of the variance is biased because it does not account for the degree of freedom used by $\hat\mu$ — the MLE optimises fit, not unbiasedness. The bias vanishes as $n \to \infty$, consistent with the asymptotic theory.



Log-likelihood of the exponential failure rate in Example 20.18, shifted so that its maximum is 0. The MLE sits at the peak; the values of λ where ℓ has fallen by $\frac{1}{2}$ (red line) give an approximate 68% likelihood interval, which is visibly asymmetric.

Worked Example 20.17 — Uniform: method of moments versus maximum likelihood

Timing jitter is modelled as Uniform$(0,\theta)$ (in ns). Five observations: $0.8,\ 2.9,\ 1.7,\ 3.6,\ 2.2$. Estimate θ by both methods and compare their quality.

Step 1 — MoM. $E[X]=\theta/2$, so $\hat\theta_{\text{MoM}}=2\bar x=2(2.24)=4.48$ ns. It is unbiased, with $\operatorname{Var}=4\operatorname{Var}(X)/n=4\theta^2/(12n)=\theta^2/(3n)$.

Step 2 — MLE. $L(\theta)=\theta^{-n}$ if $\theta\ge x_{(n)}$, and 0 otherwise (some observation would be impossible). L decreases in θ, so it is maximised at the smallest admissible value: $\hat\theta_{\text{ML}}=x_{(n)}=3.6$ ns. The likelihood equation $\ell'=0$ has no solution — the maximum is at a boundary, and the regularity conditions of the CRLB fail.

Step 3 — bias correction. The maximum of n uniforms has $E[X_{(n)}]=n\theta/(n+1)$, so $\hat\theta_{\text{U}}=\frac{n+1}{n}x_{(n)}=4.32$ ns is unbiased, with variance $\theta^2/(n(n+2))$.

Step 4 — compare. For $n=5$: $\operatorname{Var}\hat\theta_{\text{MoM}}=\theta^2/15$, $\operatorname{Var}\hat\theta_{\text{U}}=\theta^2/35$. The order-statistic estimator is more than twice as efficient, and its advantage grows linearly with n (variance $\propto 1/n^2$ instead of $1/n$). Note also that MoM could produce an estimate *smaller* than the largest observation — a logically impossible value — for unlucky samples.

Worked Example 20.18 — Failure rate from a life test

Eight units run to failure at $120,\ 340,\ 75,\ 510,\ 260,\ 195,\ 430,\ 90$ h. Assume exponential lifetimes and find the MLE of λ, its standard error and the MLE of the MTBF.

Step 1 — log-likelihood. $\ell(\lambda)=\sum\left(\ln\lambda-\lambda t_i\right)=n\ln\lambda-\lambda\sum t_i=8\ln\lambda-2020\lambda$.

Step 2 — maximise. $\ell'(\lambda)=8/\lambda-2020=0$ gives $\hat\lambda=8/2020=3.96\times10^{-3}$ h^{-1}. $\ell''=-8/\lambda^2<0$ confirms a maximum.

Step 3 — standard error. Observed information $-\ell''(\hat\lambda)=n/\hat\lambda^2$, so $\text{SE}(\hat\lambda)\approx\hat\lambda/\sqrt{n}=1.40\times10^{-3}$ h^{-1} — a 35% relative uncertainty from eight failures.

Step 4 — invariance. $\widehat{\text{MTBF}}=1/\hat\lambda=\bar t=252.5$ h.

Comment. The relative uncertainty $1/\sqrt{n}$ depends only on the number of *failures*. Reliability demonstrations are expensive precisely because small failure rates produce few failures; Section 20.7 gives an exact interval using the chi-square distribution.

Worked Example 20.19 — Rayleigh parameter of a noise envelope

Envelope samples of narrowband receiver noise (mV): $1.2,\ 0.7,\ 2.1,\ 1.5,\ 0.9,\ 1.8$. Estimate σ by ML and by the method of moments.

Step 1 — log-likelihood. $\ell(\sigma^2)=\sum\ln r_i-n\ln\sigma^2-\frac{1}{2\sigma^2}\sum r_i^2$.

Step 2 — maximise. $\partial\ell/\partial\sigma^2=-\frac{n}{\sigma^2}+\frac{1}{2\sigma^4}\sum r_i^2=0\Rightarrow\hat\sigma^2=\frac{1}{2n}\sum r_i^2=\frac{12.64}{12}=1.053$ mV^2, so $\hat\sigma_{\text{ML}}=1.026$ mV (invariance).

Step 3 — method of moments. $E[R]=\sigma\sqrt{\pi/2}$, so $\hat\sigma_{\text{MoM}}=\bar r/1.2533=1.367/1.2533=1.090$ mV.

Step 4 — interpretation. The MLE uses $\sum r_i^2$, which is the estimated *noise power* ($E[R^2]=2\sigma^2$): it is the natural statistic, and $2n\hat\sigma^2/\sigma^2\sim\chi^2_{2n}$ exactly, which gives exact intervals. The two estimates differ by 6% — well within the sampling scatter for $n=6$.

Worked Example 20.20 — Cramér–Rao bound for a DC level

A DC voltage A is measured in white Gaussian noise of $\sigma = 2$ mV with $n = 25$ samples.

Step 1 — Fisher information. $\ln f(x;A) = -\frac{(x-A)^2}{2\sigma^2} + \text{const}$, $\partial_A^2 \ln f = -1/\sigma^2$, so $I(A) = 1/\sigma^2$.

Step 2 — bound. $\operatorname{Var}(\hat{A}) \geq \sigma^2/n = 4/25 = 0.16\ \text{mV}^2$, i.e. SD ≥ 0.4 mV.

Step 3 — efficiency of the mean. $\operatorname{Var}(\bar{X}) = \sigma^2/n$ equals the bound, so the sample mean is efficient. The median, with asymptotic variance $\pi\sigma^2/(2n) = 0.251\ \text{mV}^2$, reaches only 64% efficiency.

Step 4 — non-Gaussian noise. For Laplacian (double-exponential) noise with the same variance, the Fisher information doubles to $2/\sigma^2$ and the MLE becomes the *median*, which is then efficient while the mean is only 50% efficient. The best estimator depends on the noise distribution — a key lesson of estimation theory.

Common Pitfall — Maximum likelihood with few data

The attractive properties of the MLE are *asymptotic*. With small n it can be noticeably biased ($\hat{\sigma}^2$ with divisor n; $\hat{\lambda} = 1/\bar{t}$), and the Gaussian approximation to its distribution can be poor (the log-likelihood in Example 20.18 is visibly asymmetric). Quote small-sample results with exact intervals where available, or check by simulation (Ch. 24).

Engineering Note — Estimators inside equipment

A spectrum analyser's "noise marker" estimates power by averaging squared magnitudes (the Rayleigh MLE in disguise); its "video averaging" in log mode instead averages decibels, which is biased low by 2.51 dB for Gaussian noise — a correction built into good instruments. A GPS receiver computes position by iterative least squares, i.e. maximum likelihood under Gaussian range errors, and reports a dilution-of-precision that is the CRLB-like covariance of the fix.

20.7 Confidence intervals

From a point to an interval

A point estimate without an indication of its reliability is of limited use: "the noise floor is -112.3 dBm" means one thing if the estimate is good to 0.1 dB and quite another if it is good to 3 dB. A **confidence interval** reports a range of plausible parameter values together with a stated probability that the *procedure* captures the true value.

Confidence interval

An interval $[L, U]$ whose endpoints are statistics $L = g_1(X_1,\dots,X_n)$, $U = g_2(X_1,\dots,X_n)$ is a $100(1-\alpha)\%$ **confidence interval** for θ if

$$P(L \leq \theta \leq U) = 1 - \alpha \quad \text{for every value of } \theta.$$

$1-\alpha$ is the **confidence level** (coverage probability). One-sided bounds $(-\infty, U]$ or $[L, \infty)$ are defined similarly.

The probability statement concerns the random endpoints, not θ, which is fixed. Once the data are in and the interval is, say, $[2.475,\ 2.530]$ V, the true value either is or is not in it; the 95% describes the long-run success rate of the method. If many laboratories each compute a 95% interval from their own data, about 95% of the intervals will contain the true value.

The pivotal method

Most intervals in practice are built from a **pivot**: a function $Q(X_1,\dots,X_n;\theta)$ whose distribution is known and does not depend on θ. If $q_{\alpha/2}$ and $q_{1-\alpha/2}$ are quantiles of that distribution, then $P(q_{\alpha/2} \leq Q \leq q_{1-\alpha/2}) = 1-\alpha$, and solving the inequalities for θ yields the interval. The sampling theorems of Section 20.5 supply the pivots:

Parameter	Conditions	Pivot	Distribution
μ	Gaussian (or large n), σ known	$(\bar{X}-\mu)/(\sigma/\sqrt{n})$	$\mathcal{N}(0,1)$
μ	Gaussian, σ unknown	$(\bar{X}-\mu)/(S/\sqrt{n})$	t_{n-1}
σ^2	Gaussian	$(n-1)S^2/\sigma^2$	χ^2_{n-1}
σ_1^2/σ_2^2	two Gaussian samples	$(S_1^2/\sigma_1^2)/(S_2^2/\sigma_2^2)$	F_{n_1-1,n_2-1}
λ (exponential)	complete sample	$2\lambda\sum T_i$	χ^2_{2n}

Below, z_α, $t_{\alpha,\nu}$ and $\chi^2_{\alpha,\nu}$ denote **upper** α-points: $P(Z > z_\alpha) = \alpha$, and so on.

Interval for a mean

Confidence intervals for a mean

σ **known** (or n large, with s in place of σ):

$$\bar{x} \pm z_{\alpha/2}\frac{\sigma}{\sqrt{n}}.$$

σ **unknown, Gaussian data:**

$$\bar{x} \pm t_{\alpha/2,\,n-1}\frac{s}{\sqrt{n}}.$$

Derivation of the t interval. $P\big(-t_{\alpha/2,n-1} \le \frac{\bar{X}-\mu}{S/\sqrt{n}} \le t_{\alpha/2,n-1}\big) = 1-\alpha$; multiplying through by $S/\sqrt{n}$ and rearranging for μ gives $P\big(\bar{X} - t\,S/\sqrt{n} \le \mu \le \bar{X} + t\,S/\sqrt{n}\big) = 1-\alpha$. $\square$

The half-width $E = z_{\alpha/2}\sigma/\sqrt{n}$ is the **margin of error**. Inverting it gives the sample size needed for a target margin:

$$n = \left(\frac{z_{\alpha/2}\,\sigma}{E}\right)^2.$$

Because of the $1/\sqrt{n}$ law, halving the interval requires four times the data. The t interval is robust to moderate non-normality (thanks to the CLT) once n exceeds about 15–20, unless the data are strongly skewed or contain outliers.

Interval for a variance

Confidence interval for σ^2 (Gaussian data)

$$\frac{(n-1)s^2}{\chi^2_{\alpha/2,\,n-1}} \;\le\; \sigma^2 \;\le\; \frac{(n-1)s^2}{\chi^2_{1-\alpha/2,\,n-1}}.$$

Taking square roots gives the interval for σ.

The interval is not symmetric about s^2, because the chi-square distribution is skewed; the upper limit lies further from s^2 than the lower. Unlike the t interval, it is *not* robust to non-Gaussian data (Section 20.5).

Interval for a proportion

For x successes in n trials, $\hat{p} = x/n$. The textbook **Wald interval** $\hat{p} \pm z_{\alpha/2}\sqrt{\hat{p}(1-\hat{p})/n}$ is simple but performs poorly when np is small: its actual coverage can fall well below the nominal level, and it can extend below zero. The **Wilson score interval** inverts the test statistic $(\hat{p}-p)/\sqrt{p(1-p)/n}$ exactly, solving a quadratic in p:

$$\frac{\hat{p} + \dfrac{z^2}{2n} \;\pm\; z\sqrt{\dfrac{\hat{p}(1-\hat{p})}{n} + \dfrac{z^2}{4n^2}}}{1 + \dfrac{z^2}{n}}, \qquad z = z_{\alpha/2}.$$

It is recommended for routine use. The exact (Clopper–Pearson) interval, computed from binomial tail probabilities, is conservative (coverage at least $1-\alpha$) and is preferred for contractual or safety-related claims.

Interval for a difference of means

For two independent samples, the **Welch interval** is

$$(\bar{x}_1 - \bar{x}_2) \pm t_{\alpha/2,\,\nu}\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}, \qquad \nu = \frac{\left(s_1^2/n_1 + s_2^2/n_2\right)^2}{\dfrac{(s_1^2/n_1)^2}{n_1-1} + \dfrac{(s_2^2/n_2)^2}{n_2-1}},$$

where ν is the Welch–Satterthwaite effective degrees of freedom — the same formula reappears in the GUM (Section 20.10). If the two variances are known to be equal, the **pooled** variance $s_p^2 = \frac{(n_1-1)s_1^2 + (n_2-1)s_2^2}{n_1+n_2-2}$ with n_1+n_2-2 degrees of freedom may be used instead. For paired data (the same units measured twice), compute the differences d_i and use the one-sample t interval on them — pairing removes unit-to-unit variation and usually gives a much narrower interval.

Confidence, prediction and tolerance intervals

Three different questions are often confused:

Interval	Question	Gaussian form	As $n \to \infty$
Confidence for μ	where is the population mean?	$\bar{x} \pm t\,s/\sqrt{n}$	shrinks to a point
Prediction	where will the *next single* observation fall?	$\bar{x} \pm t\,s\sqrt{1+1/n}$	tends to $\mu \pm z\sigma$
Tolerance	where do $P\%$ of all units lie (with confidence γ)?	$\bar{x} \pm k\,s$ (tabulated k)	tends to $\mu \pm z\sigma$

The prediction interval follows because $X_{\text{new}} - \bar{X}$ has variance $\sigma^2(1 + 1/n)$. A datasheet "typical" range or a production limit is a tolerance-interval question, not a confidence-interval question.

Worked Example 20.21 — Interval for a reference voltage

Use the eight readings of Example 20.3: $\bar{x} = 2.5025$ V, $s = 32.40$ mV, $n = 8$.

(a) σ unknown. $\nu = 7$, $t_{0.025,7} = 2.365$. Half-width $= 2.365 \times 32.40/\sqrt{8} = 27.1$ mV. The 95% CI is $[2.4754,\ 2.5296]$ V.

(b) If $\sigma = 32.4$ mV were known from long experience with this ADC, the half-width would be $1.960 \times 32.4/\sqrt{8} = 22.5$ mV. The t interval is 21% wider: the price of estimating σ from only eight readings.

(c) Sample size. To obtain a 95% half-width of 5 mV (with $\sigma \approx 32.4$ mV): $n = (1.96 \times 32.4/5)^2 = 161.3$, so $n = 162$ readings.

(d) Prediction. A single future reading will lie in $2.5025 \pm 2.365 \times 32.40\sqrt{1 + 1/8} = 2.5025 \pm 0.0813$ V with 95% probability — three times wider than the CI for the mean.

Worked Example 20.22 — Interval for the noise standard deviation

From the same data, find a 95% CI for σ.

Step 1 — quantiles. For χ^2_7: $\chi^2_{0.975,7} = 1.690$, $\chi^2_{0.025,7} = 16.013$.

Step 2 — interval for σ^2. $(n-1)s^2 = 7 \times 1.05 \times 10^{-3} = 7.35 \times 10^{-3}$ V^2. The interval is $[7.35 \times 10^{-3}/16.013,\ 7.35 \times 10^{-3}/1.690] = [4.59 \times 10^{-4},\ 4.35 \times 10^{-3}]$ V^2.

Step 3 — interval for σ. $[21.4,\ 66.0]$ mV, around the point estimate 32.4 mV. The upper limit is double the estimate: a standard deviation from eight readings is known only to within a factor of about two.

Worked Example 20.23 — Defect rate: Wald, Wilson and exact

A sample of $n = 200$ boards contains $x = 6$ with solder defects. Find a 95% CI for the defect rate p.

Step 1 — estimate. $\hat{p} = 0.030$, $\sqrt{\hat{p}(1-\hat{p})/n} = 0.01206$.

Step 2 — Wald. $0.030 \pm 1.96(0.01206) = [0.0064,\ 0.0536]$.

Step 3 — Wilson. With $z^2/n = 0.01921$: centre $= (0.030 + 0.00960)/1.01921 = 0.0389$; half-width $= 1.96\sqrt{1.455 \times 10^{-4} + 2.40 \times 10^{-5}}/1.01921 = 0.0250$. Interval $[0.0138,\ 0.0639]$.

Step 4 — exact (Clopper–Pearson). $[0.0111,\ 0.0642]$.

Comment. With only six defects, the Wald interval is shifted too far to the left and is too short on the right; Wilson is close to the exact interval. Note the asymmetry: the data are compatible with a defect rate more than twice the point estimate.

Worked Example 20.24 — Exact interval for a failure rate, and zero-failure tests

(a) In Example 20.18, $n = 8$ failures in total time $\sum t_i = 2020$ h. The pivot $2\lambda \sum T_i \sim \chi^2_{16}$, with $\chi^2_{0.975,16} = 6.908$ and $\chi^2_{0.025,16} = 28.845$. Hence

$$\frac{6.908}{2 \times 2020} \le \lambda \le \frac{28.845}{2 \times 2020} \quad \Longrightarrow \quad 1.71 \times 10^{-3} \le \lambda \le 7.14 \times 10^{-3}\ \text{h}^{-1},$$

and the MTBF lies in $[140,\ 585]$ h with 95% confidence. The interval is strongly asymmetric about $\hat{\lambda} = 3.96 \times 10^{-3}$ — compare the Gaussian approximation $\hat{\lambda} \pm 1.96\,\text{SE} = [1.2,\ 6.7] \times 10^{-3}$.

(b) Zero failures. A supplier claims $\lambda \le 10^{-4}$ h^{-1}. How many device-hours T of testing with no failures demonstrate this at 90% confidence? For a time-terminated test with zero failures, the one-sided upper bound is $\lambda_U = \chi^2_{0.10,2}/(2T) = 4.605/(2T) = 2.303/T$. Setting $\lambda_U = 10^{-4}$ gives $T = 23\,026$ device-hours — e.g. 100 units for 230 h. (The same "rule of three" in another guise: with zero failures, the 95% upper bound is $3/T$.)

Common Pitfall — "There is a 95% probability that μ is in this interval"

In the frequentist framework used here, μ is not random, so this sentence is not strictly meaningful; the 95% is a property of the procedure. A related error is to judge two results "different" only if their 95% intervals do not overlap: two intervals can overlap substantially while the difference between the means is still significant. Compare means with an interval or test for the *difference* instead.

Engineering Note — Coverage factors in measurement reports

Calibration certificates quote an expanded uncertainty $U = ku_c$ with $k = 2$ "corresponding to a coverage probability of approximately 95%". This is the GUM version of a confidence interval: $k = 2$ replaces $z_{0.025} = 1.96$, and when the effective degrees of freedom are small, k is taken from the t distribution instead (Section 20.10).

20.8 Hypothesis testing

Decisions under uncertainty

Many engineering questions have yes/no answers: Does this batch meet the 1% tolerance? Did the firmware update change the mean current draw? Is the new supplier's capacitor noisier? Is this random number generator uniform? Is there a target in this radar cell? A **hypothesis test** is a rule for answering such questions from data, with controlled probabilities of the two possible mistakes.

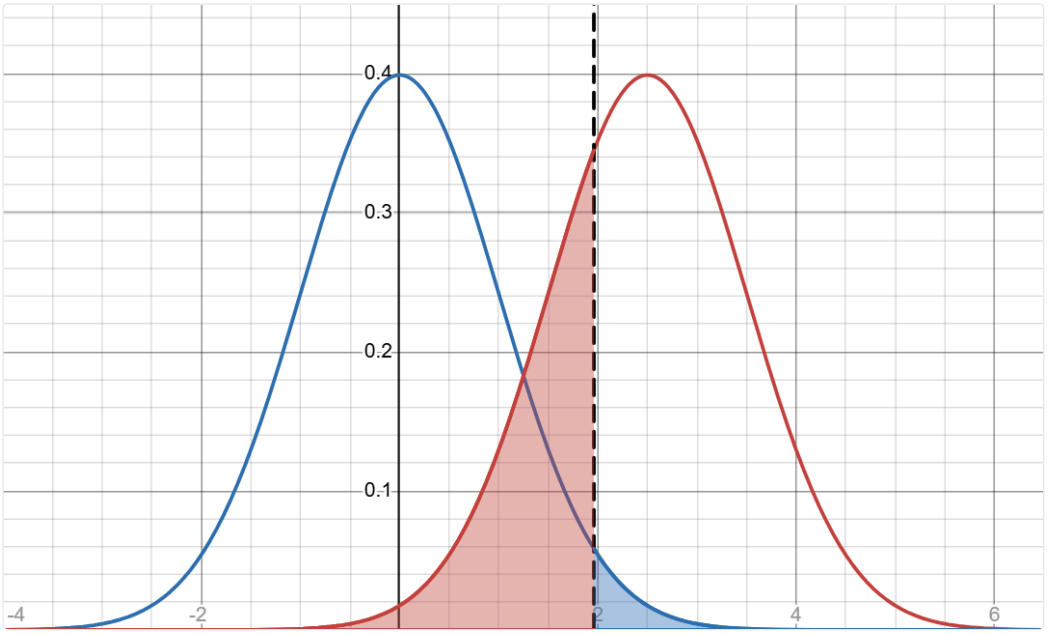
Hypotheses, test statistic, rejection region

- The **null hypothesis** H_0 is the default claim (no change, no effect, meets specification); the **alternative** H_1 is what we look for evidence of.
- A **test statistic** T is a statistic whose distribution under H_0 is known.
- The **rejection (critical) region** $\mathcal{R}$ is the set of values of T for which H_0 is rejected.
- A hypothesis such as $\mu = \mu_0$ that fixes the distribution completely is **simple**; one such as $\mu > \mu_0$ is **composite**.

	H_0 **true**	H_0 **false**
Reject H_0	**Type I error** (false alarm), probability α	correct (detection), probability $1-\beta$ = **power**
Do not reject H_0	correct	**Type II error** (miss), probability β

The **significance level** $\alpha = P(\text{reject } H_0 \mid H_0)$ is chosen in advance, conventionally 0.05 or 0.01. The **power** $1-\beta$ depends on how far the truth is from H_0, on n, and on α. For a fixed sample size, α and β trade against each other: moving the threshold to reduce false alarms increases misses. Only more data (or less noise) reduces both.

The radar vocabulary is exact, not metaphorical: α is the probability of false alarm P_{FA} and $1-\beta$ the probability of detection P_{D}; plotting P_{D} against P_{FA} as the threshold varies gives the **receiver operating characteristic** (ROC).



Distribution of the standardised statistic under H_0 (blue, mean 0) and under an alternative (red, mean 2.5), with threshold 1.96 (dashed). The blue area to the right is $\alpha = 0.025$; the red area to the left is $\beta = 0.295$. Moving the threshold right shrinks α and grows β.

The p-value

p-value

The **p-value** of an observed statistic t_{obs} is the probability, computed under H_0, of obtaining a value of T at least as extreme (in the direction of H_1) as t_{obs}:

$$p = P_{H_0}(T \geq t_{\text{obs}}) \ \text{(upper one-sided)}, \qquad p = P_{H_0}(|T| \geq |t_{\text{obs}}|) \ \text{(two-sided, symmetric } T).$$

Rejecting H_0 when $p \leq \alpha$ is equivalent to the fixed-α test.

The p-value measures how surprising the data would be *if H_0 were true*. It is not the probability that H_0 is true, and it is not the probability that the result is due to chance. A small p says "either H_0 is false or something unlikely happened"; a large p says the data are compatible with H_0 — which is not the same as evidence *for* H_0, particularly when n is small and the test has little power.

Duality of tests and confidence intervals

A two-sided level-α test of $H_0 : \theta = \theta_0$ rejects exactly when θ_0 lies outside the $100(1-\alpha)\%$ confidence interval built from the same pivot.

Proof. Both statements are the same inequality on the pivot: $|(\hat\theta - \theta_0)/\,\text{SE}| > c$ (reject) is equivalent to $\theta_0 \notin [\hat\theta - c\,\text{SE},\ \hat\theta + c\,\text{SE}]$. $\square$

The interval is usually more informative than the test result: it says not only *whether* the parameter differs from θ_0 but *by how much* it plausibly differs.

The general procedure

1. State H_0 and H_1 (one- or two-sided) *before* looking at the data.
2. Choose α, and ideally the sample size needed for adequate power at the smallest effect that matters.
3. Choose the test statistic and check its assumptions (independence, normality, equal variances).
4. Compute the statistic and the p-value (or compare with the critical value).
5. State the conclusion in the engineering context, with the size of the effect (a confidence interval), not just "significant".

Tests for means

One-sample z and t tests

For $H_0 : \mu = \mu_0$:

$$Z = \frac{\bar{X} - \mu_0}{\sigma/\sqrt{n}} \sim \mathcal{N}(0,1) \ \ (\sigma \text{ known}), \qquad T = \frac{\bar{X} - \mu_0}{S/\sqrt{n}} \sim t_{n-1} \ \ (\sigma \text{ unknown, Gaussian data}).$$

Reject at level α when $|Z| > z_{\alpha/2}$ (two-sided), $Z > z_\alpha$ ($H_1 : \mu > \mu_0$) or $Z < -z_\alpha$ ($H_1 : \mu < \mu_0$); likewise for T with $t_{\alpha/2,n-1}$ or $t_{\alpha,n-1}$.

Power and sample size. If the true mean is $\mu_0 + \delta$, the z statistic has mean $\delta\sqrt{n}/\sigma$, so for the one-sided test

$$1 - \beta = Q\Big(z_\alpha - \frac{\delta\sqrt{n}}{\sigma}\Big), \qquad n = \Big(\frac{(z_\alpha + z_\beta)\,\sigma}{\delta}\Big)^2,$$

and for a two-sided test z_α is replaced by $z_{\alpha/2}$ (neglecting the tiny opposite tail). The ratio δ/σ is the **effect size**; detecting an effect of a tenth of a standard deviation needs about a hundred times more data than detecting one of a full standard deviation.

Two-sample and paired tests

- **Welch t test** ($H_0 : \mu_1 = \mu_2$, independent samples, unequal variances): $T = \dfrac{\bar{X}_1 - \bar{X}_2}{\sqrt{S_1^2/n_1 + S_2^2/n_2}}$, approximately t_ν with the Welch–Satterthwaite ν of Section 20.7.
- **Pooled t test** (equal variances assumed): denominator $S_p\sqrt{1/n_1 + 1/n_2}$, exactly $t_{n_1+n_2-2}$.
- **Paired t test** (each unit measured under both conditions): one-sample t test on the differences $D_i = X_{1i} - X_{2i}$, with $n - 1$ degrees of freedom.

Chi-square tests

Test for a variance. For Gaussian data and $H_0 : \sigma^2 = \sigma_0^2$, the statistic $\chi^2 = (n-1)S^2/\sigma_0^2 \sim \chi^2_{n-1}$ under H_0. Large values indicate $\sigma^2 > \sigma_0^2$.

Goodness of fit. Data are classified into K categories with observed counts O_k; under H_0 the category probabilities are p_k, so the expected counts are $E_k = np_k$. **Pearson's statistic**

$$\chi^2 = \sum_{k=1}^{K} \frac{(O_k - E_k)^2}{E_k}$$

is approximately χ^2_{K-1-m} under H_0, where m is the number of parameters estimated from the data to compute the p_k. *Why chi-square:* each O_k is approximately Gaussian with variance close to E_k (Poisson-like counting), so each term is roughly a squared standard Gaussian; the constraint $\sum O_k = n$ removes one degree of freedom and each fitted parameter removes another. The approximation requires expected counts that are not too small — the usual rule is $E_k \geq 5$; merge sparse categories otherwise.

Independence in a contingency table. For an $r \times c$ table of counts O_{ij} with row totals R_i, column totals C_j and grand total n, the expected counts under independence are $E_{ij} = R_i C_j / n$, and $\sum_{i,j}(O_{ij} - E_{ij})^2/E_{ij}$ is approximately $\chi^2_{(r-1)(c-1)}$.

F test for equality of variances

For two independent Gaussian samples and $H_0 : \sigma_1^2 = \sigma_2^2$, $F = S_1^2/S_2^2 \sim F_{n_1-1,n_2-1}$. For a two-sided test, put the larger variance in the numerator and double the upper-tail probability. Like the chi-square variance test, it is sensitive to non-normality; Levene's test is a robust alternative.

The Neyman–Pearson lemma

Which test is *best*? For two simple hypotheses the answer is known exactly.

Neyman–Pearson lemma

For testing $H_0 : \theta = \theta_0$ against $H_1 : \theta = \theta_1$, the test that rejects H_0 when the **likelihood ratio**

$$\Lambda(\mathbf{x}) = \frac{L(\theta_1; \mathbf{x})}{L(\theta_0; \mathbf{x})} > \eta$$

(with η chosen so that the size is α) has the greatest power among all tests of size at most α.

For a Gaussian mean with known σ, $\ln \Lambda$ is an increasing linear function of $\bar{x}$ when $\mu_1 > \mu_0$, so the optimal test is "reject when $\bar{x}$ is large" — the z test. The likelihood-ratio test is the foundation of optimal detection in communications and radar: the matched filter followed by a threshold is the Neyman–Pearson detector for a known signal in white Gaussian noise.

Worked Example 20.25 — z test and power for a regulator

A 5.000 V regulator line has known output noise between units of $\sigma = 20$ mV. After a component change, $n = 25$ units give $\bar{x} = 5.009$ V. Has the mean shifted? Use $\alpha = 0.05$.

Step 1 — hypotheses. $H_0 : \mu = 5.000$, $H_1 : \mu \neq 5.000$ (two-sided: a shift either way matters).

Step 2 — statistic. $\text{SE} = 20/\sqrt{25} = 4$ mV; $z = 9/4 = 2.25$.

Step 3 — decision. $|z| > 1.96$; $p = 2Q(2.25) = 0.0244$. Reject H_0: the shift is statistically significant. The 95% CI for the shift is 9 ± 7.8 mV, i.e. $[1.2,\ 16.8]$ mV.

Step 4 — power. What is the probability that this test detects a true shift of $\delta = 10$ mV? The statistic then has mean $10/4 = 2.5$: power $= Q(1.96 - 2.5) + \Phi(-1.96 - 2.5) = 0.705$. A 10 mV shift would be missed 30% of the time.

Step 5 — sample size for 90% power. $n = \left((1.960 + 1.282) \times 20/10\right)^2 = 42.0$, so 43 units.

Worked Example 20.26 — One-sample t test and the danger of low power

For the eight reference readings of Example 20.3, test $H_0 : \mu = 2.500$ V.

$t = (2.5025 - 2.5000)/(0.03240/\sqrt{8}) = 0.0025/0.01146 = 0.218$ with 7 degrees of freedom; $p = 0.83$. There is no evidence of an offset. But the 95% CI is $[2.475,\ 2.530]$ V: offsets as large as ± 27 mV are entirely compatible with the data. "Not significant" here means "not enough data to tell", not "no offset".

Worked Example 20.27 — Paired versus unpaired comparison of drift

Six precision resistors are measured (kΩ) before and after a 1000 h burn-in:

Unit	1	2	3	4	5	6
Before	10.02	9.98	10.05	10.01	9.97	10.03
After	10.06	10.01	10.08	10.06	9.99	10.07

Step 1 — paired analysis. Differences $d_i = 0.04,\ 0.03,\ 0.03,\ 0.05,\ 0.02,\ 0.04$; $\bar{d} = 0.0350$, $s_d = 0.01049$. $t = 0.0350/(0.01049/\sqrt{6}) = 8.17$ with 5 degrees of freedom, $p = 0.00045$. The drift is unmistakable.

Step 2 — (wrong) unpaired analysis. Treating the columns as independent samples gives $t = 1.82$, $p = 0.10$ — "not significant".

Step 3 — explanation. Unit-to-unit variation (about 30 Ω) is much larger than the drift (35 Ω on average, but with spread only 10 Ω). Pairing subtracts each unit's own value and removes that variation. Always use the paired test when the same units are measured twice; the unpaired test is not only less powerful but answers a different question.

Worked Example 20.28 — Comparing two suppliers: Welch t and F tests

Capacitance (nF) of samples from two suppliers:

A: $47.2,\ 46.8,\ 47.5,\ 47.1,\ 46.9,\ 47.4,\ 47.0,\ 47.3$ ($n_1 = 8$, $\bar{x}_1 = 47.150$, $s_1 = 0.245$)

B: $46.1,\ 47.9,\ 46.5,\ 48.2,\ 45.8,\ 47.6,\ 46.9$ ($n_2 = 7$, $\bar{x}_2 = 47.000$, $s_2 = 0.924$)

Step 1 — means (Welch). $\text{SE} = \sqrt{0.245^2/8 + 0.924^2/7} = 0.360$; $t = 0.150/0.360 = 0.417$. Welch–Satterthwaite: $\nu = 6.74$. $p = 0.69$. No evidence that the means differ.

Step 2 — variances (F). $F = s_2^2/s_1^2 = 0.8533/0.0600 = 14.2$ with $(6, 7)$ degrees of freedom. The upper 2.5% point of $F_{6,7}$ is 5.12, so $H_0 : \sigma_1 = \sigma_2$ is rejected; the two-sided $p = 0.0026$.

Step 3 — conclusion. The suppliers agree on average, but supplier B's parts scatter almost four times as widely — exactly the difference that matters for a filter with tight tolerance. Note that the pooled t test would have been inappropriate here, since its equal-variance assumption is clearly violated; Welch's test does not need it.

Worked Example 20.29 — Chi-square tests for a bit generator and for shift dependence

(a) Goodness of fit. A hardware random-bit generator produces 400 two-bit symbols with counts 00: 112, 01: 91, 10: 85, 11: 112. Under H_0 (uniform) each expected count is 100:

$$\chi^2 = \frac{12^2 + 9^2 + 15^2 + 12^2}{100} = \frac{594}{100} = 5.94, \qquad \nu = 4 - 1 = 3.$$

The 5% critical value of χ^2_3 is 7.81; $p = 0.115$. No evidence of bias at this sample size (but a real generator would be tested with millions of symbols and a full test suite).

(b) Independence. Defective boards by shift: day 18 of 400, night 34 of 400. Under independence the expected defectives are 26 per shift and the expected good boards 374. Then

$$\chi^2 = \frac{8^2}{26} + \frac{8^2}{374} + \frac{8^2}{26} + \frac{8^2}{374} = 5.27, \qquad \nu = (2-1)(2-1) = 1,$$

exceeding 3.84; $p = 0.022$. The defect rate depends on shift (whether the cause is the shift itself or something correlated with it is a separate, engineering question).

Worked Example 20.30 — A borderline variance test

A sensor's noise is specified as $\sigma \le 2.0$ mV. Fifteen readings give $s = 2.6$ mV. Test $H_0 : \sigma = 2.0$ against $H_1 : \sigma > 2.0$ at $\alpha = 0.05$.

$\chi^2 = 14 \times 2.6^2 / 2.0^2 = 23.66$; the upper 5% point of χ^2_{14} is 23.68; $p = 0.0503$. Formally, H_0 is not rejected. Practically, a result this close to the threshold says the evidence is marginal; the sensible engineering response is to collect more readings, not to treat $p = 0.0503$ and $p = 0.0497$ as opposite conclusions.

Common Pitfall — Multiple testing and data dredging

Testing 20 independent parameters of a product at $\alpha = 0.05$ when nothing has changed produces at least one "significant" result with probability $1 - 0.95^{20} = 0.64$. When many tests are made, control the family-wise error, e.g. by the **Bonferroni** rule (use α/m for each of m tests), or the false-discovery rate. Choosing which hypothesis to test *after* seeing which looks interesting invalidates the stated α entirely.

Common Pitfall — Statistical versus practical significance

With 10^6 samples, a 0.01 mV offset in a 5 V supply can be "highly significant" ($p < 10^{-6}$) and completely irrelevant. With 5 samples, a 50 mV offset may be "not significant" and very relevant. Always report the estimated effect and its confidence interval alongside the p-value.

Engineering Note — Production test limits as hypothesis tests

A pass/fail limit on a test station is a hypothesis test performed on every unit. Measurement noise causes good units near the limit to fail (false rejects, Type I from the producer's view) and bad units to pass (escapes, Type II). **Guard-banding** moves the test limit inside the specification by a multiple of the measurement uncertainty to cut escapes at the cost of more false rejects — the α–β trade-off in hardware.

20.9 Regression

Fitting relations between variables

Calibration curves, sensor characterisation, extracting a time constant from a step response, finding a device's temperature coefficient, modelling battery capacity against cycle count: all of these fit a functional relation $y \approx g(x; \boldsymbol{\beta})$ to noisy data. **Regression analysis** estimates the parameters $\boldsymbol{\beta}$, quantifies their uncertainty, and — just as importantly — checks whether the assumed form of g is adequate. This section treats the statistical side; the optimisation side (nonlinear least squares, regularisation) is in Ch. 23.

The simple linear model

Simple linear regression model

$$Y_i = \beta_0 + \beta_1 x_i + \varepsilon_i, \qquad i = 1, \dots, n,$$

where the x_i are known (not random, or measured without appreciable error) and the errors ε_i are independent with $E[\varepsilon_i] = 0$ and constant variance $\mathrm{Var}(\varepsilon_i) = \sigma^2$. For exact intervals and tests we further assume $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$.

Least-squares estimates

The **least-squares** estimates minimise the sum of squared vertical deviations

$$S(\beta_0, \beta_1) = \sum_{i=1}^{n} \big(y_i - \beta_0 - \beta_1 x_i\big)^2.$$

Setting both partial derivatives to zero (Ch. 6) gives the **normal equations**

$$\frac{\partial S}{\partial \beta_0} = -2\sum (y_i - \beta_0 - \beta_1 x_i) = 0, \qquad \frac{\partial S}{\partial \beta_1} = -2\sum x_i (y_i - \beta_0 - \beta_1 x_i) = 0.$$

Least-squares line

$$\hat\beta_1 = \frac{S_{xy}}{S_{xx}} = r\,\frac{s_y}{s_x}, \qquad \hat\beta_0 = \bar y - \hat\beta_1 \bar x.$$

The fitted line passes through $(\bar x, \bar y)$, and the residuals $e_i = y_i - \hat y_i$ satisfy $\sum e_i = 0$ and $\sum x_i e_i = 0$.

Derivation. The first normal equation gives $\bar y = \beta_0 + \beta_1 \bar x$, i.e. the line passes through the centroid. Substituting $\beta_0 = \bar y - \beta_1 \bar x$ into the second and using $\sum x_i (y_i - \bar y) = S_{xy}$, $\sum x_i (x_i - \bar x) = S_{xx}$ gives $S_{xy} - \beta_1 S_{xx} = 0$. The residual identities are the normal equations themselves. □

Under Gaussian errors, least squares is maximum likelihood (Section 20.6). Without the Gaussian assumption, the **Gauss–Markov theorem** guarantees that least squares gives the *best linear unbiased estimators* (minimum variance among all unbiased estimators that are linear in the y_i), provided the errors are uncorrelated with equal variance.

Sampling properties and inference

Since $\hat\beta_1 = \sum (x_i - \bar x) Y_i / S_{xx}$ is a linear combination of the independent Y_i,

$$E[\hat\beta_1] = \beta_1, \qquad \operatorname{Var}(\hat\beta_1) = \frac{\sigma^2}{S_{xx}}, \qquad \operatorname{Var}(\hat\beta_0) = \sigma^2\Big(\frac{1}{n} + \frac{\bar x^2}{S_{xx}}\Big), \qquad \operatorname{Cov}(\hat\beta_0, \hat\beta_1) = -\frac{\sigma^2 \bar x}{S_{xx}}.$$

The error variance is estimated from the residuals with $n - 2$ degrees of freedom (two parameters fitted):

$$s^2 = \frac{\mathrm{SSE}}{n-2} = \frac{1}{n-2}\sum_{i=1}^{n} e_i^2.$$

Inference for the regression line (Gaussian errors)

1. $\dfrac{\hat\beta_1 - \beta_1}{s/\sqrt{S_{xx}}} \sim t_{n-2}$; a $100(1-\alpha)\%$ CI for the slope is $\hat\beta_1 \pm t_{\alpha/2,n-2}\, s/\sqrt{S_{xx}}$.
2. CI for the **mean response** at x_0: $\hat y_0 \pm t_{\alpha/2,n-2}\, s\sqrt{\dfrac{1}{n} + \dfrac{(x_0 - \bar x)^2}{S_{xx}}}$.
3. **Prediction interval** for a new observation at x_0: $\hat y_0 \pm t_{\alpha/2,n-2}\, s\sqrt{1 + \dfrac{1}{n} + \dfrac{(x_0 - \bar x)^2}{S_{xx}}}$.

The term $(x_0 - \bar x)^2 / S_{xx}$ makes both bands narrowest at $\bar x$ and flare outwards: the line is pinned down best at the centre of the data, and uncertainty in the slope is amplified with distance. This is the quantitative argument against extrapolation. The formula $\operatorname{Var}(\hat\beta_1) = \sigma^2 / S_{xx}$ also guides experiment design: to measure a slope precisely, spread the x values as widely as the model remains valid — placing half the points at each end maximises S_{xx}, although it leaves no way to detect curvature.

Analysis of variance and r^2

Each observation's deviation from the mean splits into an explained part and a residual: $y_i - \bar y = (\hat y_i - \bar y) + (y_i - \hat y_i)$. Squaring and summing, the cross term vanishes (by the residual identities), giving the **ANOVA decomposition**

$$\underbrace{\sum (y_i - \bar y)^2}_{\mathrm{SST}} = \underbrace{\sum (\hat y_i - \bar y)^2}_{\mathrm{SSR}} + \underbrace{\sum (y_i - \hat y_i)^2}_{\mathrm{SSE}}.$$

Coefficient of determination

$$r^2 = \frac{\mathrm{SSR}}{\mathrm{SST}} = 1 - \frac{\mathrm{SSE}}{\mathrm{SST}},$$

the fraction of the variation in y explained by the fitted line. In simple linear regression it equals the square of the Pearson correlation r (Section 20.3). With p parameters, the **adjusted** $\bar r^2 = 1 - \dfrac{\mathrm{SSE}/(n-p)}{\mathrm{SST}/(n-1)}$ penalises extra parameters.

The overall significance of the regression is tested by $F = \dfrac{\mathrm{SSR}/1}{\mathrm{SSE}/(n-2)} \sim F_{1,n-2}$ under $H_0 : \beta_1 = 0$; in simple regression $F = t^2$ for the slope.

Residual analysis

The model assumptions — correct functional form, independent errors, constant variance, Gaussian errors — are checked by examining the residuals e_i, ideally the **standardised residuals** e_i / s. A good fit leaves residuals that look like structureless noise. Characteristic patterns diagnose specific failures:

Residual pattern	Plotted against	Diagnosis	Remedy
U-shape or arch	x or $\hat y$	missing curvature	add x^2 term, transform, physical model
Funnel (spread grows with x)	x or $\hat y$	non-constant variance	weighted least squares, log transform
Runs, waves	time/order	correlated errors, drift	model the drift, randomise run order
One very large $\lvert e_i/s\rvert$ (> 3)	—	outlier	check the point; robust fit
Curved normal-probability plot	normal quantiles	non-Gaussian errors	robust methods; intervals approximate

A point can also be **influential** without having a large residual: a point at extreme x (high **leverage** $h_{ii} = \frac{1}{n} + \frac{(x_i - \bar{x})^2}{S_{xx}}$) pulls the line towards itself. Cook's distance combines residual and leverage to measure how much the fit changes when a point is deleted.

Matrix form and multiple regression

With p parameters, write the model as $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, where the $n \times p$ **design matrix** $\mathbf{X}$ has a column of ones and one column per regressor (for a polynomial fit: $1,\ x_i,\ x_i^2, \dots$). Minimising $\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2$ gives the normal equations and their solution (Ch. 8, Ch. 23):

$$\mathbf{X}^{\mathsf{T}}\mathbf{X}\,\hat{\boldsymbol{\beta}} = \mathbf{X}^{\mathsf{T}}\mathbf{y}, \qquad \hat{\boldsymbol{\beta}} = (\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{y}, \qquad \operatorname{Cov}(\hat{\boldsymbol{\beta}}) = \sigma^2(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}, \qquad s^2 = \frac{\mathrm{SSE}}{n-p}.$$

Geometrically, $\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol{\beta}}$ is the orthogonal projection of $\mathbf{y}$ onto the column space of $\mathbf{X}$, and the residual vector is orthogonal to every column — the matrix form of $\sum e_i = 0$, $\sum x_i e_i = 0$. The diagonal of the "hat" matrix $\mathbf{H} = \mathbf{X}(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}$ gives the leverages. Numerically, solve by QR factorisation rather than by forming $\mathbf{X}^{\mathsf{T}}\mathbf{X}$, whose condition number is the square of that of $\mathbf{X}$ (Ch. 22).

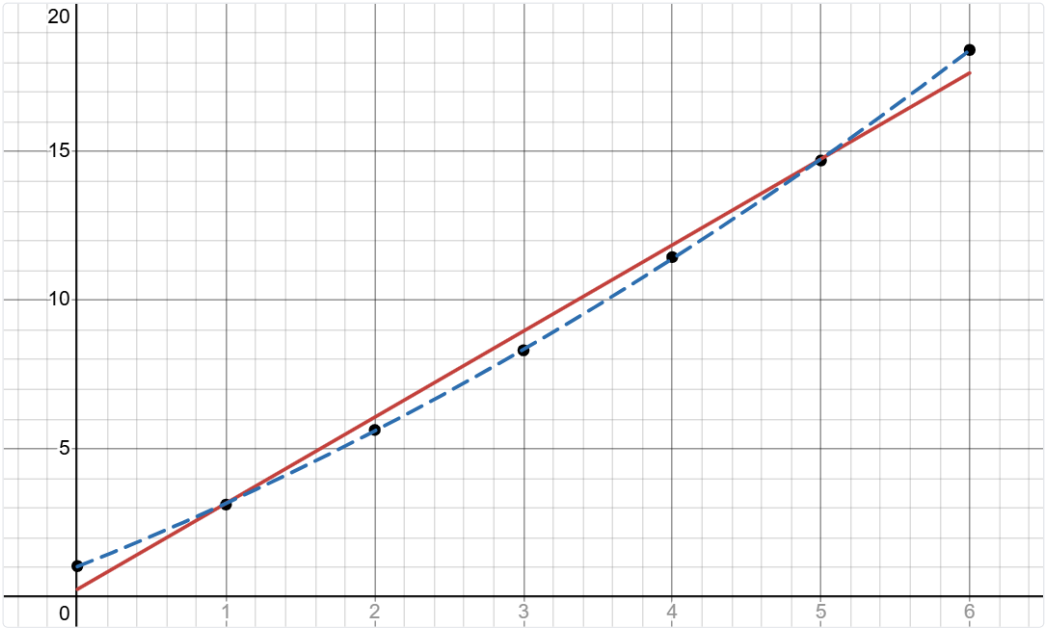
If the errors have different variances σ_i^2, **weighted least squares** minimises $\sum w_i(y_i - \mathbf{x}_i^{\mathsf{T}}\boldsymbol{\beta})^2$ with $w_i = 1/\sigma_i^2$, giving $\hat{\boldsymbol{\beta}} = (\mathbf{X}^{\mathsf{T}}\mathbf{W}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{W}\mathbf{y}$ — the regression version of the weighted mean of Section 20.2.

Linearising transformations

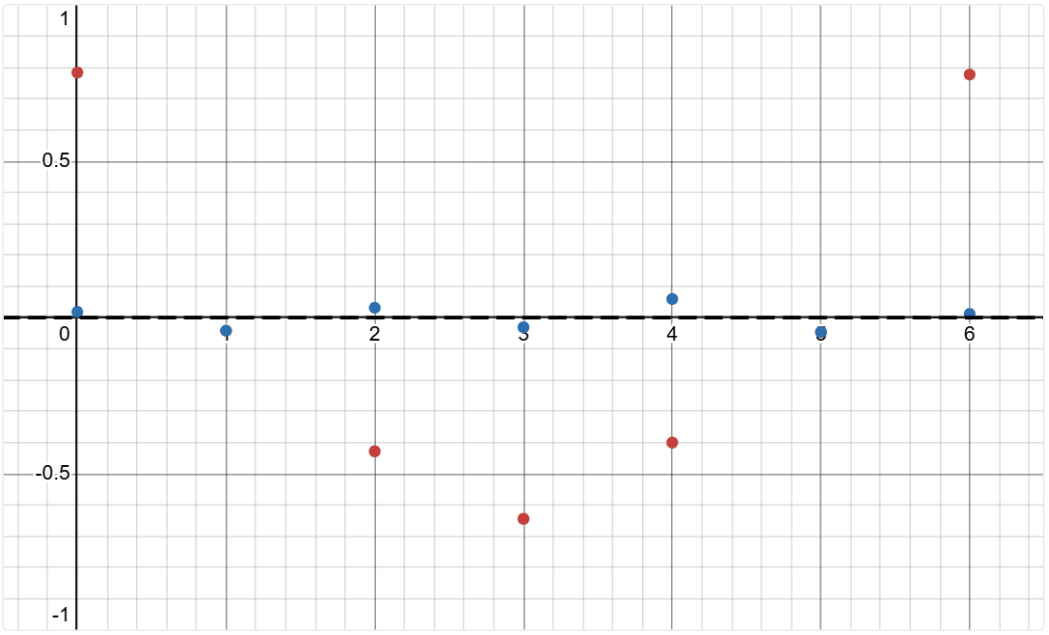
Many physical laws become linear after a transformation, and ordinary linear regression can then be used:

Model	Transformation	Linear form
$y = Ae^{-t/\tau}$ (RC discharge)	$\ln y$	$\ln y = \ln A - t/\tau$
$y = Ax^b$ (power law)	$\ln y,\ \ln x$	$\ln y = \ln A + b \ln x$
$I = I_s\left(e^{V/(nV_T)} - 1\right)$, $I \gg I_s$ (diode)	$\ln I$	$\ln I = \ln I_s + V/(nV_T)$
$R = R_0 e^{B(1/T - 1/T_0)}$ (NTC thermistor)	$\ln R,\ 1/T$	$\ln R = \text{const} + B/T$

A transformation also transforms the errors. If y has constant *absolute* noise σ, then $\ln y$ has noise $\approx \sigma/y$, which grows as y decays; the unweighted log fit then over-weights the small, noisy late values. Use weights $w_i \propto y_i^2$ in the log domain, or fit the nonlinear model directly (Ch. 23).



Data of Example 20.33 with the straight-line fit (red, $r^2 = 0.992$) and the quadratic fit (blue, dashed). Both look acceptable on this scale — the residual plot below shows the difference.



Residuals of the straight-line fit (red) form a clear U: the model is missing curvature. Residuals of the quadratic fit (blue) are small and patternless.

Worked Example 20.31 — Calibrating an RTD

Fit $R = \beta_0 + \beta_1 T$ to the data of Example 20.6 and give the sensitivity with a 95% CI.

Step 1 — slope and intercept. From Example 20.6, $S_{TT} = 7000$, $S_{TR} = 2692$, $\bar{T} = 50$, $\bar{R} = 119.333$. Hence $\hat{\beta}_1 = 2692/7000 = 0.384571\ \Omega/^\circ\text{C}$ and $\hat{\beta}_0 = 119.333 - 0.384571(50) = 100.105\ \Omega$.

Step 2 — residuals. $e_i = R_i - \hat{R}_i = -0.105,\ +0.104,\ +0.012,\ +0.021,\ +0.030,\ -0.062\ \Omega$ (they sum to zero). $\text{SSE} = 0.02705\ \Omega^2$.

Step 3 — error variance. $s^2 = 0.02705/4 = 6.76 \times 10^{-3}\ \Omega^2$, $s = 0.0822\ \Omega$.

Step 4 — standard errors. $\text{SE}(\hat{\beta}_1) = 0.0822/\sqrt{7000} = 9.83 \times 10^{-4}\ \Omega/^\circ\text{C}$; $\text{SE}(\hat{\beta}_0) = 0.0822\sqrt{1/6 + 2500/7000} = 0.0595\ \Omega$.

Step 5 — CI for the slope. $t_{0.025,4} = 2.776$: $\beta_1 \in 0.38457 \pm 0.00273 = [0.3818,\ 0.3873]\ \Omega/^\circ\text{C}$. Relative to $R_0 \approx 100\ \Omega$, this is a temperature coefficient of about $0.385\%/^\circ\text{C}$, consistent with the IEC value $0.00385\ /^\circ\text{C}$ for industrial platinum.

Step 6 — r^2 and the residual pattern. $r^2 = 1 - 0.02705/1035.29 = 0.99997$. The residuals are negative at both ends and positive in the middle — a faint arch consistent with the known negative quadratic term of platinum. A quadratic fit gives a curvature coefficient $-4.9 \times 10^{-5}\ \Omega/(^\circ\text{C})^2$, close to the Callendar–Van Dusen value -5.8×10^{-5} for a 100 Ω sensor. With six points and residuals near the noise level, the evidence for curvature is weak in isolation, but physics supports the quadratic model.

Worked Example 20.32 — Using the calibration: inverse prediction and bands

Using the fit of Example 20.31:

(a) Mean response at $T = 50\ ^\circ\text{C}$. $\hat{R} = 119.333\ \Omega$; half-width $2.776 \times 0.0822\sqrt{1/6} = 0.093\ \Omega$.

(b) Prediction for a single new reading at $50\ ^\circ\text{C}$. Half-width $2.776 \times 0.0822\sqrt{1 + 1/6} = 0.247\ \Omega$.

(c) Inverse prediction. The sensor reads $R = 120.00\ \Omega$. Solving the fitted line for T: $\hat{T} = (120.00 - 100.105)/0.384571 = 51.73\ ^\circ\text{C}$. Its uncertainty is roughly the prediction half-width converted to temperature: $0.247/0.3846 \approx 0.64\ ^\circ\text{C}$ (95%). This "calibrate y on x, then invert" procedure is the standard calibration method when the reference temperatures are known much better than the resistance readings.

(d) Extrapolation. At $T = 300\ ^\circ\text{C}$ the linear fit predicts $215.48\ \Omega$; the true Pt100 value is about $212.05\ \Omega$. The curvature invisible over 0–100 °C causes an error of $3.4\ \Omega$ ($9\ ^\circ\text{C}$) — far outside any band computed from the fit, because those bands assume the model is correct.

Worked Example 20.33 — Detecting curvature from the residuals

A sensor gives $y = 1.05,\ 3.12,\ 5.63,\ 8.31,\ 11.45,\ 14.70,\ 18.42$ at $x = 0, 1, \ldots, 6$.

Step 1 — straight line. $\bar{x} = 3$, $S_{xx} = 28$, $S_{xy} = 81.09$: $\hat{\beta}_1 = 2.8961$, $\hat{\beta}_0 = 0.2661$. SSE $= 1.982$, SST $= 236.82$, $r^2 = 0.9916$.

Step 2 — residuals. $0.78,\ -0.04,\ -0.43,\ -0.64,\ -0.40,\ -0.05,\ 0.78$: positive at the ends, negative in the middle. Despite $r^2 > 0.99$ the line is systematically wrong.

Step 3 — quadratic. With design matrix columns $(1,\ x,\ x^2)$, solving $\mathbf{X}^{\mathsf{T}}\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}^{\mathsf{T}}\mathbf{y}$ gives $\hat{y} = 1.032 + 1.977x + 0.1532x^2$. Residuals are now all below 0.06 in magnitude with no pattern, and SSE $= 0.00987$ — two hundred times smaller.

Step 4 — is the improvement real? The partial F statistic for adding one parameter is $F = \frac{(1.982 - 0.00987)/1}{0.00987/4} = 799$ on $(1, 4)$ degrees of freedom, overwhelmingly significant. Adjusted $\bar{r}^2$ rises from 0.9900 to 0.99994.

Worked Example 20.34 — Time constant from an RC discharge

A capacitor discharges through a resistor; the voltage is sampled at $t = 0, 1, \ldots, 5$ ms: $5.02,\ 3.01,\ 1.86,\ 1.12,\ 0.67,\ 0.41$ V. Estimate τ.

Step 1 — linearise. $y_i = \ln v_i = 1.6134,\ 1.1019,\ 0.6206,\ 0.1133,\ -0.4005,\ -0.8916$.

Step 2 — fit. $\bar{t} = 2.5$, $S_{tt} = 17.5$, $S_{ty} = -8.7698$: slope $\hat{\beta}_1 = -0.50113$ ms^{-1}, intercept $\hat{\beta}_0 = 1.6124$.

Step 3 — parameters. $\hat{\tau} = -1/\hat{\beta}_1 = 1.9955$ ms, $\hat{V}_0 = e^{1.6124} = 5.015$ V.

Step 4 — uncertainty. $s = 0.00849$ (in ln units), $\mathrm{SE}(\hat{\beta}_1) = 0.00849/\sqrt{17.5} = 0.00203$. By first-order propagation (Section 20.10), $\mathrm{SE}(\hat{\tau}) = \mathrm{SE}(\hat{\beta}_1)/\hat{\beta}_1^2 = 0.0081$ ms. So $\tau = 1.996 \pm 0.022$ ms (95%, $t_{0.025,4} = 2.776$).

Step 5 — check. The residuals in the log domain $(+0.001,\ -0.009,\ +0.011,\ +0.004,\ -0.008,\ +0.002)$ show no trend, so a single exponential is adequate. If the noise were constant in volts, the later points (small v) would show larger log-residuals and a weighted fit would be preferable.

Common Pitfall — r^2 is not a test of model adequacy

A high r^2 says the line explains most of the variation *in this data set*; it says nothing about whether the functional form is right (Examples 20.31 and 20.33), whether it can be extrapolated, or whether the errors are independent. r^2 also depends on the range of x: the same physical relation sampled over a wider range gives a higher r^2. Judge fits by residual plots and by the size of s relative to the required accuracy.

Common Pitfall — Errors in x and regression dilution

Least squares assumes x is known exactly. If x is measured with noise of variance σ_u^2, the fitted slope is biased towards zero by the factor $S_{xx}/(S_{xx} + (n-1)\sigma_u^2)$ (**regression dilution**). When both variables are noisy and comparably so, use errors-in-variables methods (orthogonal/Deming regression) or make sure the reference variable is far more accurate than the response.

Engineering Note — Linearity specifications

An ADC's or sensor's "integral non-linearity" is the maximum residual from a fitted straight line, expressed in LSB or % of full scale. Datasheets specify whether the line is the *end-point* line (through the first and last codes) or the *best-fit* (least-squares) line; the best-fit figure is always smaller, sometimes by a factor of two, so the two are not comparable.

20.10 Experimental uncertainty

Why a common framework

A measurement result is incomplete without a statement of its uncertainty: without one, results cannot be compared with each other, with specifications, or with theory. Before 1993, laboratories used incompatible conventions ("random" and "systematic" errors combined linearly by some, in quadrature by others, at 1σ by some and 3σ by others). The *Guide to the Expression of Uncertainty in Measurement* (**GUM**, JCGM 100), issued jointly by BIPM, IEC, ISO and other bodies, established one method that is now used by every accredited calibration laboratory. It is the statistics of this chapter applied systematically to measurement.

Vocabulary

Measurand, error and uncertainty

- The **measurand** Y is the quantity intended to be measured (the resistance of *this* resistor at 23 °C).
- The **measurement model** $Y = f(X_1, \ldots, X_N)$ expresses the measurand in terms of **input quantities** X_i (readings, calibration corrections, environmental quantities).
- The **error** is the difference between the measured value and the true value; it is unknowable.
- The **standard uncertainty** $u(x_i)$ of an input estimate x_i is the standard deviation of the probability distribution that describes our knowledge of X_i.
- The **combined standard uncertainty** $u_c(y)$ is the standard uncertainty of the output estimate $y = f(x_1, \ldots, x_N)$.
- The **expanded uncertainty** $U = k\,u_c(y)$ defines an interval $y \pm U$ expected to contain a large fraction (the **coverage probability**, typically 95%) of the values that could reasonably be attributed to Y; k is the **coverage factor**.

Two further terms are often confused. **Accuracy** (closeness to the true value) is a qualitative concept; **precision** refers to the scatter of repeated readings (repeatability under the same conditions, reproducibility under changed conditions). Uncertainty is the quantitative statement that covers both. Known systematic effects are *corrected* — the GUM assumes the result has been corrected for all recognised significant systematic effects — and the uncertainty of each correction becomes an input to the budget.

Type A and Type B evaluation

The GUM classifies uncertainty components not by their physical nature ("random" vs "systematic") but by the **method used to evaluate them**.

Type A evaluation

Evaluation by statistical analysis of a series of observations. For n independent repeated readings $q_1, \dots, q_n$ of an input quantity, the estimate is $\bar{q}$ and

$$u(\bar{q}) = \frac{s(q)}{\sqrt{n}}, \qquad \nu = n - 1 \text{ degrees of freedom.}$$

This is the standard error of the mean of Section 20.5. If a well-characterised *pooled* standard deviation s_p from earlier extensive experiments is available, it can replace $s(q)$ (with its larger degrees of freedom), which is valuable when only a few readings are taken in the measurement itself.

Type B evaluation

Evaluation by any other means: manufacturer's specifications, calibration certificates, data from handbooks, resolution of a display, experience with similar instruments. The available information is converted to a standard deviation by assuming a probability distribution.

Information available	Assumed distribution	Standard uncertainty
Certificate: "U at $k = 2$" (or "95%")	Gaussian	$u = U/k$ (or $U/1.96$)
Limits $\pm a$, no other knowledge (specification, tolerance)	rectangular (uniform)	$u = a/\sqrt{3} \approx 0.577a$
Limits $\pm a$, values near centre more likely	triangular	$u = a/\sqrt{6} \approx 0.408a$
Quantity varies sinusoidally between $\pm a$ (e.g. RF mismatch, temperature cycling)	U-shaped (arcsine)	$u = a/\sqrt{2} \approx 0.707a$
Digital resolution δ (one count)	rectangular, half-width $\delta/2$	$u = \delta/\sqrt{12} \approx 0.289\delta$

The factors come from the variances of the distributions: uniform on $[-a, a]$ has variance $a^2/3$ (Section 20.4); the symmetric triangular distribution has variance $a^2/6$; the arcsine distribution of $a \sin\theta$ with θ uniform has variance $E[a^2 \sin^2\theta] = a^2/2$.

Type A and Type B uncertainties are both standard deviations and are combined in the same way. A Type B component with well-founded limits may be assigned effectively infinite degrees of freedom. When the limits themselves are uncertain, the GUM gives the approximation $\nu \approx \tfrac{1}{2}\big(\Delta u/u\big)^{-2}$, where $\Delta u/u$ is the relative uncertainty of the uncertainty (e.g. limits believed reliable to 25% give $\nu = 8$).

The law of propagation of uncertainty

Linearise the model about the input estimates (Ch. 4, Ch. 6):

$$Y \approx f(x_1, \dots, x_N) + \sum_{i=1}^{N} c_i\,(X_i - x_i), \qquad c_i = \left.\frac{\partial f}{\partial X_i}\right|_{\mathbf{x}}.$$

The c_i are **sensitivity coefficients**; they convert the uncertainty of each input into units of the output. Taking the variance of the linear approximation, with $\mathbf{c} = (c_1, \dots, c_N)^{\mathsf{T}}$ and the input covariance matrix $\boldsymbol{\Sigma}_x$, gives Section 20.3's rule $\operatorname{Var}(\mathbf{c}^{\mathsf{T}}\mathbf{X}) = \mathbf{c}^{\mathsf{T}}\boldsymbol{\Sigma}_x\mathbf{c}$:

Law of propagation of uncertainty (GUM)

$$u_c^2(y) = \sum_{i=1}^{N} c_i^2 u^2(x_i) + 2\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} c_i c_j\, u(x_i, x_j),$$

where $u(x_i, x_j) = r(x_i, x_j)\, u(x_i)\, u(x_j)$ is the estimated covariance. For **uncorrelated** inputs,

$$u_c(y) = \sqrt{\sum_{i=1}^{N} \big(c_i\, u(x_i)\big)^2},$$

the root-sum-of-squares (RSS) of the individual contributions $u_i(y) = |c_i| u(x_i)$.

Two special cases are used constantly:

- **Sums and differences** $Y = \sum a_i X_i$: $c_i = a_i$, so $u_c^2 = \sum a_i^2 u^2(x_i)$ (plus covariance terms).
- **Products and quotients** $Y = A\, X_1^{p_1} X_2^{p_2} \cdots X_N^{p_N}$: $c_i = p_i y / x_i$, so the **relative** uncertainties combine:

$$\left(\frac{u_c(y)}{y}\right)^2 = \sum_{i=1}^{N} \left(p_i \frac{u(x_i)}{x_i}\right)^2.$$

The RSS combination has an important practical consequence: the largest contributions dominate. A component one third the size of the largest adds only about 5% to u_c. Effort spent reducing small components is wasted; the **uncertainty budget** shows where improvement is worthwhile.

Correlated inputs. If two inputs are fully correlated ($r = +1$, e.g. two voltages measured with the same uncalibrated meter on the same range), their contributions add *linearly*: $u_c = |c_1 u_1 + c_2 u_2|$. For a sum of two such readings this increases the uncertainty; for a difference or a ratio it can cancel it — the reason ratio and substitution methods (bridges, comparators, ratiometric ADC references) are so accurate.

Validity. The law of propagation is first order. It is accurate when the model is nearly linear over the range $x_i \pm u(x_i)$, i.e. when the second-order terms $\tfrac{1}{2}\sum \frac{\partial^2 f}{\partial X_i^2} u^2(x_i)$ are negligible compared with u_c. It fails, for example, for $Y = X^2$ when $x \approx 0$ (the linear term vanishes) or for strongly nonlinear functions such as decibel conversions of very noisy quantities. GUM Supplement 1 then prescribes the **Monte Carlo method**: draw M (typically 10^6) samples of each input from its assigned distribution, evaluate the model for each draw, and take the mean, standard deviation and the $2.5\%/97.5\%$ percentiles of the resulting output sample (Ch. 24).

Effective degrees of freedom and the coverage factor

If u_c is dominated by Type A components with few degrees of freedom, u_c is itself uncertain and $k = 2$ gives less than 95% coverage. The output is then treated as t-distributed with an effective number of degrees of freedom given by the **Welch–Satterthwaite formula**:

$$\nu_{\text{eff}} = \frac{u_c^4(y)}{\displaystyle\sum_{i=1}^{N} \frac{u_i^4(y)}{\nu_i}}, \qquad u_i(y) = |c_i| u(x_i).$$

It is obtained by matching the variance of the estimated u_c^2 to that of a scaled χ^2_ν variable: each u_i^2 estimated with ν_i degrees of freedom has $\operatorname{Var}(u_i^2) \approx 2u_i^4/\nu_i$ (Section 20.5), these add, and a χ^2_ν-based estimate of u_c^2 would have variance $2u_c^4/\nu$. The coverage factor is then $k = t_{0.025,\nu_{\text{eff}}}$ (truncating ν_{eff} down to an integer): for $\nu_{\text{eff}} \geq 30$, $k \approx 2$; for $\nu_{\text{eff}} = 5$, $k = 2.57$.

Reporting

The GUM recommends stating the result as, for example,

$$R = 4.9748\ \text{k}\Omega \pm 0.0045\ \text{k}\Omega,$$

"where the number following the symbol $\pm$ is the numerical value of an expanded uncertainty $U = k u_c$, with U determined from a combined standard uncertainty $u_c = 2.3\ \Omega$ and a coverage factor $k = 2$, corresponding to a coverage probability of approximately 95%." Uncertainties are rounded to at most two significant digits, and the result is rounded to the same decimal position. A compact equivalent with standard uncertainty is $R = 4.9748(23)\ \text{k}\Omega$, the digits in parentheses being u_c in units of the last digit.

Worked Example 20.35 — Type B evaluations from a datasheet and a certificate

(a) DMM specification. On the 10 V range a DMM is specified to $\pm(0.02\%$ of reading $+\ 5$ counts), with resolution 0.1 mV. For a reading of 4.9852 V: $a = 0.0002(4.9852) + 0.0005 = 1.497$ mV. With no further knowledge, rectangular: $u = 1.497/\sqrt{3} = 0.864$ mV.

(b) Resolution. One count $\delta = 0.1$ mV: $u = 0.1/\sqrt{12} = 0.029$ mV — negligible beside (a). (The DMM specification usually already includes resolution; it is listed separately here only to show its size.)

(c) Certificate. A standard resistor's certificate states $U = 0.8\ \mu\Omega/\Omega$ at $k = 2$. Then $u = 0.4\ \mu\Omega/\Omega$, with ν taken from the certificate or as large.

(d) RF mismatch. A power meter's mismatch uncertainty has limits ± 0.10 dB, arising from an unknown relative phase of reflections, so the U-shaped distribution applies: $u = 0.10/\sqrt{2} = 0.071$ dB — larger than the rectangular value 0.058 dB, because the error spends most of its time near the limits.

Worked Example 20.36 — Propagation for a product: power in a resistor

$P = V^2/R$ with $V = 12.00$ V, $u(V) = 0.02$ V and $R = 47.0\ \Omega$, $u(R) = 0.2\ \Omega$ (uncorrelated).

Step 1 — estimate. $P = 144/47 = 3.0638$ W.

Step 2 — relative uncertainties. $u(V)/V = 0.167\%$, $u(R)/R = 0.426\%$.

Step 3 — combine with exponents $p_V = 2$, $p_R = -1$.

$$\frac{u_c(P)}{P} = \sqrt{(2 \times 0.167\%)^2 + (0.426\%)^2} = \sqrt{0.111 + 0.181}\,\% = 0.541\%.$$

So $u_c(P) = 0.0166$ W and $U = 0.033$ W ($k = 2$): $P = 3.064 \pm 0.033$ W.

Step 4 — sensitivity coefficients (the same thing, explicitly). $c_V = 2V/R = 0.5106$ W/V, $c_R = -V^2/R^2 = -0.06519$ W/Ω; contributions 0.0102 W and 0.0130 W; RSS = 0.0166 W.

Step 5 — Monte Carlo check. Drawing 10^6 Gaussian samples of V and R and evaluating V^2/R gives mean 3.0639 W, standard deviation 0.0165 W and a 95% interval $[3.0316,\ 3.0964]$ W, confirming the linearised result: the model is nearly linear over $\pm u$.

Worked Example 20.37 — Correlated inputs: series and ratio

Two nominally equal 1 kΩ resistors are measured with the same ohmmeter, whose calibration uncertainty 0.5 Ω is common to both readings (correlation $r = 1$); random reading noise is negligible.

(a) Series combination $R_s = R_1 + R_2$: $c_1 = c_2 = 1$, so $u_c^2 = 0.25 + 0.25 + 2(1)(1)(0.5)(0.5) = 1.0\ \Omega^2$, $u_c = 1.0\ \Omega$. Ignoring the correlation would give $0.71\ \Omega$ — an underestimate.

(b) Ratio $Q = R_1/R_2$: write the calibration error as a common scale factor. With $c_1 = 1/R_2$ and $c_2 = -R_1/R_2^2$ (both $\approx \pm 10^{-3}\ \Omega^{-1}$), $u_c^2 \approx (10^{-3} \times 0.5)^2 + (10^{-3} \times 0.5)^2 - 2(10^{-3})(10^{-3})(0.25) = 0$. The common error cancels completely in the ratio. This is why a resistance bridge or a ratiometric measurement (sensor and ADC sharing one reference) can be far more accurate than the absolute accuracy of its parts.

Worked Example 20.38 — A complete uncertainty budget: $R = V/I$

A resistor is measured by passing a current and reading voltage and current with two DMMs. Ten simultaneous readings give $\bar{V} = 4.9852$ V with $s(V) = 1.2$ mV and $\bar{I} = 1.00210$ mA with $s(I) = 0.30\ \mu$A. The voltmeter is specified as in Example 20.35(a); the ammeter as $\pm(0.05\%$ of reading $+ 0.2\ \mu$A). Assume the two meters' errors are uncorrelated, as is the reading noise.

Step 1 — model and estimate. $R = V/I = 4.9852/1.00210 = 4.97475$ kΩ.

Step 2 — sensitivity coefficients. $c_V = 1/I = 0.99790$ kΩ/V; $c_I = -V/I^2 = -4.9643$ kΩ/mA.

Step 3 — input uncertainties.

- V, Type A: $1.2/\sqrt{10} = 0.379$ mV, $\nu = 9$.
- V, Type B (specification): 0.864 mV, $\nu = \infty$.
- I, Type A: $0.30/\sqrt{10} = 0.0949\ \mu$A, $\nu = 9$.
- I, Type B: $a = 0.0005(1.00210\text{ mA}) + 0.2\ \mu\text{A} = 0.701\ \mu$A; $u = 0.701/\sqrt{3} = 0.405\ \mu$A, $\nu = \infty$.

Step 4 — budget.

Source	$u(x_i)$	c_i	$\lvert u_i(R)\rvert$ (Ω)	ν_i
V repeatability (A)	0.379 mV	0.9979 kΩ/V	0.38	9
V meter spec (B, rect.)	0.864 mV	0.9979 kΩ/V	0.86	∞
I repeatability (A)	0.0949 μA	−4.964 kΩ/mA	0.47	9
I meter spec (B, rect.)	0.405 μA	−4.964 kΩ/mA	2.01	∞
Combined $u_c(R)$			**2.27**	$\nu_{\text{eff}} \approx 3400$

Step 5 — combine. $u_c = \sqrt{0.38^2 + 0.86^2 + 0.47^2 + 2.01^2} = 2.27\ \Omega$ (relative 0.046%).

Step 6 — effective degrees of freedom. $\nu_{\text{eff}} = 2.27^4/\left(0.38^4/9 + 0.47^4/9\right) \approx 3.4 \times 10^3$; Type B components dominate, so $k = 2$ is appropriate.

Step 7 — report. $R = 4.9748\ \text{k}\Omega \pm 0.0045\ \text{k}\Omega$ ($k = 2$, $\approx 95\%$).

Step 8 — read the budget. The ammeter specification contributes $2.01^2/2.27^2 = 78\%$ of the variance. Taking more readings (reducing the Type A terms) would barely help; a better ammeter, or measuring the current as the voltage across a calibrated standard resistor (turning the measurement into a ratio, Example 20.37), would.

Worked Example 20.39 — When few readings dominate: Welch–Satterthwaite

A frequency is measured four times; the Type A standard uncertainty of the mean is $u_A = 0.8$ Hz ($\nu = 3$). The counter's timebase contributes a Type B $u_B = 0.5$ Hz ($\nu = \infty$).

Step 1 — combine. $u_c = \sqrt{0.8^2 + 0.5^2} = 0.943$ Hz.

Step 2 — degrees of freedom. $\nu_{\text{eff}} = 0.943^4/(0.8^4/3) = 0.792/0.1365 = 5.8$, truncated to 5.

Step 3 — coverage factor. $k = t_{0.025,5} = 2.57$, so $U = 2.57 \times 0.943 = 2.4$ Hz. Using $k = 2$ would give 1.9 Hz and an actual coverage of only about 90%.

Step 4 — improvement. Taking 16 readings instead of 4 would halve u_A to 0.4 Hz (if s is unchanged) and raise ν to 15; then $u_c = 0.64$ Hz, $\nu_{\text{eff}} \approx 98$, $k \approx 1.98$ and $U \approx 1.3$ Hz — nearly half the previous value.

Common Pitfall — Adding uncertainties linearly, or double counting

Adding all contributions linearly ("worst case") overstates the uncertainty for independent inputs; RSS is correct unless the inputs are correlated. Conversely, listing the same physical effect twice — e.g. a DMM's resolution in addition to a specification that already includes it, or the scatter of readings that already reflects the temperature fluctuation you also list as Type B — inflates the budget. Each physical effect should appear once.

Common Pitfall — Confusing tolerance with uncertainty

A 1% resistor's tolerance is the limit of its deviation from nominal, a Type B input with $u = 1\%/\sqrt{3} = 0.58\%$ if nothing else is known. Once the resistor has been *measured*, its value is known to the measurement uncertainty, which is usually far smaller; the tolerance is then irrelevant. Using tolerance limits as if they were 1σ values, or as if they were 95% limits, are both common errors.

Engineering Note — Uncertainty and conformance decisions

Deciding whether a measured value conforms to a specification must account for the measurement uncertainty: a reading 0.3% inside a $\pm 1\%$ limit with $U = 0.5\%$ does not prove conformance. Standards such as ISO 14253-1 and ILAC-G8 formalise this with **guard bands** of width related to U — the measurement-uncertainty version of the production-test trade-off in Section 20.8. A common rule of thumb is a **test uncertainty ratio** of at least 4:1 between the specification tolerance and the measurement's expanded uncertainty.

Summary

Topic	Key formula or fact
Sample mean, variance	$\bar{x} = \frac{1}{n}\sum x_i,\ s^2 = \frac{1}{n-1}\sum (x_i - \bar{x})^2$ (unbiased)
Robust spread	$\mathrm{IQR} = Q_3 - Q_1$; fences $Q_1 - 1.5\,\mathrm{IQR}$, $Q_3 + 1.5\,\mathrm{IQR}$; $\sigma \approx 1.4826\,\mathrm{MAD}$
Weighted mean	$\bar{x}_w = \sum w_i x_i / \sum w_i$, $w_i = 1/u_i^2$, $u(\bar{x}_w) = (\sum w_i)^{-1/2}$
RMS and variance	$V_{\mathrm{rms}}^2 = V_{\mathrm{DC}}^2 + \sigma_v^2$
Correlation	$r = S_{xy}/\sqrt{S_{xx}S_{yy}}$, $-1 \le r \le 1$; Spearman $r_s = 1 - 6\sum d_i^2/(n(n^2-1))$
Covariance propagation	$\mathbf{\Sigma}_Y = \mathbf{A}\mathbf{\Sigma}_X\mathbf{A}^{\mathsf{T}}$; $\mathrm{Var}(X \pm Y) = \sigma_X^2 + \sigma_Y^2 \pm 2\,\mathrm{Cov}$
Binomial / Poisson	$np,\ np(1-p)\ /\ \lambda,\ \lambda$
Uniform / exponential	$\frac{a+b}{2},\ \frac{(b-a)^2}{12}\ /\ \frac{1}{\lambda},\ \frac{1}{\lambda^2}$; memoryless
Rayleigh	$E[R] = \sigma\sqrt{\pi/2}$, $E[R^2] = 2\sigma^2$, $P(R > r) = e^{-r^2/(2\sigma^2)}$
χ_k^2, t_ν, F_{d_1,d_2}	sum of k squared $\mathcal{N}(0,1)$; $Z/\sqrt{V/\nu}$; ratio of normalised χ^2
Sample mean	$E\bar{X} = \mu$, $\mathrm{SE} = \sigma/\sqrt{n}$; CLT: $\frac{\bar{X}-\mu}{\sigma/\sqrt{n}} \to \mathcal{N}(0,1)$
Gaussian sampling	$(n-1)S^2/\sigma^2 \sim \chi_{n-1}^2$; $\frac{\bar{X}-\mu}{S/\sqrt{n}} \sim t_{n-1}$; $\bar{X} \perp S^2$
Estimator quality	$\mathrm{MSE} = \mathrm{Var} + b^2$; CRLB $\mathrm{Var}\,\hat{\theta} \ge 1/(nI(\theta))$
MLE	maximise $\ell(\theta) = \sum \ln f(x_i;\theta)$; $\mathrm{SE} \approx 1/\sqrt{-\ell''(\hat{\theta})}$; Gaussian noise $\Rightarrow$ least squares
CI for mean	$\bar{x} \pm z_{\alpha/2}\sigma/\sqrt{n}$; $\bar{x} \pm t_{\alpha/2,n-1}s/\sqrt{n}$; $n = (z_{\alpha/2}\sigma/E)^2$
CI for variance	$\left[(n-1)s^2/\chi^2_{\alpha/2,n-1},\ (n-1)s^2/\chi^2_{1-\alpha/2,n-1}\right]$
Tests	z, t (one-sample, Welch, paired); $\chi^2 = \sum(O-E)^2/E$ with $K-1-m$ d.o.f.; $F = s_1^2/s_2^2$
Errors	$\alpha = P(\text{reject} \mid H_0)$, $\beta = P(\text{accept} \mid H_1)$; power $= 1-\beta$; $n = ((z_\alpha + z_\beta)\sigma/\delta)^2$
Regression	$\hat{\beta}_1 = S_{xy}/S_{xx}$, $\hat{\beta}_0 = \bar{y} - \hat{\beta}_1\bar{x}$, $s^2 = \mathrm{SSE}/(n-2)$, $\mathrm{SE}(\hat{\beta}_1) = s/\sqrt{S_{xx}}$
r^2, matrix LS	$r^2 = 1 - \mathrm{SSE}/\mathrm{SST}$; $\hat{\boldsymbol{\beta}} = (\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{y}$, $\mathrm{Cov} = \sigma^2(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}$
Type A / Type B	$u = s/\sqrt{n}$ ($\nu = n-1$); rectangular $a/\sqrt{3}$, triangular $a/\sqrt{6}$, U-shaped $a/\sqrt{2}$, resolution $\delta/\sqrt{12}$
Propagation (GUM)	$u_c^2 = \sum c_i^2 u^2(x_i) + 2\sum_{i<j} c_i c_j u(x_i,x_j)$, $c_i = \partial f/\partial x_i$
Products	$(u_c/y)^2 = \sum (p_i u(x_i)/x_i)^2$ for $y = A\prod x_i^{p_i}$
Expanded uncertainty	$U = k u_c$; $\nu_{\mathrm{eff}} = u_c^4/\sum(u_i^4/\nu_i)$; $k = t_{0.025,\nu_{\mathrm{eff}}}$ (≈ 2 for large ν)

Chapter 21 — Random Processes

> **Prerequisites:** Ch. 16 (Fourier Transforms), Ch. 17 (Z-Transforms), Ch. 19 (Probability), Ch. 20 (Statistical Analysis) **Learning outcomes:** After this chapter you can …
>
> - describe a random process as an ensemble of sample functions, distinguish ensemble averages from time averages, and compute mean, autocorrelation and autocovariance functions;
> - test a process for strict- and wide-sense stationarity and use the properties of autocorrelation and cross-correlation functions;
> - move between autocorrelation and power spectral density with the Wiener–Khinchin theorem, and compute the output mean, autocorrelation and PSD $S_{YY} = |H|^2 S_{XX}$ of an LTI system with random input, in continuous and discrete time (including AR(1) sequences);
> - work with Gaussian processes, white and band-limited white noise, and the noise-equivalent bandwidth of a filter;
> - decide when time averages may replace ensemble averages (ergodicity) and how long a record must be;
> - carry out standard noise calculations: thermal noise $4kTRB$, kT/C noise, SNR after filtering and averaging, and the matched filter.

A random variable (Ch. 19) assigns a number to each outcome of an experiment. Many engineering signals — the hiss at a receiver output, a speech waveform, the bit stream on a serial link, the drift of a gyroscope, the error of an ADC over time — are not single numbers but *functions of time* whose exact shape cannot be predicted in advance. Yet they are far from lawless: the noise at the output of a given amplifier always has about the same RMS value, its spectrum always has about the same shape, and a filter always reduces it by about the same amount. A **random process** is the mathematical object that captures this combination of unpredictable detail and predictable statistics. It assigns a whole waveform to each outcome of an experiment.

This chapter develops the **second-order theory** of random processes — means, correlation functions and power spectra. Second-order theory is remarkably economical: it is exactly what is preserved and transformed by linear systems, it completely characterizes Gaussian processes, and it answers the questions an engineer asks most often (What is the noise power? How is it distributed over frequency? How much does this filter remove? How long must I average?). We use the Fourier transform conventions of Ch. 16 ($X(\omega) = \int x(t) e^{-j\omega t} dt$) and the discrete-time transforms of Ch. 17 throughout, and the probability language of Ch. 19.

21.1 Random sequences and processes

Motivation

Suppose you connect an oscilloscope across a resistor at room temperature, set a large vertical gain, and press "single" a hundred times. Every trace is different — no two records of thermal noise ever coincide — but every trace has the same "look": the same typical amplitude, the same graininess. If you sample all hundred traces at the instant $t_1 = 3$ μs after the trigger, the hundred numbers you collect form a histogram that looks Gaussian with zero mean. If you instead take *one* trace and histogram its values along time, you get, for this kind of noise, the same Gaussian. These two procedures — averaging *across* records at a fixed time, and averaging *along* one record — are the two fundamental operations of this chapter, and the question of when they agree (ergodicity, §21.7) is one of its central themes.

Definition and the two viewpoints

Random process

Let $(\Omega, \mathcal{F}, P)$ be a probability space and T an index set. A **random process** (stochastic process) is a family of random variables $\{X(t),\ t \in T\}$ all defined on the same Ω. For each outcome $\zeta \in \Omega$ the function $t \mapsto X(t, \zeta)$ is a **sample function** (realization, sample path); the collection of all sample functions is the **ensemble**.

- $T \subseteq \mathbb{R}$ (an interval): **continuous-time** process $X(t)$.
- $T \subseteq \mathbb{Z}$: **discrete-time** process or **random sequence** $X[n]$.

Independently, the *values* may be continuous (a noise voltage) or discrete (a bit, a count).

A random process is thus a function of two variables, $X(t, \zeta)$, and there are two ways to slice it:

- **Fix t:** $X(t_1, \cdot)$ is an ordinary random variable with CDF $F_X(x; t_1) = P\{X(t_1) \le x\}$ and pdf $f_X(x; t_1) = \partial F_X / \partial x$. Everything in Ch. 19 applies to it.
- **Fix ζ:** $X(\cdot, \zeta_1)$ is a deterministic waveform — the single trace you see on the oscilloscope. Everything in Chs. 15–17 (Fourier series, transforms) applies to it, at least formally.

We follow the usual convention of suppressing ζ and writing $X(t)$; lowercase $x(t)$ denotes one particular sample function.

The four combinations of continuous/discrete time and continuous/discrete values all occur in practice:

	continuous values	discrete values
continuous time	thermal noise voltage $V_n(t)$	random telegraph signal ± 1; photon count $N(t)$
discrete time	sampled noise $V_n[n] = V_n(nT_s)$	data bits $b[n] \in \{0, 1\}$; quantized samples

Finite-dimensional distributions

A single random variable is described by its CDF. A random process involves infinitely many random variables, and their joint behaviour matters: the probability that a noise voltage exceeds a threshold at two instants 1 ns apart is very different from the probability for two instants 1 s apart.

Finite-dimensional distributions

The k**-th order distribution** of $X(t)$ is the joint CDF

$$F_X(x_1,\dots,x_k;\,t_1,\dots,t_k) = P\{X(t_1)\le x_1,\dots,X(t_k)\le x_k\},$$

with joint pdf $f_X(x_1,\dots,x_k;t_1,\dots,t_k)$. The process is **specified in distribution** when these are known for every k and every choice of times $t_1,\dots,t_k$.

Kolmogorov's extension theorem guarantees that any *consistent* family of finite-dimensional distributions (marginalizing the $(k+1)$-th order distribution over one variable gives the k-th order one, and permuting the times permutes the variables) defines a random process. In practice we almost never know all of these distributions. Two situations are tractable:

1. **The process is built explicitly** from a few random variables, e.g. $X(t) = A\cos(\omega_0 t + \Theta)$. Then all distributions follow from those of A and Θ.
2. **The process is Gaussian** (§21.5). Then the first two moments determine everything.

Otherwise we settle for the first two moments, which is what the rest of this section introduces.

Ensemble averages: mean, autocorrelation, autocovariance

Mean, autocorrelation, autocovariance

$$\mu_X(t) = E[X(t)] = \int_{-\infty}^{\infty} x\, f_X(x;t)\,dx$$

$$R_{XX}(t_1,t_2) = E[X(t_1)X(t_2)] = \iint x_1 x_2\, f_X(x_1,x_2;t_1,t_2)\,dx_1\,dx_2$$

$$C_{XX}(t_1,t_2) = E\big[(X(t_1)-\mu_X(t_1))(X(t_2)-\mu_X(t_2))\big] = R_{XX}(t_1,t_2) - \mu_X(t_1)\mu_X(t_2)$$

The **variance function** is $\sigma_X^2(t) = C_{XX}(t,t)$ and the **mean-square value** (average power at time t, in a 1 Ω normalization) is $E[X^2(t)] = R_{XX}(t,t)$. The **correlation coefficient** is $\rho_{XX}(t_1,t_2) = C_{XX}(t_1,t_2)/(\sigma_X(t_1)\sigma_X(t_2)) \in [-1,1]$. For a complex process, $R_{XX}(t_1,t_2) = E[X(t_1)X^*(t_2)]$ and $C_{XX}(t_1,t_2) = R_{XX}(t_1,t_2) - \mu_X(t_1)\mu_X^*(t_2)$.

These are **ensemble averages**: at each time they average over all outcomes ζ, i.e. vertically across the ensemble of traces. The mean function $\mu_X(t)$ is a deterministic function of time (for example, a DC offset that drifts as an amplifier warms up). The autocorrelation is a deterministic function of *two* times: it measures how strongly the value at t_1 is (linearly) related to the value at t_2.

Two facts follow immediately from the definition and are used constantly:

- **Symmetry:** $R_{XX}(t_1,t_2) = R_{XX}(t_2,t_1)$ for a real process (and $R_{XX}(t_1,t_2) = R_{XX}^*(t_2,t_1)$ for a complex one).
- **Non-negative definiteness:** for any times $t_1,\dots,t_n$ and real constants $a_1,\dots,a_n$,

$$\sum_{i=1}^{n}\sum_{k=1}^{n} a_i a_k\, R_{XX}(t_i,t_k) = E\Big[\Big(\sum_i a_i X(t_i)\Big)^2\Big] \ge 0.$$

So the matrix $[R_{XX}(t_i,t_k)]$ is a correlation matrix (Ch. 19) for every choice of times. Not every symmetric function of two variables can be an autocorrelation.

For two processes on the same probability space we also define the **cross-correlation** $R_{XY}(t_1,t_2) = E[X(t_1)Y(t_2)]$ and **cross-covariance** $C_{XY}(t_1,t_2) = R_{XY}(t_1,t_2) - \mu_X(t_1)\mu_Y(t_2)$; they are studied in §21.3.

Time averages

For a single sample function $x(t)$ we can also average *along time*:

Time averages of a sample function

$$\langle x\rangle = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} x(t)\,dt, \qquad \mathcal{R}_x(\tau) = \langle x(t+\tau)x(t)\rangle = \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} x(t+\tau)x(t)\,dt.$$

For a sequence, $\langle x\rangle = \lim_{N\to\infty}\frac{1}{2N+1}\sum_{n=-N}^{N} x[n]$, and similarly for $\mathcal{R}_x[k]$.

The two kinds of average are conceptually very different:

	Ensemble average $E[\cdot]$	**Time average** $\langle\cdot\rangle$
averages over	outcomes ζ at fixed t	time t for fixed ζ
result	deterministic function of t	a number (or a function of τ) that may depend on ζ, i.e. a random variable
what you need	many independent records	one long record
what a DC voltmeter reads	—	$\langle x\rangle$ (over its averaging time)
what a true-RMS meter reads	—	$\sqrt{\langle x^2\rangle}$

Laboratory instruments compute time averages; theory is most easily done with ensemble averages. A process for which the two coincide (with probability 1) is called **ergodic** — §21.7 makes this precise and shows that it is a genuine assumption, not a tautology.

A catalogue of standard processes

Process	Construction	Typical EE use
Random-phase sinusoid	$X(t) = A\cos(\omega_0 t + \Theta)$, $\Theta \sim U[0, 2\pi)$	oscillator with unknown phase; carrier at a receiver
i.i.d. sequence	$X[n]$ independent, identically distributed	data symbols; ideal discrete white noise
Bernoulli / binary sequence	$X[n] \in \{-1, +1\}$ i.i.d., equally likely	random data bits, PRBS test patterns
Random walk	$S[n] = \sum_{k=1}^{n} X[k]$, $X[k]$ i.i.d. ± 1	phase-noise accumulation, drift, integrated error
Moving average MA(q)	$X[n] = \sum_{k=0}^{q} b_k W[n-k]$, W i.i.d.	FIR-filtered noise
Autoregressive AR(1)	$X[n] = aX[n-1] + W[n]$	IIR-filtered noise, sensor bias, channel fading (§21.4)
Random binary waveform	$X(t) = \sum_k a_k\, p(t - kT - D)$, $a_k = \pm A$, $D \sim U[0, T)$	NRZ data on a cable
Random telegraph signal	$X(t) = \pm 1$, sign flips at Poisson times of rate λ	burst (RTS) noise in MOSFETs, on/off traffic
Poisson counting process	$N(t)$ = number of events in $(0, t]$, rate λ	photon and electron arrivals, shot noise
Wiener process	limit of a scaled random walk (§21.5)	Brownian motion, oscillator phase noise
Gaussian process	all finite-dimensional distributions Gaussian	thermal noise, aggregate interference

A useful structural property shared by the random walk, the Poisson process and the Wiener process is:

Independent increments

$X(t)$ has **independent increments** if for any $t_1 < t_2 < \cdots < t_k$ the increments $X(t_2) - X(t_1),\ X(t_3) - X(t_2), \ldots, X(t_k) - X(t_{k-1})$ are mutually independent. It has **stationary increments** if the distribution of $X(t+s) - X(t)$ depends only on s.

For a process with independent increments starting from $X(0) = 0$, the autocovariance has the universal form $C_{XX}(t_1, t_2) = \sigma_X^2(\min(t_1, t_2))$: for $t_1 \le t_2$, write $X(t_2) = X(t_1) + [X(t_2) - X(t_1)]$; the bracket is independent of $X(t_1)$, so $\operatorname{Cov}(X(t_1), X(t_2)) = \operatorname{Var} X(t_1)$.

Worked examples

Worked Example 21.1 — Mean and autocorrelation of a random-phase sinusoid

Let $X(t) = A\cos(\omega_0 t + \Theta)$ with constants A, ω_0 and $\Theta \sim U[0, 2\pi)$.

Step 1 — mean. The pdf of Θ is $1/(2\pi)$ on $[0, 2\pi)$, so

$$\mu_X(t) = \frac{1}{2\pi}\int_0^{2\pi} A\cos(\omega_0 t + \theta)\, d\theta = 0 \quad \text{for every } t,$$

because a cosine integrates to zero over a full period of its argument.

Step 2 — autocorrelation. Using $\cos a \cos b = \tfrac{1}{2}[\cos(a-b) + \cos(a+b)]$,

$$R_{XX}(t_1, t_2) = \frac{A^2}{2} E\big[\cos\omega_0(t_1 - t_2)\big] + \frac{A^2}{2} E\big[\cos(\omega_0(t_1 + t_2) + 2\Theta)\big] = \frac{A^2}{2}\cos\omega_0(t_1 - t_2).$$

The first expectation is of a constant; the second is zero because 2Θ is uniform over two full periods.

Step 3 — interpretation. R_{XX} depends only on $t_1 - t_2$, not on absolute time — the hallmark of stationarity (§21.2). The power $R_{XX}(t, t) = A^2/2$ is the familiar mean-square value of a sinusoid of amplitude A.

Step 4 — first-order pdf. Since $\omega_0 t + \Theta \pmod{2\pi}$ is uniform, $X(t)$ has the arcsine pdf $f_X(x) = 1/(\pi\sqrt{A^2 - x^2})$ for $|x| < A$, the same for every t. A numerical check: $\int_{-A}^{A} x^2/(\pi\sqrt{A^2 - x^2})\, dx = A^2/2$. ✓

Step 5 — time averages. Take one sample function, $x(t) = A\cos(\omega_0 t + \theta_1)$. Its time average is 0 and its time autocorrelation is $\langle x(t+\tau)x(t)\rangle = \frac{A^2}{2}\cos\omega_0\tau$ — the same as the ensemble results, whatever θ_1 is. This process is ergodic (§21.7).

Worked Example 21.2 — Random walk: variance that grows

Let $S[0] = 0$ and $S[n] = \sum_{k=1}^{n} X[k]$ for $n \ge 1$, with $X[k]$ i.i.d., $P(X = \pm 1) = \tfrac{1}{2}$, so $E[X] = 0$ and $E[X^2] = 1$.

Mean. $\mu_S[n] = \sum_{k=1}^{n} E[X[k]] = 0$.

Autocorrelation. $R_{SS}[n_1, n_2] = E\Big[\sum_{k=1}^{n_1}\sum_{l=1}^{n_2} X[k]X[l]\Big] = \sum_k\sum_l E[X[k]X[l]]$. By independence $E[X[k]X[l]] = \delta[k-l]$, so only the terms with $k = l \le \min(n_1, n_2)$ survive:

$$R_{SS}[n_1, n_2] = \min(n_1, n_2).$$

This agrees with the independent-increments formula $C(t_1, t_2) = \sigma^2(\min(t_1, t_2))$.

Consequences. $\sigma_S^2[n] = n$: the ensemble spreads like $\sqrt{n}$. After $n = 10^4$ steps the typical excursion is about 100, and by the central limit theorem $P\{|S[10^4]| > 200\} \approx 2Q(2) \approx 0.046$. The correlation coefficient between $S[n]$ and $S[4n]$ is $n/\sqrt{n \cdot 4n} = 1/2$ for every n: the walk "remembers" its past indefinitely. Integrated noise — e.g. oscillator phase driven by white frequency noise, or the position estimate of an inertial navigator integrating noisy accelerometer readings — behaves the same way.

Worked Example 21.3 — The Poisson counting process

$N(t)$, $t \geq 0$, counts events in $(0, t]$; it has independent, stationary increments and $N(t+s) - N(t) \sim \text{Poisson}(\lambda s)$. Hence $\mu_N(t) = \lambda t$ and $\sigma_N^2(t) = \lambda t$.

Autocorrelation. For $t_1 \leq t_2$, by the independent-increments argument $C_{NN}(t_1, t_2) = \text{Var}\, N(t_1) = \lambda t_1$. So in general

$$C_{NN}(t_1, t_2) = \lambda \min(t_1, t_2), \qquad R_{NN}(t_1, t_2) = \lambda \min(t_1, t_2) + \lambda^2 t_1 t_2.$$

Numbers. A photodiode receives photons at $\lambda = 10^9$ s^{-1}. In a 1 μs window the expected count is $\lambda t = 1000$ with standard deviation $\sqrt{1000} = 31.6$, a relative fluctuation of 3.2%. This $1/\sqrt{\lambda t}$ fluctuation is **shot noise**; the corresponding photocurrent noise has one-sided PSD $2qI$ (§21.8). Note the mean grows with t, so $N(t)$ is not stationary — but its *increments over fixed-length windows* are.

Worked Example 21.4 — Sampling a process gives a random sequence

A continuous-time process $X(t)$ with $\mu_X = 0$ and $R_{XX}(t_1, t_2) = \sigma^2 e^{-\alpha|t_1 - t_2|}$ is sampled every T_s seconds: $X[n] = X(nT_s)$. Then

$$R_{XX}[n_1, n_2] = E[X(n_1 T_s) X(n_2 T_s)] = \sigma^2 e^{-\alpha T_s |n_1 - n_2|} = \sigma^2 a^{|n_1 - n_2|}, \qquad a = e^{-\alpha T_s}.$$

With $\alpha = 1000$ s^{-1} (correlation time 1 ms) and $T_s = 100$ μs, $a = e^{-0.1} = 0.905$: adjacent samples are 90% correlated, and samples are essentially uncorrelated ($\rho < 0.05$) only when $|n_1 - n_2| \geq 30$. Sampling at $T_s = 5$ ms instead gives $a = e^{-5} = 0.0067$: practically uncorrelated samples. This geometric autocorrelation is exactly that of the AR(1) sequence we study in §21.4 — sampling a first-order Gauss–Markov process produces an AR(1) sequence.

Common Pitfall — confusing the two averages

$E[X(t)]$ is a function of t computed across the ensemble; $\langle x \rangle$ is a number computed along one record. Writing "the mean of the noise" without saying which is ambiguous. For a process like $X(t) = A$ (a random constant, see §21.7), $E[X(t)] = E[A]$ but $\langle x \rangle = A$: they differ for every outcome except those with $A = E[A]$.

Engineering Note

Measurement noise, quantization error, channel noise, phase noise and interference are all modelled as random processes. What we need for design is rarely the full set of finite-dimensional distributions; it is the mean (DC offset), the power (RMS value) and *how that power is spread over time lag and frequency*. The autocorrelation (§21.3) and the power spectral density (§21.4) carry exactly this information, and linear systems transform them by simple rules.

21.2 Stationarity

Motivation

Most of the convenient machinery of signal analysis — transfer functions, spectra, filters designed once and used forever — rests on **time invariance**. For random signals the corresponding idea is that the *statistics* of the process do not change with time: the noise from a resistor in thermal equilibrium looks statistically the same today as tomorrow, even though no two sample functions agree. Stationarity is what makes the autocorrelation a function of one variable (the lag) instead of two, and that in turn is what allows the Fourier transform to enter (§21.4). Without it, the notion of a "noise spectrum" is not even well defined.

Strict-sense stationarity

Strict-sense stationarity (SSS)

$X(t)$ is **strict-sense stationary** if all its finite-dimensional distributions are invariant under a time shift: for every k, every set of times $t_1, \ldots, t_k$ and every shift c,

$$F_X(x_1, \ldots, x_k;\, t_1 + c, \ldots, t_k + c) = F_X(x_1, \ldots, x_k;\, t_1, \ldots, t_k).$$

If this holds only for $k \leq N$, the process is **stationary of order** N.

Consequences for an SSS process:

- **First order** ($k = 1$): $f_X(x; t) = f_X(x)$ does not depend on t. In particular $\mu_X(t) = \mu_X$ and $\sigma_X^2(t) = \sigma_X^2$ are constants.
- **Second order** ($k = 2$): $f_X(x_1, x_2; t_1, t_2)$ depends on the times only through $\tau = t_1 - t_2$ (choose $c = -t_2$). Hence $R_{XX}(t_1, t_2)$ is a function of $t_1 - t_2$ alone.

i.i.d. sequences are strictly stationary

If $X[n]$ are independent and identically distributed with CDF F, then $X[n]$ is SSS.

Proof. For any distinct $n_1, \ldots, n_k$ and shift c, independence gives $F_X(x_1, \ldots, x_k; n_1 + c, \ldots, n_k + c) = \prod_i F(x_i)$, which does not involve c. $\square$

A memoryless function of an SSS process, $Y(t) = g(X(t))$, is again SSS (the joint distribution of $Y(t_1 + c), \ldots, Y(t_k + c)$ is determined by that of $X(t_1 + c), \ldots, X(t_k + c)$). So is the output of any time-invariant (possibly nonlinear) system with memory driven by an SSS input, once start-up transients have died away.

SSS is a strong requirement and is hard to verify from data: it constrains distributions of every order. For linear-system analysis a much weaker condition, involving only the first two moments, suffices.

Wide-sense stationarity

Wide-sense stationarity (WSS)

$X(t)$ is **wide-sense stationary** (weakly stationary) if

1. $E[X^2(t)] < \infty$ for all t,
2. $\mu_X(t) = \mu_X$ is constant, and
3. $R_{XX}(t_1, t_2)$ depends only on $\tau = t_1 - t_2$.

We then write, with a slight abuse of notation,

$$R_{XX}(\tau) = E[X(t+\tau)X(t)], \qquad C_{XX}(\tau) = R_{XX}(\tau) - \mu_X^2, \qquad \sigma_X^2 = C_{XX}(0).$$

For a random sequence: $E[X[n]] = \mu_X$ and $R_{XX}[k] = E[X[n+k]X[n]]$ independent of n.

Joint wide-sense stationarity

$X(t)$ and $Y(t)$ are **jointly WSS** if each is WSS and $R_{XY}(t_1, t_2) = E[X(t_1)Y(t_2)]$ depends only on $t_1 - t_2$. We write $R_{XY}(\tau) = E[X(t+\tau)Y(t)]$.

Relations between the notions:

- **SSS with finite second moment** $\Rightarrow$ **WSS.** Shown above.
- **WSS** $\not\Rightarrow$ **SSS** in general (Example 21.8 below).
- **For Gaussian processes, WSS** $\Leftrightarrow$ **SSS** (§21.5), because the mean and autocovariance determine all finite-dimensional distributions.
- Each of X and Y being WSS does **not** make them jointly WSS. For example, with X WSS and $Y(t) = X(-t)$ (also WSS), $R_{XY}(t_1, t_2) = R_{XX}(t_1 + t_2)$, which depends on the sum of the times.

Engineering Note — why "WSS" is the working assumption

Every result about filters and spectra in this chapter needs only WSS. Since estimating higher-order distributions takes enormous amounts of data, practising engineers almost always mean "WSS" when they say "stationary". When a noise source is additionally Gaussian — the usual case for thermal noise and many aggregate interference sources — nothing is lost.

Testing for stationarity: worked examples

The procedure is always the same: compute $\mu_X(t)$ and $R_{XX}(t+\tau, t)$ and check whether t drops out.

Worked Example 21.5 — Random phase, random amplitude, random pair

(a) $X(t) = A\cos(\omega_0 t + \Theta)$, $\Theta \sim U[0, 2\pi)$: from Example 21.1, $\mu_X = 0$ and $R_{XX}(t+\tau, t) = \frac{A^2}{2}\cos\omega_0\tau$. **WSS.** (In fact SSS: shifting time by c is the same as shifting Θ by $\omega_0 c$, which leaves its uniform distribution modulo 2π unchanged.)

(b) $Y(t) = B\cos\omega_0 t$ with B a random variable, $E[B] = \mu_B$, $E[B^2] = m_2$:

$$\mu_Y(t) = \mu_B\cos\omega_0 t, \qquad R_{YY}(t+\tau, t) = m_2\cos\omega_0(t+\tau)\cos\omega_0 t = \frac{m_2}{2}\big[\cos\omega_0\tau + \cos\omega_0(2t+\tau)\big].$$

If $\mu_B \neq 0$ the mean depends on t; even with $\mu_B = 0$, R_{YY} depends on t through the second term. **Not WSS.** Physically: every sample function passes through zero at the same instants $t = (k + \tfrac{1}{2})\pi/\omega_0$, so the ensemble power $R_{YY}(t,t) = m_2\cos^2\omega_0 t$ is zero there.

(c) $Z(t) = B\cos\omega_0 t + C\sin\omega_0 t$ with B, C zero mean, uncorrelated, both of variance σ^2:

$$\begin{aligned} \mu_Z(t) &= 0, \\ R_{ZZ}(t_1, t_2) &= E[B^2]\cos\omega_0 t_1\cos\omega_0 t_2 + E[C^2]\sin\omega_0 t_1\sin\omega_0 t_2 + E[BC]\sin\omega_0(t_1+t_2) \\ &= \sigma^2\cos\omega_0(t_1 - t_2). \end{aligned}$$

WSS. The random phase is supplied by the random pair (B, C). If $E[B^2] \neq E[C^2]$ or $E[BC] \neq 0$, the t-dependence returns — both conditions are necessary. Z is WSS for *any* distribution of (B, C) with these moments, but it is SSS only if (B, C) is circularly symmetric (e.g. jointly Gaussian with equal variances).

Worked Example 21.6 — A phase that is not uniform enough

Let $X(t) = A\cos(\omega_0 t + \Theta)$ with $\Theta \sim U[0, \pi]$ (only half a cycle). Then

$$\mu_X(t) = \frac{A}{\pi}\int_0^{\pi}\cos(\omega_0 t + \theta)\,d\theta = \frac{A}{\pi}\big[\sin(\omega_0 t + \pi) - \sin\omega_0 t\big] = -\frac{2A}{\pi}\sin\omega_0 t.$$

The mean oscillates with amplitude $2A/\pi \approx 0.637A$, so the process is **not WSS**. Curiously, the autocorrelation is still $\frac{A^2}{2}\cos\omega_0(t_1 - t_2)$: the term $E[\cos(\omega_0(t_1 + t_2) + 2\Theta)]$ vanishes because 2Θ *is* uniform on $[0, 2\pi)$. Conditions 2 and 3 of the WSS definition are independent, and both must be checked. (The autocovariance, $R_{XX} - \mu_X(t_1)\mu_X(t_2)$, does depend on both times.)

Worked Example 21.7 — Random binary (NRZ) waveform

Let $X(t) = \sum_{k=-\infty}^{\infty} a_k\, p(t - kT - D)$, where $p(t) = 1$ for $0 \le t < T$ and 0 otherwise, the a_k are i.i.d. with $P(a_k = \pm A) = \tfrac{1}{2}$, and the timing offset $D \sim U[0, T)$ is independent of the a_k. This models a data stream whose clock phase is unknown to the observer.

Step 1 — mean. $E[X(t)] = \sum_k E[a_k]\, E[p(t - kT - D)] = 0$.

Step 2 — the product. $X(t)$ and $X(t+\tau)$ are each $\pm A$. If t and $t+\tau$ fall in the **same** bit interval, $X(t+\tau)X(t) = a_k^2 = A^2$. If they fall in **different** intervals, the product is $a_k a_l$ with $k \ne l$, which has zero mean. So

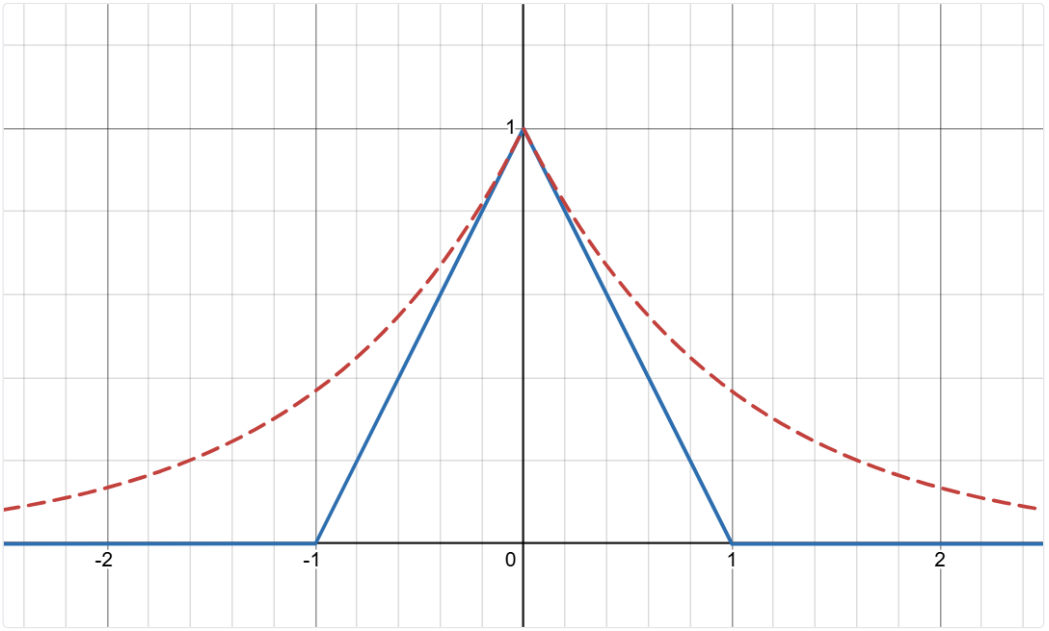
$$R_{XX}(t+\tau, t) = A^2\, P\{t \text{ and } t+\tau \text{ lie in the same bit}\}.$$

Step 3 — the probability. For $|\tau| \ge T$ it is 0. For $0 \le \tau < T$: the bit boundaries are at $kT + D$, and since D is uniform, the position of t within its bit, $U = (t - D) \bmod T$, is uniform on $[0, T)$. Both instants lie in the same bit iff $U + \tau < T$, which has probability $(T - \tau)/T$. By symmetry the same holds for $\tau < 0$ with $|\tau|$.

Result.

$$R_{XX}(\tau) = \begin{cases} A^2\left(1 - \dfrac{|\tau|}{T}\right), & |\tau| < T, \\ 0, & |\tau| \ge T. \end{cases}$$

The process is **WSS** with a triangular autocorrelation. Without the random offset D (a fixed, known clock) the probability in Step 3 depends on where t sits within its bit, and $R_{XX}(t+\tau, t)$ is periodic in t with period T — the process is then cyclostationary (below). The triangle reappears in §21.4 as the sinc^2 spectrum of NRZ data.



Triangular autocorrelation of the random NRZ waveform ($A = 1$, $T = 1$, blue) and the exponential autocorrelation $e^{-2\lambda|\tau|}$ of a random telegraph signal with the same average switching rate $\lambda = 1/(2T)$ (red, dashed). The NRZ signal is completely decorrelated after one bit; the telegraph signal, whose switching instants are not tied to a clock, decorrelates only gradually.

Worked Example 21.8 — WSS but not strictly stationary

Build a sequence of independent variables with $X[n] \sim \mathcal{N}(0, 1)$ for even n and $X[n] = \pm 1$ with probability $\tfrac{1}{2}$ each for odd n. Then $E[X[n]] = 0$ and $E[X^2[n]] = 1$ for all n, and $E[X[n+k]X[n]] = 0$ for $k \ne 0$ by independence, so

$$\mu_X = 0, \qquad R_{XX}[k] = \delta[k].$$

The sequence is **WSS** (indeed white, §21.6). But the first-order distribution alternates between a Gaussian and two point masses, so $P\{X[n] > 1.5\}$ equals $Q(1.5) \approx 0.067$ for even n and 0 for odd n: **not SSS**. A second-order description cannot see this difference — a reminder that "white" and "i.i.d." are not the same thing.

Cyclostationarity

Wide-sense cyclostationarity

$X(t)$ is **wide-sense cyclostationary** with period T_0 if

$$\mu_X(t + T_0) = \mu_X(t), \qquad R_{XX}(t_1 + T_0, t_2 + T_0) = R_{XX}(t_1, t_2) \quad \text{for all } t, t_1, t_2.$$

Digitally modulated signals $X(t) = \sum_k a_k\, p(t - kT_b)$ with a fixed clock, sampled-and-held noise, and noise in switched-capacitor and mixer circuits (whose operating point is periodically pumped by a clock or local oscillator) are all cyclostationary. The standard way of bringing them into the WSS framework is to randomize the time origin.

Stationarizing a cyclostationary process

If $X(t)$ is wide-sense cyclostationary with period T_0 and $D \sim U[0, T_0)$ is independent of X, then $Y(t) = X(t - D)$ is WSS with

$$\mu_Y = \frac{1}{T_0}\int_0^{T_0} \mu_X(t)\, dt, \qquad R_{YY}(\tau) = \bar{R}_{XX}(\tau) = \frac{1}{T_0}\int_0^{T_0} R_{XX}(t+\tau, t)\, dt.$$

Proof. Condition on $D = d$: $E[Y(t+\tau)Y(t) \mid D = d] = R_{XX}(t+\tau-d,\, t-d)$. Averaging over d uniform on one period gives $\frac{1}{T_0}\int_{t-T_0}^{t} R_{XX}(s+\tau, s)\, ds$ with $s = t - d$. Because $s \mapsto R_{XX}(s+\tau, s)$ is T_0-periodic, the integral over any interval of length T_0 is the same, so the result does not depend on t. The mean is handled identically. □

The **period-averaged autocorrelation** $\bar{R}_{XX}(\tau)$ is what a spectrum analyzer effectively measures for a cyclostationary signal, because the analyzer's sweep is not synchronized to the data clock. Example 21.7 is exactly this construction applied to NRZ data.

Non-stationary processes in practice

Many processes are not stationary but are close enough for practical purposes:

- **Asymptotically stationary:** a stable filter switched on at $t = 0$ with a WSS input produces an output whose statistics converge to stationary values as the transient decays (the AR(1) sequence started from $X[0] = 0$ in §21.4 is an example).
- **Locally stationary:** speech is commonly treated as stationary over 20–30 ms frames; a radio channel's fading statistics are stationary over distances of tens of wavelengths.
- **Stationary increments:** the random walk, Poisson process and Wiener process are not stationary, but their increments over fixed lags are. Oscillator phase noise and clock-jitter accumulation are analyzed this way (Allan variance).

Common Pitfall — stationarity belongs to the ensemble

Stationarity is a property of the *ensemble*, not of one record. A single sample function of a stationary process can look "non-stationary" over a short window (a burst of large values happens by chance), and a non-stationary process such as slow thermal drift can look stationary over a short window. Before invoking stationarity, state the time scale over which the assumption is meant to hold, and check that the record is long compared with the correlation time but short compared with the time scale of drift.

21.3 Autocorrelation and cross-correlation

Motivation

The autocorrelation function answers a simple question: *if I know the value of the signal now, how much do I know about its value τ seconds from now?* For thermal noise in a wideband amplifier the answer is "almost nothing after a few nanoseconds"; for the slowly wandering bias of a MEMS gyroscope, "a great deal, even after minutes". The **cross-correlation** asks the same question about two different signals, and it is the workhorse of synchronization, ranging, system identification and interference analysis: whenever an engineer needs to know whether, and with what delay, one signal is contained in another, a correlator is involved.

Throughout this section $X(t)$ and $Y(t)$ are real and (jointly) WSS unless stated otherwise.

Properties of the autocorrelation function

Properties of the autocorrelation function

1. **Power:** $R_{XX}(0) = E[X^2(t)] \ge 0$ is the average power (mean-square value).
2. **Even symmetry:** $R_{XX}(-\tau) = R_{XX}(\tau)$.
3. **Peak at the origin:** $|R_{XX}(\tau)| \le R_{XX}(0)$ for all τ.
4. **Non-negative definiteness:** for all n, times $t_1, \dots, t_n$ and real $a_1, \dots, a_n$,

$$\sum_{i=1}^{n}\sum_{k=1}^{n} a_i a_k\, R_{XX}(t_i - t_k) \ge 0.$$

Equivalently (Bochner's theorem, §21.4), its Fourier transform is non-negative. 5. **Periodicity:** if $R_{XX}(T_0) = R_{XX}(0)$ for some $T_0 \neq 0$, then R_{XX} is periodic with period T_0, and $X(t + T_0) = X(t)$ with probability 1 for every t. 6. **DC component:** if X has no periodic components and $\mu_X \neq 0$, then $R_{XX}(\tau) \to \mu_X^2$ as $|\tau| \to \infty$; i.e. $C_{XX}(\tau) \to 0$. 7. **Continuity:** if R_{XX} is continuous at $\tau = 0$, it is continuous everywhere.

Proofs.

1. Definition with $\tau = 0$.
2. $R_{XX}(-\tau) = E[X(t-\tau)X(t)]$; substitute $s = t - \tau$ and use stationarity: $E[X(s)X(s+\tau)] = R_{XX}(\tau)$.
3. Cauchy–Schwarz for random variables (Ch. 19): $\big(E[X(t+\tau)X(t)]\big)^2 \le E[X^2(t+\tau)]\,E[X^2(t)] = R_{XX}(0)^2$. Alternatively, $0 \le E[(X(t+\tau) \pm X(t))^2] = 2R_{XX}(0) \pm 2R_{XX}(\tau)$.
4. $0 \le E\big[(\sum_i a_i X(t_i))^2\big]$ expands to the double sum.

5. $E[(X(t+T_0)-X(t))^2] = 2R_{XX}(0) - 2R_{XX}(T_0) = 0$, so $X(t+T_0) = X(t)$ with probability 1. Then $R_{XX}(\tau+T_0) = E[X(t+\tau+T_0)X(t)] = E[X(t+\tau)X(t)] = R_{XX}(\tau)$.
6. Write $X = \mu_X + \tilde{X}$ with $\tilde{X}$ zero mean; $R_{XX} = \mu_X^2 + C_{XX}$, and "no periodic components" is the (informal) condition that $C_{XX}(\tau) \to 0$ — values far apart become uncorrelated.
7. $|R_{XX}(\tau+h) - R_{XX}(\tau)| = |E[(X(t+\tau+h) - X(t+\tau))X(t)]| \le \sqrt{E[(X(t+h)-X(t))^2]\,R_{XX}(0)} = \sqrt{2(R_{XX}(0) - R_{XX}(h))R_{XX}(0)}$, which tends to 0 as $h \to 0$ if R_{XX} is continuous at 0. $\square$

Property 7 has a physical reading: $E[(X(t+h)-X(t))^2] = 2[R_{XX}(0) - R_{XX}(h)]$. So R_{XX} continuous at 0 is exactly the statement that the process is **mean-square continuous** — its sample values do not jump on average. A large curvature of R_{XX} at the origin means a rapidly fluctuating process.

Reading an autocorrelation. A typical autocorrelation of a zero-mean noise process is a peaked, even function:

- its **height** $R_{XX}(0)$ is the power;
- its **width** is the correlation time — how long the process "remembers";
- its **shape at the origin** tells how smooth the sample functions are: a cusp ($e^{-\alpha|\tau|}$) means continuous but non-differentiable paths; a rounded top ($e^{-\alpha\tau^2}$, sinc) means smooth paths;
- a **constant floor** μ_X^2 at large lags is DC; a **persistent oscillation** is a sinusoidal component.

Correlation coefficient and correlation time

The normalized autocovariance

$$\rho_{XX}(\tau) = \frac{C_{XX}(\tau)}{C_{XX}(0)} \in [-1, 1]$$

is the **correlation coefficient function**. Several definitions of a single **correlation time** are in use; the two most common are

$$\tau_c = \int_0^\infty \rho_{XX}(\tau)\,d\tau \qquad \text{or} \qquad \tau_e : \ \rho_{XX}(\tau_e) = e^{-1}.$$

For $\rho = e^{-\alpha|\tau|}$ both give $1/\alpha$. Samples spaced much farther apart than τ_c are nearly uncorrelated; this is what makes long averages effective (§21.7).

Worked examples on autocorrelation

Worked Example 21.9 — Random telegraph signal

$X(t)$ takes values ± 1 and switches sign at the event times of a Poisson process of rate λ; $P(X(0) = 1) = \tfrac{1}{2}$, independent of the switching times.

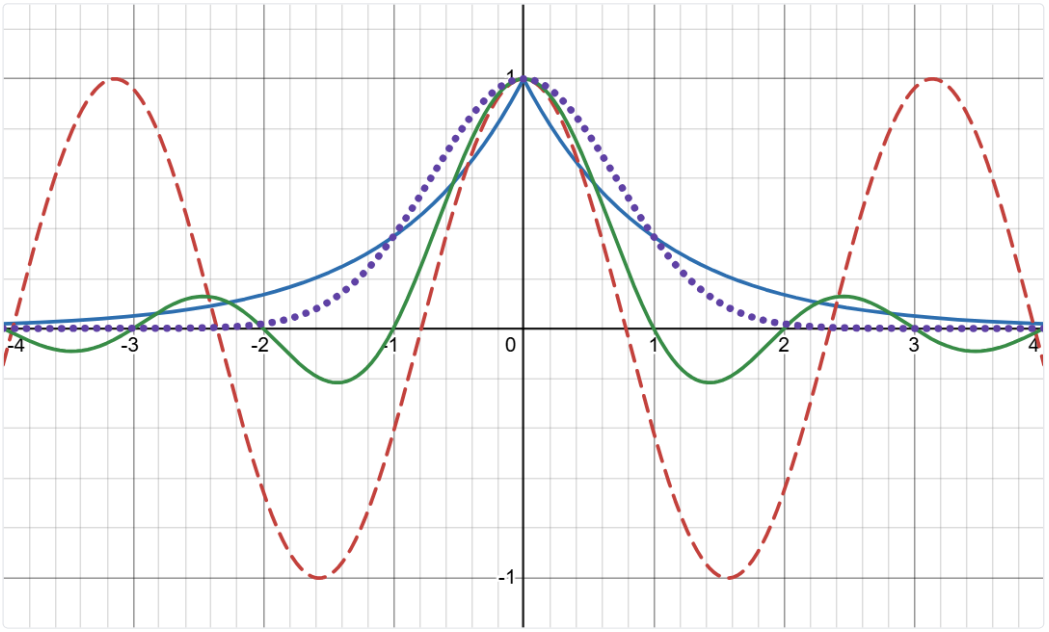
Step 1 — mean. By symmetry $P(X(t) = 1) = \tfrac{1}{2}$ for all t, so $\mu_X = 0$.

Step 2 — the product. $X(t+\tau)X(t) = +1$ if an even number of switches occurs in the interval between t and $t+\tau$ and -1 if odd. The number of switches N in an interval of length $|\tau|$ is Poisson with mean $\lambda|\tau|$.

Step 3 — sum the series.

$$R_{XX}(\tau) = P(N \text{ even}) - P(N \text{ odd}) = \sum_{k=0}^{\infty} (-1)^k \frac{(\lambda|\tau|)^k}{k!} e^{-\lambda|\tau|} = e^{-\lambda|\tau|} e^{-\lambda|\tau|} = e^{-2\lambda|\tau|}.$$

Interpretation. Power $R_{XX}(0) = 1$ (obvious, since $X^2 = 1$), correlation time $\tau_c = 1/(2\lambda)$. With $\lambda = 10^4$ switches per second (a typical MOSFET random-telegraph-noise trap), $\tau_c = 50\ \mu$s; values 200 µs apart have correlation $e^{-4} = 0.018$. The cusp at $\tau = 0$ reflects the jumps of the sample paths.



Four valid autocorrelation shapes: exponential (telegraph or RC-filtered noise, blue — note the cusp), cosine (random-phase sinusoid, red — never decays because the process is periodic), sinc (band-limited white noise, green — negative lobes are allowed) and Gaussian (smooth, differentiable noise, purple). All are even and peak at $\tau = 0$.

Worked Example 21.10 — Is this a valid autocorrelation?

Consider the rectangular function $g(\tau) = 1$ for $|\tau| \le 1$ and 0 otherwise. It is even, non-negative and peaks at 0 — properties 1–3 hold. Is it an autocorrelation?

Test property 4 with times $t_1 = 0,\ t_2 = 1,\ t_3 = 2$. The matrix $[g(t_i - t_k)]$ is

$$\mathbf{G} = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix}, \qquad \mathbf{a} = \begin{bmatrix} 1 \\ -1 \\ 1 \end{bmatrix} : \quad \mathbf{a}^{\mathsf{T}}\mathbf{G}\mathbf{a} = 3 + 2(-1 - 1 + 0) = -1 < 0.$$

A "variance" of -1 is impossible, so g **is not an autocorrelation**. (The eigenvalues of $\mathbf{G}$ are 1 and $1 \pm \sqrt{2}$; one is negative.) In the frequency domain the same conclusion is immediate: the Fourier transform of g is $2\sin\omega/\omega$, which goes negative, violating $S_{XX} \ge 0$ (§21.4).

By contrast the triangle $1 - |\tau|$ (Example 21.7) has transform $\sin^2(\omega/2)/(\omega/2)^2 \ge 0$ and is valid. Being even and peaked is necessary but nowhere near sufficient.

Worked Example 21.11 — Moving-average (MA(1)) sequence

Let $W[n]$ be i.i.d. with zero mean and variance σ_W^2, and define the two-tap FIR output $X[n] = W[n] + bW[n-1]$.

Step 1 — mean: $E[X[n]] = 0$.

Step 2 — autocorrelation. $R_{XX}[k] = E\big[(W[n+k] + bW[n+k-1])(W[n] + bW[n-1])\big]$. Using $E[W[i]W[l]] = \sigma_W^2\delta[i-l]$, the four cross terms survive only when their indices match:

$$R_{XX}[0] = \sigma_W^2(1 + b^2), \qquad R_{XX}[\pm 1] = b\,\sigma_W^2, \qquad R_{XX}[k] = 0 \ \ (|k| \ge 2).$$

Step 3 — numbers. With $b = 0.5$, $\sigma_W^2 = 1$: $R_{XX}[0] = 1.25$, $R_{XX}[\pm 1] = 0.5$, $\rho_{XX}[1] = 0.4$. Notice $|\rho_{XX}[1]| = |b|/(1 + b^2) \le \tfrac{1}{2}$ for every b: an MA(1) sequence can never have lag-1 correlation exceeding 0.5 in magnitude. If a measured sequence has $\hat\rho[1] = 0.8$ and $\hat\rho[k] \approx 0$ for $k \ge 2$, it cannot be MA(1) — such constraints are exactly the non-negative-definiteness of property 4.

Generalization. For an FIR filter $X[n] = \sum_{m=0}^{q} b_m W[n-m]$ driven by white noise, $R_{XX}[k] = \sigma_W^2 \sum_m b_m b_{m+k}$ (the deterministic autocorrelation of the coefficient sequence), which vanishes for $|k| > q$.

Derivatives of a WSS process

Many physical quantities are derivatives of others (current in a capacitor, velocity from position), so it is useful to know the correlation of $X'(t)$. If $R_{XX}(\tau)$ is twice differentiable at $\tau = 0$, then $X(t)$ is **mean-square differentiable** and, interchanging derivative and expectation,

$$R_{X'X}(\tau) = E[X'(t+\tau)X(t)] = \frac{d}{d\tau}R_{XX}(\tau), \qquad R_{X'X'}(\tau) = E[X'(t+\tau)X'(t)] = -\frac{d^2}{d\tau^2}R_{XX}(\tau).$$

Derivation. $R_{X'X}(\tau) = \frac{\partial}{\partial t_1}E[X(t_1)X(t_2)]\big|_{t_1 = t+\tau, t_2 = t} = R'_{XX}(\tau)$. Then $R_{X'X'}(\tau) = \frac{\partial}{\partial t_2}R_{X'X}(t_1 - t_2) = -R''_{XX}(\tau)$.

Two consequences: since R_{XX} is even, $R'_{XX}(0) = 0$ and so $E[X'(t)X(t)] = 0$ — **a WSS process and its derivative are uncorrelated at the same instant**. And the derivative's power is $E[X'^2] = -R''_{XX}(0)$, which is finite only if R_{XX} is smooth at the origin.

Worked Example 21.12 — Smooth versus rough noise

(a) $R_{XX}(\tau) = \sigma^2 e^{-\alpha\tau^2}$. Then $R'_{XX} = -2\alpha\tau\sigma^2 e^{-\alpha\tau^2}$ and

$$R_{X'X'}(\tau) = -R''_{XX}(\tau) = 2\alpha\sigma^2(1 - 2\alpha\tau^2)e^{-\alpha\tau^2}, \qquad E[X'^2] = 2\alpha\sigma^2.$$

With $\sigma = 1$ mV and $\alpha = 10^8$ s^{-2}, the RMS slope is $\sqrt{2\times 10^8} \times 10^{-3} = 14.1$ V/s. This value is needed, for instance, to convert voltage noise into timing jitter at a comparator: $\sigma_t \approx \sigma_v/|\text{slope of the signal}|$, and the expected rate of zero crossings (Rice's formula, §21.5).

(b) $R_{XX}(\tau) = \sigma^2 e^{-\alpha|\tau|}$ has a cusp at 0: $R''_{XX}(0)$ does not exist (formally, $-R''_{XX}$ contains $2\alpha\sigma^2\delta(\tau)$). The process is mean-square continuous but **not differentiable** — the derivative would have infinite power. RC-filtered white noise and the telegraph signal are of this kind; their paths are rough at every scale down to where the idealized model breaks down.

Cross-correlation

Cross-correlation and cross-covariance

For jointly WSS X and Y:

$$R_{XY}(\tau) = E[X(t+\tau)Y(t)], \qquad C_{XY}(\tau) = R_{XY}(\tau) - \mu_X\mu_Y.$$

X and Y are **uncorrelated** if $C_{XY}(\tau) = 0$ for all τ, and **orthogonal** if $R_{XY}(\tau) = 0$ for all τ. Independent processes are uncorrelated; zero-mean uncorrelated processes are orthogonal.

The ordering convention matters: here the *first* subscript carries the time shift $+\tau$. Some texts use $E[X(t)Y(t+\tau)]$, which reverses the sign of τ. Check the convention before using a published formula.

Properties of the cross-correlation

1. $R_{XY}(\tau) = R_{YX}(-\tau)$ — **not** even in general; its peak may be anywhere.
2. $|R_{XY}(\tau)| \le \sqrt{R_{XX}(0) R_{YY}(0)}$.
3. $|R_{XY}(\tau)| \le \tfrac{1}{2}\big[R_{XX}(0) + R_{YY}(0)\big]$.
4. If $Z = X + Y$: $R_{ZZ}(\tau) = R_{XX}(\tau) + R_{YY}(\tau) + R_{XY}(\tau) + R_{YX}(\tau)$. For uncorrelated X, Y with at least one of them zero mean, $R_{ZZ} = R_{XX} + R_{YY}$: **powers of uncorrelated zero-mean processes add**.

Proofs. (1) Substitute $s = t + \tau$ in $E[X(t+\tau)Y(t)] = E[Y(s-\tau)X(s)] = R_{YX}(-\tau)$. (2) Cauchy–Schwarz. (3) The geometric mean is at most the arithmetic mean. (4) Expand $E[(X(t+\tau) + Y(t+\tau))(X(t) + Y(t))]$. □

Property 4 is the reason noise powers, not noise voltages, are added when independent sources are combined: two independent 1 mV-rms noise sources in series give $\sqrt{2}$ mV rms, not 2 mV.

Worked Example 21.13 — Signal plus independent noise

A WSS signal $S(t)$ with $R_{SS}(\tau) = 4e^{-100|\tau|}$ V^2 is corrupted by independent zero-mean noise $N(t)$ with $R_{NN}(\tau) = 0.25e^{-10^5|\tau|}$ V^2. The observed process is $X = S + N$.

Autocorrelation. By property 4 with $R_{SN} = R_{NS} = E[S]E[N] = 0$:

$$R_{XX}(\tau) = 4e^{-100|\tau|} + 0.25e^{-10^5|\tau|}.$$

Total power $R_{XX}(0) = 4.25$ V^2 (2.06 V rms); SNR $= 4/0.25 = 16$ (12.0 dB).

Separating them by lag. At $\tau = 50\ \mu$s the noise term is $0.25e^{-5} = 0.0017$ while the signal term is $4e^{-0.005} = 3.98$. A correlator evaluated at a lag longer than the noise correlation time but shorter than the signal's sees almost pure signal: the "spike" at the origin of a measured autocorrelation is the signature of wideband noise, and its height is the noise power. This is how noise power is often estimated in practice without switching the signal off.

Cross-correlation with the clean signal. $R_{XS}(\tau) = E[(S(t+\tau) + N(t+\tau))S(t)] = R_{SS}(\tau)$: independent noise drops out of a cross-correlation entirely (on average).

Worked Example 21.14 — Time-delay estimation

A transmitted signal $X(t)$ (WSS, zero mean, $R_{XX}(\tau) = e^{-1000|\tau|}$) arrives as $Y(t) = 0.5\,X(t - D) + N(t)$ with $D = 2$ ms and noise $N(t)$ zero mean and independent of X.

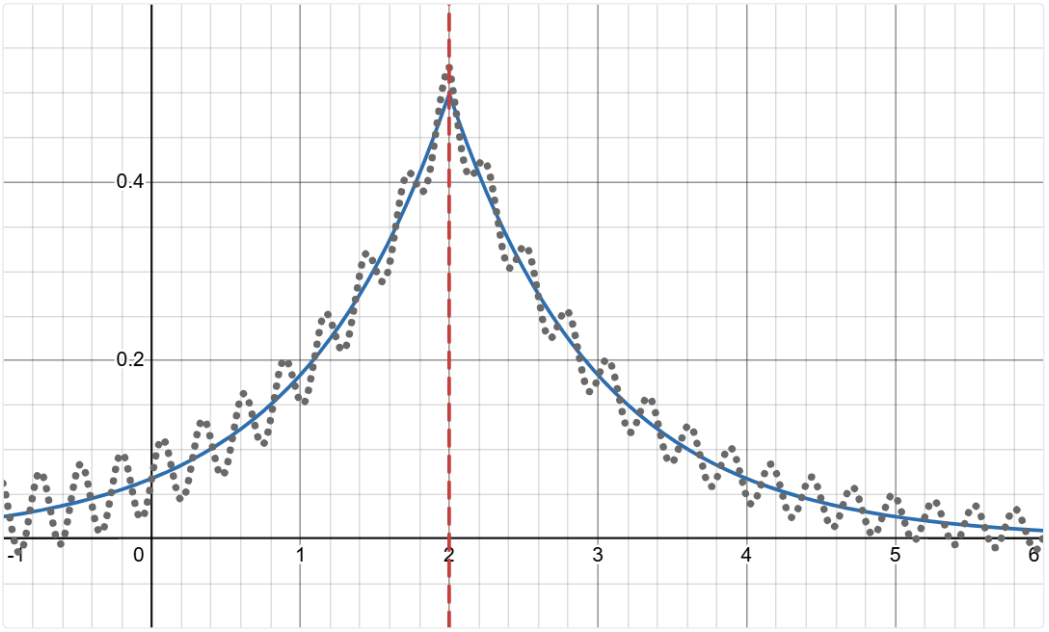
Step 1.

$$R_{YX}(\tau) = E[Y(t+\tau)X(t)] = 0.5\,E[X(t+\tau-D)X(t)] + E[N(t+\tau)]E[X(t)] = 0.5\,R_{XX}(\tau - D).$$

Step 2. So $R_{YX}(\tau) = 0.5\,e^{-1000|\tau - 0.002|}$, which peaks with value 0.5 at $\tau = D = 2$ ms. By property 1, $R_{XY}(\tau) = R_{YX}(-\tau)$ peaks at $\tau = -2$ ms.

Step 3 — resolution. The peak's half-width (where R_{YX} falls to $0.5\,e^{-1}$) is ± 1 ms. Two echoes closer than about one correlation time of X merge into one peak. Hence radar and GPS use signals with very **short correlation times** (wide bandwidth): a GPS C/A code with chip duration $T_c \approx 0.98\ \mu$s has a triangular autocorrelation of half-width T_c, corresponding to about 300 m of range, and receivers interpolate the peak to a small fraction of that.

Independent noise does not shift the peak; it only adds random fluctuations to the *estimated* correlation, whose size decreases with averaging time (§21.7).



Cross-correlation $R_{YX}(\tau)$ of Example 21.14 with τ in milliseconds (blue): the peak locates the delay $D = 2$ ms. The grey dotted curve suggests what a finite-length estimate looks like — fluctuations from the noise ride on top, but the peak location is preserved.

Engineering Note — correlators everywhere

In discrete time, $R_{XX}[k] = E[X[n+k]X[n]]$ and $R_{XY}[k] = E[X[n+k]Y[n]]$. Correlators in GNSS receivers (code phase search), preamble synchronizers in Wi-Fi and Ethernet PHYs, lock-in amplifiers (correlation with a reference sinusoid), time-domain reflectometers and acoustic source localizers all compute sample cross-correlations against a known reference and then look for the peak. The mathematics of this section — especially "independent noise drops out of R_{YX}" — is the reason they work.

Common Pitfall — correlation is not causation, and zero correlation is not independence

$R_{XY} \equiv 0$ says only that there is no *linear* relation at any lag. $Y(t) = X^2(t) - E[X^2]$ for a zero-mean Gaussian X is uncorrelated with X (odd moments of a Gaussian vanish) but completely determined by it. For jointly Gaussian processes, and only then, uncorrelated implies independent (§21.5).

21.4 Power spectral density

Motivation

Filters, amplifiers and channels are characterized by their frequency response, so the natural question about noise is *how its power is distributed over frequency*. For a deterministic energy signal $x(t)$, Parseval's theorem (Ch. 16) says $|X(\omega)|^2/(2\pi)$ is the energy per unit angular frequency. A sample function of a WSS process, however, has the same statistics forever, so its energy is infinite and its Fourier transform does not exist in the ordinary sense. The way out is to work with **power** per unit bandwidth, averaged over the ensemble. The remarkable fact — the Wiener–Khinchin theorem — is that this spectral power density is simply the Fourier transform of the autocorrelation function. Correlation in the time domain and power distribution in the frequency domain are two views of the same second-order information.

Definition via the truncated transform

Power spectral density

For a WSS process $X(t)$, let $X_T(t) = X(t)$ for $|t| \le T$ and 0 otherwise, with Fourier transform $X_T(\omega) = \int_{-T}^{T} X(t) e^{-j\omega t} dt$. The **power spectral density** (PSD) is

$$S_{XX}(\omega) = \lim_{T \to \infty} \frac{E\big[|X_T(\omega)|^2\big]}{2T}.$$

The quantity $|X_T(\omega)|^2/(2T)$ for one sample function is the **periodogram**: energy density of the truncated record divided by its duration, i.e. power density. The PSD is its ensemble average in the limit of a long record.

The Wiener–Khinchin theorem

Wiener–Khinchin theorem

If $X(t)$ is WSS and $\int_{-\infty}^{\infty} |\tau R_{XX}(\tau)|\, d\tau < \infty$ (so that the limit below may be taken; the result holds in the distributional sense under much weaker conditions), then the PSD and the autocorrelation are a Fourier-transform pair:

$$S_{XX}(\omega) = \int_{-\infty}^{\infty} R_{XX}(\tau)\, e^{-j\omega\tau}\, d\tau, \qquad R_{XX}(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{XX}(\omega)\, e^{j\omega\tau}\, d\omega.$$

Proof. Write the squared magnitude as a double integral and take the expectation inside:

$$E\big[|X_T(\omega)|^2\big] = E\Big[\int_{-T}^{T}\!\!\int_{-T}^{T} X(t)X(s)e^{-j\omega(t-s)}\, dt\, ds\Big] = \int_{-T}^{T}\!\!\int_{-T}^{T} R_{XX}(t-s)e^{-j\omega(t-s)}\, dt\, ds.$$

The integrand depends only on $\tau = t - s$. In the (t, s) square of side $2T$, the line $t - s = \tau$ has length proportional to $2T - |\tau|$ for $|\tau| \le 2T$; changing variables to (τ, s) gives

$$E\big[|X_T(\omega)|^2\big] = \int_{-2T}^{2T} (2T - |\tau|)\, R_{XX}(\tau) e^{-j\omega\tau}\, d\tau.$$

Dividing by $2T$:

$$\frac{E|X_T(\omega)|^2}{2T} = \int_{-2T}^{2T} \Big(1 - \frac{|\tau|}{2T}\Big) R_{XX}(\tau) e^{-j\omega\tau}\, d\tau.$$

As $T \to \infty$ the triangular weight tends to 1 for each fixed τ, and the error term $\frac{1}{2T}\int |\tau R_{XX}(\tau)| d\tau \to 0$ under the stated condition. The limit is $\int R_{XX}(\tau) e^{-j\omega\tau} d\tau$. The inverse relation is the Fourier inversion theorem. $\square$

The triangular weight in the proof is worth remembering: a finite record of length $2T$ "sees" the autocorrelation through a triangular window, which is why spectral estimates from finite data are always smeared (§21.7).

A deep converse is **Bochner's theorem**: a continuous function $R(\tau)$ is non-negative definite (property 4 of §21.3) if and only if it is the inverse Fourier transform of a non-negative (possibly generalized) spectral measure. So a candidate autocorrelation is valid exactly when its transform is non-negative — the easiest test in practice (Example 21.10).

Properties of the PSD

Properties of the PSD

1. $S_{XX}(\omega)$ is **real** and **non-negative**: $S_{XX}(\omega) \geq 0$.
2. For real X, $S_{XX}(-\omega) = S_{XX}(\omega)$ (even).
3. **Total power:**
$$E[X^2(t)] = R_{XX}(0) = \frac{1}{2\pi}\int_{-\infty}^{\infty} S_{XX}(\omega)\,d\omega = \int_{-\infty}^{\infty} S_{XX}(2\pi f)\,df.$$
4. **Power in a band.** The power in the band $\omega_1 \leq |\omega| \leq \omega_2$ (both signs of frequency counted) is
$$P_{[\omega_1,\omega_2]} = \frac{1}{\pi}\int_{\omega_1}^{\omega_2} S_{XX}(\omega)\,d\omega.$$
5. **DC and periodic components.** A non-zero mean contributes $2\pi\mu_X^2\,\delta(\omega)$; a sinusoidal component of amplitude A at ω_0 contributes $\frac{\pi A^2}{2}[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]$.
6. **Zero-frequency value:** $S_{XX}(0) = \int R_{XX}(\tau)\,d\tau$ — the area under the autocorrelation. For a zero-mean process this governs the variance of long time averages (§21.7).

Proofs. (1) Non-negativity is immediate from the definition as a limit of $E|X_T|^2/(2T) \geq 0$. Reality follows from R_{XX} being even: $S_{XX}(\omega) = \int R_{XX}(\tau)\cos\omega\tau\,d\tau$. (2) Cosine is even. (3) Set $\tau = 0$ in the inverse transform. (4) Integrate the PSD over $\omega_1 \leq |\omega| \leq \omega_2$ and use evenness. That this really is "the power passed by an ideal bandpass filter" follows from the LTI result $S_{YY} = |H|^2 S_{XX}$ below. (5) Transform of a constant and of a cosine. (6) Set $\omega = 0$. □

Common Pitfall — ω versus f, one-sided versus two-sided

With the angular-frequency convention used here, power is $\frac{1}{2\pi}\int S_{XX}(\omega)\,d\omega$. Expressed per hertz, $S_X(f) = S_{XX}(2\pi f)$ and power is $\int_{-\infty}^{\infty} S_X(f)\,df$, with units V^2/Hz. Instrument data sheets and spectrum analyzers usually quote the **one-sided** PSD $G_X(f) = 2S_X(f)$ for $f \geq 0$, so that power is $\int_0^{\infty} G_X(f)\,df$. Noise densities in $\mathrm{nV}/\sqrt{\mathrm{Hz}}$ are $\sqrt{G_X(f)}$. Mixing these conventions produces factor-of-2 or factor-of-2π errors; write the convention next to every PSD you quote.

Standard transform pairs

With $\alpha > 0$, sinc-type expressions written out explicitly:

$R_{XX}(\tau)$	$S_{XX}(\omega)$	**origin**
$\sigma^2 e^{-\alpha\lvert\tau\rvert}$	$\dfrac{2\alpha\sigma^2}{\alpha^2+\omega^2}$	RC-filtered white noise, telegraph signal
$\dfrac{A^2}{2}\cos\omega_0\tau$	$\dfrac{\pi A^2}{2}\big[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)\big]$	random-phase sinusoid
μ^2 (constant)	$2\pi\mu^2\delta(\omega)$	DC
$\dfrac{N_0}{2}\delta(\tau)$	$\dfrac{N_0}{2}$	white noise
$N_0 B\,\dfrac{\sin 2\pi B\tau}{2\pi B\tau}$	$\dfrac{N_0}{2}$ for $\lvert\omega\rvert < 2\pi B$, else 0	band-limited white noise
$\sigma^2\big(1-\lvert\tau\rvert/T\big)$ for $\lvert\tau\rvert \leq T$, else 0	$\sigma^2 T\,\dfrac{\sin^2(\omega T/2)}{(\omega T/2)^2}$	random NRZ data
$\sigma^2 e^{-\alpha\tau^2}$	$\sigma^2\sqrt{\pi/\alpha}\;e^{-\omega^2/(4\alpha)}$	smooth (Gaussian-shaped) noise
$\sigma^2 e^{-\alpha\lvert\tau\rvert}\cos\omega_0\tau$	$\alpha\sigma^2\Big[\dfrac{1}{\alpha^2+(\omega-\omega_0)^2}+\dfrac{1}{\alpha^2+(\omega+\omega_0)^2}\Big]$	narrowband (bandpass) noise

The last pair follows from the first by the modulation theorem: multiplying R_{XX} by $\cos\omega_0\tau$ shifts half the spectrum to $+\omega_0$ and half to $-\omega_0$.

Worked examples

Worked Example 21.15 — Exponential autocorrelation and the Lorentzian spectrum

Let $R_{XX}(\tau) = \sigma^2 e^{-\alpha|\tau|}$.

Step 1 — transform. Split the integral at $\tau = 0$:

$$S_{XX}(\omega) = \sigma^2\left[\int_0^\infty e^{-(\alpha+j\omega)\tau}d\tau + \int_0^\infty e^{-(\alpha-j\omega)\tau}d\tau\right] = \sigma^2\left[\frac{1}{\alpha+j\omega} + \frac{1}{\alpha-j\omega}\right] = \frac{2\alpha\sigma^2}{\alpha^2+\omega^2}.$$

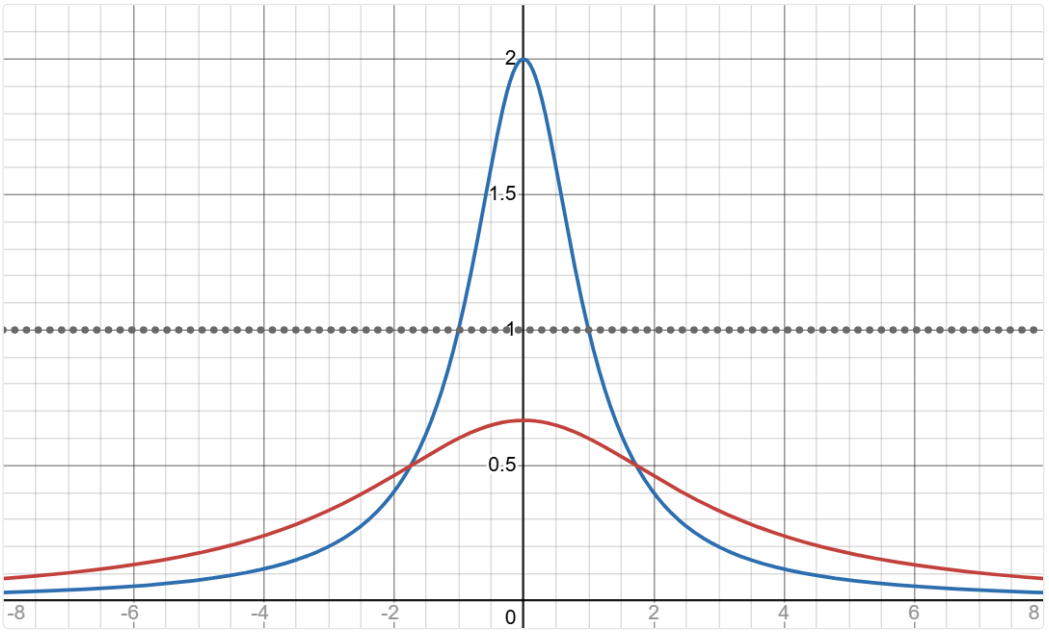
Step 2 — check the power. $\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{2\alpha\sigma^2}{\alpha^2+\omega^2}d\omega = \frac{2\alpha\sigma^2}{2\pi}\cdot\frac{\pi}{\alpha} = \sigma^2 = R_{XX}(0)$. ✓

Step 3 — power in a band. By property 4, the power in $|\omega| \le \omega_1$ is

$$\frac{1}{\pi}\int_0^{\omega_1}\frac{2\alpha\sigma^2}{\alpha^2+\omega^2}d\omega = \frac{2\sigma^2}{\pi}\arctan\frac{\omega_1}{\alpha}.$$

With $\alpha = 1000\ \text{s}^{-1}$ and a 1 kHz bandwidth ($\omega_1 = 2\pi\times 1000$), the fraction is $\frac{2}{\pi}\arctan(6.283) = 0.900$: 90% of the power lies below 1 kHz. Half the power lies below $\omega = \alpha$ (159 Hz), which is also the half-power (−3 dB) point of the spectrum.

Step 4 — interpretation. Shorter correlation time (larger α) means a wider, flatter spectrum with the same total power: time scale and bandwidth trade off exactly as for deterministic signals (Ch. 16). The value at the origin, $S_{XX}(0) = 2\sigma^2/\alpha = \int R_{XX}d\tau$, confirms property 6.



Lorentzian PSDs $S_{XX}(\omega) = 2\alpha/(\alpha^2+\omega^2)$ for $\alpha = 1$ (blue) and $\alpha = 3$ (red), both with $\sigma^2 = 1$. The areas under the two curves are equal (same power); faster decorrelation spreads that power over a wider band. The grey line marks half the peak of the blue curve, reached at $\omega = \alpha = 1$.

Worked Example 21.16 — Spectrum of random NRZ data

From Example 21.7, $R_{XX}(\tau) = A^2(1 - |\tau|/T)$ for $|\tau| < T$.

Step 1 — transform. The triangle of half-width T and height 1 is the self-convolution of a rectangle of width T and height $1/\sqrt{T}$; its transform is therefore the square of the rectangle's transform:

$$S_{XX}(\omega) = A^2 T\,\frac{\sin^2(\omega T/2)}{(\omega T/2)^2}.$$

In hertz, $S_X(f) = A^2T\left[\sin(\pi fT)/(\pi fT)\right]^2$, with nulls at $f = k/T$, $k \neq 0$.

Step 2 — power in the main lobe. Total power is A^2. The fraction in $|f| < 1/T$ is

$$\int_{-1/T}^{1/T} T\left[\frac{\sin \pi fT}{\pi fT}\right]^2 df = \int_{-1}^{1}\left[\frac{\sin \pi u}{\pi u}\right]^2 du \approx 0.903.$$

So a 1 Gb/s NRZ stream ($T = 1$ ns) has 90.3% of its power below 1 GHz, while the remaining 9.7% in the sidelobes is what causes crosstalk and EMI — the motivation for pulse shaping.

Step 3 — check at DC. $S_{XX}(0) = A^2T = \int R_{XX}\,d\tau$ (area of the triangle $= A^2T$). ✓ There is no impulse at DC because the data are equally likely $\pm A$ (zero mean). With unipolar data $\{0, A\}$ the mean is $A/2$ and an impulse $2\pi(A/2)^2\delta(\omega)$ appears.

Worked Example 21.17 — Separating a sinusoid from noise in the spectrum

$X(t) = 2\cos(2\pi \cdot 50\, t + \Theta) + N(t)$, $\Theta \sim U[0, 2\pi)$, with N independent zero-mean noise of $R_{NN}(\tau) = 0.5e^{-200|\tau|}$. Then

$$R_{XX}(\tau) = 2\cos(100\pi\tau) + 0.5e^{-200|\tau|}, \qquad S_{XX}(\omega) = 2\pi\big[\delta(\omega - 100\pi) + \delta(\omega + 100\pi)\big] + \frac{200}{200^2 + \omega^2}.$$

The sinusoid's power 2 sits in two impulses of weight 2π each (check: $\frac{1}{2\pi} \cdot 2 \cdot 2\pi = 2$); the noise's power 0.5 is spread as a Lorentzian. In a measured spectrum with resolution bandwidth Δf, a line appears as a peak of height $\approx P_{\text{line}}/\Delta f$ while the noise floor stays at its density; halving Δf raises the line 3 dB above the floor. In the autocorrelation the same separation appears in the lag domain: the cosine persists forever, the noise dies out within about $5/200 = 25$ ms.

Cross-power spectral density

Cross-power spectral density

For jointly WSS X, Y:

$$S_{XY}(\omega) = \int_{-\infty}^{\infty} R_{XY}(\tau) e^{-j\omega\tau} d\tau, \qquad S_{YX}(\omega) = S_{XY}^*(\omega) \;\; (\text{real } X, Y).$$

S_{XY} is complex in general; its phase carries delay information. The **magnitude-squared coherence** is

$$\gamma_{XY}^2(\omega) = \frac{|S_{XY}(\omega)|^2}{S_{XX}(\omega) S_{YY}(\omega)} \in [0, 1],$$

which measures how linearly related X and Y are at each frequency (Cauchy–Schwarz in the frequency domain).

For the delayed-echo model of Example 21.14, $R_{YX}(\tau) = 0.5 R_{XX}(\tau - D)$ gives $S_{YX}(\omega) = 0.5\, e^{-j\omega D} S_{XX}(\omega)$: a linear phase of slope $-D$. Measuring that slope estimates the delay; this is the frequency-domain twin of peak-picking the cross-correlation.

LTI systems with random inputs

This is the single most-used result of the chapter. Let a WSS process $X(t)$ drive a stable LTI system with impulse response $h(t)$ and frequency response $H(\omega) = \int h(t) e^{-j\omega t} dt$, producing

$$Y(t) = \int_{-\infty}^{\infty} h(\alpha) X(t - \alpha)\, d\alpha.$$

Input–output relations for LTI systems

Y is WSS, jointly WSS with X, and

$$\begin{aligned} \mu_Y &= \mu_X\, H(0), \\ R_{YX}(\tau) &= h(\tau) * R_{XX}(\tau), & S_{YX}(\omega) &= H(\omega)\, S_{XX}(\omega), \\ R_{XY}(\tau) &= h(-\tau) * R_{XX}(\tau), & S_{XY}(\omega) &= H^*(\omega)\, S_{XX}(\omega), \\ R_{YY}(\tau) &= h(\tau) * h(-\tau) * R_{XX}(\tau), & S_{YY}(\omega) &= |H(\omega)|^2 S_{XX}(\omega). \end{aligned}$$

The output power is

$$E[Y^2] = R_{YY}(0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} |H(\omega)|^2 S_{XX}(\omega)\, d\omega.$$

If X is Gaussian, so is Y (§21.5).

Derivation.

- **Mean.** $E[Y(t)] = \int h(\alpha) E[X(t-\alpha)] d\alpha = \mu_X \int h(\alpha) d\alpha = \mu_X H(0)$ — the DC gain applied to the DC value.
- **Cross-correlation.** $R_{YX}(\tau) = E[Y(t+\tau)X(t)] = \int h(\alpha) E[X(t+\tau-\alpha)X(t)]\, d\alpha = \int h(\alpha) R_{XX}(\tau - \alpha)\, d\alpha = (h * R_{XX})(\tau)$. Independent of t, so X, Y are jointly WSS.
- **Autocorrelation.** $R_{YY}(\tau) = E[Y(t+\tau)Y(t)] = \int h(\beta) E[Y(t+\tau)X(t-\beta)]\, d\beta = \int h(\beta) R_{YX}(\tau + \beta)\, d\beta$. With $\beta \to -\beta$ this is the convolution of R_{YX} with $h(-\tau)$.
- **Spectra.** Transform the convolutions, using $\mathcal{F}\{h(-\tau)\} = H(-\omega) = H^*(\omega)$ for real h. Then $S_{YY} = H\, H^*\, S_{XX} = |H|^2 S_{XX}$. □

Notice that only $|H|$ affects the output PSD: the **phase response of a filter has no effect on the output noise power or spectrum**, although it does affect the cross-spectrum S_{YX} and hence the shape of the noise waveforms.

More generally, if $Y_1 = h_1 * X$ and $Y_2 = h_2 * X$ are two filtered versions of the same input,

$$S_{Y_1 Y_2}(\omega) = H_1(\omega) H_2^*(\omega) S_{XX}(\omega).$$

If the passbands of H_1 and H_2 do not overlap, $S_{Y_1 Y_2} \equiv 0$: **outputs of non-overlapping filters are uncorrelated** — the basis of filter-bank spectrum analyzers and of treating different frequency bins of noise as independent.

Two immediate uses of the theorem:

- **System identification with white noise.** If $S_{XX} = N_0/2$ then $R_{YX}(\tau) = \frac{N_0}{2}h(\tau)$: cross-correlating the output with a white input measures the impulse response directly. Pseudo-random binary sequences (PRBS), whose autocorrelation is very nearly an impulse, are used for exactly this in acoustics and in-circuit test.
- **Shaping filters.** Any rational PSD $S(\omega) = |H(\omega)|^2 N_0/2$ can be generated by filtering white noise through H — the basis of noise simulation and of Kalman-filter noise models. Finding a stable, minimum-phase H from a given S is called **spectral factorization**.

Worked Example 21.18 — White noise through an RC lowpass

$H(\omega) = 1/(1 + j\omega RC)$ and $S_{XX} = N_0/2$ (white noise, §21.6).

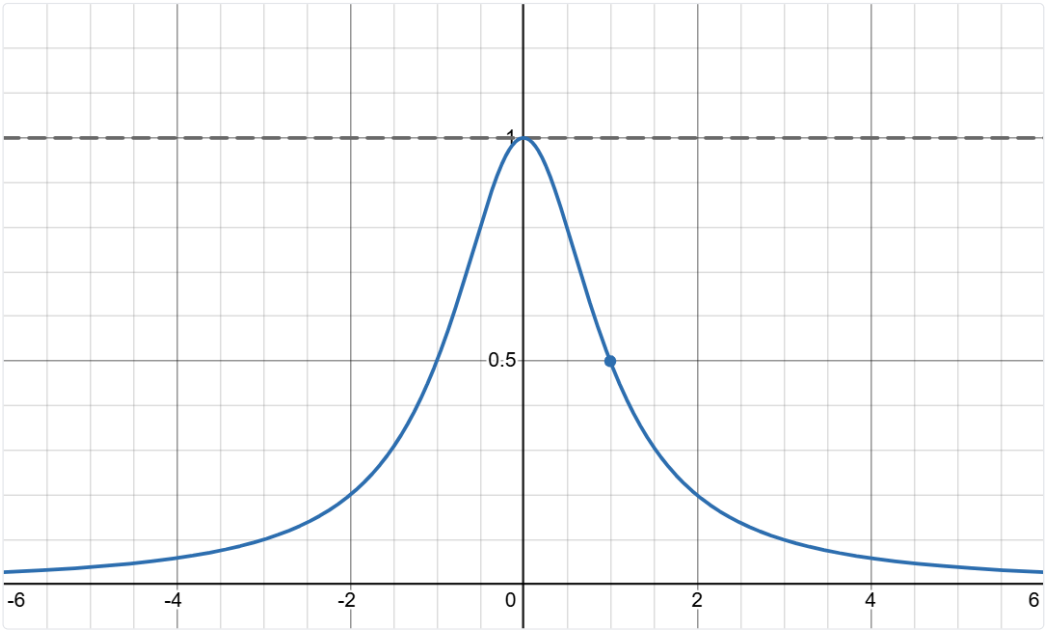
Step 1 — output PSD. $S_{YY} = |H|^2 S_{XX} = \dfrac{N_0/2}{1 + \omega^2 R^2 C^2}$. Writing $\alpha = 1/(RC)$, $S_{YY} = \dfrac{N_0}{2} \cdot \dfrac{\alpha^2}{\alpha^2 + \omega^2} = \dfrac{N_0 \alpha}{4} \cdot \dfrac{2\alpha}{\alpha^2 + \omega^2}$.

Step 2 — output autocorrelation. Matching with Example 21.15 ($\sigma^2 = N_0\alpha/4$):

$$R_{YY}(\tau) = \frac{N_0}{4RC}\, e^{-|\tau|/RC}, \qquad E[Y^2] = \frac{N_0}{4RC}.$$

Step 3 — cross-check in the time domain. $h(t) = \alpha e^{-\alpha t}u(t)$, so $R_{YY}(0) = \frac{N_0}{2}\int h^2 dt = \frac{N_0}{2} \cdot \frac{\alpha^2}{2\alpha} = \frac{N_0\alpha}{4}$. ✓ (For white input, $E[Y^2] = \frac{N_0}{2}\int h^2(t)\,dt$ — the output power is the input density times the filter's impulse-response energy.)

Step 4 — numbers. $R = 1$ kΩ, $C = 1$ μF ($RC = 1$ ms), $N_0/2 = 10^{-6}$ V²/Hz: $E[Y^2] = 2 \times 10^{-6}/(4 \times 10^{-3}) = 5 \times 10^{-4}$ V², i.e. 22.4 mV rms. The output samples decorrelate on the time scale RC: white noise has become exponentially correlated (Lorentzian) noise.



White input PSD (normalized to 1, dashed) and the output PSD of a first-order RC lowpass, $|H(\omega)|^2 = 1/(1 + \omega^2 R^2 C^2)$, plotted against ωRC. The filter turns white noise into Lorentzian, exponentially correlated noise.

Worked Example 21.19 — Coloured noise through a differentiator-like highpass

The noise of Example 21.15 ($\sigma^2 = 1$ V², $\alpha = 1000$ s^{-1}) is applied to a first-order highpass $H(\omega) = \dfrac{j\omega\tau_0}{1 + j\omega\tau_0}$ with $\tau_0 = 1$ ms (corner at $\omega = 1000$ rad/s, equal to α). Find the output power.

Step 1. $|H|^2 = \dfrac{\omega^2\tau_0^2}{1 + \omega^2\tau_0^2} = \dfrac{\omega^2}{\alpha^2 + \omega^2}$ (since $1/\tau_0 = \alpha$).

Step 2. $S_{YY} = \dfrac{\omega^2}{\alpha^2 + \omega^2} \cdot \dfrac{2\alpha\sigma^2}{\alpha^2 + \omega^2} = \dfrac{2\alpha\sigma^2\omega^2}{(\alpha^2 + \omega^2)^2}$.

Step 3. Using $\int_{-\infty}^{\infty} \frac{\omega^2}{(\alpha^2+\omega^2)^2} d\omega = \frac{\pi}{2\alpha}$,

$$E[Y^2] = \frac{1}{2\pi} \cdot 2\alpha\sigma^2 \cdot \frac{\pi}{2\alpha} = \frac{\sigma^2}{2} = 0.5 \text{ V}^2.$$

A highpass whose corner coincides with the noise's own corner removes exactly half the noise power. The complementary lowpass $1/(1 + j\omega\tau_0)$ passes $\frac{1}{2\pi}\int \frac{\alpha^2}{\alpha^2+\omega^2}\frac{2\alpha\sigma^2}{\alpha^2+\omega^2} d\omega = \sigma^2/2$ as well: the two outputs' powers add to the input power here because $|H_{LP}|^2 + |H_{HP}|^2 = 1$ — a power-complementary pair.

Discrete-time random sequences

All of the above has an exact discrete-time counterpart, which is what is actually computed in DSP systems.

Discrete-time Wiener–Khinchin and LTI relations

For a WSS sequence with $\sum_k |R_{XX}[k]| < \infty$,

$$S_{XX}(e^{j\Omega}) = \sum_{k=-\infty}^{\infty} R_{XX}[k]\, e^{-j\Omega k}, \qquad R_{XX}[k] = \frac{1}{2\pi}\int_{-\pi}^{\pi} S_{XX}(e^{j\Omega}) e^{j\Omega k}\, d\Omega,$$

a 2π-periodic, real, non-negative spectrum in the normalized frequency Ω (rad/sample). The power is $E[X^2[n]] = \frac{1}{2\pi}\int_{-\pi}^{\pi} S_{XX}(e^{j\Omega})d\Omega$. If $Y[n] = \sum_m h[m]X[n-m]$ with $H(e^{j\Omega}) = \sum_m h[m]e^{-j\Omega m}$, then

$$\mu_Y = \mu_X H(e^{j0}), \qquad S_{YX}(e^{j\Omega}) = H(e^{j\Omega})S_{XX}(e^{j\Omega}), \qquad S_{YY}(e^{j\Omega}) = |H(e^{j\Omega})|^2 S_{XX}(e^{j\Omega}).$$

In z-transform form, $S_{YY}(z) = H(z)H(z^{-1})S_{XX}(z)$.

The derivation is word-for-word the continuous one with sums for integrals. When a continuous process is sampled at rate $f_s = 1/T_s$, $\Omega = \omega T_s$, and the sampled PSD is the aliased sum $S_{X_d}(e^{j\Omega}) = \frac{1}{T_s}\sum_m S_{XX}\left(\frac{\Omega - 2\pi m}{T_s}\right)$; for a process band-limited below $f_s/2$ there is no aliasing.

The AR(1) sequence

First-order autoregressive (AR(1)) sequence

$$X[n] = aX[n-1] + W[n], \qquad |a| < 1,$$

where $W[n]$ is zero-mean white noise with variance σ_W^2 ("innovations"), with $W[n]$ uncorrelated with past values $X[n-1], X[n-2], \ldots$.

This is the discrete-time analogue of RC-filtered white noise and the simplest model of a correlated sequence. We derive its statistics in three independent ways.

(i) As a filtered white sequence. The recursion is an LTI filter with $H(z) = \dfrac{1}{1 - az^{-1}}$, $h[n] = a^n u[n]$. In steady state,

$$S_{XX}(e^{j\Omega}) = \frac{\sigma_W^2}{|1 - ae^{-j\Omega}|^2} = \frac{\sigma_W^2}{1 - 2a\cos\Omega + a^2},$$

and the variance is $\sigma_W^2 \sum_{n\ge 0} h^2[n] = \sigma_W^2 \sum a^{2n} = \dfrac{\sigma_W^2}{1-a^2}$.

(ii) Yule–Walker recursion. Multiply the recursion by $X[n-k]$ ($k \ge 1$) and take expectations. Since $W[n]$ is uncorrelated with the past, $E[W[n]X[n-k]] = 0$, giving

$$R_{XX}[k] = aR_{XX}[k-1] \quad (k \ge 1) \qquad \Longrightarrow \qquad R_{XX}[k] = R_{XX}[0]\, a^{|k|}.$$

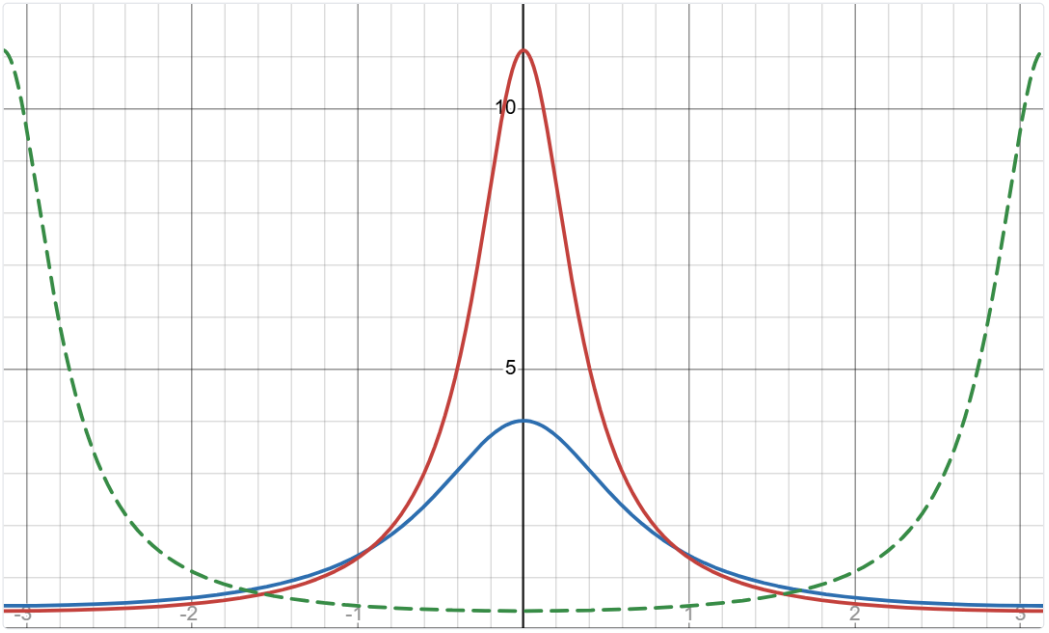
For $k = 0$: $R_{XX}[0] = E[(aX[n-1] + W[n])^2] = a^2 R_{XX}[0] + \sigma_W^2$, so $R_{XX}[0] = \sigma_W^2/(1-a^2)$. Hence

$$R_{XX}[k] = \frac{\sigma_W^2}{1-a^2}\, a^{|k|}.$$

(iii) Wiener–Khinchin check. Summing the two geometric series,

$$\sum_k \frac{\sigma_W^2}{1-a^2} a^{|k|} e^{-j\Omega k} = \frac{\sigma_W^2}{1-a^2}\left[\frac{1}{1-ae^{-j\Omega}} + \frac{1}{1-ae^{j\Omega}} - 1\right] = \frac{\sigma_W^2}{1 - 2a\cos\Omega + a^2}. \checkmark$$

The spectrum is lowpass for $0 < a < 1$ (peak $\sigma_W^2/(1-a)^2$ at $\Omega = 0$) and highpass for $-1 < a < 0$ (peak at $\Omega = \pi$, with alternating-sign correlation $R[k] \propto a^{|k|}$). As $a \to 1$ the correlation time $-1/\ln a \approx 1/(1-a)$ samples grows and the spectrum concentrates near DC; at $a = 1$ the recursion becomes the random walk of Example 21.2, which has no stationary state.



AR(1) power spectra $S_{XX}(e^{j\Omega}) = 1/(1 - 2a\cos\Omega + a^2)$ over one period $-\pi \le \Omega \le \pi$ ($\sigma_W^2 = 1$): $a = 0.5$ (blue) and $a = 0.7$ (red) are lowpass, sharper for larger a; $a = -0.7$ (green, dashed) is the mirror-image highpass spectrum.

Worked Example 21.20 — AR(1) statistics and start-up transient

Take $a = 0.9$, $\sigma_W^2 = 1$.

Step 1 — steady state. $\sigma_X^2 = 1/(1 - 0.81) = 5.263$; $\rho[k] = 0.9^{|k|}$, so $\rho[10] = 0.349$ and $\rho[22] = 0.098$. The spectrum ranges from $S(e^{j0}) = 1/(0.1)^2 = 100$ down to $S(e^{j\pi}) = 1/(1.9)^2 = 0.277$ — a 25.6 dB lowpass. Its half-power point solves $1 - 1.8\cos\Omega + 0.81 = 2(0.01)$, giving $\Omega_{3\text{dB}} = 0.105$ rad/sample $\approx 1 - a$.

Step 2 — power check by integration. $\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{d\Omega}{1.81 - 1.8\cos\Omega} = \frac{1}{\sqrt{1.81^2 - 1.8^2}} = \frac{1}{\sqrt{0.0361}} = 5.263$. ✓ (Using $\frac{1}{2\pi}\int_{-\pi}^{\pi} \frac{d\Omega}{A - B\cos\Omega} = 1/\sqrt{A^2 - B^2}$ for $A > |B|$.)

Step 3 — transient. If the recursion starts at $X[0] = 0$, then $X[n] = \sum_{m=0}^{n-1} a^m W[n-m]$ and

$$\operatorname{Var} X[n] = \sigma_W^2 \frac{1 - a^{2n}}{1 - a^2}.$$

After $n = 10$ steps the variance is 4.62 (88% of the steady state); after $n = 50$, 5.263 to four digits. The process is **asymptotically WSS**. In simulation, discard the first several correlation times of output ("burn-in"), or start from $X[0] \sim \mathcal{N}(0, \sigma_W^2/(1 - a^2))$, which makes the sequence stationary from the start.

Worked Example 21.21 — Fitting an AR(1) model to measured correlations

The bias of a temperature sensor, sampled once per second, has estimated autocorrelation $\hat{R}[0] = 2.0\ \text{K}^2$ and $\hat{R}[1] = 1.6\ \text{K}^2$. Fit an AR(1) model and predict the bias one and ten seconds ahead.

Step 1 — parameters (Yule–Walker). $\hat{a} = \hat{R}[1]/\hat{R}[0] = 0.8$ and $\hat{\sigma}_W^2 = \hat{R}[0](1 - \hat{a}^2) = 2.0 \times 0.36 = 0.72\ \text{K}^2$.

Step 2 — one-step prediction. Given the present value $X[n] = x$, the best linear predictor of $X[n+1]$ is $\hat{X}[n+1] = ax = 0.8x$, with error $W[n+1]$ of variance 0.72 — compared with 2.0 without using x. Knowledge of the present removes 64% ($= a^2$) of the uncertainty.

Step 3 — ten steps ahead. Iterating, $\hat{X}[n+10] = a^{10}x = 0.107x$, error variance $\sigma_X^2(1 - a^{20}) = 2.0(1 - 0.0115) = 1.977\ \text{K}^2$: after ten correlation times the present value is nearly useless for prediction.

Step 4 — continuous-time equivalent. Matching $a = e^{-\alpha T_s}$ with $T_s = 1$ s gives $\alpha = -\ln 0.8 = 0.223\ \text{s}^{-1}$, i.e. a Gauss–Markov process (§21.5) with correlation time 4.5 s. This is the standard bias model in a Kalman filter.

Engineering Note — why AR models are everywhere

AR(p) models $X[n] = \sum_{i=1}^{p} a_i X[n-i] + W[n]$ generalize the above and are fitted by solving the Yule–Walker equations, a Toeplitz linear system in $R_{XX}[0], \dots, R_{XX}[p]$ (solved efficiently by the Levinson–Durbin recursion). They underlie linear-predictive speech coding (LPC in mobile-phone codecs), high-resolution "parametric" spectrum estimation, channel-fading simulators and the process models of Kalman filters.

21.5 Gaussian processes

Motivation

Second-order theory tells us means, correlations and spectra, but an engineer often needs *probabilities*: How often will the noise exceed the decision threshold? What is the chance that a sensor error exceeds its specification? In general such questions need the full distribution. For one enormously important class — Gaussian processes — the mean and autocorrelation already determine every distribution, so everything computed in §§21.3–21.4 converts directly into probabilities. And Gaussian processes are not a mathematical convenience only: by the central limit theorem (Ch. 19), any signal formed as the sum of a very large number of small, independent contributions — the thermal agitation of 10^{20} electrons, the superposition of many weak interferers, the accumulated effect of many small manufacturing variations — is very nearly Gaussian.

Definition

Gaussian process

$X(t)$ is a **Gaussian process** if for every k and every set of times $t_1, \dots, t_k$ the random vector $\mathbf{X} = [X(t_1), \dots, X(t_k)]^{\mathsf{T}}$ is jointly Gaussian (Ch. 19):

$$f_{\mathbf{X}}(\mathbf{x}) = \frac{1}{(2\pi)^{k/2}(\det \mathbf{C})^{1/2}} \exp\Big(-\tfrac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^{\mathsf{T}} \mathbf{C}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \Big),$$

with $\mu_i = \mu_X(t_i)$ and $C_{ik} = C_{XX}(t_i, t_k)$. (If $\mathbf{C}$ is singular the vector is a degenerate Gaussian, defined through its characteristic function $\Phi_{\mathbf{X}}(\boldsymbol{\omega}) = \exp\big(j\boldsymbol{\omega}^{\mathsf{T}}\boldsymbol{\mu} - \tfrac{1}{2}\boldsymbol{\omega}^{\mathsf{T}}\mathbf{C}\boldsymbol{\omega}\big)$.) An equivalent definition: **every finite linear combination** $\sum_i a_i X(t_i)$ is a (possibly degenerate) Gaussian random variable.

Two processes X, Y are **jointly Gaussian** if every vector formed from samples of both is jointly Gaussian.

Common Pitfall — Gaussian marginals are not enough

A process whose first-order pdf $f_X(x;t)$ is Gaussian for every t need **not** be a Gaussian process. Example: let $Z \sim \mathcal{N}(0,1)$ and $S = \pm 1$ independent and equally likely; the pair (Z, SZ) has Gaussian marginals, but $Z + SZ$ equals 0 with probability $\frac{1}{2}$, which no Gaussian variable does. The joint Gaussian property must hold for all finite collections of samples.

Key properties

Properties of Gaussian processes

1. **Second-order specification:** a Gaussian process is completely specified, in distribution, by $\mu_X(t)$ and $C_{XX}(t_1, t_2)$. Conversely, for any function $\mu(t)$ and any symmetric non-negative-definite $C(t_1, t_2)$ there exists a Gaussian process with these moments.
2. **WSS ⇔ SSS** for Gaussian processes.
3. **Uncorrelated ⇒ independent:** jointly Gaussian samples (or processes) that are uncorrelated are independent.
4. **Closure under linear operations:** if X is Gaussian, then the output of any linear system — samples, sums, derivatives, integrals, LTI filtering — is Gaussian and jointly Gaussian with X.
5. **Linear conditional means:** for jointly Gaussian X and Y, $E[Y \mid X]$ is an affine function of X, so the best (minimum mean-square error) estimator of one Gaussian quantity from others is linear, and the error variance does not depend on the observed values.

Proof sketches.

1. The joint pdf above involves only $\boldsymbol{\mu}$ and $\mathbf{C}$. Existence follows from Kolmogorov's extension theorem, because the Gaussian distributions with these parameters are consistent (marginals of Gaussians are Gaussian with the corresponding sub-vector and sub-matrix).
2. If X is WSS, the mean vector and covariance matrix of $[X(t_1 + c), \ldots, X(t_k + c)]$ are $\mu_X \mathbf{1}$ and $[C_{XX}(t_i - t_k)]$, which do not involve c. By property 1 the joint distribution is therefore shift-invariant for every k: SSS.
3. If $\mathbf{C}$ is diagonal, the quadratic form in the exponent separates into a sum and the joint pdf factors into the product of the marginals.
4. A sample, sum or finite difference of Gaussian samples is a linear combination, hence Gaussian by the equivalent definition. An integral $\int h(\alpha) X(t-\alpha)\,d\alpha$ is a mean-square limit of Riemann sums, each Gaussian; mean-square limits of Gaussian variables are Gaussian (their characteristic functions $e^{j\omega\mu_n - \omega^2\sigma_n^2/2}$ converge to one of the same form). Derivatives are limits of difference quotients, likewise.
5. For jointly Gaussian (X, Y) with correlation coefficient ρ, the conditional distribution of Y given $X = x$ is $\mathcal{N}\big(\mu_Y + \rho\frac{\sigma_Y}{\sigma_X}(x - \mu_X),\ \sigma_Y^2(1-\rho^2)\big)$ (Ch. 19). □

Property 4 is what makes Gaussian noise analysis tractable: to find the distribution of a filtered Gaussian noise sample we need only its mean and variance, both of which follow from $\mu_Y = \mu_X H(0)$ and $S_{YY} = |H|^2 S_{XX}$ (§21.4). Non-Gaussian inputs, by contrast, generally produce outputs whose distributions are hard to compute — although narrowband filtering of almost any wideband noise tends to make the output *more* Gaussian (a central-limit effect: each output sample is a weighted sum of many nearly independent input samples).

Worked examples

Worked Example 21.22 — Probability of a large increment

$X(t)$ is a zero-mean Gaussian WSS process with $R_{XX}(\tau) = 4e^{-|\tau|}$ (units V², τ in seconds). Find $P\{X(1) - X(0) > 2\}$.

Step 1 — distribution of the increment. $D = X(1) - X(0)$ is a linear combination of jointly Gaussian samples, hence Gaussian, with mean 0 and

$$\operatorname{Var}(D) = R_{XX}(0) + R_{XX}(0) - 2R_{XX}(1) = 8 - 8e^{-1} = 5.057\ \text{V}^2, \qquad \sigma_D = 2.249\ \text{V}.$$

Step 2 — probability. $P\{D > 2\} = Q(2/2.249) = Q(0.889) \approx 0.187$, where $Q(x) = 1 - \Phi(x)$.

Step 3 — comparison. $P\{X(0) > 2\} = Q(2/2) = Q(1) \approx 0.159$. The correlation between $X(0)$ and $X(1)$ is $\rho = e^{-1} = 0.368$; if the samples were independent, $\operatorname{Var}(D)$ would be 8, and if perfectly correlated it would be 0. The general formula $\operatorname{Var}[X(t+\tau) - X(t)] = 2[R_{XX}(0) - R_{XX}(\tau)]$ — the **structure function** — is used to specify jitter and drift over a given time interval.

Worked Example 21.23 — Predicting a Gaussian process

Same process as Example 21.22. The value $X(0) = 3$ V is observed. Find the distribution of $X(0.5)$ and the probability that it still exceeds 3 V.

Step 1 — correlation. $\rho = R_{XX}(0.5)/R_{XX}(0) = e^{-0.5} = 0.607$.

Step 2 — conditional distribution (property 5 with $\mu = 0$, $\sigma_X = \sigma_Y = 2$):

$$X(0.5) \mid X(0) = 3 \ \sim\ \mathcal{N}\big(\rho \cdot 3,\ 4(1-\rho^2)\big) = \mathcal{N}(1.820,\ 2.528).$$

The conditional standard deviation is 1.590 V.

Step 3 — probability. $P\{X(0.5) > 3 \mid X(0) = 3\} = Q\big((3 - 1.820)/1.590\big) = Q(0.742) \approx 0.229$, compared with the unconditional $P\{X(0.5) > 3\} = Q(1.5) = 0.067$. Knowing that the noise is high now makes it more than three times as likely to be high half a second later.

Remark. Because the conditional variance $4(1-\rho^2)$ does not depend on the observed value, the prediction error of this optimal linear predictor is known in advance — the fact that makes Kalman-filter covariance computations possible before any data arrive. For the exponential autocorrelation, observing X at earlier times $t < 0$ in addition to $X(0)$ would not improve the prediction: this is the Markov property of the Gauss–Markov process (below).

Worked Example 21.24 — Zero-crossing rate (Rice's formula)

For a zero-mean stationary Gaussian process with twice-differentiable R_{XX}, the expected number of crossings of the level u per unit time (both directions) is **Rice's formula**

$$\nu_u = \frac{1}{\pi}\sqrt{\frac{-R_{XX}''(0)}{R_{XX}(0)}}\,\exp\!\Big(-\frac{u^2}{2R_{XX}(0)}\Big).$$

Sketch. A crossing occurs in $(t, t+dt)$ if $X(t)$ is within $|X'(t)|dt$ of u. Since $X(t)$ and $X'(t)$ are uncorrelated (§21.3), hence independent (Gaussian), the expected count is $dt\, f_X(u)\, E|X'| = dt\, f_X(u)\sqrt{2/\pi}\,\sigma_{X'}$. With $\sigma_{X'}^2 = -R_{XX}''(0)$ and $f_X(u) = e^{-u^2/2\sigma^2}/(\sqrt{2\pi}\sigma)$ the formula follows.

Check on a sinusoid. For $R_{XX} = \cos\omega_0\tau$, $\nu_0 = \omega_0/\pi = 2f_0$: two zero crossings per period. ✓

Band-limited noise. For flat noise on $|f| < B$, $R_{XX}(\tau) = \sigma^2\frac{\sin 2\pi B\tau}{2\pi B\tau}$ and $-R_{XX}''(0)/R_{XX}(0) = (2\pi B)^2/3$, so $\nu_0 = 2B/\sqrt{3}$. With $B = 1$ kHz: $\nu_0 = 1155$ crossings per second. Crossings of $u = 3\sigma$ (both directions) occur at $1155\,e^{-4.5} = 12.8$ per second, i.e. about 6.4 upward excursions per second. This is how false-trigger rates of comparators and false-alarm rates of threshold detectors are estimated.

Gauss–Markov and Wiener processes

Gauss–Markov (Ornstein–Uhlenbeck) process

The stationary Gaussian process with

$$R_{XX}(\tau) = \sigma^2 e^{-\alpha|\tau|}, \qquad S_{XX}(\omega) = \frac{2\alpha\sigma^2}{\alpha^2+\omega^2}$$

is the only stationary Gaussian process (up to trivial cases) that is also **Markov**: given $X(t)$, the future is independent of the past. It is the output of a first-order lowpass filter driven by white Gaussian noise, $\dot X = -\alpha X + W$, and its samples at spacing T_s form an AR(1) sequence with $a = e^{-\alpha T_s}$ (Example 21.4).

It is the standard model for slowly varying sensor biases and drifts (gyroscope bias, clock frequency error, the bias of Example 21.21) and for the velocity of a Brownian particle.

Wiener process (Brownian motion)

$W(t)$, $t \ge 0$, is the Gaussian process with $W(0) = 0$, independent stationary increments, $W(t+s) - W(t) \sim \mathcal{N}(0, \sigma^2 s)$. Equivalently, it is the zero-mean Gaussian process with

$$R_{WW}(t_1, t_2) = \sigma^2 \min(t_1, t_2).$$

The Wiener process is the continuous-time limit of the random walk: scale steps of size $\pm\sigma\sqrt{\Delta t}$ every Δt seconds; by the CLT, the walk at time t is approximately $\mathcal{N}(0, \sigma^2 t)$, and its autocorrelation $\sigma^2\Delta t\min(n_1, n_2) \to \sigma^2\min(t_1, t_2)$. It is not stationary ($\mathrm{Var}\,W(t) = \sigma^2 t$), its paths are continuous but nowhere differentiable, and — formally — its derivative is white Gaussian noise of PSD σ^2 (§21.6): $\frac{\partial^2}{\partial t_1 \partial t_2}\sigma^2\min(t_1,t_2) = \sigma^2\delta(t_1 - t_2)$. Free-running oscillator phase noise is modelled as a Wiener process, which is why phase error grows like $\sqrt{t}$ and why the phase-noise spectrum of an oscillator falls as $1/f^2$ away from the carrier.

Bandpass Gaussian noise

At the output of a narrowband IF or RF filter centred at ω_0, noise looks like a sinusoid at ω_0 with slowly wandering amplitude and phase. This is made precise by the quadrature representation.

In-phase/quadrature representation of narrowband noise

Let $N(t)$ be zero-mean, WSS, Gaussian with PSD concentrated in $|\omega \mp \omega_0| < W$, $W < \omega_0$. Then

$$N(t) = N_c(t)\cos\omega_0 t - N_s(t)\sin\omega_0 t = R(t)\cos\big(\omega_0 t + \Phi(t)\big),$$

where the in-phase and quadrature components N_c, N_s are jointly Gaussian, zero-mean, lowpass processes, each with the same power as N:

$$E[N_c^2] = E[N_s^2] = E[N^2] = \sigma^2, \qquad S_{N_cN_c}(\omega) = S_{N_sN_s}(\omega) = \big[S_{NN}(\omega-\omega_0) + S_{NN}(\omega+\omega_0)\big]_{|\omega|<W}.$$

If S_{NN} is symmetric about $\pm\omega_0$, N_c and N_s are independent. At any instant the **envelope** $R = \sqrt{N_c^2 + N_s^2}$ is **Rayleigh** distributed and the phase Φ is uniform on $[0, 2\pi)$, independent of R:

$$f_R(r) = \frac{r}{\sigma^2}e^{-r^2/(2\sigma^2)}\ (r \ge 0), \qquad P\{R > r\} = e^{-r^2/(2\sigma^2)}.$$

The Rayleigh result follows from transforming the pdf of two independent $\mathcal{N}(0,\sigma^2)$ variables to polar coordinates (Ch. 19): $f_{R\Phi}(r,\phi) = \frac{r}{2\pi\sigma^2}e^{-r^2/2\sigma^2}$, which factors.

Worked Example 21.25 — Envelope-detector false-alarm threshold

A radar receiver's IF noise is Gaussian narrowband noise with power σ^2. An envelope detector declares a target when $R(t)$ exceeds a threshold r_0. Choose r_0 so that the probability of a false alarm on any single sample is $P_{fa} = 10^{-6}$.

Step 1. $P\{R > r_0\} = e^{-r_0^2/(2\sigma^2)} = 10^{-6}$, so $r_0 = \sigma\sqrt{2\ln 10^6} = \sigma\sqrt{27.63} = 5.26\,\sigma$.

Step 2 — compare with a baseband threshold. For a real Gaussian sample, $P\{N > 5.26\sigma\} = Q(5.26) \approx 7.2 \times 10^{-8}$, about 14 times smaller. The envelope combines two independent Gaussian components, so large values are more probable; using the Gaussian tail here would make the false-alarm rate 14 times worse than designed.

Step 3 — in decibels. The threshold is $20\log_{10} 5.26 = 14.4$ dB above the RMS noise of each component, which sets the minimum detectable signal of the radar.

Engineering Note — where Gaussianity fails

The Gaussian model is excellent for thermal noise and usually for the sum of many independent interferers, but it fails for impulsive noise (lightning, ignition, switching transients), for a small number of dominant interferers, for quantization error of a slowly varying signal (closer to uniform), and for clipped or rectified signals. Heavy-tailed noise makes rare large errors far more likely than $Q(\cdot)$ predicts; robust detectors and median filters are the response. Always check a histogram, ideally on a logarithmic probability axis where the Gaussian tail is a parabola.

21.6 White noise

Motivation

Every receiver, amplifier and sensor adds noise, and in most cases that noise is spread almost uniformly over a frequency range far wider than the circuit that processes it. The thermal noise of a resistor is flat to within 1% up to about 100 GHz at room temperature; the circuits that see it have bandwidths of hertz to gigahertz. In such cases the detailed spectrum of the noise beyond the circuit's passband is irrelevant — only its *density* inside the passband matters. **White noise** is the idealization that makes this explicit: a flat PSD at all frequencies, characterized by one number. It is the "impulse" of random-signal analysis — unphysical on its own, indispensable as an input.

Definition and interpretation

White noise

A zero-mean WSS process $W(t)$ is **white** if its PSD is constant over all frequencies:

$$S_{WW}(\omega) = \frac{N_0}{2} \quad \Longleftrightarrow \quad R_{WW}(\tau) = \frac{N_0}{2}\,\delta(\tau).$$

If in addition W is Gaussian, it is **white Gaussian noise** (WGN). The factor $\frac{1}{2}$ is a convention that makes N_0 the **one-sided** PSD, in V^2/Hz (or W/Hz for available power).

Consequences of the definition:

- **Infinite power.** $R_{WW}(0) = \infty$; equivalently $\frac{1}{2\pi}\int \frac{N_0}{2}\,d\omega$ diverges. White noise is not a process with finite-variance samples; it is a generalized process that only makes sense after filtering or integration, just as $\delta(t)$ only makes sense under an integral.
- **Uncorrelated at every separation.** $R_{WW}(\tau) = 0$ for every $\tau \neq 0$, however small: the process has no memory at all.
- **Filtered white noise is well defined.** By §21.4, a filter h with finite energy turns it into a finite-power process with

$$S_{YY}(\omega) = \frac{N_0}{2}|H(\omega)|^2, \qquad R_{YY}(\tau) = \frac{N_0}{2}\int h(t+\tau)h(t)\,dt, \qquad E[Y^2] = \frac{N_0}{2}\int_{-\infty}^{\infty} h^2(t)\,dt.$$

The output autocorrelation is the *deterministic autocorrelation of the impulse response*: the filter "imprints" its own memory on the noise.

- **Integrated white noise is a Wiener process.** $\int_0^t W(s)\,ds$ has variance $\frac{N_0}{2}t$ and independent increments (§21.5).

White noise is useful precisely *because* physical noise is flat over a band far wider than any system that processes it, so only N_0 matters and the system's own bandwidth sets the output power.

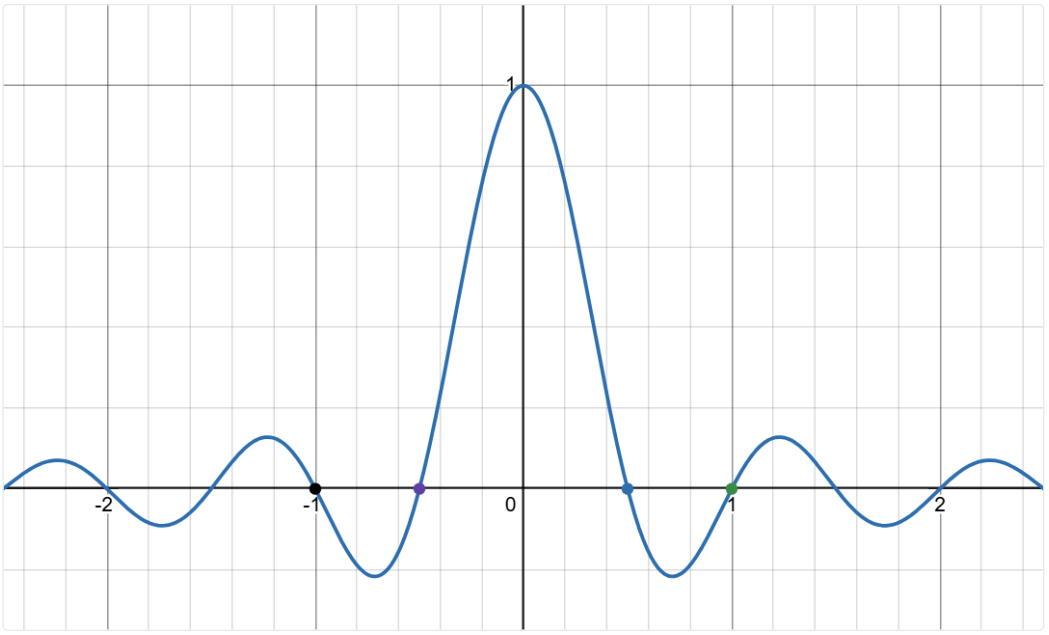
Band-limited white noise

Band-limited (lowpass) white noise

$$S_{XX}(\omega) = \begin{cases} N_0/2, & |\omega| < 2\pi B \\ 0, & \text{otherwise} \end{cases} \quad \Longrightarrow \quad R_{XX}(\tau) = N_0 B\,\frac{\sin(2\pi B\tau)}{2\pi B\tau}.$$

Derivation. $R_{XX}(\tau) = \frac{1}{2\pi}\int_{-2\pi B}^{2\pi B} \frac{N_0}{2} e^{j\omega\tau}\,d\omega = \frac{N_0}{2}\cdot\frac{1}{2\pi}\cdot\frac{2\sin(2\pi B\tau)}{\tau} = N_0 B\,\frac{\sin(2\pi B\tau)}{2\pi B\tau}$.

The power is $R_{XX}(0) = N_0 B$: **noise power = one-sided density × bandwidth**. This is the single most-used formula in link budgets.



Normalized autocorrelation of band-limited white noise with $B = 1$: zeros at $\tau = k/(2B)$. Samples taken at the Nyquist rate $2B$ are uncorrelated — and, if the noise is Gaussian, independent.

Similarly, **bandpass white noise** with density $N_0/2$ on $|f \mp f_0| < B/2$ has $R_{XX}(\tau) = N_0 B \frac{\sin \pi B\tau}{\pi B\tau} \cos 2\pi f_0 \tau$ and power $N_0 B$ — a sinc envelope on a carrier, consistent with the narrowband representation of §21.5.

Discrete-time white noise

Discrete-time white noise and sampling

A sequence $W[n]$ with $E[W[n]] = 0$ and $R_{WW}[k] = \sigma_W^2\,\delta[k]$ has the flat spectrum $S_{WW}(e^{j\Omega}) = \sigma_W^2$ for all Ω, and — unlike its continuous-time counterpart — finite power σ_W^2. Sampling band-limited white noise of bandwidth B at exactly $f_s = 2B$ produces discrete white noise with $\sigma_W^2 = N_0 B$.

Proof of the sampling statement. $R_{XX}[k] = R_{XX}(k/(2B)) = N_0 B \frac{\sin \pi k}{\pi k} = N_0 B\,\delta[k]$. □

Sampling at a higher rate $f_s > 2B$ gives correlated samples (sinc values at non-integer multiples of π); sampling unfiltered wideband noise at f_s aliases all of its power into $[-f_s/2, f_s/2]$. This is why an anti-aliasing filter is needed even when the *signal* is band-limited: without it, wideband noise is folded into the band of interest and the SNR degrades.

Worked Example 21.26 — Noise power in a receiver bandwidth

White noise with two-sided PSD $N_0/2 = 10^{-8}$ V^2/Hz passes through an ideal lowpass filter of bandwidth $B = 5$ kHz.

Step 1. $P = N_0 B = 2 \times 10^{-8} \times 5 \times 10^3 = 10^{-4}$ V^2, so $V_{\text{rms}} = 10$ mV.

Step 2 — scaling. Doubling the bandwidth doubles the noise power (+3 dB) and raises the RMS noise by $\sqrt{2}$ to 14.1 mV. Halving it gives 7.07 mV. In general $V_{\text{rms}} \propto \sqrt{B}$, which is why noise densities are quoted in V/$\sqrt{\text{Hz}}$: here $\sqrt{N_0} = \sqrt{2 \times 10^{-8}} = 141\ \mu\text{V}/\sqrt{\text{Hz}}$, and $141\ \mu\text{V} \times \sqrt{5000} = 10$ mV. ✓

Step 3 — samples. If this output is sampled at $f_s = 10$ kHz $= 2B$, the samples are uncorrelated with variance 10^{-4} V^2; if the noise is Gaussian, $P\{|v| > 30\ \text{mV}\} = 2Q(3) = 0.0027$ per sample, i.e. about 27 samples per second exceed ± 30 mV.

Noise-equivalent bandwidth

Real filters do not have brick-wall responses. To keep the convenient formula "power = density × bandwidth", we define the bandwidth that makes it exact.

Noise-equivalent bandwidth

For a lowpass filter with DC gain $H(0) \neq 0$, the **noise-equivalent bandwidth** is

$$B_N = \frac{1}{|H(0)|^2} \int_0^\infty |H(2\pi f)|^2\, df,$$

the width (in Hz) of an ideal rectangular filter of the same peak gain that passes the same white-noise power. For a bandpass filter, replace $|H(0)|$ by the peak gain $|H(2\pi f_0)|$ and integrate over $f > 0$.

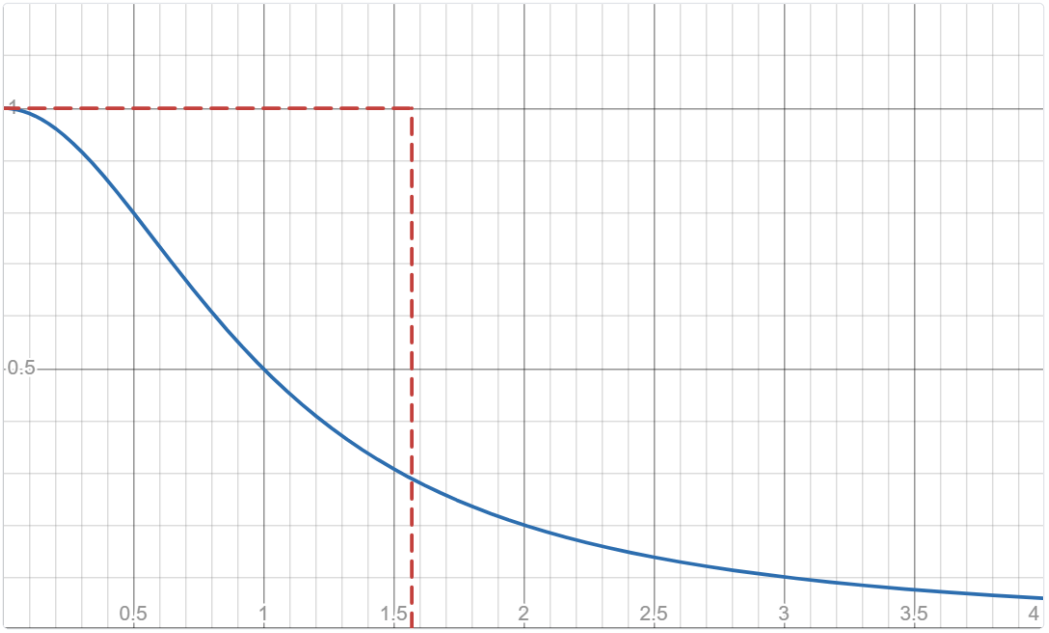
With this definition the output power of a filter driven by white noise of one-sided density N_0 is exactly

$$E[Y^2] = N_0\, B_N\, |H(0)|^2.$$

By Parseval's theorem there is an equivalent **time-domain formula**:

$$B_N = \frac{\int_{-\infty}^{\infty} h^2(t)\,dt}{2\left(\int_{-\infty}^{\infty} h(t)\,dt\right)^2},$$

since $\int_0^\infty |H(2\pi f)|^2 df = \tfrac{1}{2}\int_{-\infty}^{\infty}|H|^2 df = \tfrac{1}{2}\int h^2 dt$ and $H(0) = \int h\,dt$.



Noise-equivalent bandwidth of a first-order lowpass, with frequency normalized to $f_{3\text{dB}}$: the area under $|H|^2 = 1/(1+x^2)$ (blue) over $x>0$ is $\pi/2$, equal to the area of the red rectangle of height 1 and width $\pi/2 \approx 1.571$.

Worked Example 21.27 — Noise bandwidth of RC filters

(a) Single RC lowpass. $|H(2\pi f)|^2 = 1/(1+(2\pi f RC)^2)$, $H(0)=1$:

$$B_N = \int_0^\infty \frac{df}{1+(2\pi f RC)^2} = \frac{1}{2\pi RC}\cdot\frac{\pi}{2} = \frac{1}{4RC} = \frac{\pi}{2} f_{3\text{dB}},$$

where $f_{3\text{dB}} = 1/(2\pi RC)$. The time-domain formula agrees: $h = \frac{1}{RC}e^{-t/RC}u(t)$, $\int h^2 = \frac{1}{2RC}$, $\int h = 1$, so $B_N = \frac{1}{4RC}$. ✓ With $RC = 1$ ms, $f_{3\text{dB}} = 159$ Hz and $B_N = 250$ Hz: using $f_{3\text{dB}}$ in place of B_N would underestimate the noise power by 36% (1.96 dB).

(b) Two identical RC sections, buffered. $|H|^2 = 1/(1+(2\pi f RC)^2)^2$. With $u = 2\pi f RC$ and $\int_0^\infty \frac{du}{(1+u^2)^2} = \frac{\pi}{4}$,

$$B_N = \frac{1}{2\pi RC}\cdot\frac{\pi}{4} = \frac{1}{8RC}.$$

The 3 dB frequency of the cascade solves $(1+u^2)^2 = 2$, $u = \sqrt{\sqrt{2}-1} = 0.644$, so $f_{3\text{dB}} = 0.1024/RC$ and $B_N/f_{3\text{dB}} = 1.22$. Steeper skirts bring B_N closer to $f_{3\text{dB}}$.

The ratio $B_N/f_{3\text{dB}}$ for an n-th order Butterworth lowpass is $\dfrac{\pi/(2n)}{\sin(\pi/(2n))}$:

order n	1	2	3	4	∞
$B_N/f_{3\text{dB}}$	1.571	1.111	1.047	1.026	1

Worked Example 21.28 — Averaging as filtering

A **moving-average** (integrate-and-dump) filter outputs $Y(t) = \frac{1}{T}\int_{t-T}^{t} X(s)\,ds$, i.e. $h(t) = \frac{1}{T}$ on $[0,T]$. Then $\int h = 1$, $\int h^2 = 1/T$ and

$$B_N = \frac{1/T}{2\cdot 1^2} = \frac{1}{2T}.$$

Averaging white noise of density N_0 for T seconds gives output variance $N_0/(2T)$. A digital voltmeter integrating over one power-line cycle ($T = 20$ ms at 50 Hz) has $B_N = 25$ Hz; increasing the integration time to 10 cycles reduces the noise bandwidth to 2.5 Hz and the RMS noise by $\sqrt{10}$. The frequency response, $|H(2\pi f)| = |\sin \pi f T/(\pi f T)|$, also has nulls at multiples of $1/T$ — which is why integrating over exact line cycles rejects hum.

Worked Example 21.29 — Noise bandwidth of a tuned circuit

A second-order bandpass (e.g. a parallel RLC tank driven by a current, with voltage output) has

$$|H(2\pi f)|^2 = \frac{1}{1 + Q^2\left(f/f_0 - f_0/f\right)^2}$$

with peak gain 1 at f_0 and $B_{3\text{dB}} = f_0/Q$. The integral (by contour methods, Ch. 18, or numerically) is

$$B_N = \int_0^\infty |H|^2 df = \frac{\pi f_0}{2Q} = \frac{\pi}{2} B_{3\text{dB}}.$$

For a 10.7 MHz IF filter with $Q = 50$: $B_{3\text{dB}} = 214$ kHz, $B_N = 336$ kHz. A numerical check with $f_0 = 1$, $Q = 50$ gives 0.03138 against $\pi/100 = 0.03142$ (the small difference is the truncated tail). The same $\pi/2$ factor as the first-order lowpass appears because the bandpass response is the lowpass response mapped onto the frequency axis.

Coloured noise

Noise whose PSD is not flat is called **coloured**. The common types are named by their spectral slope:

Name	One-sided PSD	Autocorrelation behaviour	Where it occurs
white	$G(f) = N_0$	$\delta(\tau)$	thermal, shot noise
pink / flicker	$\propto 1/f$	very long memory, no finite variance over $0 < f < \infty$	MOSFETs, carbon resistors, oscillator close-in phase noise
brown / red	$\propto 1/f^2$	integral of white noise (Wiener)	random walk, free-running oscillator phase
Lorentzian	$\propto 1/(1 + (f/f_c)^2)$	$e^{-2\pi f_c \lvert\tau\rvert}$	RC-filtered white, RTS noise
blue / violet	$\propto f$, $\propto f^2$	derivative-like	differentiated noise, noise-shaped quantization

Worked Example 21.30 — Integrating a white-plus-flicker noise density

An op-amp has input voltage noise with one-sided density $G(f) = e_w^2\left(1 + f_c/f\right)$, white level $e_w = 10\ \text{nV}/\sqrt{\text{Hz}}$ and **1/f corner** $f_c = 100$ Hz. Find the RMS noise from $f_1 = 0.1$ Hz to $f_2 = 10$ kHz.

Step 1 — integrate.

$$\overline{v^2} = \int_{f_1}^{f_2} e_w^2\left(1 + \frac{f_c}{f}\right) df = e_w^2\left[(f_2 - f_1) + f_c \ln\frac{f_2}{f_1}\right].$$

Step 2 — numbers. $e_w^2 = 10^{-16}\ \text{V}^2/\text{Hz}$; $(f_2 - f_1) = 9999.9$ Hz; $f_c \ln(10^5) = 100 \times 11.51 = 1151$ Hz. Total $\overline{v^2} = 10^{-16} \times 11151 = 1.115 \times 10^{-12}\ \text{V}^2$, so $v_{\text{rms}} = 1.06\ \mu\text{V}$.

Step 3 — interpretation. The 1/f part contributes the equivalent of 1151 Hz of white bandwidth, i.e. 10% of the total power. Its contribution grows only logarithmically with the observation time ($f_1 \approx 1/T_{\text{obs}}$): each additional decade at low frequency adds $f_c \ln 10 = 230$ Hz. The variance does not converge as $f_1 \to 0$ — flicker noise has no well-defined stationary variance, a symptom of its very long memory.

Common Pitfall — "white" is not "Gaussian"

"White" refers to the *spectrum* (uncorrelated samples); "Gaussian" refers to the *amplitude distribution*. They are independent properties. A random ± 1 i.i.d. sequence is white but not Gaussian; the Gauss–Markov process is Gaussian but not white; thermal noise is both. Statements such as "white noise has a Gaussian distribution" or "Gaussian noise has a flat spectrum" are false in general.

Engineering Note — quantization noise as discrete white noise

An ADC with step Δ, digitizing a busy signal, adds an error that is well modelled as discrete white noise, uniformly distributed on $[-\Delta/2, \Delta/2]$, with variance $\Delta^2/12$ spread evenly over $|f| < f_s/2$. Its one-sided density is therefore $\Delta^2/(6 f_s)$: **oversampling** by a factor M (then filtering to the signal band) reduces the in-band quantization noise by M — 3 dB, or half a bit, per doubling of f_s. Noise-shaping ($\Sigma\Delta$) converters go further by making the quantization noise "blue", pushing it out of band.

21.7 Ergodicity

Motivation

Everything so far has been defined by ensemble averages — expectations over infinitely many hypothetical repetitions of the experiment. In the laboratory we usually have **one** long record: one amplifier, one data capture, one night of sensor logging. A spectrum analyzer, an RMS voltmeter and an oscilloscope's "average" mode all compute *time* averages over that single record. The property that justifies replacing $E[\cdot]$ by $\langle\cdot\rangle$ is **ergodicity**. It is not automatic, and the theory below tells us both *when* it holds and *how long* the record must be for the time average to be accurate — the practical question behind every measurement-time specification.

Time averages as random variables

For a finite record, define the time averages

$$\langle X\rangle_T = \frac{1}{2T}\int_{-T}^{T} X(t)\,dt, \qquad \hat{R}_T(\tau) = \frac{1}{2T}\int_{-T}^{T} X(t+\tau)X(t)\,dt.$$

Because they are computed from a random sample function, these are **random variables**. For a WSS process, interchanging expectation and integration,

$$E\big[\langle X\rangle_T\big] = \frac{1}{2T}\int_{-T}^{T} \mu_X\,dt = \mu_X,$$

so $\langle X\rangle_T$ is an **unbiased estimator** of μ_X (Ch. 20). The question is whether its variance shrinks to zero as T grows.

Ergodicity in the mean and in autocorrelation

A WSS process is **mean-ergodic** if $\langle X\rangle_T \to \mu_X$ in mean square as $T\to\infty$:

$$\lim_{T\to\infty} E\big[(\langle X\rangle_T - \mu_X)^2\big] = 0.$$

It is **autocorrelation-ergodic** if $\hat{R}_T(\tau) \to R_{XX}(\tau)$ in mean square for every τ, and **ergodic** (in the strict sense) if *every* time average of every measurable function of the process converges to the corresponding ensemble average. For a sequence, replace $\frac{1}{2T}\int_{-T}^{T}$ by $\frac{1}{N}\sum_{n=0}^{N-1}$.

The mean-ergodic theorem

Mean-ergodic theorem (Slutsky)

For a WSS process,

$$\operatorname{Var}\big(\langle X\rangle_T\big) = \frac{1}{2T}\int_{-2T}^{2T} C_{XX}(\tau)\Big(1-\frac{|\tau|}{2T}\Big)d\tau,$$

and X is mean-ergodic if and only if this tends to zero. Equivalently (Slutsky's condition), $\frac{1}{2T}\int_{-2T}^{2T} C_{XX}(\tau)\,d\tau \to 0$. A **sufficient** condition is $\int_{-\infty}^{\infty}|C_{XX}(\tau)|\,d\tau < \infty$, in which case, for large T,

$$\operatorname{Var}\big(\langle X\rangle_T\big) \approx \frac{1}{2T}\int_{-\infty}^{\infty} C_{XX}(\tau)\,d\tau = \frac{S_{CC}(0)}{2T},$$

where $S_{CC}(0)$ is the PSD of the zero-mean part $X-\mu_X$ at zero frequency. For a WSS sequence with N samples: $\operatorname{Var}(\bar{X}_N) = \frac{1}{N}\sum_{|k|<N}\big(1-\frac{|k|}{N}\big)C_{XX}[k] \approx \frac{1}{N}\sum_k C_{XX}[k]$.

Derivation.

$$\operatorname{Var}\big(\langle X\rangle_T\big) = E\Big[\Big(\frac{1}{2T}\int_{-T}^{T}(X(t)-\mu_X)dt\Big)^2\Big] = \frac{1}{4T^2}\int_{-T}^{T}\int_{-T}^{T} C_{XX}(t-s)\,dt\,ds.$$

This is the same double integral over a square that appeared in the proof of Wiener–Khinchin (§21.4), with $\omega=0$. Collapsing it along lines $t-s=\tau$ gives $\frac{1}{4T^2}\int_{-2T}^{2T}(2T-|\tau|)C_{XX}(\tau)\,d\tau$, which is the stated formula. If $\int|C_{XX}|<\infty$, the triangular weight tends to 1 and the integral is bounded, so the variance behaves like $(1/2T)\int C_{XX}$ and tends to zero. □

Two important interpretations:

- **Effective number of independent samples.** If X had independent samples every Δ seconds, a record of length $2T$ would contain $2T/\Delta$ of them and the variance of the mean would be $\sigma_X^2\Delta/(2T)$. Comparing with the formula, a correlated process behaves as if it had independent samples spaced $\Delta_{\text{eff}} = \int C_{XX}\,d\tau/\sigma_X^2 = 2\tau_c$ apart (twice the correlation time). The **effective sample size** is $N_{\text{eff}} = 2T/(2\tau_c)$.
- **Frequency-domain view.** Averaging over $2T$ is a lowpass filter of noise bandwidth $B_N = 1/(4T)$ (Example 21.28 with $T\to 2T$). The residual fluctuation is the noise power in that tiny band around DC, $2\cdot S_{CC}(0)\cdot B_N = S_{CC}(0)/(2T)$ — exactly the formula. Only the noise density at DC matters, which is why 1/f noise, whose density diverges at DC, defeats long averaging.

Worked Example 21.31 — How long must we average?

A sensor output is $X(t)=\mu+N(t)$, where N has $C_{NN}(\tau)=\sigma^2 e^{-\alpha|\tau|}$ with $\sigma = 1$ mV and $\alpha = 1000\ \text{s}^{-1}$. We estimate μ by averaging a record of total length $2T = 1$ s.

Step 1 — asymptotic formula.

$$\operatorname{Var}(\hat{\mu}) \approx \frac{1}{2T}\int_{-\infty}^{\infty}\sigma^2 e^{-\alpha|\tau|}d\tau = \frac{1}{2T}\cdot\frac{2\sigma^2}{\alpha} = \frac{2\times 10^{-6}}{1\times 1000} = 2\times 10^{-9}\ \text{V}^2,$$

so the standard error is $\sqrt{2\times10^{-9}} \approx 44.7\ \mu\text{V}$.

Step 2 — exact formula. Evaluating the triangular-weighted integral exactly with $L=2T$ gives $\frac{2\sigma^2}{\alpha L}\Big[1-\frac{1-e^{-\alpha L}}{\alpha L}\Big] = 2\times10^{-9}(1-0.001) = 1.998\times 10^{-9}\ \text{V}^2$: the asymptotic formula is excellent once $L \gg 1/\alpha$.

Step 3 — effective samples. $\tau_c = 1/\alpha = 1$ ms, so $N_{\text{eff}} = L/(2\tau_c) = 500$, and $\sigma/\sqrt{500} = 44.7\ \mu$V. ✓ Sampling the record at 1 MHz (a million samples) does not help: the samples are highly correlated, and the error is set by the 500 effectively independent ones.

Step 4 — design. To reach a standard error of 10 μV, we need $N_{\text{eff}} = (1\ \text{mV}/10\ \mu\text{V})^2 = 10^4$, i.e. $L = 2\tau_c N_{\text{eff}} = 20$ s of data.

Worked Example 21.32 — Sample mean of an AR(1) sequence

Take the AR(1) sequence of Example 21.20 ($a = 0.9$, $\sigma_W^2 = 1$, $\sigma_X^2 = 5.263$) and $N = 1000$ samples.

Step 1 — sum of covariances. $\sum_k C_{XX}[k] = \sigma_X^2 \sum_k a^{|k|} = \sigma_X^2 \frac{1+a}{1-a} = 5.263 \times 19 = 100$. (This equals $S_{XX}(e^{j0}) = \sigma_W^2/(1-a)^2 = 100$, as it must.)

Step 2 — variance of the mean. $\mathrm{Var}(\bar{X}_N) \approx 100/1000 = 0.1$; the exact finite-$N$ sum gives 0.0991. Standard error 0.316.

Step 3 — comparison with i.i.d. Treating the samples as independent would give $\sigma_X^2/N = 0.00526$ — **19 times too small**, an error bar $\sqrt{19} = 4.4$ times too optimistic. The effective sample size is $N_{\text{eff}} = N\frac{1-a}{1+a} = 52.6$.

This is a common error when applying the confidence intervals of Ch. 20 to time-series data: those formulas assume independent observations.

Non-ergodic processes

Worked Example 21.33 — Stationary processes that are not ergodic

(a) Random constant. Let $X(t) = A$ for all t, where $A \sim \mathcal{N}(0,1)$. Then $\mu_X = 0$ and $R_{XX}(\tau) = 1$: the process is SSS. But each sample function is a constant, so $\langle x \rangle_T = A$, which is not 0 in general. Here $C_{XX}(\tau) = 1$ does not decay, and the variance formula gives $\mathrm{Var}\langle X \rangle_T = 1 \not\to 0$. One record never reveals the ensemble mean. In the PSD this shows up as an impulse $2\pi\delta(\omega)$ in the spectrum of the zero-mean part — a random DC component.

(b) Random-phase sinusoid. $A\cos(\omega_0 t + \Theta)$ with fixed A *is* ergodic in mean and autocorrelation: every sample function has time average 0 and time autocorrelation $\frac{A^2}{2}\cos\omega_0\tau$ (Example 21.1, Step 5).

(c) Random amplitude and phase. $A\cos(\omega_0 t + \Theta)$ with *random* A (independent of Θ) is still mean-ergodic, but **not autocorrelation-ergodic**: the time autocorrelation of one record is $\frac{A^2}{2}\cos\omega_0\tau$, while the ensemble one is $\frac{E[A^2]}{2}\cos\omega_0\tau$. A power meter on one record reports that record's $A^2/2$.

(d) Random choice of source. A switch, set once at random, connects either a 1 mV-rms or a 10 mV-rms noise source to the output. The resulting process is stationary, with ensemble power $\frac{1}{2}(1 + 100) = 50.5$ mV^2, but every individual record has time-average power 1 or 100 mV^2 — never 50.5. Non-ergodicity typically means "the ensemble is a mixture of different sub-populations, and each record sees only one".

The general principle: a stationary process fails to be ergodic when some random quantity is fixed for the whole record (an amplitude, a DC offset, a choice of state). In engineering terms, ergodicity is a statement that **one device, observed for a long time, is representative of the population of devices**. This is plausible for the thermal noise of a resistor; it is false for, say, the offset voltage of op-amps, which varies from unit to unit but is constant in time for each unit. Unit-to-unit variation needs ensemble statistics (many devices), not long records.

Autocorrelation ergodicity

Autocorrelation-ergodicity is mean-ergodicity of the product process $Z_\tau(t) = X(t+\tau)X(t)$, whose autocovariance involves **fourth** moments of X. For a zero-mean Gaussian process, the Isserlis (Wick) moment theorem gives $E[X_1X_2X_3X_4] = R_{12}R_{34} + R_{13}R_{24} + R_{14}R_{23}$, and one finds

$$C_{Z_\tau Z_\tau}(s) = R_{XX}^2(s) + R_{XX}(s+\tau)R_{XX}(s-\tau).$$

Autocorrelation ergodicity of Gaussian processes

A zero-mean stationary Gaussian process with $\int_{-\infty}^{\infty} R_{XX}^2(\tau)\,d\tau < \infty$ (equivalently, finite-energy correlation, which holds whenever its spectrum has no impulses and is square-integrable) is autocorrelation-ergodic. More generally, a stationary Gaussian process is ergodic (in every sense) if and only if its spectrum has no discrete (impulsive) part.

So for Gaussian noise without spectral lines — the typical receiver-noise case — time averages of any kind converge to ensemble averages, which is why the ergodic assumption is so rarely questioned in noise measurements.

Estimating correlations and spectra from data

From N samples $x[0], \ldots, x[N-1]$ of a zero-mean sequence, the standard estimators are

$$\hat{R}_{XX}[k] = \frac{1}{N}\sum_{n=0}^{N-1-k} x[n+k]x[n] \quad (0 \le k < N), \qquad \hat{R}_{XX}[-k] = \hat{R}_{XX}[k],$$

$$\hat{S}_{XX}(e^{j\Omega}) = \frac{1}{N}\Big|\sum_{n=0}^{N-1} x[n]e^{-j\Omega n}\Big|^2 = \sum_{|k|<N} \hat{R}_{XX}[k]e^{-j\Omega k} \quad \text{(periodogram)}.$$

Properties (all resting on an ergodicity assumption):

- **Bias of $\hat{R}$.** $E[\hat{R}_{XX}[k]] = \big(1 - \frac{|k|}{N}\big)R_{XX}[k]$: biased (a triangular taper), but asymptotically unbiased, and guaranteed non-negative definite. Dividing by $N - |k|$ instead removes the bias but can produce invalid (non-positive-definite) estimates at large lags.
- **Bias of the periodogram.** $E[\hat{S}] = \frac{1}{2\pi}\big(S_{XX} * F_N\big)(e^{j\Omega})$, the true spectrum convolved with the Fejér kernel $F_N(\Omega) = \frac{1}{N}\frac{\sin^2(N\Omega/2)}{\sin^2(\Omega/2)}$: finite records smear spectral detail finer than about $2\pi/N$ rad/sample and leak power from strong peaks into their sidelobes. Windowing (Hann, Blackman) lowers the sidelobes at the expense of resolution.
- **Variance of the periodogram.** For Gaussian noise, at each frequency $\hat{S} \approx S \cdot \chi_2^2/2$ — an exponential random variable whose standard deviation equals its mean, **however large N is**. The raw periodogram is not a consistent estimator: more data gives more frequency points, not smoother ones.
- **Welch's method.** Split the record into K segments of length L, window each, compute K periodograms and average them. The variance drops by about K (more with 50% overlap), while the resolution coarsens to $\sim f_s/L$. This is what every FFT spectrum analyzer's "averaging" does.

Worked Example 21.34 — Planning a Welch spectral estimate

A noise signal is captured at $f_s = 100$ kHz for 1 s ($N = 10^5$ samples). We want a PSD estimate with about 100 Hz resolution and better than 10% relative standard deviation.

Step 1 — segment length. Resolution $\approx f_s/L$; choose $L = 1024$, giving $\Delta f = 97.7$ Hz.

Step 2 — number of segments. Non-overlapping: $K = \lfloor 10^5/1024 \rfloor = 97$. Relative standard deviation of the averaged estimate $\approx 1/\sqrt{K} = 1/\sqrt{97} = 10.2\%$ — just at the target. With 50% overlap and a Hann window, $K \approx 194$ segments whose effective independence is about 0.9, bringing the relative error to roughly 7.5%.

Step 3 — trade-off. Halving L to 512 doubles K (relative error $\div\sqrt{2}$) but doubles Δf to 195 Hz. Resolution × (relative error)^2 × record length is roughly constant — a time–bandwidth uncertainty relation for spectral estimation: to get both fine resolution and low variance, you need a long record.

Common Pitfall — ergodicity cannot be checked from one record

Ergodicity is a property relating one record to the ensemble; a single record, however long, cannot reveal whether other records would behave differently (Example 21.33(d)). It must be justified physically ("this noise is generated by the same mechanism in every realization, with no hidden parameters fixed per record") or checked with several independent records — for instance, several devices or several power-up cycles.

21.8 Applications to communications and measurement

Motivation

The tools of §§21.1–21.7 combine into a short, repeatable procedure that settles most noise questions in circuits, instruments and communication links: model each noise source by its PSD, carry it through the system with $|H|^2$, add the PSDs of independent sources, integrate to get power, and — if the noise is Gaussian — convert powers into probabilities with $Q(\cdot)$. This section applies that procedure to the physical noise sources an EE meets most often (thermal and shot noise), to the figures of merit used to specify them (noise bandwidth, SNR, noise figure), and to the central design question of detection: which filter makes a known signal most visible in white noise? The aim is to show the mathematics at work; the device physics and communication-system design belong to other courses.

Thermal (Johnson–Nyquist) noise

The random thermal motion of charge carriers in a resistor R at absolute temperature T produces a fluctuating open-circuit voltage. Because it is the sum of the effects of an enormous number of independent carrier collisions, each lasting about 10^{-14} s, it is to an excellent approximation zero-mean, **Gaussian** (central limit theorem) and **white** up to frequencies of order $kT/h \approx 6$ THz at 300 K.

Johnson–Nyquist formula

The open-circuit noise voltage of a resistor R in thermal equilibrium at temperature T has

$$G_V(f) = 4kTR \ \ \text{V}^2/\text{Hz (one-sided)}, \qquad S_V(f) = 2kTR \ \ \text{(two-sided, per Hz)},$$

where $k = 1.380649 \times 10^{-23}$ J/K is Boltzmann's constant. In a bandwidth B (or noise bandwidth B_N):

$$\overline{v_n^2} = 4kTRB.$$

Equivalently (Norton form), a noise current source of one-sided PSD $G_I = 4kT/R$ in parallel with a noiseless R.

Sketch of Nyquist's argument. Connect two equal resistors R by a lossless transmission line of characteristic impedance R and length L; everything is at temperature T. Each resistor delivers noise power into the line, matched, so it is absorbed by the other. Now short both ends: the line becomes a resonator with modes at $f_m = mc/(2L)$, i.e. $2L\,B/c$ modes in a band B. By the equipartition theorem each mode holds average energy kT, so the energy in band B is $kT \cdot 2LB/c$; the line delivers it in a transit time L/c in each direction, giving power kTB from each resistor into the other. A resistor with open-circuit noise voltage v_n delivers $\overline{v_n^2}/(4R)$ into a matched load, so $\overline{v_n^2}/(4R) = kTB$, i.e. $\overline{v_n^2} = 4kTRB$. □

Two corollaries are used constantly:

- **Available noise power** $P_n = kTB$, independent of R: $kT_0 = 4.00 \times 10^{-21}$ W/Hz at the reference temperature $T_0 = 290$ K, i.e. **−174 dBm/Hz**.
- **Combining resistors.** Independent noise sources add in power. Two resistors in series: $4kT(R_1 + R_2)B$ — the same as one resistor $R_1 + R_2$. In parallel: $4kT(R_1 \parallel R_2)B$. More generally, the noise of any passive network of resistors, capacitors and inductors at a uniform temperature is $4kT\,\mathrm{Re}\{Z(f)\}$ per hertz, where Z is the network's impedance (the fluctuation–dissipation theorem).

Worked Example 21.35 — Resistor noise in audio and RF bands

(a) Audio. $R = 10\ \text{k}\Omega$, $T = 300$ K, $B = 20$ kHz:

$$v_{n,\text{rms}} = \sqrt{4kTRB} = \sqrt{4 \times 1.381 \times 10^{-23} \times 300 \times 10^{4} \times 2 \times 10^{4}} = \sqrt{3.31 \times 10^{-12}} \approx 1.82\ \mu\text{V}.$$

The often-quoted figure $\sqrt{4kTR} \approx 12.9\ \text{nV}/\sqrt{\text{Hz}}$ for 10 kΩ is the same result per root-hertz ($12.9\ \text{nV} \times \sqrt{20000} = 1.82\ \mu\text{V}$ ✓).

(b) RF. $R = 50\ \Omega$, $T = 290$ K, $B = 1$ MHz: $\overline{v_n^2} = 8.0 \times 10^{-13}\ \text{V}^2$, $v_{n,\text{rms}} = 0.895\ \mu$V open-circuit. The available power is $kTB = 4.0 \times 10^{-15}\ \text{W} = -114$ dBm — the noise floor of a 1 MHz-wide receiver before any amplifier noise is added.

(c) Parallel combination. Two 1 kΩ resistors in parallel at 300 K, $B = 10$ kHz: equivalent 500 Ω, $v_{n,\text{rms}} = \sqrt{4kT \cdot 500 \cdot 10^{4}} = 0.288\ \mu$V. Check via Norton sources: each contributes current density $4kT/1000$; the two independent currents add in power to $8kT/1000$, and across 500 Ω give voltage density $8kT/1000 \times 500^2 = 4kT \times 500$. ✓

Worked Example 21.36 — kT/C noise

Model a resistor R (with its noise source) connected across a capacitor C. The capacitor voltage is the RC-lowpass output of white noise with one-sided density $4kTR$, i.e. $N_0/2 = 2kTR$ two-sided.

Step 1. By Example 21.18, $\overline{v_C^2} = \dfrac{N_0}{4RC} = \dfrac{4kTR}{4RC} = \dfrac{kT}{C}$.

Step 2 — the resistance cancels. A larger R produces more noise density but a proportionally narrower noise bandwidth $B_N = 1/(4RC)$. Equivalently, by equipartition, the capacitor's mean stored energy $\tfrac{1}{2}C\overline{v_C^2}$ equals $\tfrac{1}{2}kT$.

Step 3 — numbers. For $C = 1$ pF at 300 K, $v_{\text{rms}} = \sqrt{4.14 \times 10^{-21}/10^{-12}} \approx 64\ \mu$V. For a 12-bit ADC with 1 V full scale (LSB $= 244\ \mu$V), the quantization noise is $244/\sqrt{12} = 70\ \mu$V rms, so a 1 pF sampling capacitor already contributes noise comparable to the quantization error. This sets a floor on the noise of sample-and-hold circuits, switched-capacitor filters and CMOS image-sensor pixels, and is why low-noise ADC front ends use large sampling capacitors.

Shot noise

Current in a diode or photodetector consists of discrete charges q crossing a barrier at random (Poisson) times. Modelling the current as $I(t) = q\sum_k \delta(t - t_k)$ with Poisson arrivals of rate $\lambda = \bar{I}/q$ (Example 21.3), one finds that its fluctuation about the mean $\bar{I}$ is white with one-sided density

$$G_I(f) = 2q\bar{I} \qquad \Longrightarrow \qquad \overline{i_n^2} = 2q\bar{I}B.$$

Sketch. For a Poisson impulse train of rate λ, the autocovariance is $\lambda q^2\delta(\tau)$ (increments over disjoint intervals are independent), so the two-sided PSD of the fluctuation is $\lambda q^2 = q\bar{I}$, and the one-sided density is $2q\bar{I}$.

For example, a photodiode current of $\bar{I} = 1\ \mu$A in a 1 MHz bandwidth has $\sqrt{2 \times 1.602 \times 10^{-19} \times 10^{-6} \times 10^{6}} = 0.566$ nA rms of shot noise — a relative fluctuation of 5.7×10^{-4}, the $1/\sqrt{\lambda t}$ law of Example 21.3 in another form.

Signal-to-noise ratio, noise figure and averaging

Signal-to-noise ratio

For a signal component with power P_s and an additive noise component with power P_n at the same point, $\text{SNR} = P_s/P_n$, usually quoted as $10\log_{10}(\text{SNR})$ dB. If signal $s(t)$ (deterministic or random, with PSD S_{ss}) and independent noise with PSD S_{NN} pass through H,

$$\text{SNR}_{\text{out}} = \frac{\frac{1}{2\pi}\int |H|^2 S_{ss}\, d\omega}{\frac{1}{2\pi}\int |H|^2 S_{NN}\, d\omega}.$$

Noise factor and noise figure

For a two-port with available gain G, driven by a source at $T_0 = 290$ K, the **noise factor** is

$$F = \frac{\text{SNR}_{\text{in}}}{\text{SNR}_{\text{out}}} = 1 + \frac{T_e}{T_0} \;\geq 1,$$

where T_e is the **equivalent input noise temperature**: the amplifier's internal noise referred to its input as if it were extra thermal noise kT_eB. The **noise figure** is $NF = 10\log_{10} F$ dB.

For a cascade of stages with gains $G_1, G_2, \ldots$ and noise factors $F_1, F_2, \ldots$, refer each stage's added noise to the input of the chain by dividing by the gain preceding it. Because the noise contributions are independent, their powers add, and one obtains **Friis's formula**:

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \cdots$$

Worked Example 21.37 — Receiver noise floor and cascade

A receiver front end has an LNA with $NF_1 = 1.5$ dB ($F_1 = 1.413$) and gain 15 dB ($G_1 = 31.6$), followed by a mixer with $NF_2 = 10$ dB ($F_2 = 10$).

Step 1 — cascade. $F = 1.413 + \dfrac{10 - 1}{31.6} = 1.413 + 0.285 = 1.697$, i.e. $NF = 2.30$ dB. The noisy mixer costs only 0.8 dB because the LNA's gain divides its contribution.

Step 2 — sensitivity. The noise floor referred to the input in a noise bandwidth $B_N = 200$ kHz is $-174 + 10\log_{10}(2 \times 10^5) + NF = -174 + 53.0 + 2.3 = -118.7$ dBm. If the demodulator needs SNR $= 10$ dB, the minimum detectable signal is -108.7 dBm.

Step 3 — reversing the order. Put the mixer first; suppose it is passive with a conversion loss of 7 dB ($G = 0.2$). Then $F = 10 + \dfrac{1.413 - 1}{0.2} = 12.07$, i.e. $NF = 10.8$ dB — 8.5 dB worse, and the sensitivity drops to about -100 dBm. The first stage dominates; this is the mathematical reason the lowest-noise, highest-gain stage goes first.

SNR gain from averaging

If a deterministic waveform $s(t)$ is observed M times in independent zero-mean noise of variance σ^2 (per sample), and the M records are averaged point by point (synchronous or **coherent averaging**), the signal is unchanged while the noise variance becomes σ^2/M. The SNR improves by a factor M (10 dB per decade of M). If the noise in successive records is correlated with correlation coefficients ρ_{ik}, the improvement is $M^2/\sum_{i,k}\rho_{ik}$ instead.

Proof. The average of the noise samples has variance $\frac{1}{M^2}\sum_{i,k}\operatorname{Cov}(N_i, N_k) = \frac{\sigma^2}{M^2}\sum_{i,k}\rho_{ik}$, which is σ^2/M for uncorrelated records. □

This is how oscilloscopes, evoked-potential recorders and radar pulse integrators dig repetitive signals out of noise; Example 21.31 is the same principle for a constant signal.

The matched filter

A pulse $s(t)$ of known shape, nonzero only on $[0, T]$, is received in additive white noise of two-sided PSD $N_0/2$. It is passed through a filter h and the output is sampled at time T_0. Which h makes the pulse most visible — i.e. maximizes the output SNR at T_0?

At the sampling instant the signal output is $y_s(T_0) = \int h(\alpha)s(T_0 - \alpha)\,d\alpha$, and the noise output has variance $\frac{N_0}{2}\int h^2(\alpha)\,d\alpha$ (§21.6). So

$$\mathrm{SNR}(T_0) = \frac{\left(\int h(\alpha)s(T_0-\alpha)\,d\alpha\right)^2}{\frac{N_0}{2}\int h^2(\alpha)\,d\alpha}.$$

Matched filter

The output SNR at T_0 is maximized by

$$h_{\mathrm{opt}}(t) = c\,s(T_0 - t) \qquad (\text{any constant } c \neq 0), \qquad H_{\mathrm{opt}}(\omega) = c\,S^*(\omega)e^{-j\omega T_0},$$

and the maximum is

$$\mathrm{SNR}_{\max} = \frac{2E}{N_0}, \qquad E = \int s^2(t)\,dt,$$

which depends only on the pulse **energy**, not its shape. Choosing $T_0 = T$ makes h_{opt} causal.

Proof. By the Cauchy–Schwarz inequality for integrals,

$$\left(\int h(\alpha)s(T_0-\alpha)\,d\alpha\right)^2 \le \int h^2(\alpha)\,d\alpha \cdot \int s^2(T_0-\alpha)\,d\alpha = E\int h^2(\alpha)\,d\alpha,$$

with equality iff $h(\alpha) \propto s(T_0 - \alpha)$. Substituting, $\mathrm{SNR} \le E/(N_0/2) = 2E/N_0$. □

The filter's impulse response is the pulse **reversed in time**; equivalently, its output at T_0 is the **correlation** $\int r(t)s(t)\,dt$ of the received waveform with the known pulse — a correlator receiver. Its frequency response emphasizes the frequencies where the signal is strong ($|H| \propto |S|$) and aligns all their phases to peak simultaneously at T_0. For coloured noise of PSD S_{NN}, the same argument applied after a whitening filter gives $H_{\mathrm{opt}} \propto S^*(\omega)e^{-j\omega T_0}/S_{NN}(\omega)$.

Worked Example 21.38 — Matched filter for a rectangular pulse, and what a simple RC filter loses

Pulse. $s(t) = A$ on $[0, T]$, $A = 1$ mV, $T = 1$ ms; noise $N_0/2 = 10^{-10}$ V^2/Hz.

Step 1 — matched filter. $h(t) = s(T - t)$ is again a rectangle on $[0, T]$: the **integrate-and-dump** filter. $E = A^2 T = 10^{-9}$ V^{2}s and

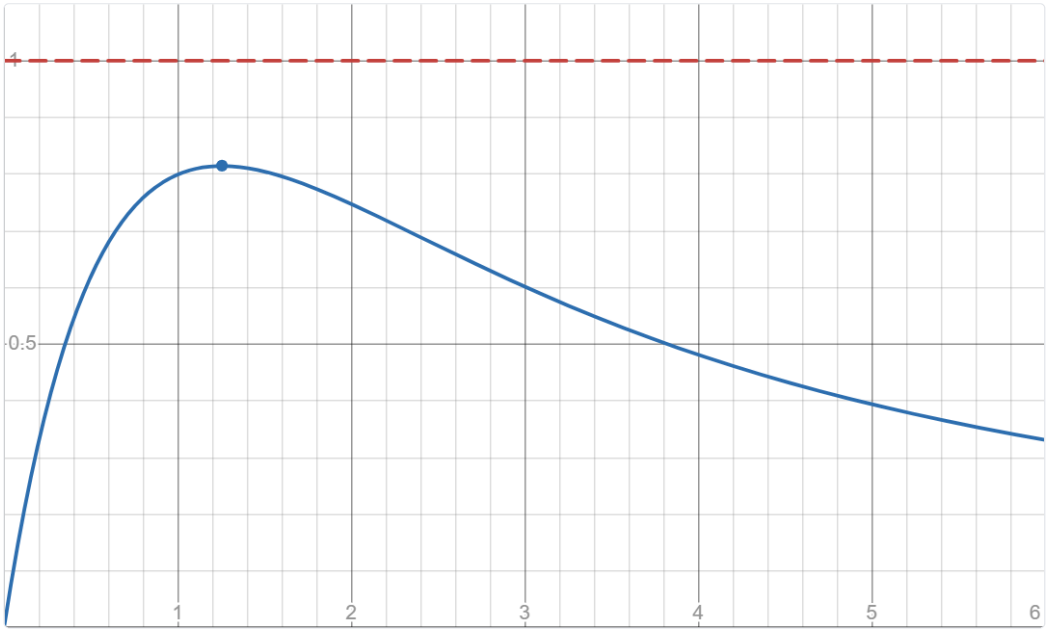
$$\mathrm{SNR}_{\max} = \frac{2E}{N_0} = \frac{2 \times 10^{-9}}{2 \times 10^{-10}} = 10 \ \ (10 \text{ dB}).$$

Step 2 — detection. For antipodal signalling ($\pm s(t)$) with a threshold at zero and Gaussian noise, the error probability is $P_e = Q\big(\sqrt{\mathrm{SNR}_{\max}}\big) = Q\big(\sqrt{2E/N_0}\big) = Q(3.16) = 7.8 \times 10^{-4}$. Raising E/N_0 to 9.6 dB gives the textbook $P_e \approx 10^{-5}$.

Step 3 — RC lowpass instead. Use $H = 1/(1 + j\omega RC)$ and sample at T. The signal output is $A(1 - e^{-T/RC})$; the noise variance is $N_0/(4RC)$ (Example 21.18). With $x = T/RC$,

$$\mathrm{SNR}_{RC} = \frac{A^2(1 - e^{-x})^2}{N_0/(4RC)} = \frac{2E}{N_0} \cdot \frac{2(1 - e^{-x})^2}{x}.$$

The factor $g(x) = 2(1 - e^{-x})^2/x$ is maximized numerically at $x = 1.26$ (i.e. $RC = 0.80\,T$), where $g = 0.815$: the best RC filter is only 0.89 dB worse than the matched filter. Too narrow a filter ($x \to 0$) cuts signal; too wide ($x \to \infty$) admits noise.



SNR of an RC lowpass relative to the matched filter for a rectangular pulse, against $x = T/RC$ (blue). The matched filter (red, dashed) is the upper bound set by Cauchy–Schwarz; the RC filter comes within 0.89 dB of it at $T/RC \approx 1.26$.

Engineering Note — estimation filters

The matched filter maximizes SNR for *detecting* a known pulse. When instead a random signal $S(t)$ must be *estimated* from $X = S + N$, the filter minimizing $E[(S - \hat{S})^2]$ is the (non-causal) **Wiener filter** $H(\omega) = S_{SX}(\omega)/S_{XX}(\omega) = S_{SS}/(S_{SS} + S_{NN})$ for independent S, N: it passes frequencies where the signal dominates and attenuates those where the noise does. Its recursive, time-domain counterpart for state-space models is the Kalman filter. Both are built entirely from the correlation functions and spectra of this chapter.

Engineering Note — the noise-calculation workflow

Nearly every noise calculation in circuits and communications follows the same steps: (1) model each noise source by its PSD (thermal $4kTR$, shot $2qI$, amplifier e_n^2, i_n^2, flicker $\propto 1/f$); (2) transfer each to the output with its own $|H_i(\omega)|^2$; (3) add the PSDs of independent sources; (4) integrate (or multiply by a noise bandwidth) to get power; (5) refer to the input by dividing by the signal gain if an input-referred figure is wanted; (6) if Gaussian, convert to probabilities with $Q(\cdot)$; (7) if the result comes from a measurement, check the averaging time with the ergodic formulas of §21.7.

Common Pitfall — adding RMS values

Independent noise sources add **in power** (mean-square), never in RMS: 1 μV and 1 μV rms of independent noise give 1.41 μV, not 2 μV. Only fully correlated sources (the same noise reaching the output by two paths) add in amplitude — and then with their relative phase, possibly cancelling. Also remember that the PSD conventions (one-sided G, two-sided S, per hertz or per rad/s) must be the same for all terms before adding.

Summary

Concept	Key formula
Mean, autocorrelation	$\mu_X(t) = E[X(t)]$, $R_{XX}(t_1, t_2) = E[X(t_1)X(t_2)]$

Concept	Key formula
Autocovariance	$C_{XX}(t_1,t_2) = R_{XX}(t_1,t_2) - \mu_X(t_1)\mu_X(t_2)$
Time averages	$\langle x\rangle = \lim \frac{1}{2T}\int_{-T}^{T} x\,dt$, $\langle x(t+\tau)x(t)\rangle$
Independent increments	$C_{XX}(t_1,t_2) = \sigma_X^2(\min(t_1,t_2))$; random walk $\min(n_1,n_2)$; Poisson $\lambda\min(t_1,t_2)$
WSS	μ_X constant, $R_{XX}(\tau) = E[X(t+\tau)X(t)]$
Cyclostationary → WSS	$\bar{R}_{XX}(\tau) = \frac{1}{T_0}\int_0^{T_0} R_{XX}(t+\tau,t)\,dt$
Autocorrelation properties	$R_{XX}(0) = E[X^2]$, even, $\lvert R_{XX}(\tau)\rvert \le R_{XX}(0)$, non-negative definite
Derivative	$R_{X'X'}(\tau) = -R''_{XX}(\tau)$; $E[X'X] = 0$
Cross-correlation	$R_{XY}(\tau) = E[X(t+\tau)Y(t)] = R_{YX}(-\tau)$
Wiener–Khinchin	$S_{XX}(\omega) = \int R_{XX}(\tau)e^{-j\omega\tau}d\tau$
Power	$E[X^2] = \frac{1}{2\pi}\int S_{XX}(\omega)\,d\omega = \int S_X(f)\,df = \int_0^\infty G_X(f)\,df$
Exponential pair	$\sigma^2 e^{-\alpha\lvert\tau\rvert} \leftrightarrow 2\alpha\sigma^2/(\alpha^2+\omega^2)$
NRZ data	$A^2(1-\lvert\tau\rvert/T) \leftrightarrow A^2T\,\sin^2(\omega T/2)/(\omega T/2)^2$
LTI output	$\mu_Y = \mu_X H(0)$, $S_{YX} = HS_{XX}$, $S_{YY} = \lvert H\rvert^2 S_{XX}$
Discrete WK, LTI	$S_{XX}(e^{j\Omega}) = \sum_k R_{XX}[k]e^{-j\Omega k}$; $S_{YY} = \lvert H(e^{j\Omega})\rvert^2 S_{XX}$
AR(1)	$R_{XX}[k] = \frac{\sigma_W^2}{1-a^2}a^{\lvert k\rvert}$, $S_{XX} = \frac{\sigma_W^2}{1-2a\cos\Omega+a^2}$
Gaussian conditional	$X(t+\tau)\mid X(t)=x \sim \mathcal{N}(\rho x,\ \sigma^2(1-\rho^2))$ (zero mean)
Rice's formula	$\nu_u = \frac{1}{\pi}\sqrt{-R''(0)/R(0)}\,e^{-u^2/2R(0)}$
Narrowband envelope	Rayleigh: $P\{R>r\} = e^{-r^2/2\sigma^2}$
White noise	$S = N_0/2$, $R = \frac{N_0}{2}\delta(\tau)$; filtered: $E[Y^2] = \frac{N_0}{2}\int h^2 dt$
Band-limited white noise	$R = N_0 B\,\frac{\sin 2\pi B\tau}{2\pi B\tau}$, power $N_0 B$
Noise-equivalent bandwidth	$B_N = \frac{1}{\lvert H(0)\rvert^2}\int_0^\infty \lvert H(2\pi f)\rvert^2 df$; RC: $1/(4RC)$; averager: $1/(2T)$
Variance of time average	$\mathrm{Var}\langle X\rangle_T \approx \frac{1}{2T}\int C_{XX}(\tau)d\tau$; sequence: $\frac{1}{N}\sum_k C_{XX}[k]$
Thermal noise	$\overline{v_n^2} = 4kTRB$; available kTB (−174 dBm/Hz); on a capacitor kT/C
Shot noise	$\overline{i_n^2} = 2q\bar{I}B$
Friis	$F = F_1 + (F_2-1)/G_1 + \cdots$
Matched filter	$h(t) = s(T_0 - t)$, $\mathrm{SNR}_{\max} = 2E/N_0$

Part VII — Numerical and Computational Mathematics

Chapter 22 — Numerical Methods

> **Prerequisites:** Ch. 4 (Differential Calculus — Taylor's theorem), Ch. 5 (Integral Calculus), Ch. 8 (Matrices and Linear Systems), Ch. 10 (Eigenvalues and Eigenvectors), Ch. 11–13 (ODEs and PDEs) **Learning outcomes:** After this chapter you can …
>
> - explain how IEEE-754 floating-point numbers are stored, bound the rounding error of an arithmetic operation, and recognise catastrophic cancellation;
> - separate truncation error from rounding error, and distinguish the *conditioning* of a problem from the *stability* of an algorithm;
> - solve nonlinear equations by bisection, Newton–Raphson, secant and fixed-point iteration, and predict their order of convergence and failure modes;
> - build interpolating polynomials (Lagrange, Newton) and cubic splines, explain the Runge phenomenon and cure it with Chebyshev nodes, and compute least-squares polynomial approximations;
> - derive finite-difference and quadrature rules with their error orders, and accelerate them by Richardson extrapolation;
> - integrate ODEs with Euler and Runge–Kutta methods, recognise stiffness, and discretise the heat, wave and Laplace equations with step sizes that respect stability (CFL) limits;
> - state the consistency–stability–convergence relationship (Lax equivalence) and carry out a von Neumann stability analysis.

Almost every quantitative result an engineer produces today passes through a computer. SPICE solves the nonlinear equations of a circuit by Newton's method; an electromagnetic field solver discretises Maxwell's equations on a grid; a control engineer simulates a plant by integrating ODEs with an adaptive Runge–Kutta method; a DSP engineer worries about whether a 16-bit accumulator will overflow. In each case the answer on the screen is *not* the exact mathematical answer — it is an approximation, and its quality depends on choices that the user often leaves at default values without understanding them.

This chapter is about those choices. The guiding questions are always the same three:

1. **What is computed?** (the algorithm, i.e. the discrete approximation to a continuous problem);
2. **How wrong is it?** (truncation error from the discretisation, rounding error from finite-precision arithmetic, and how both propagate);
3. **How does the error behave as we refine?** (order of convergence, stability, cost).

Throughout, small Python snippets show the idea in executable form; every number quoted in a worked example was checked by running such code in IEEE-754 double precision.

22.1 Floating-point arithmetic

Why an engineer must care

Real numbers have infinitely many digits; computer words have 16, 32 or 64 bits. Every real number that enters a computation is therefore replaced by a nearby *representable* number, and every arithmetic operation on representable numbers is followed by a rounding back to the representable set. Usually the resulting errors are around 10^{-16} relative and harmless. Occasionally they are amplified into total nonsense — a subtraction of nearly equal numbers, a recursion that multiplies errors by n at every step, a matrix that is nearly singular. To tell the two situations apart you need a precise model of floating-point arithmetic.

Floating-point number systems

Floating-point number system

A (normalised, binary) floating-point number system $\mathbb{F}(p, e_{\min}, e_{\max})$ consists of zero and all numbers of the form

$$x = \pm\,(1.d_1 d_2 \ldots d_{p-1})_2 \times 2^{e}, \qquad d_i \in \{0,1\}, \quad e_{\min} \le e \le e_{\max}.$$

The integer p is the **precision** (number of significant bits, including the leading 1), $(1.d_1 \ldots d_{p-1})_2$ is the **significand** (or mantissa) and e the **exponent**.

Two features follow at once.

- **The numbers are not evenly spaced.** Between 2^{e} and 2^{e+1} there are exactly 2^{p-1} equally spaced numbers with spacing 2^{e-p+1}. Each time you cross a power of two the spacing doubles. Relative spacing, however, is roughly constant: this is the whole point of floating point.
- **There is a largest and a smallest positive normalised number**, $x_{\max} = (2 - 2^{1-p})\,2^{e_{\max}}$ and $x_{\min} = 2^{e_{\min}}$. Results larger than $x_{\max}$ **overflow**; results smaller than $x_{\min}$ **underflow**.

Machine epsilon, unit roundoff, ulp

- **Machine epsilon** $\varepsilon_M = 2^{1-p}$ is the distance from 1 to the next larger floating-point number.
- **Unit roundoff** $u = \tfrac{1}{2}\varepsilon_M = 2^{-p}$ is the maximum relative error committed when a real number in the normal range is rounded to nearest.
- The **ulp** (unit in the last place) of x is the spacing of floating-point numbers near x: $\operatorname{ulp}(x) = 2^{e-p+1}$ when $2^{e} \le |x| < 2^{e+1}$.

Be aware that some texts (and MATLAB's `eps`) call ε_M "machine epsilon" while others reserve that name for u. The factor of two rarely matters, but always check which one a bound uses.

The IEEE-754 standard

Since 1985 essentially all hardware has implemented the IEEE-754 standard (revised 2008 and 2019). The formats an EE meets most often are:

Format	Total bits	Sign / exponent / fraction bits	Precision p	$\varepsilon_M = 2^{1-p}$	Largest normal	Smallest normal
binary16 (half)	16	1 / 5 / 10	11	9.77×10^{-4}	65504	6.10×10^{-5}
binary32 (single, `float`)	32	1 / 8 / 23	24	1.19×10^{-7}	3.40×10^{38}	1.18×10^{-38}
binary64 (double)	64	1 / 11 / 52	53	2.22×10^{-16}	1.80×10^{308}	2.23×10^{-308}

So single precision carries about 7 significant decimal digits and double precision about 16.

Encoding. A binary64 word is laid out as

$$\underbrace{s}_{1\text{ bit}}\ \underbrace{E}_{11\text{ bits}}\ \underbrace{f}_{52\text{ bits}}, \qquad x = (-1)^s\,(1.f)_2 \times 2^{E-1023} \quad (1 \le E \le 2046).$$

The exponent is stored with a **bias** of 1023 (127 for single), so that the stored field E is an unsigned integer. The leading 1 of the significand is *not* stored ("hidden bit"), which is why 52 stored fraction bits give $p = 53$. The two extreme exponent fields are reserved:

Stored E	f	Meaning
0	0	± 0 (signed zero)
0	$\neq 0$	**subnormal**: $(-1)^s (0.f)_2 \times 2^{-1022}$
$1 \ldots 2046$	any	normal number
2047	0	$\pm\infty$
2047	$\neq 0$	NaN (Not a Number)

Subnormals fill the gap between 0 and $x_{\min}$ evenly ("gradual underflow"); the smallest positive subnormal double is $2^{-1074} \approx 4.94 \times 10^{-324}$. Infinities and NaNs make arithmetic *closed*: $1/0 = +\infty$, $0/0 = \text{NaN}$, $\sqrt{-1} = \text{NaN}$, and any comparison involving NaN is false (so `x != x` is the classic NaN test).

Worked Example 22.1 — Encoding a number in binary64

Encode $x = 5.75$.

Step 1 — binary expansion. $5 = 101_2$ and $0.75 = 0.11_2$, so $x = 101.11_2$.

Step 2 — normalise. $101.11_2 = 1.0111_2 \times 2^2$, so $s = 0$, $e = 2$, fraction $f = 0111\,000\ldots0$ (52 bits).

Step 3 — bias the exponent. $E = 2 + 1023 = 1025 = 100\,0000\,0001_2$.

Step 4 — assemble. 0 10000000001 0111 0000 … Grouping in fours: 0100 0000 0001 0111 0000 …, i.e. the hexadecimal word `0x4017000000000000`.

Check. In Python, `struct.pack('>d', 5.75).hex()` returns `'4017000000000000'`. Because 5.75 has a finite binary expansion, it is stored *exactly*.

Worked Example 22.2 — Why $0.1 + 0.2 \neq 0.3$

In binary, $0.1 = 0.0\overline{0011}_2$ repeats forever, so it must be rounded. The stored double nearest to 0.1 is

$$\text{fl}(0.1) = 0.1000000000000000055511151231257827\ldots$$

(hex `0x3FB9999999999A` — note the final `A`: the repeating `9` pattern rounded up). The absolute error is 5.55×10^{-18}, so the relative error is $5.55 \times 10^{-18}/0.1 \approx 5.6 \times 10^{-17} < u = 1.11 \times 10^{-16}$, as promised.

Adding $\text{fl}(0.1) + \text{fl}(0.2)$ and rounding gives `0.30000000000000004`, which is one ulp above $\text{fl}(0.3)$. Likewise, adding 0.1 ten times in a loop gives `0.9999999999999999`. Neither result is a bug; each is the correctly rounded result of operations on numbers that were never exactly 0.1, 0.2, 0.3.

Lesson. Never test floating-point results for exact equality. Use a tolerance, e.g. `abs(a-b) <= rtol*max(abs(a),abs(b)) + atol`.

Rounding and the standard model

IEEE-754 requires the five basic operations $+, -, \times, \div, \sqrt{}$ to be **correctly rounded**: the result is the exact real result, rounded to the representable set according to the current rounding mode (default: *round to nearest, ties to even*). This single requirement gives the most useful model in numerical analysis.

Standard model of floating-point arithmetic

Let $\text{fl}(\cdot)$ denote rounding to nearest, and let $u = 2^{-p}$. If x lies in the normal range, then

$$\text{fl}(x) = x(1+\delta), \qquad |\delta| \le u.$$

Consequently, for floating-point numbers a, b and $\circ \in \{+, -, \times, \div\}$ (no overflow or underflow),

$$\text{fl}(a \circ b) = (a \circ b)(1+\delta), \qquad |\delta| \le u.$$

Proof sketch. Suppose $2^e \le x < 2^{e+1}$. Representable numbers in this interval are spaced $\Delta = 2^{e-p+1}$ apart, so the nearest one is within $\Delta/2 = 2^{e-p}$ of x. Dividing by $x \ge 2^e$ gives a relative error at most $2^{-p} = u$. Correct rounding means the computed $a \circ b$ is just fl applied to the exact result. $\square$

The model says that *each individual operation* is accurate to about 16 digits in double precision. Large errors can only arise from the way errors from many operations accumulate or are amplified, which is the subject of Section 22.2.

Consequences: non-associativity and summation error

Floating-point addition is commutative but **not associative**. In double precision, $(10^{16} + 1) - 10^{16} = 0$ because $10^{16} + 1$ rounds to 10^{16} (the ulp at 10^{16} is 2), whereas $10^{16} + (1 - 10^{16}) = 1$. The order of operations matters.

For a sum $s_n = x_1 + \cdots + x_n$ computed left to right, repeated application of the standard model gives

$$|\hat{s}_n - s_n| \;\le\; (n-1)\,u \sum_{i=1}^{n} |x_i| + O(u^2).$$

The bound grows linearly in n; in practice, with randomly signed rounding errors, the error typically grows like $\sqrt{n}\,u$. For a million-term sum in single precision ($u \approx 6 \times 10^{-8}$) the worst-case bound is already of order 6×10^{-2} relative — a serious problem for, say, accumulating energy in a long FFT or a power meter. Two cures:

- **Pairwise summation** (add in a binary tree): error bound $O(u \log_2 n)$. NumPy's `sum` does this.
- **Compensated (Kahan) summation**: carry a correction term that recaptures the low-order bits lost in each addition; the error bound becomes $2u \sum |x_i| + O(nu^2)$, essentially independent of n.

```
def kahan_sum(xs):
    s, c = 0.0, 0.0           # running sum and compensation
    for x in xs:
        y = x - c             # subtract the error from last time
        t = s + y             # low bits of y may be lost here ...
        c = (t - s) - y       # ... and are recovered algebraically
        s = t
    return s
```

Catastrophic cancellation

Cancellation

When two nearly equal numbers $a \approx b$ that already carry relative errors are subtracted, the leading digits cancel and the relative error of $a - b$ is magnified by the factor $|a|/|a - b|$. The subtraction itself is exact (Sterbenz's lemma: if $b/2 \le a \le 2b$ then $a - b$ is exactly representable); it merely *exposes* the errors that were already present.

Worked Example 22.3 — Evaluating $1 - \cos x$ for small x

Compute $g(x) = (1 - \cos x)/x^2$ at $x = 1.2 \times 10^{-5}$. The exact value is very close to $\tfrac{1}{2}$ (Taylor: $\tfrac{1}{2} - x^2/24$).

Naive formula. $\cos x = 1 - 7.2 \times 10^{-11} + \ldots$ is computed with absolute error up to about $u \approx 1.1 \times 10^{-16}$. The subtraction $1 - \cos x \approx 7.2 \times 10^{-11}$ then has relative error up to $1.1 \times 10^{-16} / 7.2 \times 10^{-11} \approx 1.5 \times 10^{-6}$. In double precision the naive formula returns 0.4999997330 — only six correct digits.

Rewritten formula. Use the identity $1 - \cos x = 2\sin^2(x/2)$, which involves no subtraction. This returns 0.49999999999400, correct to full precision.

At $x = 10^{-8}$ the naive formula gives $1 - \cos x = 0$ exactly (because $\cos x$ rounds to 1), a 100 % error, while $2\sin^2(x/2) = 5.0 \times 10^{-17}$ is correct.

Worked Example 22.4 — A stable quadratic formula

Solve $x^2 - 10^8 x + 1 = 0$. The roots are $x_1 \approx 10^8$ and $x_2 \approx 10^{-8}$.

Textbook formula. $x_2 = \left(10^8 - \sqrt{10^{16} - 4}\right)/2$. Here $\sqrt{10^{16} - 4}$ rounds to a number within one ulp ($\approx 1.5 \times 10^{-8}$) of 10^8, and subtracting it from 10^8 cancels all the good digits. Double precision returns $x_2 = 7.45 \times 10^{-9}$, a 25 % error.

Stable approach. Compute the large-magnitude root without cancellation, $x_1 = \left(-b + \operatorname{sign}(-b)\sqrt{b^2 - 4ac}\right)/(2a) = 10^8$, then use Vieta's relation $x_1 x_2 = c/a$: $x_2 = c/(a x_1) = 10^{-8}$, correct to full precision.

The general rule: **rearrange formulas so that nearly equal quantities that carry error are never subtracted.**

Overflow, underflow and scaling

Intermediate results can overflow even when the final answer is modest. Computing the magnitude of a phasor $|a + jb| = \sqrt{a^2 + b^2}$ with $a = b = 10^{200}$ overflows at a^2, although the answer 1.41×10^{200} is representable. Library functions such as `hypot(a,b)` scale first: with $m = \max(|a|, |b|)$, $\sqrt{a^2 + b^2} = m\sqrt{(a/m)^2 + (b/m)^2}$. Similarly, probabilities of long sequences (Ch. 19) and likelihoods underflow, which is why they are accumulated as logarithms.

Common Pitfall — Comparing floats and counting with floats

Loops such as `t = 0.0; while t != 1.0: t += 0.1` never terminate, because t steps over 1.0. Loop over an integer counter and compute $t = n\,h$ from it. The same applies to time stepping in simulations: computing $t_n = nh$ avoids the drift that $t \mathrel{+}= h$ accumulates.

Engineering Note — Fixed point versus floating point in DSP

Many low-cost DSPs and FPGAs use **fixed-point** arithmetic, e.g. the Q15 format, a 16-bit two's-complement integer k representing $k/2^{15} \in [-1, 1)$. The spacing is uniform ($2^{-15} \approx 3.05 \times 10^{-5}$), so the *absolute* error is constant but the *relative* error of small signals is large, and sums can overflow. Designers therefore scale filter coefficients and signals carefully and analyse quantisation noise statistically (each rounding is modelled as additive uniform noise of variance $\Delta^2/12$ — see Ch. 19–21). Floating point removes most scaling headaches at the cost of silicon area and power; half precision (binary16) and bfloat16 are now common in machine-learning accelerators, where $\varepsilon_M \approx 10^{-3}$ is acceptable.

22.2 Numerical error

Measuring error

Absolute and relative error

If $\hat{x}$ approximates x, the **absolute error** is $|\hat{x} - x|$ and, for $x \neq 0$, the **relative error** is

$$\rho(\hat{x}) = \frac{|\hat{x} - x|}{|x|}.$$

For vectors replace $|\cdot|$ by a norm. $\hat{x}$ has about k **correct significant digits** when $\rho \lesssim 0.5 \times 10^{-k}$.

Relative error is dimensionless and scale-invariant, which is why it is the natural measure for floating-point results ($\rho \leq u$ after a single rounding). Absolute error is the right measure near zero, where relative error is meaningless: a computed voltage of 3×10^{-17} V where the exact answer is 0 has an infinite relative error but is perfectly acceptable.

Sources of error

Any numerical answer is contaminated by four distinct kinds of error, and it pays to keep them apart:

1. **Modelling error** — the equations idealise reality (an ideal diode, a lumped-element line, a linearised amplifier). Not a numerical issue, but often the largest error (Ch. 25).
2. **Data error** — component tolerances, measurement noise, constants known to finite accuracy.
3. **Truncation (discretisation) error** — the error of replacing a limiting process by a finite one: truncating a Taylor series, replacing a derivative by a difference quotient, an integral by a finite sum, an infinite iteration by a finite number of steps. It exists even in exact arithmetic and typically behaves like Ch^p for a step h.
4. **Rounding error** — from finite-precision arithmetic (Section 22.1). It exists even for an exact algorithm and typically behaves like $C'u/h^q$ when it is amplified by small steps.

Worked Example 22.5 — Truncation error of a Taylor series

How many terms of $e^x = \sum_{k} x^k/k!$ are needed to compute e with error below 10^{-6}?

Step 1 — remainder. By Taylor's theorem with Lagrange remainder (Ch. 4), truncating after the x^n term leaves

$$R_n(1) = \frac{e^{\xi}}{(n+1)!}, \qquad 0 < \xi < 1, \qquad \text{so} \quad 0 < R_n(1) < \frac{e}{(n+1)!}.$$

Step 2 — solve the inequality. We need $(n+1)! > e \times 10^6 \approx 2.72 \times 10^6$. Since $9! = 362\,880$ and $10! = 3\,628\,800$, $n+1 = 10$, i.e. $n = 9$ (ten terms, $k = 0, \dots, 9$).

Check. $\sum_{k=0}^{9} 1/k! = 2.718281526$, and $e - 2.718281526 = 3.03 \times 10^{-7} < 10^{-6}$. The truncation error is a property of the *formula*; rounding contributes only $\sim 10^{-16}$ here.

Order notation

We write $E(h) = O(h^p)$ as $h \to 0$ if $|E(h)| \leq Ch^p$ for some constant C and all sufficiently small h. A method with error $O(h^p)$ is said to be **of order** p. The order tells you how the error responds to refinement: halving h divides the error by about 2^p. Conversely, from errors E_1, E_2 at steps h_1, h_2 you can *measure* the order:

$$p \approx \frac{\ln(E_1/E_2)}{\ln(h_1/h_2)}.$$

This "observed order" test is the single most useful debugging tool for numerical code: if a method that should be second order shows $p \approx 1$, there is a bug (often in a boundary condition).

For iterations $x_k \to x^*$ the analogous notion is the order of convergence q: $|x_{k+1} - x^*| \approx C|x_k - x^*|^q$ (Section 22.3).

Propagation of errors

If $y = f(x_1, \dots, x_n)$ and each input carries a small error Δx_i, a first-order Taylor expansion (Ch. 6) gives

$$\Delta y \approx \sum_{i=1}^{n} \frac{\partial f}{\partial x_i}\, \Delta x_i.$$

Bounding term by term gives the **worst-case** estimate $|\Delta y| \le \sum_i |\partial f/\partial x_i|\,|\Delta x_i|$. If the errors are independent random variables with standard deviations σ_i, the variance formula (Ch. 19–20) gives the **root-sum-square** estimate $\sigma_y^2 \approx \sum_i (\partial f/\partial x_i)^2 \sigma_i^2$. For products and quotients it is convenient to work with relative errors: if $y = x_1^{a_1} x_2^{a_2} \cdots$, then $\Delta y / y \approx \sum_i a_i \, \Delta x_i / x_i$.

Worked Example 22.6 — Error in a computed power

A resistor $R = 50\ \Omega \pm 2\%$ carries a measured voltage $V = 10\ \text{V} \pm 1\%$. Estimate the error in $P = V^2/R$.

Nominal value. $P = 100/50 = 2\ \text{W}$.

Relative sensitivities. $P = V^2 R^{-1}$, so $\Delta P/P \approx 2\,\Delta V/V - \Delta R/R$.

Worst case. $2(1\%) + 1(2\%) = 4\%$, i.e. $P = 2.00 \pm 0.08\ \text{W}$.

Statistical (independent tolerances treated as standard deviations). $\sqrt{(2\cdot 1\%)^2 + (2\%)^2} = 2.83\%$, i.e. $\pm 0.057\ \text{W}$.

The squared voltage doubles its relative error — the exponent in a power law is exactly the condition number defined next.

Conditioning of a problem

Error propagation describes how the *problem* responds to perturbations of its data, independently of any algorithm. This intrinsic sensitivity is captured by a condition number.

Condition number of a scalar function

The (relative) condition number of evaluating a differentiable f at x is

$$\kappa_f(x) = \lim_{\varepsilon \to 0} \sup_{|\Delta x| \le \varepsilon |x|} \frac{|f(x+\Delta x) - f(x)|/|f(x)|}{|\Delta x|/|x|} = \left| \frac{x\, f'(x)}{f(x)} \right|.$$

The problem is **well-conditioned** if κ is modest and **ill-conditioned** if κ is large. A relative data error ρ produces a relative result error of about $\kappa \rho$.

Worked Example 22.7 — Condition numbers of elementary operations

Problem	$\kappa_f(x)$	Comment
$f(x) = \sqrt{x}$	$\tfrac{1}{2}$	always well-conditioned
$f(x) = x^n$	$\lvert n \rvert$	squaring doubles relative error (Example 22.6)
$f(x) = e^x$	$\lvert x \rvert$	ill-conditioned for large $\lvert x \rvert$: e^{700} is sensitive
$f(x) = \ln x$	$1/\lvert \ln x \rvert$	ill-conditioned near $x = 1$
$f(x) = x - 1$	$\lvert x/(x-1) \rvert$	at $x = 1.0001$: $\kappa = 10\,001$
$f(x) = \tan x$	$\lvert x/(\sin x \cos x) \rvert$	ill-conditioned near $x = \pi/2$

The entry for $x - 1$ is cancellation (Section 22.1) seen as a *conditioning* statement: subtracting nearly equal numbers is an ill-conditioned problem, so no algorithm can save you if x itself is inexact.

For a linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ the corresponding quantity is the **matrix condition number** (Ch. 8)

$$\kappa(\mathbf{A}) = \|\mathbf{A}\|\,\|\mathbf{A}^{-1}\| = \frac{\sigma_{\max}}{\sigma_{\min}} \quad \text{(2-norm)},$$

and perturbation theory gives, for $\mathbf{A}(\mathbf{x}+\Delta\mathbf{x}) = \mathbf{b} + \Delta\mathbf{b}$,

$$\frac{\|\Delta\mathbf{x}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A})\, \frac{\|\Delta\mathbf{b}\|}{\|\mathbf{b}\|}.$$

Derivation. $\Delta\mathbf{x} = \mathbf{A}^{-1}\Delta\mathbf{b}$ gives $\|\Delta\mathbf{x}\| \le \|\mathbf{A}^{-1}\|\|\Delta\mathbf{b}\|$, and $\mathbf{b} = \mathbf{A}\mathbf{x}$ gives $\|\mathbf{b}\| \le \|\mathbf{A}\|\|\mathbf{x}\|$, i.e. $1/\|\mathbf{x}\| \le \|\mathbf{A}\|/\|\mathbf{b}\|$. Multiply the two inequalities. $\square$

A rule of thumb follows: **solving a linear system in floating point loses about $\log_{10}\kappa(\mathbf{A})$ decimal digits.**

Worked Example 22.8 — An ill-conditioned circuit matrix

Consider

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.0001 \end{bmatrix}, \qquad \mathbf{b} = \begin{bmatrix} 2 \\ 2.0001 \end{bmatrix} \Rightarrow \mathbf{x} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.$$

Such matrices arise when two nodes are joined by a very small resistance compared with everything else, so their equations are nearly identical.

Condition number. $\kappa_2(\mathbf{A}) \approx 4.0 \times 10^4$.

Perturb the data. Change b_2 by 10^{-4} to 2.0002 — a relative change $\|\Delta\mathbf{b}\|/\|\mathbf{b}\| = 10^{-4}/2.83 = 3.5 \times 10^{-5}$. The solution becomes $\mathbf{x} = (0, 2)^{\mathsf{T}}$: a relative change of $\|(-1, 1)\|/\|(1, 1)\| = 100\%$.

Compare with the bound. $\kappa \cdot 3.5 \times 10^{-5} \approx 1.4$, so the observed amplification ($\approx 2.8 \times 10^4$) is close to the worst case. Nothing is wrong with the solver — the *problem* is ill-conditioned.

Hilbert matrices $H_{ij} = 1/(i + j - 1)$, which appear in least-squares polynomial fitting (Section 22.6), are a notorious family: $\kappa_2(\mathbf{H}_3) \approx 524$, $\kappa_2(\mathbf{H}_5) \approx 4.8 \times 10^5$, $\kappa_2(\mathbf{H}_8) \approx 1.5 \times 10^{10}$, $\kappa_2(\mathbf{H}_{12}) \approx 1.6 \times 10^{16}$ — at $n = 12$ double precision has no correct digits left.

Stability of an algorithm

Conditioning belongs to the problem; **stability** belongs to the algorithm. Let f be the exact map from data to result and $\hat{f}$ the algorithm executed in floating point.

Forward error, backward error, backward stability

- The **forward error** is $|\hat{f}(x) - f(x)|$ (relative: divided by $|f(x)|$).
- The **backward error** is the smallest $|\Delta x|/|x|$ such that $\hat{f}(x) = f(x + \Delta x)$: how much would the data have to change for the computed answer to be *exact*?
- An algorithm is **backward stable** if its backward error is $O(u)$ for all inputs. It is (forward) **unstable** if it can produce forward errors much larger than $\kappa_f(x)\,u$.

These ideas combine in the most important inequality in numerical analysis:

$$\text{forward error} \lesssim \text{condition number} \times \text{backward error}.$$

A backward-stable algorithm therefore delivers the best accuracy the problem allows: about $\kappa\,u$. Gaussian elimination with partial pivoting, Householder QR and the standard algorithms for $\sqrt{}$, sin, the FFT, etc. are backward stable (or nearly so). When a computed answer is bad, ask first: *is the problem ill-conditioned, or is my algorithm unstable?* The cures are completely different — reformulate the problem (or get better data) in the first case, change the algorithm in the second.

Worked Example 22.9 — An unstable recurrence and its stable reversal

Let $I_n = \int_0^1 x^n e^{x-1}\,dx$. Integration by parts gives the exact recurrence

$$I_n = 1 - n\,I_{n-1}, \qquad I_0 = 1 - e^{-1} \approx 0.632121.$$

Since $0 < x^n e^{x-1} \le x^n$, we know $0 < I_n < 1/(n+1)$, so $I_n \to 0$ slowly.

Forward recurrence in double precision.

n	0	1	5	10	15	17	18	19	20
$\hat{I}_n$	0.632121	0.367879	0.145533	0.083877	0.059034	0.057192	−0.029454	1.55962	−30.1924

By $n = 17$ the value has started to *increase* and at $n = 18$ it is negative, both impossible.

Explanation. An error ϵ_0 in I_0 (about $u \cdot I_0 \approx 7 \times 10^{-17}$ from rounding) propagates as $\epsilon_n = -n\,\epsilon_{n-1}$, so $|\epsilon_n| = n!\,|\epsilon_0|$. With $20! \approx 2.4 \times 10^{18}$, $|\epsilon_{20}| \sim 10^2$ — consistent in order of magnitude with the observed -30. The *problem* (computing I_{20}) is perfectly well conditioned; the *algorithm* is unstable.

Stable reversal. Run the recurrence backwards, $I_{n-1} = (1 - I_n)/n$. Now errors are *divided* by n at every step. Starting from the crude guess $I_{30} = 0$ (error $< 1/31$) and recurring down, the error at $n = 20$ is reduced by $30!/20! \approx 1.1 \times 10^{14}$ and is below 10^{-15}. This gives $I_{20} = 0.0455449$, $I_{10} = 0.0838771$, and $I_0 = 0.6321205588285577$, which agrees with $1 - e^{-1}$ to all 16 digits.

Common Pitfall — Blaming the computer for an ill-conditioned problem

Using higher precision (quad, arbitrary precision) cures *instability* only by brute force and does nothing for a problem whose *data* are uncertain. If the entries of $\mathbf{b}$ in Example 22.8 are known only to 10^{-4}, the solution is unknown to 100 % no matter how the arithmetic is done. Conversely, a large residual from a backward-stable solver is a sign of a bug, not of ill-conditioning: backward-stable methods always produce small residuals $\|\mathbf{b} - \mathbf{A}\hat{\mathbf{x}}\| \approx u\|\mathbf{A}\|\|\hat{\mathbf{x}}\|$ even when $\hat{\mathbf{x}}$ is inaccurate.

Engineering Note — Ill-conditioning in practice

Ill-conditioned problems are common in EE: polynomial root-finding from coefficients (Wilkinson showed that changing the x^{19} coefficient of $\prod_{k=1}^{20}(x-k)$ by 2^{-23} moves some roots far into the complex plane), high-order IIR filters implemented in direct form (pole positions are ill-conditioned functions of the polynomial coefficients — hence the universal use of cascaded second-order sections), deconvolution and inverse problems (which need regularisation), and nodal analysis with resistances spanning many decades. Recognising ill-conditioning — and reformulating to avoid it — is a design skill.

22.3 Root-finding methods

The problem

Given a continuous $f:\mathbb{R}\to\mathbb{R}$, find x^* with $f(x^*)=0$. Nonlinear equations without closed-form solutions appear constantly in engineering: the operating point of a diode or transistor circuit, the resonant frequency of a distributed structure ($\tan\beta\ell=\dots$), the propagation constant of a waveguide mode, the time at which a transient crosses a threshold, Kepler-type equations in orbital mechanics, the break frequency at which a gain equals -3 dB. All practical methods are **iterative**: they generate a sequence $x_0, x_1, x_2, \dots$ that (one hopes) converges to x^*.

Two questions organise the subject: **Does the iteration converge** (from which starting points)? And **how fast**?

Existence and bracketing

Intermediate value theorem (root form)

If f is continuous on $[a,b]$ and $f(a)f(b)<0$, then f has at least one root in (a,b).

An interval with a sign change is called a **bracket**. Bracketing methods (bisection, regula falsi, Brent) keep a bracket at every step and therefore *cannot fail* to converge to a root; open methods (Newton, secant, fixed-point) use only the current iterates, converge faster near the root, but can diverge from a poor start. Robust library routines (`scipy.optimize.brentq`, MATLAB `fzero`) combine both: open steps when they behave, bisection steps when they do not.

Order of convergence

Order of convergence

Let $x_k\to x^*$ and $e_k=x_k-x^*$. The sequence converges with **order** $q\ge 1$ and **asymptotic constant** C if

$$\lim_{k\to\infty}\frac{|e_{k+1}|}{|e_k|^q}=C, \qquad 0<C<\infty,$$

with $C<1$ required when $q=1$. The cases $q=1$, $1<q<2$ and $q=2$ are called **linear**, **superlinear** and **quadratic** convergence.

The practical meaning: with linear convergence the number of correct digits grows by a *fixed amount* $-\log_{10}C$ per iteration; with order q the number of correct digits is *multiplied by* q per iteration. Quadratic convergence roughly doubles the digits each step, so from 2 correct digits one reaches full double precision in about three steps.

Fixed-point iteration

Rewrite $f(x)=0$ in the equivalent form $x=g(x)$ and iterate

$$x_{k+1}=g(x_k).$$

A **fixed point** of g is a point with $g(x^*)=x^*$. There are many ways to rewrite one equation: for $x^2-2=0$ one could use $g(x)=2/x$, $g(x)=x-(x^2-2)/3$, or $g(x)=\tfrac12(x+2/x)$ — and they behave very differently.

Contraction mapping (Banach fixed-point) theorem, scalar form

Suppose g maps the closed interval $I=[a,b]$ into itself and is a contraction there:

$$|g(x)-g(y)|\le L|x-y| \quad \text{for all } x,y\in I, \qquad 0\le L<1$$

(sufficient: g differentiable with $|g'(x)|\le L<1$ on I). Then

1. g has exactly one fixed point $x^*\in I$;
2. for every $x_0\in I$ the iteration $x_{k+1}=g(x_k)$ converges to x^*;
3. the error satisfies $|x_k-x^*|\le L^k|x_0-x^*|$ and the computable bound $|x_k-x^*|\le \dfrac{L}{1-L}|x_k-x_{k-1}|$.

Proof sketch. $|x_{k+1}-x_k|=|g(x_k)-g(x_{k-1})|\le L|x_k-x_{k-1}|$, so the step lengths decrease geometrically and $\sum|x_{k+1}-x_k|$ converges; hence (x_k) is Cauchy and has a limit $x^*\in I$ (I is closed). Continuity of g gives $g(x^*)=x^*$. If y^* were a second fixed point, $|x^*-y^*|=|g(x^*)-g(y^*)|\le L|x^*-y^*|$ forces $x^*=y^*$. Finally $|x_k-x^*|=|g(x_{k-1})-g(x^*)|\le L|x_{k-1}-x^*|$, and the a posteriori bound follows from $|x_{k-1}-x^*|\le|x_{k-1}-x_k|+|x_k-x^*|$. $\square$

Local behaviour. Near the fixed point, Taylor expansion gives

$$e_{k+1}=g(x^*+e_k)-g(x^*)=g'(x^*)\,e_k+\tfrac12 g''(\xi_k)e_k^2.$$

Hence:

- if $0 < |g'(x^*)| < 1$: **linear** convergence with $C = |g'(x^*)|$; if $g'(x^*) < 0$ the iterates alternate sides of x^*, if $g'(x^*) > 0$ they approach monotonically;
- if $|g'(x^*)| > 1$: the fixed point **repels** and the iteration diverges from it;
- if $g'(x^*) = 0$ and $g''(x^*) \neq 0$: **quadratic** convergence. More generally, if $g'(x^*) = \cdots = g^{(q-1)}(x^*) = 0 \neq g^{(q)}(x^*)$, the order is q. Newton's method (Section 22.4) is precisely the choice of g that makes $g'(x^*) = 0$.

Worked Example 22.10 — Solving $x = \cos x$

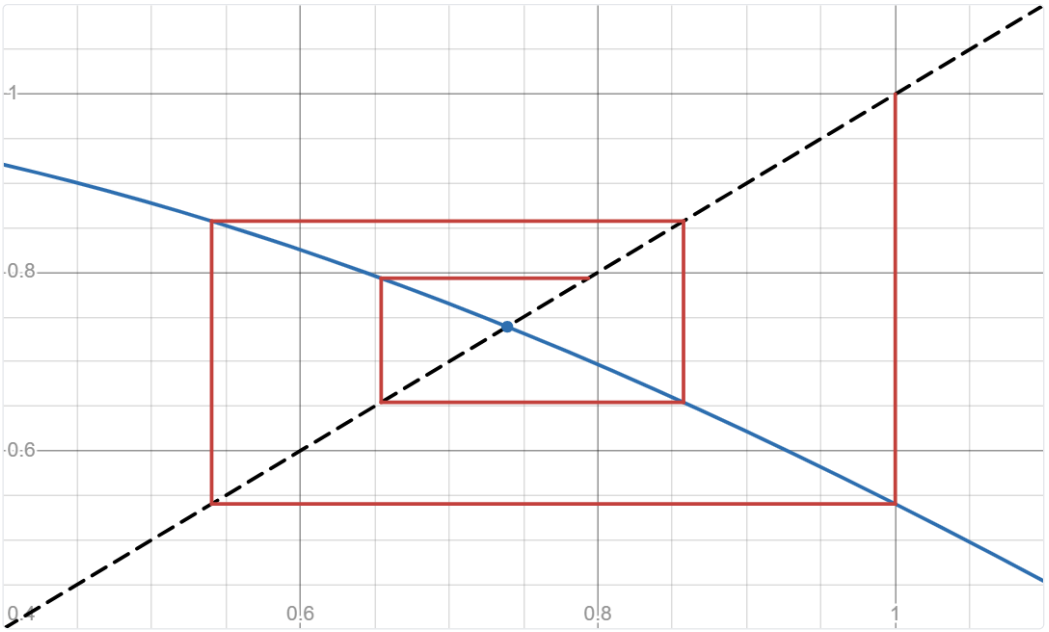
Step 1 — check the theorem. Take $I = [0, 1]$. Then cos maps I into $[\cos 1, 1] = [0.540, 1] \subset I$, and $|g'(x)| = |\sin x| \leq \sin 1 = 0.841 < 1$ on I. So there is a unique fixed point and the iteration converges from any $x_0 \in I$.

Step 2 — iterate from $x_0 = 1$.

k	1	2	3	4	5	6	10
x_k	0.540302	0.857553	0.654290	0.793480	0.701369	0.763960	0.744237

Step 3 — rate. The fixed point is $x^* = 0.7390851332$ and $g'(x^*) = -\sin x^* = -0.6736$. The iterates alternate about x^* (negative g') and each error is about 0.67 times the previous one: only $-\log_{10} 0.674 \approx 0.17$ digits per iteration, so about 90 iterations are needed for full double precision. Linear convergence with a constant this close to 1 is slow — the motivation for Newton's method.

The **cobweb diagram** makes the geometry visible: from (x_k, x_k) on the line $y = x$, move vertically to the curve $y = g(x)$, then horizontally back to $y = x$; the abscissa is x_{k+1}. A slope g' between -1 and 0 produces an inward spiral.



Cobweb diagram for $x_{k+1} = \cos x_k$ from $x_0 = 1$: because $-1 < g'(x^*) < 0$ the path spirals inward to the fixed point $x^* \approx 0.739$.

Worked Example 22.11 — Three rearrangements of $x^2 = 2$

$g(x)$	$g'(x^*)$ at $x^* = \sqrt{2}$	Behaviour from $x_0 = 1$
$2/x$	-1	$1, 2, 1, 2, \ldots$ — oscillates forever
$x - (x^2 - 2)/3$	$1 - 2\sqrt{2}/3 = 0.0572$	$1.3333, 1.4074, 1.41381, 1.414190, 1.4142122$ — linear, gains ≈ 1.24 digits per step
$\frac{1}{2}(x + 2/x)$	0	$1.5, 1.41667, 1.4142157, 1.41421356237469, 1.414213562373095$ — quadratic

The third rearrangement is Newton's method (Heron's ancient square-root algorithm): its errors are $8.6 \times 10^{-2}, 2.5 \times 10^{-3}, 2.1 \times 10^{-6}, 1.6 \times 10^{-12}$ and then machine precision — digits double each step. The choice of g is everything.

The secant method

Newton's method (next section) needs f'. If the derivative is unavailable or expensive — f may be the output of a circuit simulation — replace it by the slope of the chord through the last two iterates:

$$x_{k+1} = x_k - f(x_k)\,\frac{x_k - x_{k-1}}{f(x_k) - f(x_{k-1})}.$$

Geometrically, x_{k+1} is where the secant line through $(x_{k-1}, f(x_{k-1}))$ and $(x_k, f(x_k))$ crosses the axis. Only one *new* function evaluation is needed per step.

Convergence of the secant method

If $f \in C^2$ near a simple root x^* ($f'(x^*) \neq 0$) and x_0, x_1 are sufficiently close to x^*, the secant iterates converge with order

$$q = \varphi = \frac{1+\sqrt{5}}{2} \approx 1.618, \qquad \text{and} \quad e_{k+1} \approx \frac{f''(x^*)}{2f'(x^*)}\, e_k\, e_{k-1}.$$

Derivation sketch. Expanding f about x^* to second order in the secant formula gives $e_{k+1} \approx M e_k e_{k-1}$ with $M = f''(x^*)/(2f'(x^*))$. Try $|e_{k+1}| \approx A|e_k|^q$; then $|e_{k-1}| \approx (|e_k|/A)^{1/q}$ and substitution gives $A|e_k|^q \approx MA^{-1/q}|e_k|^{1+1/q}$. Matching exponents, $q = 1 + 1/q$, i.e. $q^2 - q - 1 = 0$, whose positive root is the golden ratio. □

Per function evaluation the secant method is actually more efficient than Newton when f' costs as much as f: two secant steps (two evaluations) multiply the digits by $\varphi^2 = 2.618 > 2$, whereas one Newton step (two evaluations: f and f') multiplies them by 2.

Worked Example 22.12 — Secant method for $x^3 - x - 2 = 0$

$f(1) = -2$, $f(2) = 4$, so $[1, 2]$ is a bracket. Start with $x_0 = 1$, $x_1 = 2$.

Step 1. $x_2 = 2 - 4 \cdot \dfrac{2-1}{4-(-2)} = 2 - \dfrac{4}{6} = 1.333333.$

Subsequent steps (root $x^* = 1.5213797068$):

k	2	3	4	5	6	7	8
x_k	1.333333	1.462687	1.531169	1.520926	1.521376	1.5213797080	1.5213797068
$\lvert e_k \rvert$	1.9×10^{-1}	5.9×10^{-2}	9.8×10^{-3}	4.5×10^{-4}	3.4×10^{-6}	1.2×10^{-9}	3×10^{-15}

Order check. $\ln(1.2 \times 10^{-9}/3.4 \times 10^{-6}) / \ln(3.4 \times 10^{-6}/4.5 \times 10^{-4}) = (-7.95)/(-4.89) = 1.63 \approx \varphi$. Note that the secant method does not maintain a bracket: x_2 and x_3 both lie below the root, and x_4 overshoots it.

Regula falsi (false position) uses the same chord formula but keeps the two points that bracket the root. It always converges, but typically only linearly, because one endpoint tends to get "stuck". The Illinois modification (halve the stored function value at a stuck endpoint) and Brent's method repair this.

Stopping criteria

An iteration needs a rule for stopping. Common tests, usually combined:

- **step size:** $|x_{k+1} - x_k| \le \text{atol} + \text{rtol}\,|x_{k+1}|$;
- **residual:** $|f(x_k)| \le \tau$;
- **bracket width** (bracketing methods): $b_k - a_k \le \text{tol}$;
- **iteration cap** — always, to guard against non-convergence.

Neither the step test nor the residual test alone is reliable. For a function with a very flat zero ($f'(x^*)$ small), the residual can be tiny far from the root; for a steep function, the residual can be large even at the floating-point number closest to the root. The **attainable accuracy** of any root-finder is limited by conditioning: if f can only be evaluated to absolute accuracy δ, the root is determined only to about $\delta/|f'(x^*)|$ (the "condition number of a root" is $1/|f'(x^*)|$), and much worse for a multiple root.

Polynomial roots

For polynomials, special methods exist. The most robust general approach — used by `numpy.roots` and MATLAB `roots` — is to form the **companion matrix** whose characteristic polynomial is $p(x)$ and compute its eigenvalues by the QR algorithm (Ch. 10). Once one root r is found, **deflation** divides $p(x)$ by $(x - r)$ (synthetic division) to obtain a lower-degree polynomial for the remaining roots; deflation should proceed from the smallest-magnitude roots to limit error growth. Remember Wilkinson's warning (Section 22.2): roots are often ill-conditioned functions of the coefficients, so if you have the polynomial in factored or state-space form, do not multiply it out.

Common Pitfall — Multiple and clustered roots

At a root of multiplicity $m > 1$, f touches the axis without (for even m) changing sign, so bracketing methods may not even see it, and f is so flat that rounding errors of size δ smear the root over an interval of width about $(\delta\, m!/|f^{(m)}(x^*)|)^{1/m}$ — in double precision a double root is typically determined only to about 8 digits. Newton and secant methods slow to linear convergence there (Section 22.4).

Engineering Note — Root-finding inside simulators

SPICE's DC operating-point analysis is a multidimensional root-finding problem $\mathbf{F}(\mathbf{v}) = \mathbf{0}$ (Kirchhoff's current law at every node). It uses Newton's method with damping, "source stepping" (ramping supplies from zero) and "gmin stepping" (adding small conductances to ground) — all techniques to bring the starting point inside the region of convergence. The message "no convergence in DC analysis" is a root-finder giving up.

22.4 Bisection and Newton–Raphson methods

These two methods are the extremes of the root-finding spectrum: bisection is slow but guaranteed, Newton–Raphson is fast but needs a good start. Every serious root-finder is built from one or both.

The bisection method

Given a bracket $[a_0, b_0]$ with $f(a_0)f(b_0) < 0$, repeat for $k = 0, 1, 2, \dots$:

1. $m_k = \tfrac{1}{2}(a_k + b_k)$;
2. if $f(a_k)f(m_k) < 0$ set $[a_{k+1}, b_{k+1}] = [a_k, m_k]$, otherwise $[a_{k+1}, b_{k+1}] = [m_k, b_k]$.

The bracket halves every step and always contains a root.

Bisection error bound

If f is continuous on $[a_0, b_0]$ with $f(a_0)f(b_0) < 0$, the midpoints satisfy

$$|m_k - x^*| \le \frac{b_0 - a_0}{2^{k+1}}$$

for some root $x^* \in [a_0, b_0]$. Hence an absolute accuracy τ is guaranteed after

$$k \ \ge\ \log_2 \frac{b_0 - a_0}{\tau} - 1 \quad \text{iterations.}$$

Proof. By induction $b_k - a_k = (b_0 - a_0)/2^k$ and $[a_k, b_k]$ contains a root by the intermediate value theorem; the midpoint is within half the width of every point of the bracket. $\square$

The error bound halves each step, so bisection behaves like a linearly convergent method with $C = \tfrac{1}{2}$: one binary digit, or $\log_{10} 2 \approx 0.3$ decimal digits, per function evaluation. Its virtues: it needs only continuity and sign evaluations, the iteration count is known *in advance*, and it is immune to round-off misbehaviour (as long as the sign of f is computed correctly). In floating point compute the midpoint as `a + (b - a)/2` and test signs with `copysign` or `sign(fa) != sign(fm)` rather than `fa*fm < 0`, which can underflow to zero.

```
def bisect(f, a, b, tol=1e-12, maxit=200):
    fa = f(a)
    for _ in range(maxit):
        m = a + (b - a) / 2
        fm = f(m)
        if fm == 0 or (b - a) / 2 < tol:
            return m
        if (fa < 0) != (fm < 0):   # sign change in [a, m]
            b = m
        else:
            a, fa = m, fm
    return a + (b - a) / 2
```

Worked Example 22.13 — Bisection for $x^3 - x - 2 = 0$

Bracket. $f(1) = -2 < 0$, $f(2) = 4 > 0$.

k	a_k	b_k	m_k	$f(m_k)$
0	1	2	1.5	-0.125
1	1.5	2	1.75	1.609
2	1.5	1.75	1.625	0.666
3	1.5	1.625	1.5625	0.252
4	1.5	1.5625	1.53125	0.0591
5	1.5	1.53125	1.515625	-0.0341
6	1.515625	1.53125	1.5234375	0.0123
7	1.515625	1.5234375	1.51953125	-0.0110

Error check. After 8 midpoints, $|m_7 - x^*| = |1.51953 - 1.52138| = 1.8 \times 10^{-3} \le 1/2^8 = 3.9 \times 10^{-3}$. ✓

Iterations for $\tau = 10^{-6}$. $\log_2(1/10^{-6}) - 1 = 19.93 - 1$, so $k = 19$, i.e. 20 midpoint evaluations; for $\tau = 10^{-12}$ about 40. Compare Newton below.

Newton–Raphson: derivation

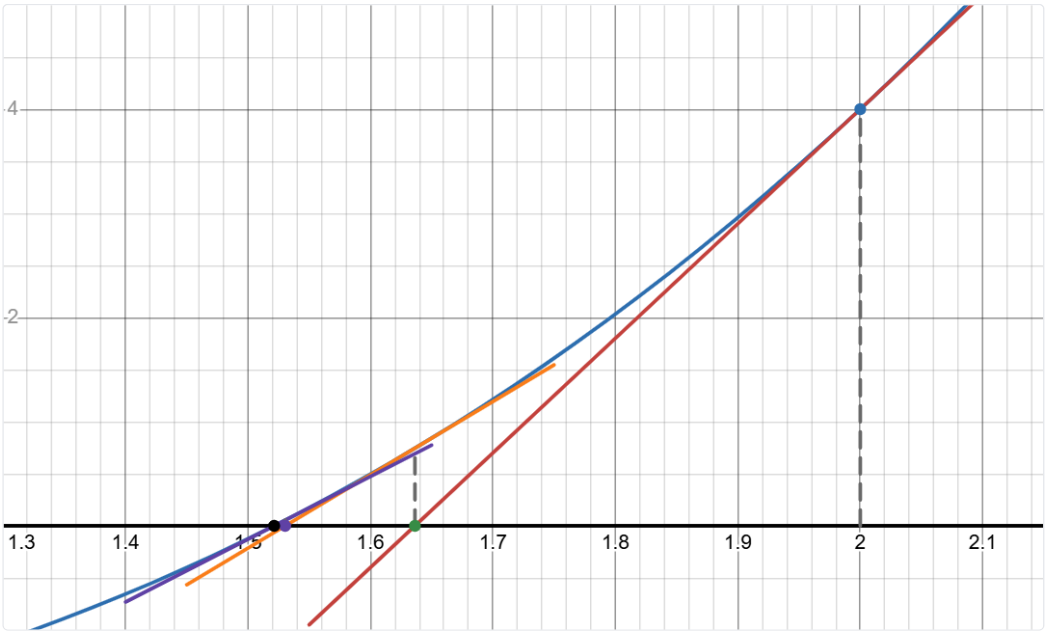
Replace f near the current iterate by its tangent line (first-order Taylor polynomial, Ch. 4):

$$f(x) \approx f(x_k) + f'(x_k)(x - x_k).$$

Setting the linear model to zero gives the next iterate

$$x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)}.$$

Equivalently, Newton is fixed-point iteration with $g(x) = x - f(x)/f'(x)$; differentiating, $g'(x) = f(x)f''(x)/f'(x)^2$, which **vanishes at a simple root**. By Section 22.3 this already suggests quadratic convergence.



Newton–Raphson for $f(x) = x^3 - x - 2$ from $x_0 = 2$: each tangent line (red, orange, purple) meets the axis at the next iterate, $x_1 = 1.6364$, $x_2 = 1.5304$, $x_3 = 1.52144$; the tangents become ever better models as the iterates close in on the root at 1.52138.

Quadratic convergence

Local quadratic convergence of Newton's method

Let $f \in C^2$ on an interval containing a simple root x^* ($f(x^*) = 0$, $f'(x^*) \neq 0$). Then there is $\delta > 0$ such that for every x_0 with $|x_0 - x^*| < \delta$ the Newton iterates converge to x^* and

$$\lim_{k \to \infty} \frac{e_{k+1}}{e_k^2} = \frac{f''(x^*)}{2f'(x^*)}.$$

Proof. Taylor's theorem about x_k evaluated at x^*:

$$0 = f(x^*) = f(x_k) + f'(x_k)(x^* - x_k) + \tfrac{1}{2} f''(\xi_k)(x^* - x_k)^2.$$

Divide by $f'(x_k)$ and rearrange using the Newton formula $x_{k+1} = x_k - f(x_k)/f'(x_k)$:

$$x_{k+1} - x^* = \frac{f''(\xi_k)}{2f'(x_k)} (x_k - x^*)^2, \qquad \text{i.e.} \quad e_{k+1} = \frac{f''(\xi_k)}{2f'(x_k)} e_k^2.$$

On a small interval around x^*, $|f'| \geq m > 0$ and $|f''| \leq M$, so $|e_{k+1}| \leq \frac{M}{2m} |e_k|^2$. If $\frac{M}{2m}|e_0| < 1$, then $|e_{k+1}| \leq \left(\frac{M}{2m}|e_0|\right) |e_k|$ and the errors decrease to zero; as $x_k \to x^*$ also $\xi_k \to x^*$, giving the limit. $\square$

The constant $M/(2m)$ explains *when* Newton is happy: small curvature f'' and steep slope f'. The radius $\delta \approx 2m/M$ of guaranteed convergence can be very small for strongly curved functions — the exponential of a diode being the prime example. (The Newton–Kantorovich theorem gives a checkable sufficient condition based on $f(x_0)$, $f'(x_0)$ and a Lipschitz bound on f'.)

Worked Example 22.14 — Newton for $x^3 - x - 2 = 0$

$f'(x) = 3x^2 - 1$. Start from the bisection midpoint $x_0 = 1.5$.

Step 1. $f(1.5) = 3.375 - 1.5 - 2 = -0.125$, $f'(1.5) = 5.75$, $x_1 = 1.5 + 0.125/5.75 = 1.5217391304$.

Further steps.

k	x_k	$\lvert e_k \rvert$	$\lvert e_k \rvert / \lvert e_{k-1} \rvert^2$
0	1.5	2.14×10^{-2}	—
1	1.521739130434783	3.59×10^{-4}	0.79
2	1.521379805964786	9.9×10^{-8}	0.77
3	1.521379706804575	7.5×10^{-15}	0.77
4	1.521379706804568	$< 10^{-16}$	—

Check against theory. $f''(x^*)/(2f'(x^*)) = 6(1.52138)/(2 \cdot 5.9438) = 0.768$, matching the last column. The number of correct digits goes $2 \to 3 \to 7 \to 14 \to 16$: four Newton steps versus about fifty bisection steps for the same accuracy.

Newton's method in circuit analysis

Worked Example 22.15 — Diode operating point

A 5 V source drives a 1 kΩ resistor in series with a silicon diode, $I_D = I_S(e^{V/V_T} - 1)$ with $I_S = 10^{-14}$ A and $V_T = 25.852$ mV (300 K). Find the diode voltage V.

Step 1 — KCL. Current through the resistor equals diode current:

$$F(V) = \frac{5 - V}{1000} - I_S\left(e^{V/V_T} - 1\right) = 0, \qquad F'(V) = -\frac{1}{1000} - \frac{I_S}{V_T}e^{V/V_T}.$$

Step 2 — good start. Engineering judgement says $V \approx 0.7$ V.

k	V_k (V)	$F(V_k)$ (A)
1	0.693518214	-1.7×10^{-4}
2	0.692561670	-3.0×10^{-6}
3	0.692543639	-1.0×10^{-9}
4	0.692543633	$\approx 10^{-16}$

So $V = 0.69254$ V and $I_D = (5 - 0.69254)/1000 = 4.307$ mA. Quadratic convergence is evident in the residuals.

Step 3 — bad start. From $V_0 = 0$ the diode term is negligible, the tangent is essentially the resistor's line, and $V_1 = 4.99999999807$ V. At 5 V the exponential is astronomically steep ($e^{5/0.0259} \approx 10^{84}$), so each subsequent Newton step reduces V by only about V_T: $4.9741, 4.9483, 4.9224, \ldots$ It would take about 165 iterations to crawl down to 0.7 V — and with a slightly larger overshoot e^{V/V_T} would overflow to ∞.

Cure. SPICE-type simulators **limit** the change in junction voltage per iteration (e.g. to a few V_T on a logarithmic scale, the "pnjlim" algorithm) or **damp** the step, $V_{k+1} = V_k - \lambda F/F'$ with $\lambda \le 1$ chosen so that $|F|$ decreases.

When Newton fails

Newton's method is only *locally* convergent. The classic failure modes are:

1. **Zero or tiny derivative.** If $f'(x_k) \approx 0$ the step is huge (the tangent is nearly horizontal).
2. **Cycling.** For $f(x) = x^3 - 2x + 2$ and $x_0 = 0$: $x_1 = 0 - 2/(-2) = 1$, $x_2 = 1 - 1/1 = 0$, and the iterates alternate $0, 1, 0, 1, \ldots$ forever, although a real root exists at $x^* \approx -1.7693$.
3. **Divergence.** For $f(x) = \arctan x$ (root 0), Newton converges only for $|x_0| < 1.3917$; from $x_0 = 1.5$ the iterates oscillate with growing magnitude ($-1.69, 2.32, -5.11, \ldots$).
4. **Convergence to an unwanted root** — the basins of attraction of different roots can be intricately interleaved (in the complex plane they form fractals).
5. **Overflow** of f itself in the first steps (Example 22.15).

Safeguarding. Robust implementations combine Newton with a bracket: if the Newton step would leave the current bracket or fails to reduce $|f|$ sufficiently, take a bisection step instead. This "Newton–bisection hybrid" (and Brent's method, which does the same with inverse quadratic interpolation) inherits bisection's guarantee and Newton's speed.

Multiple roots

At a root of multiplicity m, $f(x) = (x - x^*)^m h(x)$ with $h(x^*) \neq 0$. Then $g(x) = x - f/f'$ satisfies $g'(x^*) = 1 - 1/m$, so Newton converges only **linearly** with constant $(m-1)/m$ — for a double root, the error just halves each step. Two remedies:

- **Modified Newton**, if m is known: $x_{k+1} = x_k - m\,f(x_k)/f'(x_k)$ restores quadratic convergence (now $g'(x^*) = 0$).
- Apply Newton to $\mu(x) = f(x)/f'(x)$, which has a *simple* root at x^* whatever m is (requires f'').

Worked Example 22.16 — A double root

$f(x) = (x-1)^2(x+2)$ has a double root at 1. From $x_0 = 2$:

k	1	2	3	4	5
Newton e_k	0.556	0.298	0.155	0.0796	0.0403
Modified ($m=2$) e_k	0.111	1.95×10^{-3}	6.3×10^{-7}	6.7×10^{-14}	—

Plain Newton's errors approach the ratio $\frac{1}{2}$ predicted by $(m-1)/m$; the modified iteration is quadratic again. A practical symptom of a multiple root: Newton suddenly converges linearly with ratio $\approx 1/2$ or $2/3$.

Newton's method for systems

For $\mathbf{F} : \mathbb{R}^n \to \mathbb{R}^n$, the tangent line becomes the tangent *plane* given by the **Jacobian** $\mathbf{J}(\mathbf{x}) = [\partial F_i/\partial x_j]$ (Ch. 6):

$$\mathbf{F}(\mathbf{x}) \approx \mathbf{F}(\mathbf{x}_k) + \mathbf{J}(\mathbf{x}_k)(\mathbf{x} - \mathbf{x}_k) \quad \Longrightarrow \quad \mathbf{J}(\mathbf{x}_k)\,\Delta\mathbf{x}_k = -\mathbf{F}(\mathbf{x}_k), \qquad \mathbf{x}_{k+1} = \mathbf{x}_k + \Delta\mathbf{x}_k.$$

Each step solves a *linear* system (never form $\mathbf{J}^{-1}$). Convergence is again quadratic near a root at which $\mathbf{J}$ is nonsingular. This is exactly the inner loop of nonlinear circuit simulation, power-flow analysis in power systems (the Newton–Raphson load flow), and implicit ODE solvers (Section 22.9). When $\mathbf{J}$ is expensive, **quasi-Newton** methods (Broyden) update an approximation to it — a theme of Ch. 23.

```
import numpy as np
def newton_system(F, J, x, tol=1e-12, maxit=50):
    for _ in range(maxit):
        dx = np.linalg.solve(J(x), -F(x))
        x = x + dx
        if np.linalg.norm(dx) <= tol * (1 + np.linalg.norm(x)):
            break
    return x
```

Worked Example 22.17 — A 2×2 nonlinear system

Solve $x^2 + y^2 = 4$, $xy = 1$ (intersection of a circle and a hyperbola) starting from $(x_0, y_0) = (2, 0.5)$.

Set-up. $\mathbf{F} = \begin{bmatrix} x^2 + y^2 - 4 \\ xy - 1 \end{bmatrix}$, $\mathbf{J} = \begin{bmatrix} 2x & 2y \\ y & x \end{bmatrix}$.

Step 1. $\mathbf{F}(2, 0.5) = (0.25, 0)^{\mathsf{T}}$, $\mathbf{J} = \begin{bmatrix} 4 & 1 \\ 0.5 & 2 \end{bmatrix}$. Solving $\mathbf{J}\Delta = -\mathbf{F}$: $\det \mathbf{J} = 7.5$, $\Delta = \frac{1}{7.5}\begin{bmatrix} 2 & -1 \\ -0.5 & 4 \end{bmatrix}\begin{bmatrix} -0.25 \\ 0 \end{bmatrix} = (-0.06667, 0.01667)^{\mathsf{T}}$, so $(x_1, y_1) = (1.93333, 0.51667)$.

Further steps. $\|\mathbf{F}\|$: $0.25 \to 4.9 \times 10^{-3} \to 3.4 \times 10^{-6} \to 2.5 \times 10^{-12} \to 4 \times 10^{-16}$. The solution is $(1.9318517, 0.5176381)$.

Check. Exactly, $x^2 + y^2 = 4$ and $xy = 1$ give $(x + y)^2 = 6$, $(x - y)^2 = 2$, so $x = (\sqrt{6} + \sqrt{2})/2 = 1.9318517$, $y = (\sqrt{6} - \sqrt{2})/2 = 0.5176381$. ✓

Common Pitfall — Trusting a converged Newton iteration blindly

Newton converging tells you that you found *a* root — not necessarily the physical one. A transistor circuit with positive feedback (a latch, a Schmitt trigger) has several DC operating points; which one Newton finds depends on the starting guess. Always sanity-check the answer (signs of currents, device regions) and, for multi-stable circuits, perform a transient or continuation analysis.

Engineering Note — Newton in hardware

Reciprocal and square-root units in many processors and DSPs start from a small lookup-table estimate and refine it with one or two Newton steps, using only multiplications: for $1/a$, apply Newton to $f(x) = 1/x - a$ to get $x_{k+1} = x_k(2 - a x_k)$; for $1/\sqrt{a}$, $x_{k+1} = \tfrac{1}{2}x_k(3 - a x_k^2)$ (the iteration behind the famous "fast inverse square root"). An 8-bit table estimate becomes 16 bits after one step and 32 bits after two — quadratic convergence in silicon.

22.5 Interpolation

Motivation

Interpolation constructs a function that passes *exactly* through given data points. Engineers use it to read between the entries of a datasheet table (a transistor's h_{FE} versus I_C, a thermistor's resistance versus temperature), to implement function generators by table lookup, to resample a signal at a new rate or a fractional delay, and to draw smooth curves through simulation output. Equally important, interpolation is the *theoretical engine* behind most of this chapter: numerical differentiation (Section 22.7) differentiates an interpolant, and quadrature (Section 22.8) integrates one. The error of those methods is inherited from the interpolation error formula derived here.

Existence and uniqueness

Polynomial interpolation theorem

Given $n + 1$ distinct nodes $x_0, \dots, x_n$ and values $y_0, \dots, y_n$, there is exactly one polynomial p_n of degree at most n with $p_n(x_i) = y_i$ for $i = 0, \dots, n$.

Proof. Writing $p_n(x) = \sum_{k=0}^{n} a_k x^k$, the interpolation conditions form the linear system $\mathbf{V}\mathbf{a} = \mathbf{y}$ with the **Vandermonde matrix** $V_{ik} = x_i^k$, whose determinant is $\prod_{i<j}(x_j - x_i) \neq 0$ for distinct nodes. (Alternatively: if p and q both interpolate, $p - q$ has degree $\le n$ and $n + 1$ roots, hence is zero; existence follows from the Lagrange construction below.) □

Solving the Vandermonde system is a poor way to *compute* the interpolant: $\mathbf{V}$ is notoriously ill-conditioned (for 20 equally spaced nodes on $[0, 1]$, $\kappa(\mathbf{V}) \approx 10^{16}$). The Lagrange and Newton forms below represent the same unique polynomial in better-conditioned bases.

Lagrange form

Lagrange basis polynomials

For distinct nodes $x_0, \dots, x_n$,

$$\ell_i(x) = \prod_{\substack{j=0 \\ j \neq i}}^{n} \frac{x - x_j}{x_i - x_j}, \qquad \text{so that} \quad \ell_i(x_k) = \delta_{ik},$$

and the interpolating polynomial is

$$p_n(x) = \sum_{i=0}^{n} y_i \, \ell_i(x).$$

Each ℓ_i is a "cardinal" function: 1 at its own node, 0 at all others. The Lagrange form is ideal for theory (quadrature weights are $\int \ell_i$, differentiation weights are ℓ_i'). For computation, the algebraically equivalent **barycentric formula**

$$p_n(x) = \frac{\displaystyle\sum_{i=0}^{n} \frac{w_i}{x - x_i}\, y_i}{\displaystyle\sum_{i=0}^{n} \frac{w_i}{x - x_i}}, \qquad w_i = \frac{1}{\prod_{j \neq i}(x_i - x_j)},$$

costs $O(n)$ per evaluation once the weights are known and is numerically stable; it is what modern software uses.

Newton's divided-difference form

Divided differences

$$f[x_i] = f(x_i), \qquad f[x_i, \dots, x_{i+k}] = \frac{f[x_{i+1}, \dots, x_{i+k}] - f[x_i, \dots, x_{i+k-1}]}{x_{i+k} - x_i}.$$

Newton form of the interpolant

$$p_n(x) = f[x_0] + f[x_0, x_1](x - x_0) + f[x_0, x_1, x_2](x - x_0)(x - x_1) + \cdots + f[x_0, \dots, x_n] \prod_{j=0}^{n-1} (x - x_j).$$

Proof sketch. Let p_k interpolate at $x_0, \dots, x_k$. Then $p_{k+1} - p_k$ has degree $\le k+1$ and vanishes at $x_0, \dots, x_k$, so $p_{k+1} = p_k + c_{k+1} \prod_{j=0}^{k}(x - x_j)$, and c_{k+1} is the leading coefficient of p_{k+1}. Comparing the leading coefficients of two interpolants on overlapping node sets yields the recursive definition of the divided difference. $\square$

Two practical advantages: adding a new data point adds one term without recomputing the others, and the form is evaluated cheaply by nested multiplication (Horner's scheme). Divided differences also approximate derivatives: if $f \in C^k$, then $f[x_0, \dots, x_k] = f^{(k)}(\xi)/k!$ for some ξ in the span of the nodes.

Worked Example 22.18 — Cubic through four points, two ways

Data: $(0,1), (1,3), (2,2), (3,5)$. Find p_3 and evaluate it at $x = 1.5$.

Divided-difference table.

x_i	$f[x_i]$	first	second	third
0	1			
		$(3-1)/1 = 2$		
1	3		$(-1-2)/2 = -1.5$	
		$(2-3)/1 = -1$		$(2-(-1.5))/3 = 7/6$
2	2		$(3-(-1))/2 = 2$	
		$(5-2)/1 = 3$		
3	5			

Newton form. The top diagonal gives

$$p_3(x) = 1 + 2x - 1.5\,x(x-1) + \tfrac{7}{6}\,x(x-1)(x-2).$$

Evaluate at 1.5. $1 + 3 - 1.5(0.75) + \frac{7}{6}(1.5)(0.5)(-0.5) = 4 - 1.125 - 0.4375 = 2.4375$.

Lagrange check. With $\ell_0(1.5) = \frac{(0.5)(-0.5)(-1.5)}{(-1)(-2)(-3)} = -0.0625$, $\ell_1(1.5) = \frac{(1.5)(-0.5)(-1.5)}{(1)(-1)(-2)} = 0.5625$, $\ell_2(1.5) = \frac{(1.5)(0.5)(-1.5)}{(2)(1)(-1)} = 0.5625$, $\ell_3(1.5) = \frac{(1.5)(0.5)(-0.5)}{(3)(2)(1)} = -0.0625$ (they sum to 1, as they must): $p_3(1.5) = 1(-0.0625) + 3(0.5625) + 2(0.5625) + 5(-0.0625) = 2.4375$. ✓

Expanded, $p_3(x) = \frac{7}{6}x^3 - 5x^2 + \frac{35}{6}x + 1$, which matches `numpy.polyfit` with degree 3.

The interpolation error

Interpolation error formula

Let $f \in C^{n+1}[a,b]$ and let p_n interpolate f at distinct nodes $x_0, \dots, x_n \in [a,b]$. For every $x \in [a,b]$ there is $\xi = \xi(x) \in (a,b)$ with

$$f(x) - p_n(x) = \frac{f^{(n+1)}(\xi)}{(n+1)!}\,\omega_{n+1}(x), \qquad \omega_{n+1}(x) = \prod_{i=0}^{n}(x - x_i).$$

Proof. Fix x not a node and define $\phi(t) = f(t) - p_n(t) - \dfrac{f(x) - p_n(x)}{\omega_{n+1}(x)}\,\omega_{n+1}(t)$. Then ϕ vanishes at the $n+2$ points $x_0, \dots, x_n, x$. By Rolle's theorem applied repeatedly, $\phi^{(n+1)}$ has a zero ξ. Since $p_n^{(n+1)} = 0$ and $\omega_{n+1}^{(n+1)} = (n+1)!$, $0 = f^{(n+1)}(\xi) - (n+1)!\,(f(x) - p_n(x))/\omega_{n+1}(x)$. $\square$

The formula separates two influences: the **smoothness of** f (through $f^{(n+1)}$) and the **placement of the nodes** (through ω_{n+1}). The second factor is ours to choose.

Worked Example 22.19 — Quadratic interpolation of $\sin x$

Interpolate $\sin x$ at $0,\ \pi/4,\ \pi/2$ and estimate the error at $x = \pi/8$.

Divided differences. $f[x_0, x_1] = 0.70711/0.78540 = 0.90032$, $f[x_1, x_2] = (1 - 0.70711)/0.78540 = 0.37292$, $f[x_0, x_1, x_2] = (0.37292 - 0.90032)/1.5708 = -0.33575$.

Interpolant. $p_2(x) = 0.90032x - 0.33575\,x(x - \pi/4)$; at $\pi/8 = 0.392699$: $p_2 = 0.35355 + 0.05178 = 0.40533$.

Actual error. $\sin(\pi/8) = 0.38268$, so $|f - p_2| = 0.02265$.

Bound. $|f'''| = |\cos| \le 1$, so $|f - p_2| \le \frac{1}{3!}|(\pi/8)(\pi/8 - \pi/4)(\pi/8 - \pi/2)| = \frac{1}{6}(0.3927)(0.3927)(1.1781) = 0.0303$. The bound holds and is not wildly pessimistic.

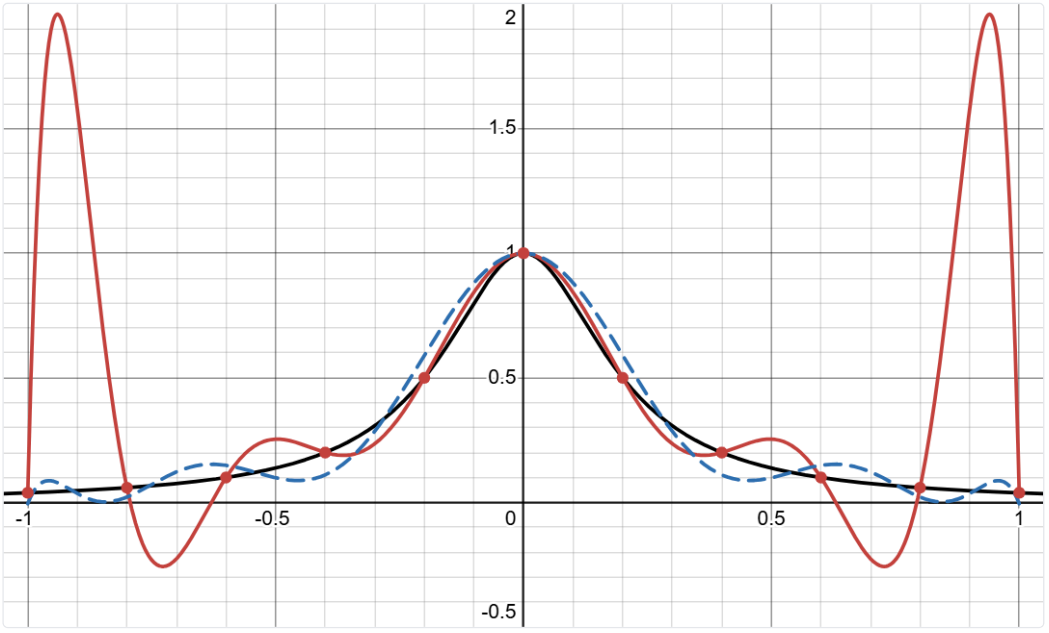
The Runge phenomenon

It is tempting to think that more nodes always give a better fit. For **equally spaced** nodes this is false, even for perfectly smooth functions. Runge's classic example is

$$f(x) = \frac{1}{1 + 25x^2}, \qquad x \in [-1, 1].$$

n (degree)	4	8	12	16	20
$\max\|f - p_n\|$, equispaced nodes	0.438	1.045	3.66	14.4	59.8
$\max\|f - p_n\|$, Chebyshev nodes	0.402	0.171	0.069	0.033	0.015

With equispaced nodes the error near the ends of the interval *grows exponentially* with n; with Chebyshev nodes (defined below) it decreases steadily.



Runge phenomenon: $f(x) = 1/(1 + 25x^2)$ (black), its degree-10 interpolant at 11 equally spaced nodes (red, nodes marked) overshooting to ≈ 1.96 near $x = \pm 0.94$ (an error of 1.92), and the degree-10 interpolant at Chebyshev nodes (blue dashed) staying within 0.11 of f everywhere.

Why it happens. Two factors in the error formula conspire. First, $|\omega_{n+1}(x)|$ for equispaced nodes is much larger near the ends of the interval than in the middle (by a factor that grows like 2^n). Second, f has complex poles at $x = \pm j/5$, close to the real interval, so its derivatives grow like $(n+1)!\,5^{n+1}$ — fast enough to beat the $(n+1)!$ in the denominator. Complex analysis (Ch. 18) makes this precise: polynomial interpolants at equispaced nodes converge only inside a certain lens-shaped region of the complex plane, and if a singularity of f lies inside that region, interpolation diverges near the endpoints.

Chebyshev nodes

Since $f^{(n+1)}$ is beyond our control, minimise the other factor: choose nodes that make $\max_{[-1,1]}|\omega_{n+1}|$ as small as possible.

Chebyshev polynomials and nodes

The Chebyshev polynomials are $T_k(x) = \cos(k \arccos x)$ on $[-1, 1]$, equivalently $T_0 = 1$, $T_1 = x$, $T_{k+1} = 2xT_k - T_{k-1}$. The **Chebyshev nodes** (of the first kind) for degree n are the $n + 1$ zeros of T_{n+1}:

$$x_i = \cos\left(\frac{(2i+1)\pi}{2(n+1)}\right), \qquad i = 0, \dots, n.$$

On a general interval $[a, b]$ use $\frac{a+b}{2} + \frac{b-a}{2}x_i$.

The nodes are projections onto the axis of equally spaced points on a semicircle, so they *cluster near the endpoints* — exactly where equispaced interpolation goes wrong.

Minimax property of Chebyshev nodes

Among all monic polynomials of degree $n+1$, $2^{-n}T_{n+1}(x)$ has the smallest maximum magnitude on $[-1,1]$, namely 2^{-n}. Consequently, for Chebyshev nodes $\omega_{n+1} = 2^{-n}T_{n+1}$ and

$$\max_{[-1,1]} |f - p_n| \le \frac{\max |f^{(n+1)}|}{2^n (n+1)!}.$$

Proof sketch. $2^{-n}T_{n+1}$ is monic and attains $\pm 2^{-n}$ alternately at the $n+2$ points $\cos(k\pi/(n+1))$. If a monic q of the same degree had smaller maximum, $2^{-n}T_{n+1} - q$ (degree $\le n$) would alternate in sign at those $n+2$ points and so have $n+1$ zeros — hence be identically zero, a contradiction. □

A finer measure of node quality is the **Lebesgue constant** $\Lambda_n = \max_x \sum_i |\ell_i(x)|$, which bounds how much interpolation can amplify errors in the data and relates the interpolation error to the best possible: $\|f - p_n\|_\infty \le (1 + \Lambda_n)\, \|f - p_n^*\|_\infty$, where p_n^* is the best (minimax) approximation. For equispaced nodes $\Lambda_n \sim 2^{n+1}/(e\, n \ln n)$ (exponential growth); for Chebyshev nodes $\Lambda_n \le \frac{2}{\pi}\ln(n+1) + 1$ (logarithmic growth, essentially optimal). With Chebyshev nodes, interpolation of any Lipschitz-continuous function converges, and for analytic functions it converges geometrically. This is the basis of the "Chebfun" philosophy of computing with functions.

Piecewise interpolation and splines

The other cure for Runge's phenomenon is to **keep the degree low and subdivide**: interpolate by a low-degree polynomial on each subinterval between nodes.

Piecewise linear interpolation (what a plotting program does when it "connects the dots") on nodes with spacing h has error

$$\max |f - s| \le \frac{h^2}{8} \max |f''|,$$

from the error formula with $n = 1$ and $\max_{[x_i, x_{i+1}]} |(x - x_i)(x - x_{i+1})| = h^2/4$. It converges for any C^2 function, but the interpolant has corners.

Cubic spline

A **cubic spline** on nodes $a = x_0 < x_1 < \cdots < x_n = b$ is a function S that is a cubic polynomial on each $[x_i, x_{i+1}]$ and has continuous first and second derivatives on $[a, b]$. An **interpolating** cubic spline also satisfies $S(x_i) = y_i$. Two extra conditions are required, typically:

- **natural**: $S''(a) = S''(b) = 0$;
- **clamped**: $S'(a)$, $S'(b)$ prescribed;
- **not-a-knot**: S''' continuous at x_1 and x_{n-1} (MATLAB/SciPy default).

Counting. n cubics have $4n$ coefficients. Interpolation at both ends of each piece gives $2n$ conditions, continuity of S' and S'' at the $n-1$ interior nodes gives $2n - 2$; two end conditions complete the count.

Derivation (moment form). Let $M_i = S''(x_i)$ and $h_i = x_{i+1} - x_i$. Since S'' is linear on each piece, integrating twice and imposing $S(x_i) = y_i$, $S(x_{i+1}) = y_{i+1}$ gives on $[x_i, x_{i+1}]$:

$$S(x) = M_i \frac{(x_{i+1} - x)^3}{6h_i} + M_{i+1} \frac{(x - x_i)^3}{6h_i} + \left(\frac{y_i}{h_i} - \frac{M_i h_i}{6}\right)(x_{i+1} - x) + \left(\frac{y_{i+1}}{h_i} - \frac{M_{i+1} h_i}{6}\right)(x - x_i).$$

Requiring S' to be continuous at each interior node x_i yields the **tridiagonal** system

$$h_{i-1} M_{i-1} + 2(h_{i-1} + h_i) M_i + h_i M_{i+1} = 6\left(\frac{y_{i+1} - y_i}{h_i} - \frac{y_i - y_{i-1}}{h_{i-1}}\right), \qquad i = 1, \dots, n-1,$$

which is strictly diagonally dominant, hence uniquely solvable in $O(n)$ operations by the Thomas algorithm (Gaussian elimination without pivoting on a tridiagonal matrix).

Properties of cubic splines

1. **Accuracy.** For $f \in C^4$ and the clamped (or not-a-knot) spline with maximum spacing h: $\|f - S\|_\infty \le \frac{5}{384} h^4 \|f^{(4)}\|_\infty$, with $O(h^3)$ for S' and $O(h^2)$ for S''.
2. **Minimum curvature.** Among all C^2 functions interpolating the data (with the same end conditions, natural case), the natural cubic spline minimises $\int_a^b (g'')^2\, dx$ — the bending energy of a thin elastic beam, which is where the name "spline" (a draughtsman's flexible strip) comes from.
3. **Locality.** Changing one data value changes S everywhere, but the influence decays geometrically (by a factor of about $2 - \sqrt{3} \approx 0.27$ per interval for uniform nodes).

Worked Example 22.20 — A natural cubic spline

Data: $(0,0),(1,1),(2,0),(3,1)$, so $h=1$ and $M_0=M_3=0$.

Step 1 — system for M_1, M_2. With $h_i=1$ the equations read $M_{i-1}+4M_i+M_{i+1}=6(y_{i+1}-2y_i+y_{i-1})$:

$$\begin{aligned} 4M_1+M_2 &= 6(0-2+0) = -12,\\ M_1+4M_2 &= 6(1-0+1) = 12, \end{aligned}$$

giving $M_1=-4$, $M_2=4$.

Step 2 — pieces. On $[0,1]$: $S_0(x) = -4\frac{x^3}{6} + \left(1+\frac{4}{6}\right)x = -\frac{2}{3}x^3 + \frac{5}{3}x$. On $[1,2]$: $S_1(x) = -\frac{2}{3}(2-x)^3 + \frac{2}{3}(x-1)^3 + \frac{5}{3}(2-x) - \frac{2}{3}(x-1)$. On $[2,3]$, by the symmetry $y_i \mapsto 1-y_{3-i}$, $S_2(x) = 1 - S_0(3-x)$.

Step 3 — check smoothness at $x=1$. $S_0'(1) = -2+\frac{5}{3} = -\frac{1}{3}$; $S_1'(1) = 2(2-1)^2 + 0 - \frac{5}{3} - \frac{2}{3} = -\frac{1}{3}$. ✓ Second derivatives: $S_0''(1) = -4 = M_1 = S_1''(1)$. ✓ And $S_1(1.5) = 0.5$, as symmetry requires.

Hermite interpolation

If derivatives are known as well as values (for example position *and* velocity, or a circuit waveform and its slope), **Hermite interpolation** matches both. Matching f and f' at $n+1$ nodes determines a unique polynomial of degree $\le 2n+1$, with error $f^{(2n+2)}(\xi)\,\omega_{n+1}(x)^2/(2n+2)!$. The piecewise cubic Hermite interpolant (matching f, f' at both ends of every interval) underlies "PCHIP", a shape-preserving interpolant that avoids the overshoots a cubic spline can produce for monotone data.

Common Pitfall — Extrapolation and high-degree fits

The interpolation error formula contains $\omega_{n+1}(x)$, which grows like $|x|^{n+1}$ outside the node interval. **Extrapolating** an interpolating polynomial beyond the data is therefore dangerous, and the higher the degree the worse. Likewise, never fit a single polynomial of degree 15 through 16 equally spaced measurements; use a spline, or least squares with a low degree (Section 22.6).

Engineering Note — Interpolation in signal processing

A DAC with a zero-order hold performs piecewise-constant interpolation; a first-order hold is piecewise linear. The ideal band-limited reconstruction of the sampling theorem (Ch. 16) is interpolation with the sinc kernel, which is the limit of Lagrange interpolation on infinitely many equally spaced nodes. Practical **fractional-delay** filters and sample-rate converters use Lagrange interpolation over 4–8 neighbouring samples, often in the efficient **Farrow** structure, whose polynomial coefficients are exactly the Newton/Lagrange coefficients of this section.

22.6 Polynomial approximation

Interpolation versus approximation

Interpolation forces the approximant through every data point. That is the wrong goal when the data are **noisy** (fitting a polynomial through every noisy sample fits the noise), when there are **more data than parameters** (a thousand measurements of a sensor characteristic that is nearly quadratic), or when we want the **best possible accuracy** for a given degree (a function-evaluation routine in a math library or an FPGA). Approximation instead minimises a measure of the error in a chosen norm:

- the **uniform (minimax, L^∞) norm** $\|f-p\|_\infty = \max_{x\in[a,b]}|f(x)-p(x)|$ — the worst-case error, used for library functions and lookup tables;
- the **least-squares (L^2) norm** $\|f-p\|_2 = \left(\int_a^b w(x)\,(f-p)^2\,dx\right)^{1/2}$ or, for data, $\left(\sum_i w_i (y_i - p(x_i))^2\right)^{1/2}$ — the energy of the error, used for data fitting because it is optimal for Gaussian noise (Ch. 20) and leads to *linear* equations.

That polynomials are a sensible choice at all is guaranteed by a classical theorem.

Weierstrass approximation theorem

If f is continuous on $[a,b]$, then for every $\varepsilon>0$ there is a polynomial p with $\|f-p\|_\infty<\varepsilon$.

A constructive proof uses the **Bernstein polynomials** $B_n f(x) = \sum_{k=0}^{n} f(k/n)\binom{n}{k}x^k(1-x)^{n-k}$ on $[0,1]$, which converge uniformly to f — but only slowly ($O(1/n)$ for smooth f). The theorem guarantees existence; the methods below achieve good accuracy at low degree.

Taylor polynomials: good locally, poor globally

A Taylor polynomial (Ch. 4) is exact at one point with all derivatives up to order n and its error, $f^{(n+1)}(\xi)(x-x_0)^{n+1}/(n+1)!$, grows rapidly away from x_0. For e^x on $[0,1]$, the degree-1 Taylor polynomial $1+x$ has maximum error $e-2 = 0.718$ at $x=1$; we shall see that other degree-1 polynomials do seven times better. Taylor polynomials are the right tool for analysis near a point (linearisation, small-signal models) and the wrong tool for approximation over an interval.

Best uniform (minimax) approximation

Chebyshev equioscillation theorem

Let $f \in C[a,b]$. A polynomial p^* of degree $\le n$ is the best uniform approximation to f if and only if there are $n+2$ points $a \le t_0 < t_1 < \cdots < t_{n+1} \le b$ at which the error $e = f - p^*$ attains its maximum magnitude with alternating signs:

$$e(t_i) = \pm(-1)^i \|f - p^*\|_\infty.$$

The best approximation exists and is unique.

The theorem is the same alternation argument that proved the minimax property of T_{n+1} in Section 22.5 (which is the special case "best approximation of x^{n+1} by lower degree"). In practice the minimax polynomial is computed by the **Remez exchange algorithm**, which iteratively adjusts a set of $n+2$ reference points until the error equioscillates. The same equioscillation principle defines **equiripple (Parks–McClellan) FIR filters** and **elliptic (Cauer) analog filters** — optimal filter design is minimax approximation.

Worked Example 22.21 — Best straight line for e^x on $[0,1]$

Seek $p^*(x) = mx + c$ with $n+2 = 3$ alternation points. Because e^x is convex, the error $e^x - mx - c$ has its extreme values at the endpoints $0, 1$ and at one interior point ξ where $e' = 0$, i.e. $e^\xi = m$.

Equioscillation conditions. $e(0) = +E$, $e(\xi) = -E$, $e(1) = +E$:

$$1 - c = E, \qquad e^\xi - m\xi - c = -E, \qquad e - m - c = E.$$

Solve. Subtract the first from the third: $m = e - 1 = 1.718282$. Then $\xi = \ln m = 0.541325$. Adding the first two equations: $1 + m - m\xi - 2c = 0$, so $c = \tfrac{1}{2}(1 + m - m\xi) = 0.894067$, and $E = 1 - c = 0.105933$.

Result. $p^*(x) = 1.718282x + 0.894067$ with $\|e^x - p^*\|_\infty = 0.1059$ — versus 0.718 for the Taylor line $1 + x$. A numerical scan of $|e^x - p^*(x)|$ on $[0,1]$ confirms the maximum 0.10593 at $x = 0,\ 0.5413,\ 1$.

Discrete least squares

Given data (x_i, y_i), $i = 1, \dots, N$, and a model $p(x) = \sum_{k=0}^{n} a_k \phi_k(x)$ that is *linear in the parameters* (for polynomials $\phi_k = x^k$, but sinusoids, exponentials with known rates, or any fixed basis work identically), least squares chooses $\mathbf{a}$ to minimise

$$S(\mathbf{a}) = \sum_{i=1}^{N} \big(y_i - p(x_i)\big)^2 = \|\mathbf{y} - \mathbf{A}\mathbf{a}\|_2^2, \qquad A_{ik} = \phi_k(x_i).$$

Setting $\nabla S = \mathbf{0}$ (Ch. 6, Ch. 23) gives the **normal equations**

$$\mathbf{A}^{\mathsf{T}}\mathbf{A}\,\mathbf{a} = \mathbf{A}^{\mathsf{T}}\mathbf{y},$$

which have a unique solution when the columns of $\mathbf{A}$ are linearly independent (for polynomials: at least $n+1$ distinct x_i). Geometrically, $\mathbf{A}\mathbf{a}$ is the orthogonal projection of $\mathbf{y}$ onto the column space of $\mathbf{A}$: the residual $\mathbf{r} = \mathbf{y} - \mathbf{A}\mathbf{a}$ is orthogonal to every column, $\mathbf{A}^{\mathsf{T}}\mathbf{r} = \mathbf{0}$ (Ch. 9).

Worked Example 22.22 — Fitting a resistor's I–V line

Measured voltage–current pairs (V in volts, I in mA): $(0, 0.1), (1, 1.9), (2, 4.2), (3, 5.8), (4, 8.1)$. Fit $I = a_0 + a_1 V$.

Normal equations. $\sum 1 = 5$, $\sum V_i = 10$, $\sum V_i^2 = 30$, $\sum I_i = 20.1$, $\sum V_i I_i = 0 + 1.9 + 8.4 + 17.4 + 32.4 = 60.1$:

$$\begin{bmatrix} 5 & 10 \\ 10 & 30 \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \end{bmatrix} = \begin{bmatrix} 20.1 \\ 60.1 \end{bmatrix}.$$

Solve. Determinant $150 - 100 = 50$; $a_1 = (5 \cdot 60.1 - 10 \cdot 20.1)/50 = (300.5 - 201)/50 = 1.99$ mA/V, $a_0 = (20.1 - 10a_1)/5 = 0.04$ mA.

Interpretation. Conductance 1.99 mS, i.e. $R = 1/1.99$ mS $= 503\ \Omega$; offset 0.04 mA (instrument offset). Residuals $0.06, -0.13, 0.18, -0.21, 0.10$ sum to zero (as orthogonality to the constant column requires) and their sum of squares is 0.107, giving an estimated noise standard deviation $\sqrt{0.107/(5-2)} = 0.19$ mA (Ch. 20).

Numerical caution. Forming $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ *squares* the condition number: $\kappa(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \kappa(\mathbf{A})^2$. For the quadratic fit to the data above, $\kappa(\mathbf{A}) = 27$ but $\kappa(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = 735$; for high-degree monomial fits the squaring is catastrophic. Stable practice is to solve the least-squares problem by a **QR factorisation** $\mathbf{A} = \mathbf{Q}\mathbf{R}$ (then $\mathbf{R}\mathbf{a} = \mathbf{Q}^{\mathsf{T}}\mathbf{y}$) or the SVD, which is what `numpy.linalg.lstsq` and MATLAB's backslash do; and to **centre and scale** the abscissae (use $(x - \bar{x})/s$) before fitting polynomials.

Continuous least squares and orthogonal polynomials

To approximate a *function* f on $[a,b]$ in the L^2 sense with $p(x) = \sum_k a_k x^k$, minimise $\int_a^b (f - p)^2 dx$. The normal equations become

$$\sum_{k=0}^{n} \left(\int_a^b x^{j+k} dx \right) a_k = \int_a^b x^j f(x)\, dx, \qquad j = 0, \dots, n.$$

On $[0,1]$ the matrix is the **Hilbert matrix** $H_{jk} = 1/(j+k+1)$ — which we met in Section 22.2 as the archetype of ill-conditioning. The monomials are a terrible basis: x^{10} and x^{11} look almost alike on $[0,1]$.

The cure is an **orthogonal basis**. If $\langle \phi_j, \phi_k \rangle = \int_a^b w\, \phi_j \phi_k\, dx = 0$ for $j \ne k$, the normal-equation matrix is diagonal and the coefficients decouple:

$$a_k = \frac{\langle f, \phi_k \rangle}{\langle \phi_k, \phi_k \rangle}.$$

This is exactly the Fourier-coefficient formula of Ch. 15 with polynomials in place of sinusoids — and, as there, adding a term does not change the previous coefficients, and the error decreases monotonically as terms are added (Bessel's inequality, Parseval).

Family	Interval	Weight $w(x)$	Recurrence	Norm $\langle \phi_k, \phi_k \rangle$
Legendre P_k	$[-1, 1]$	1	$(k+1)P_{k+1} = (2k+1)xP_k - kP_{k-1}$	$2/(2k+1)$
Chebyshev T_k	$[-1, 1]$	$(1-x^2)^{-1/2}$	$T_{k+1} = 2xT_k - T_{k-1}$	π $(k=0)$, $\pi/2$ $(k \geq 1)$
Laguerre L_k	$[0, \infty)$	e^{-x}	$(k+1)L_{k+1} = (2k+1-x)L_k - kL_{k-1}$	1
Hermite H_k	$(-\infty, \infty)$	e^{-x^2}	$H_{k+1} = 2xH_k - 2kH_{k-1}$	$\sqrt{\pi}\, 2^k k!$

The first Legendre polynomials are $P_0 = 1$, $P_1 = x$, $P_2 = \frac{1}{2}(3x^2 - 1)$, $P_3 = \frac{1}{2}(5x^3 - 3x)$. Any family of orthogonal polynomials can be generated from the monomials by Gram–Schmidt (Ch. 9), and every such family satisfies a three-term recurrence.

Worked Example 22.23 — Least-squares straight line for e^x on $[0, 1]$

Normal equations (monomial basis).

$$\begin{bmatrix} 1 & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{3} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \end{bmatrix} = \begin{bmatrix} \int_0^1 e^x dx \\ \int_0^1 x e^x dx \end{bmatrix} = \begin{bmatrix} e - 1 \\ 1 \end{bmatrix}.$$

Solve. Determinant $\frac{1}{3} - \frac{1}{4} = \frac{1}{12}$; $a_0 = 12\left(\frac{e-1}{3} - \frac{1}{2}\right) = 4e - 10 = 0.873127$, $a_1 = 12\left(1 - \frac{e-1}{2}\right) = 18 - 6e = 1.690309$.

Compare with the minimax line of Example 22.21.

Approximation	$\|e^x - p\|_\infty$	$\|e^x - p\|_2$
Taylor $1 + x$	0.718	—
Least squares $0.8731 + 1.6903x$	0.155	**0.0628**
Minimax $0.8941 + 1.7183x$	**0.106**	0.0723

Each is optimal in its own norm, and they are close to each other — a general phenomenon for smooth functions.

Worked Example 22.24 — Legendre expansion of e^x on $[-1, 1]$

Coefficients. $a_k = \frac{2k+1}{2} \int_{-1}^{1} e^x P_k(x)\, dx$:

$$a_0 = \tfrac{1}{2}(e - e^{-1}) = 1.175201, \quad a_1 = \tfrac{3}{2} \cdot 2e^{-1} = 1.103638, \quad a_2 = \tfrac{5}{2}\,(e - 7e^{-1}) = 0.357814.$$

(The integrals follow by repeated integration by parts: $\int_{-1}^{1} xe^x dx = 2/e$, $\int_{-1}^{1} x^2 e^x dx = e - 5/e$.)

Quadratic approximation. $p_2 = a_0 + a_1 x + a_2 \cdot \frac{1}{2}(3x^2 - 1) = 0.996294 + 1.103638x + 0.536722x^2$.

Accuracy. $\max_{[-1,1]} |e^x - p_2| = 0.0816$, compared with 0.218 for the Taylor quadratic $1 + x + x^2/2$. Adding $a_3 P_3$ would not change a_0, a_1, a_2.

Chebyshev series and economisation

Expanding in Chebyshev polynomials (weight $(1-x^2)^{-1/2}$) gives a series $f = \sum c_k T_k$ whose truncation is **near-minimax**: since $|T_k| \leq 1$, the truncation error is at most $\sum_{k>n} |c_k|$, and because the first omitted term $c_{n+1}T_{n+1}$ usually dominates and equioscillates $n+2$ times, the truncated series is very close to the true minimax polynomial. Interpolating at Chebyshev nodes (Section 22.5) gives almost the same polynomial and is easier to compute (by FFT).

Economisation turns a Taylor polynomial into a better approximation of lower degree: express the highest power through Chebyshev polynomials and drop the T_n term, whose magnitude is known exactly.

Worked Example 22.25 — Economising the cubic Taylor polynomial of e^x

Step 1. $e^x \approx 1 + x + \frac{1}{2}x^2 + \frac{1}{6}x^3$ on $[-1, 1]$ (max error 0.0516).

Step 2. From $T_3 = 4x^3 - 3x$: $x^3 = \frac{1}{4}(T_3 + 3x)$, so $\frac{1}{6}x^3 = \frac{1}{24}T_3 + \frac{1}{8}x$.

Step 3. Drop $\frac{1}{24}T_3$ (error at most $1/24 = 0.0417$): $e^x \approx 1 + 1.125x + 0.5x^2$.

Accuracy. A numerical scan gives $\max|e^x - (1 + 1.125x + 0.5x^2)| = 0.093$, close to the predicted $0.0516 + 0.0417$ and far better than the Taylor quadratic (0.218). For comparison, interpolating at the three Chebyshev nodes gives $1 + 1.12977x + 0.53204x^2$ with error 0.056.

Choosing the degree

In data fitting, the residual always decreases as the degree increases, until at degree $N - 1$ the fit interpolates and the residual is zero — while the polynomial oscillates wildly between data points. This is **overfitting**: the extra parameters model the noise. Choose the degree by physics (a resistor is linear; a thermistor's $\ln R$ is nearly linear in $1/T$), by checking that residuals look like white noise, or by statistical criteria (adjusted R^2, cross-validation, the F-test of Ch. 20). Weighted least squares (weights $w_i = 1/\sigma_i^2$) is appropriate when measurements have unequal uncertainties.

Common Pitfall — Fitting in the wrong variables

Least squares minimises errors in the variable you fit. Linearising an exponential model $y = Ae^{bx}$ by fitting $\ln y$ versus x is convenient but changes the error weighting — small y values (often the noisiest) get magnified influence. If the noise is additive in y, either weight the log-fit by y_i^2 or fit the nonlinear model directly (Gauss–Newton, Ch. 23).

Engineering Note — Polynomial approximation in hardware and firmware

The `sin`, `exp` and `log` routines in a math library (or an FPGA's CORDIC alternative) typically reduce the argument to a small interval and then evaluate a **minimax** polynomial or rational function of modest degree, coefficients precomputed by the Remez algorithm. Sensor linearisation in firmware — thermocouple voltage to temperature (the NIST ITS-90 polynomials are degree 8–10), strain-gauge calibration, RTD Callendar–Van Dusen curves — uses **least-squares** polynomial fits, evaluated by Horner's scheme to minimise multiplications and rounding error.

22.7 Numerical differentiation

Motivation

Derivatives are needed numerically whenever a function is known only through samples (a digitised waveform, a measured C–V curve whose slope gives doping profile), or through a black-box program (the Jacobian for Newton's method, sensitivities $\partial V_{\text{out}}/\partial R_k$ of a simulated circuit), and — most importantly — as the building block for solving differential equations on grids (Sections 22.9–22.10). Numerical differentiation is easy to do and easy to do badly: it is the one basic numerical operation in which **truncation and rounding errors pull in opposite directions**.

Finite-difference formulas from Taylor series

Let f be smooth and $h > 0$ a step. Taylor expansions about x give

$$f(x+h) = f + hf' + \tfrac{h^2}{2}f'' + \tfrac{h^3}{6}f''' + \tfrac{h^4}{24}f^{(4)} + \cdots$$
$$f(x-h) = f - hf' + \tfrac{h^2}{2}f'' - \tfrac{h^3}{6}f''' + \tfrac{h^4}{24}f^{(4)} - \cdots$$

(all derivatives evaluated at x). Rearranging the first line:

$$\textbf{forward difference:}\quad D_+ f(x) = \frac{f(x+h) - f(x)}{h} = f'(x) + \frac{h}{2}f''(\xi),$$

so the truncation error is $O(h)$ — first order. The **backward difference** $D_- f = (f(x) - f(x-h))/h$ is likewise first order. Subtracting the two expansions cancels the even terms:

$$\textbf{central difference:}\quad D_0 f(x) = \frac{f(x+h) - f(x-h)}{2h} = f'(x) + \frac{h^2}{6}f'''(\xi),$$

which is **second order**. Adding them cancels the odd terms and gives the standard second-derivative formula:

$$D_+ D_- f(x) = \frac{f(x+h) - 2f(x) + f(x-h)}{h^2} = f''(x) + \frac{h^2}{12}f^{(4)}(\xi).$$

The general pattern: a symmetric stencil kills alternate error terms, gaining one order for free.

Order of a difference approximation

A difference formula $D_h f$ approximates $f^{(m)}(x)$ with **order** p if $D_h f - f^{(m)}(x) = Ch^p f^{(m+p)}(\xi)$ with $C \neq 0$ for all smooth f. The quantity $D_h f - f^{(m)}(x)$ is the **truncation error**; C is its error constant.

Approximation	Formula	Truncation error
f' forward	$\frac{f_1 - f_0}{h}$	$\frac{h}{2}f''$
f' backward	$\frac{f_0 - f_{-1}}{h}$	$-\frac{h}{2}f''$
f' central	$\frac{f_1 - f_{-1}}{2h}$	$\frac{h^2}{6}f'''$
f' one-sided, 2nd order	$\frac{-3f_0 + 4f_1 - f_2}{2h}$	$-\frac{h^2}{3}f'''$
f' central, 4th order	$\frac{-f_2 + 8f_1 - 8f_{-1} + f_{-2}}{12h}$	$-\frac{h^4}{30}f^{(5)}$
f'' central	$\frac{f_1 - 2f_0 + f_{-1}}{h^2}$	$\frac{h^2}{12}f^{(4)}$
f'' central, 4th order	$\frac{-f_2 + 16f_1 - 30f_0 + 16f_{-1} - f_{-2}}{12h^2}$	$-\frac{h^4}{90}f^{(6)}$
f''' central	$\frac{f_2 - 2f_1 + 2f_{-1} - f_{-2}}{2h^3}$	$\frac{h^2}{4}f^{(5)}$

Here $f_k = f(x + kh)$. The one-sided second-order formula is what one uses at a boundary, where no point to the left exists (Neumann boundary conditions in Section 22.10).

Method of undetermined coefficients. Any stencil can be derived systematically. To approximate $f'(0)$ from f_0, f_1, f_2, write $f'(0) \approx (af_0 + bf_1 + cf_2)/h$, expand each f_k in Taylor series, and demand that the coefficients of f, f', f'' be $0, 1, 0$:

$$a+b+c=0, \qquad b+2c=1, \qquad \tfrac{1}{2}b+2c=0 \quad\Longrightarrow\quad (a,b,c)=\left(-\tfrac{3}{2},\ 2,\ -\tfrac{1}{2}\right),$$

which is the one-sided formula in the table. Equivalently, one can differentiate the interpolating polynomial through the stencil points (Section 22.5): the weights are $\ell_i'(x)$. That viewpoint generalises to unequally spaced points.

Worked Example 22.26 — Derivatives of e^x at $x=0$

Exact values: $f'(0)=f''(0)=1$.

h	forward	error	central	error	D_+D_- for f''	error
0.1	1.0517092	5.2×10^{-2}	1.0016675	1.67×10^{-3}	1.0008336	8.3×10^{-4}
0.05	1.0254219	2.5×10^{-2}	1.0004167	4.17×10^{-4}	1.0002084	2.1×10^{-4}

Order check. Halving h halves the forward error (ratio 2.0, order 1) and quarters the central and second-difference errors (ratio 4.0, order 2).

Error constants. Predicted forward error $\frac{h}{2}f''=0.05$ ✓; central $\frac{h^2}{6}f'''=1.67\times10^{-3}$ ✓; second difference $\frac{h^2}{12}f^{(4)}=8.3\times10^{-4}$ ✓.

Higher order. At $h=0.1$ the one-sided second-order formula gives an error of -3.6×10^{-3} (predicted $-\frac{h^2}{3}=-3.3\times10^{-3}$) — much better than the forward difference's 5.2×10^{-2} with the same points available on one side — and the five-point fourth-order formula gives -3.3×10^{-6} (predicted $-h^4/30=-3.3\times10^{-6}$).

Richardson extrapolation

If an approximation has an error expansion in known powers of h,

$$D(h)=L+c_1h^p+c_2h^q+\cdots \qquad (q>p),$$

then combining two step sizes eliminates the leading error term:

$$D(h)-L\approx c_1h^p, \quad D(h/2)-L\approx c_1(h/2)^p \quad\Longrightarrow\quad L\approx R(h)=\frac{2^pD(h/2)-D(h)}{2^p-1},$$

with error $O(h^q)$. For the central difference, $p=2$ and the expansion contains only even powers, so $R(h)=\frac{4D_0(h/2)-D_0(h)}{3}$ is **fourth order**. Repeating the process builds a triangular table (the same idea gives Romberg integration in Section 22.8). Richardson extrapolation also provides an **error estimate** for free: $D(h/2)-L\approx\frac{D(h/2)-D(h)}{2^p-1}$.

Worked Example 22.27 — Richardson for the derivative of e^x

From Example 22.26, $D_0(0.1)=1.00166750$ and $D_0(0.05)=1.00041672$.

Extrapolate. $R=\dfrac{4(1.00041672)-1.00166750}{3}=0.99999979$, error -2.1×10^{-7} — an improvement by a factor of 2000 over $D_0(0.05)$, using no new function values.

Error estimate. $(D_0(0.05)-D_0(0.1))/3=-4.17\times10^{-4}$, so $D_0(0.05)\approx L+4.17\times10^{-4}$: the estimate matches the actual error of $D_0(0.05)$ to three digits.

(Algebraically $R(h)$ equals the five-point formula with step $h/2$, whose predicted error $-(0.05)^4/30=-2.1\times10^{-7}$ agrees.)

Rounding error: the trade-off

The formulas above assume exact function values. In floating point, $f(x\pm h)$ carries an absolute error of about $u|f|$ (more if f is computed by a long program). For the forward difference these errors are divided by h, giving a total error

$$E(h)\approx \underbrace{\frac{h}{2}|f''|}_{\text{truncation}}+\underbrace{\frac{2u|f|}{h}}_{\text{rounding}}.$$

The first term falls with h, the second rises. Minimising over h ($E'(h)=0$):

$$h_{\text{opt}}=2\sqrt{\frac{u|f|}{|f''|}}\sim\sqrt{u}\approx10^{-8}, \qquad E_{\min}=2\sqrt{u|f||f''|}\sim\sqrt{u}\approx10^{-8}.$$

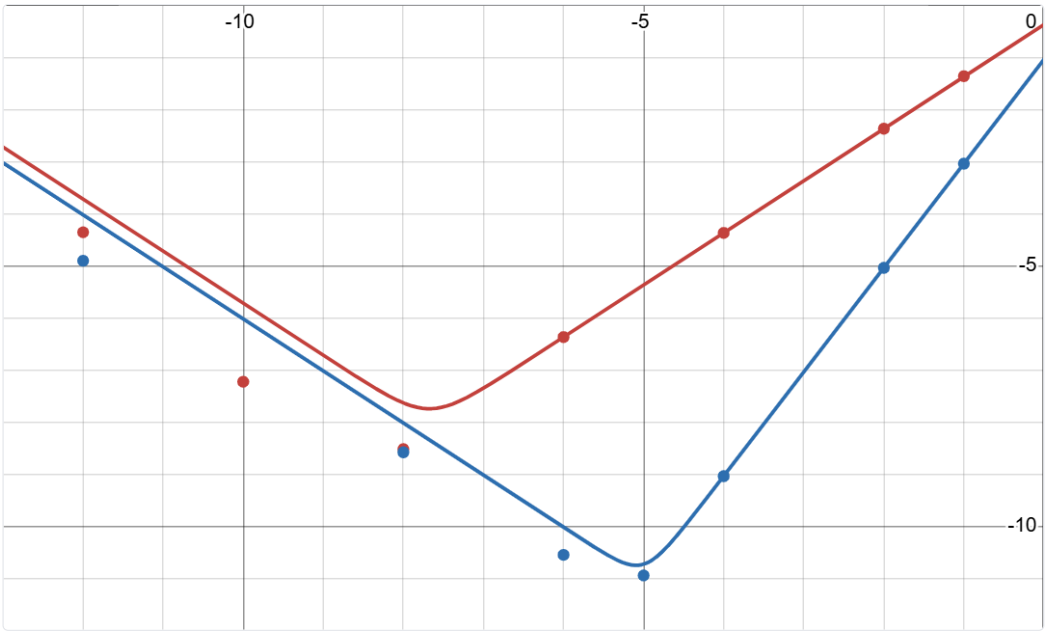
So in double precision **a forward difference can never deliver more than about 8 correct digits.** For the central difference, $E(h)\approx\frac{h^2}{6}|f'''|+u|f|/h$, giving $h_{\text{opt}}=(3u|f|/|f'''|)^{1/3}\sim u^{1/3}\approx5\times10^{-6}$ and $E_{\min}\sim u^{2/3}\approx10^{-11}$. Higher-order formulas push the optimum to larger h and smaller minimum error, but every formula for an m-th derivative suffers rounding amplification like u/h^m.

Worked Example 22.28 — The error "V" for $\frac{d}{dx}\sin x$ at $x = 1$

Exact: $\cos 1 = 0.540302306$.

h	10^{-1}	10^{-2}	10^{-4}	10^{-5}	10^{-6}	10^{-8}	10^{-10}	10^{-12}
forward error	4.3×10^{-2}	4.2×10^{-3}	4.2×10^{-5}	4.2×10^{-6}	4.2×10^{-7}	3.0×10^{-9}	5.8×10^{-8}	4.3×10^{-5}
central error	9.0×10^{-4}	9.0×10^{-6}	9.0×10^{-10}	1.1×10^{-11}	2.8×10^{-11}	2.6×10^{-9}	5.8×10^{-8}	1.2×10^{-5}

Reading the table. Both errors first fall at their theoretical rates (one decade per decade of h for forward, two for central). The forward error bottoms out near $h = 10^{-8}$ at about 3×10^{-9} (theory: $h_{\text{opt}} = 2\sqrt{u} = 2.1\times10^{-8}$, $E_{\min} \approx \sqrt{u}\cdot 2\sin 1 \approx 2\times10^{-8}$; the observed value is smaller because rounding errors partially cancel). The central error bottoms out near $h = 10^{-5}$ at about 10^{-11} (theory: $h_{\text{opt}} = (3u\tan 1)^{1/3} = 8\times10^{-6}$). For smaller h both curves *rise* along the same line, slope -1, because rounding dominates.



Total error of the forward (red) and central (blue) difference for $(\sin x)'$ at $x = 1$, on log–log axes ($x = \log_{10} h$, $y = \log_{10}$ error): model curves $\frac{h}{2}|f''| + 2u|f|/h$ and $\frac{h^2}{6}|f'''| + u|f|/h$ with measured errors as dots. Truncation dominates on the right (slopes 1 and 2), rounding on the left (slope -1).

The complex-step derivative

Engineers comfortable with j have a neat escape from the rounding trade-off when f is analytic and implemented in complex arithmetic. Expand with an *imaginary* step:

$$f(x + jh) = f(x) + jhf'(x) - \tfrac{h^2}{2}f''(x) - j\tfrac{h^3}{6}f'''(x) + \cdots \quad\Longrightarrow\quad f'(x) = \frac{\operatorname{Im}\{f(x+jh)\}}{h} + \frac{h^2}{6}f'''(x) + \cdots$$

There is **no subtraction**, hence no cancellation, so h can be taken absurdly small: with $h = 10^{-20}$ the truncation error $\sim 10^{-40}$ is invisible and the result for $(\sin x)'$ at $x = 1$ is correct to the last bit (computed error exactly 0). The method is widely used for accurate sensitivities in optimisation codes; it requires that the code for f be "complex-safe" (no `abs`, no comparisons on real parts that break analyticity).

Differentiating noisy data

Measured data contain noise of size σ that does not decrease with h. The rounding analysis then applies with $u|f|$ replaced by σ: a central difference of samples spaced h apart has noise standard deviation $\sigma/(\sqrt{2}\,h)$, and a second difference $\sqrt{6}\,\sigma/h^2$. Differentiation is a **high-pass** operation — its frequency response is $j\omega$ (Ch. 16) — so it amplifies high-frequency noise. Practical remedies smooth before (or while) differentiating: fit a local low-degree least-squares polynomial and differentiate it (the **Savitzky–Golay** filter), differentiate a smoothing spline, or use a band-limited differentiator FIR filter.

Common Pitfall — "Smaller h is always more accurate"

It is not. Below the optimum step, every halving of h *doubles* the rounding error (for a first derivative) or quadruples it (for a second). A finite-difference Jacobian in a Newton solver with $h = 10^{-14}|x|$ can be pure noise and stall the iteration. A sound default is $h = \sqrt{u}\,\max(|x|, x_{\text{typ}})$ for forward differences and $h = u^{1/3}\max(|x|, x_{\text{typ}})$ for central differences, with h rounded so that $x + h$ is exactly representable (`h = (x + h) - x`).

Engineering Note — Differentiators in practice

An oscilloscope's "derivative" math channel, a PID controller's D term and a digital tachometer all implement numerical differentiation of noisy samples. That is why PID implementations filter the derivative term (a first-order low-pass on D, "derivative kick" avoidance) and why rotational speed is often estimated by counting encoder pulses over a longer window (which is a long-baseline difference, trading bandwidth for noise) rather than by differentiating successive samples.

22.8 Numerical integration

Motivation

Definite integrals without elementary antiderivatives are everywhere: the error function in bit-error-rate calculations (Ch. 19), the RMS value of a measured waveform, the energy of a pulse, Fourier coefficients of sampled signals (Ch. 15), the inductance of a loop from Neumann's formula, radiation patterns of antennas, and integrals of tabulated data. **Quadrature** (the classical name for numerical integration) approximates

$$I(f) = \int_a^b f(x)\,dx \qquad \text{by} \qquad Q(f) = \sum_{i=0}^{n} w_i f(x_i),$$

a weighted sum of function values at **nodes** x_i with **weights** w_i. All the methods of this section are of this form; they differ in how nodes and weights are chosen.

> **Degree of exactness**
>
> A quadrature rule has **degree of exactness** (or degree of precision) d if $Q(p) = I(p)$ for every polynomial p of degree $\le d$, but not for some polynomial of degree $d+1$.

Since Q and I are both linear, it suffices to check the monomials $1, x, \dots, x^d$. A rule obtained by integrating the interpolating polynomial through $n+1$ nodes — an **interpolatory rule**, with weights $w_i = \int_a^b \ell_i(x)\,dx$ — has degree at least n.

Newton–Cotes rules

Interpolatory rules on **equally spaced** nodes are called Newton–Cotes rules.

Trapezoidal rule (linear interpolation through the endpoints):

$$\int_a^b f\,dx \approx \frac{b-a}{2}\big(f(a)+f(b)\big), \qquad E = -\frac{(b-a)^3}{12} f''(\xi).$$

Derivation of the error. By the interpolation error formula (Section 22.5), $f - p_1 = \tfrac{1}{2}f''(\xi_x)(x-a)(x-b)$. Since $(x-a)(x-b) \le 0$ on $[a,b]$ does not change sign, the integral mean-value theorem gives $\int_a^b (f-p_1)\,dx = \tfrac{1}{2}f''(\xi)\int_a^b (x-a)(x-b)\,dx = \tfrac{1}{2}f''(\xi)\left(-\tfrac{(b-a)^3}{6}\right)$. $\square$

Midpoint rule $\int_a^b f \approx (b-a) f\big(\tfrac{a+b}{2}\big)$ has error $+\tfrac{(b-a)^3}{24}f''(\xi)$ — half the trapezoidal error and of opposite sign, a fact exploited by Simpson's rule.

Simpson's rule (quadratic interpolation through a, $m = \tfrac{a+b}{2}$, b; $h = \tfrac{b-a}{2}$):

$$\int_a^b f\,dx \approx \frac{h}{3}\big(f(a) + 4f(m) + f(b)\big), \qquad E = -\frac{h^5}{90} f^{(4)}(\xi).$$

Although it interpolates with a quadratic, Simpson's rule integrates **cubics exactly** (degree of exactness 3): by symmetry about m, the rule integrates $(x-m)^3$ exactly (both sides are zero). This "bonus degree" occurs for every symmetric rule with an odd number of points. Simpson's rule can also be seen as the combination $S = \tfrac{2}{3}M + \tfrac{1}{3}T$ of midpoint and trapezoid, which cancels their f'' errors.

Higher-order Newton–Cotes rules exist (Simpson's 3/8 rule, Boole's rule), but beyond about 8 points their weights become negative and large — the integration counterpart of the Runge phenomenon — so in practice one uses low-order rules **composed** over many subintervals.

Composite rules

Divide $[a,b]$ into n subintervals of width $h = (b-a)/n$, nodes $x_i = a + ih$, and apply the basic rule on each:

$$T_n = h\left[\tfrac{1}{2}f_0 + f_1 + f_2 + \cdots + f_{n-1} + \tfrac{1}{2}f_n\right], \qquad E_T = -\frac{(b-a)h^2}{12} f''(\xi),$$

$$S_n = \frac{h}{3}\left[f_0 + 4f_1 + 2f_2 + 4f_3 + \cdots + 2f_{n-2} + 4f_{n-1} + f_n\right] \ (n \text{ even}), \qquad E_S = -\frac{(b-a)h^4}{180} f^{(4)}(\xi).$$

The composite error follows by summing the n local errors $-\tfrac{h^3}{12}f''(\xi_i)$ and replacing the average $\tfrac{1}{n}\sum f''(\xi_i)$ by $f''(\xi)$ (intermediate value theorem). Each local error is one power of h higher than the global error: $n \propto 1/h$ local errors add up. So the composite trapezoidal rule is **second order** and composite Simpson **fourth order**.

```
import numpy as np
def trapezoid(f, a, b, n):
    x = np.linspace(a, b, n + 1); y = f(x)
    return (b - a) / n * (y.sum() - 0.5 * (y[0] + y[-1]))
def simpson(f, a, b, n):                    # n must be even
    x = np.linspace(a, b, n + 1); y = f(x); h = (b - a) / n
    return h / 3 * (y[0] + y[-1] + 4 * y[1:-1:2].sum() + 2 * y[2:-1:2].sum())
```

Worked Example 22.29 — $\int_0^1 e^{-x^2}\,dx$ by trapezoid and Simpson

The exact value is $\frac{\sqrt{\pi}}{2}\operatorname{erf}(1) = 0.746824132812$.

Trapezoid, $n = 4$ ($h = 0.25$). f values: $1,\ 0.939413,\ 0.778801,\ 0.569783,\ 0.367879$. $T_4 = 0.25\,[0.5 + 0.939413 + 0.778801 + 0.569783 + 0.183940] = 0.742984$.

Simpson, $n = 4$. $S_4 = \frac{0.25}{3}\,[1 + 4(0.939413) + 2(0.778801) + 4(0.569783) + 0.367879] = 0.746855$.

n	T_n	error	S_n	error
2	0.731370	-1.55×10^{-2}	0.747180	3.6×10^{-4}
4	0.742984	-3.84×10^{-3}	0.746855	3.1×10^{-5}
8	0.745866	-9.59×10^{-4}	0.746826	2.0×10^{-6}

Orders. Trapezoid errors fall by 4.0 per halving (h^2); Simpson by 11.4 and 15.7, approaching 16 (h^4).

Error prediction. The Euler–Maclaurin formula below predicts $T_n - I \approx \frac{h^2}{12}\big(f'(1) - f'(0)\big) = \frac{h^2}{12}(-2e^{-1})$, i.e. -3.832×10^{-3} for $n = 4$, matching the observed -3.840×10^{-3}.

The Euler–Maclaurin formula and Romberg integration

Euler–Maclaurin formula

If $f \in C^{2m+2}[a, b]$, the composite trapezoidal rule satisfies

$$T_n - \int_a^b f\,dx = \sum_{k=1}^{m} \frac{B_{2k} h^{2k}}{(2k)!}\left(f^{(2k-1)}(b) - f^{(2k-1)}(a)\right) + O(h^{2m+2}),$$

where $B_2 = \frac{1}{6}$, $B_4 = -\frac{1}{30}$, $B_6 = \frac{1}{42}$, … are Bernoulli numbers. In particular the error has an expansion in **even** powers of h: $T_n = I + c_1 h^2 + c_2 h^4 + c_3 h^6 + \cdots$.

Two important consequences:

1. **Romberg integration.** Since the error expansion is in powers of h^2, Richardson extrapolation (Section 22.7) applies repeatedly. With $R_{k,0} = T_{2^k}$,

$$R_{k,m} = R_{k,m-1} + \frac{R_{k,m-1} - R_{k-1,m-1}}{4^m - 1}.$$

The column $R_{k,1}$ is exactly composite Simpson; $R_{k,2}$ is composite Boole (order 6); and so on.

2. **Periodic functions.** If f is smooth and periodic with period $b - a$, all the derivative differences $f^{(2k-1)}(b) - f^{(2k-1)}(a)$ vanish, so the trapezoidal error is smaller than *every* power of h. For analytic periodic functions the error decays **geometrically** in n. The humble trapezoidal rule is the best possible method for integrating smooth periodic functions over a full period.

Worked Example 22.30 — Romberg table for $\int_0^1 e^{-x^2}\,dx$

k	$n = 2^k$	$R_{k,0}$ (trapezoid)	$R_{k,1}$ (Simpson)	$R_{k,2}$	$R_{k,3}$
0	1	0.6839397			
1	2	0.7313703	0.7471804		
2	4	0.7429841	0.7468554	0.7468337	
3	8	0.7458656	0.7468261	0.74682417	0.74682402

For example $R_{1,1} = 0.7313703 + (0.7313703 - 0.6839397)/3 = 0.7471804$. With 9 function evaluations, $R_{3,2}$ is correct to 4×10^{-8}, versus 10^{-3} for T_8 alone. The last entry $R_{3,3}$ (-1.1×10^{-7}) is slightly worse than $R_{3,2}$: extrapolation assumes the asymptotic regime, and the crude $R_{0,0}$ (one interval!) contaminates the far corner of the table. Practical Romberg codes stop when successive diagonal entries agree to tolerance.

Worked Example 22.31 — Spectral accuracy for a periodic integrand

$I = \int_0^{2\pi} \frac{dx}{2 + \cos x} = \frac{2\pi}{\sqrt{3}} = 3.6275987285$ (residue calculus, Ch. 18). For a periodic function the trapezoidal rule with n points is simply $\frac{2\pi}{n}\sum_{i=0}^{n-1} f(2\pi i/n)$:

n	2	4	8	16
T_n	4.18879	3.66519	3.62779	3.6275987336
error	5.6×10^{-1}	3.8×10^{-2}	1.9×10^{-4}	5.1×10^{-9}

Each doubling of n *squares* the error, roughly — geometric convergence (the error behaves like $(2 - \sqrt{3})^n \approx 0.268^n$, set by the location of the integrand's poles at $\cos x = -2$). A fourth-order method would only gain a factor of 16 per doubling.

Gaussian quadrature

Newton–Cotes rules fix the nodes and choose $n+1$ weights, achieving degree n (or $n+1$). If the **nodes are free too**, there are $2n+2$ parameters and one can hope for degree $2n+1$. Gauss showed this is achievable, and optimal.

Gauss–Legendre quadrature

For each $n \geq 1$ there is a unique n-point rule

$$\int_{-1}^{1} f(x)\,dx \approx \sum_{i=1}^{n} w_i f(x_i)$$

with degree of exactness $2n-1$; no n-point rule has higher degree. Its nodes are the zeros of the Legendre polynomial P_n, all real, distinct and in $(-1,1)$, and its weights $w_i = \int_{-1}^{1} \ell_i(x)\,dx = \dfrac{2}{(1-x_i^2)[P_n'(x_i)]^2}$ are all positive. The error is

$$E_n = \frac{2^{2n+1}(n!)^4}{(2n+1)[(2n)!]^3}\, f^{(2n)}(\xi).$$

Proof sketch of exactness. Let p have degree $\leq 2n-1$. Divide by P_n: $p = qP_n + r$ with $\deg q, \deg r \leq n-1$. Then $\int_{-1}^{1} p = \int qP_n + \int r = 0 + \int r$, because P_n is orthogonal to all polynomials of lower degree (Section 22.6). At the nodes $P_n(x_i) = 0$, so $\sum w_i p(x_i) = \sum w_i r(x_i) = \int r$, the last equality because the rule is interpolatory with n nodes and $\deg r \leq n-1$. *Optimality:* $p = \prod (x - x_i)^2$ has degree $2n$, is positive, and is integrated to 0 by the rule. $\square$

n	nodes x_i	weights w_i	exact for degree
1	0	2	1
2	$\pm 1/\sqrt{3} = \pm 0.5773503$	$1,\ 1$	3
3	$0,\ \pm\sqrt{3/5} = \pm 0.7745967$	$8/9,\ 5/9,\ 5/9$	5
4	$\pm 0.3399810,\ \pm 0.8611363$	$0.6521452,\ 0.3478548$	7

Deriving the 2-point rule directly. Require $w_1 f(x_1) + w_2 f(x_2)$ to integrate $1, x, x^2, x^3$ exactly on $[-1,1]$: $w_1 + w_2 = 2$, $w_1 x_1 + w_2 x_2 = 0$, $w_1 x_1^2 + w_2 x_2^2 = \tfrac{2}{3}$, $w_1 x_1^3 + w_2 x_2^3 = 0$. Symmetry suggests $x_2 = -x_1$, $w_1 = w_2 = 1$; then $2x_1^2 = \tfrac{2}{3}$ gives $x_{1,2} = \pm 1/\sqrt{3}$.

General interval. Map $x \in [-1,1]$ to $t = \frac{a+b}{2} + \frac{b-a}{2}x$:

$$\int_a^b g(t)\,dt \approx \frac{b-a}{2} \sum_{i=1}^{n} w_i\, g\!\left(\frac{a+b}{2} + \frac{b-a}{2} x_i\right).$$

Worked Example 22.32 — Gauss–Legendre for $\int_0^1 e^{-x^2}dx$ and $\int_0^{\pi} \sin x\,dx$

2-point rule on $[0,1]$. Nodes $t = \frac{1}{2} \pm \frac{1}{2\sqrt{3}} = 0.211325,\ 0.788675$; weights $\frac{1}{2}$ each. $Q_2 = \frac{1}{2}\left(e^{-0.044658} + e^{-0.622008}\right) = \frac{1}{2}(0.956324 + 0.536865) = 0.746595$, error -2.3×10^{-4}.

3- and 4-point rules. $Q_3 = 0.7468146$ (error -9.5×10^{-6}), $Q_4 = 0.74682447$ (error 3.4×10^{-7}).

Comparison at equal cost. Q_4 with 4 evaluations beats Simpson S_8 with 9 evaluations (2.0×10^{-6}).

Second integral (exact value 2). Trapezoid $T_4 = 1.896119$, Simpson $S_4 = 2.004560$, Gauss $Q_2 = 1.935820$, $Q_3 = 2.001389$. Three function values in the right places do better than five equally spaced ones.

Other Gaussian rules. The same construction with a weight function $w(x)$ uses the corresponding orthogonal polynomials (Section 22.6): **Gauss–Chebyshev** for $\int_{-1}^{1} f(x)(1-x^2)^{-1/2}dx$ (nodes are Chebyshev nodes, equal weights π/n); **Gauss–Laguerre** for $\int_0^{\infty} f(x)e^{-x}dx$; **Gauss–Hermite** for $\int_{-\infty}^{\infty} f(x)e^{-x^2}dx$ — the natural rule for expectations over Gaussian noise (Ch. 19), e.g. average bit-error rate over a Gaussian-distributed parameter. Variants that include endpoints as nodes (Gauss–Lobatto, Gauss–Radau) underlie spectral-element field solvers and some implicit Runge–Kutta methods.

Adaptive quadrature and difficult integrands

A fixed composite rule wastes evaluations where f is smooth and under-resolves where it is not. **Adaptive** quadrature estimates the error on each subinterval — e.g. by comparing Simpson on $[a,b]$ with Simpson on its two halves, $|S_{\text{halves}} - S_{\text{whole}}|/15$ being an error estimate by Richardson's argument — and recursively bisects only the subintervals that fail the tolerance. Library routines (QUADPACK's `qags`, behind `scipy.integrate.quad`; MATLAB `integral`) use adaptive Gauss–Kronrod pairs, which reuse the Gauss nodes in a higher-order Kronrod extension so the error estimate costs few extra evaluations.

Worked Example 22.33 — An endpoint singularity

$\int_0^1 \sqrt{x}\,dx = \frac{2}{3}$. The integrand is continuous but f' is infinite at 0, so the error constants of the composite rules are infinite and convergence degrades: composite Simpson gives errors -1.3×10^{-3}, -1.6×10^{-4}, -2.0×10^{-5} for $n = 16, 64, 256$ — order $h^{1.5}$ instead of h^4. An adaptive Simpson code with tolerance 10^{-8} concentrates its subintervals near $x = 0$ and reaches an error of 2.6×10^{-11} with 317 evaluations. Better still is to remove the singularity analytically — here the substitution $x = t^2$ gives $\int_0^1 2t^2\,dt$, which Simpson integrates *exactly*.

Infinite intervals and singularities. Transform them away when possible: substitutions ($x = t^2$, $x = \tan t$, $x = t/(1-t)$), subtracting off the singular part and integrating it analytically, or Gaussian rules with the singular weight built in. For oscillatory integrands such as Fourier integrals, specialised (Filon, Levin) methods or the FFT are preferable to general-purpose quadrature.

Common Pitfall — Quadrature on data you cannot refine

When f is a table of measurements, you cannot choose the nodes, so Gaussian quadrature is unavailable, and the "error formulas" involve derivatives of an unknown function. Use composite trapezoid or Simpson (or integrate a spline fit), estimate the error by comparing the rule on all points with the rule on every second point, and remember that noise in the data integrates to a random error of order $\sigma\sqrt{b-a}\sqrt{h}$ — integration, unlike differentiation, *averages* noise down.

Engineering Note — The FFT is a trapezoidal rule

The DFT coefficient $X_k = \sum_{n=0}^{N-1} x[n] e^{-j2\pi kn/N}$ is, up to the factor T/N, the trapezoidal rule for the Fourier-series coefficient $\frac{1}{T}\int_0^T x(t)e^{-jk\omega_0 t}\,dt$ of a periodic signal. Example 22.31 explains why FFT-based spectral analysis of smooth periodic signals is so accurate — and why a *non*-periodic record (a window that does not contain an integer number of periods) loses this accuracy and produces leakage: the endpoint terms of Euler–Maclaurin no longer cancel. RMS meters, power analysers and energy meters integrate sampled $v(t)i(t)$ with exactly these rules.

22.9 Numerical solution of ODEs

The initial-value problem

Most ODEs that describe real systems — nonlinear circuits, motors with saturation, power converters, oscillators, chemical kinetics in batteries — have no closed-form solution. We consider the **initial-value problem (IVP)**

$$\mathbf{y}'(t) = \mathbf{f}(t, \mathbf{y}), \qquad \mathbf{y}(t_0) = \mathbf{y}_0,$$

where $\mathbf{y} \in \mathbb{R}^m$ is the state vector (Ch. 11–12). If $\mathbf{f}$ is continuous and **Lipschitz** in $\mathbf{y}$, $\|\mathbf{f}(t,\mathbf{y}) - \mathbf{f}(t,\mathbf{z})\| \le L\|\mathbf{y}-\mathbf{z}\|$, the solution exists and is unique (Picard–Lindelöf). Higher-order equations are reduced to first-order systems: the series RLC equation $L\ddot{q} + R\dot{q} + q/C = v(t)$ becomes, with $\mathbf{y} = (q, i)$, $i = \dot{q}$,

$$\frac{d}{dt}\begin{bmatrix} q \\ i \end{bmatrix} = \begin{bmatrix} i \\ \big(v(t) - Ri - q/C\big)/L \end{bmatrix}.$$

A numerical method produces approximations $\mathbf{y}_n \approx \mathbf{y}(t_n)$ on a grid $t_n = t_0 + nh$ (or with variable steps h_n).

Euler's method

Replace the derivative at t_n by a forward difference (Section 22.7):

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h\,\mathbf{f}(t_n, \mathbf{y}_n).$$

Geometrically, follow the tangent of the solution curve through $(t_n, \mathbf{y}_n)$ for a time h. Each step is cheap — one evaluation of $\mathbf{f}$ — but, as we shall see, inaccurate.

Local and global truncation error

- The **local truncation error** τ_{n+1} is the error made in one step starting from the exact solution: for Euler, $\tau_{n+1} = y(t_{n+1}) - y(t_n) - hf(t_n, y(t_n)) = \frac{h^2}{2}y''(\xi_n) = O(h^2)$.
- The **global error** is $e_n = y(t_n) - y_n$, the accumulated error at a fixed time t_n.
- A one-step method is **of order** p if its local truncation error is $O(h^{p+1})$; then (under a Lipschitz condition) its global error is $O(h^p)$.

Convergence of Euler's method

Let f be Lipschitz in y with constant L and let $|y''| \le M$ on $[t_0, T]$. Then the Euler iterates satisfy

$$|e_n| \le \frac{Mh}{2L}\left(e^{L(t_n - t_0)} - 1\right), \qquad t_0 \le t_n \le T,$$

so the global error is $O(h)$: Euler's method is first order.

Proof. Subtract the Euler step from the exact relation $y(t_{n+1}) = y(t_n) + hf(t_n, y(t_n)) + \tau_{n+1}$:

$$e_{n+1} = e_n + h\big[f(t_n, y(t_n)) - f(t_n, y_n)\big] + \tau_{n+1} \;\Rightarrow\; |e_{n+1}| \le (1 + hL)|e_n| + \tfrac{M}{2}h^2.$$

With $e_0 = 0$, induction gives $|e_n| \le \frac{M}{2}h^2 \sum_{k=0}^{n-1}(1+hL)^k = \frac{Mh}{2L}\big((1+hL)^n - 1\big)$, and $(1+hL)^n \le e^{nhL}$. $\square$

The proof displays the general mechanism, which we shall meet again in Section 22.11: **global error = (local errors, $O(h^{p+1})$ each) × (number of steps, $O(1/h)$) × (an amplification factor that stays bounded — stability)**.

Worked Example 22.34 — Charging an RC circuit with Euler's method

A capacitor charges through R from a 5 V step, $\tau = RC = 1$ ms: $\dot v = (5 - v)/\tau$, $v(0) = 0$, exact $v = 5(1 - e^{-t/\tau})$. Use $h = 0.2$ ms.

Step 1. $v_1 = 0 + 0.2 \cdot (5 - 0)/1 = 1.0$ V (exact 0.906).

Step 2. $v_2 = 1 + 0.2(5 - 1) = 1.8$ V (exact 1.648).

t (ms)	0.2	0.4	0.6	0.8	1.0
Euler v_n (V)	1.000	1.800	2.440	2.952	3.362
exact (V)	0.906	1.648	2.256	2.753	3.161

Interpretation. Here $v_n = 5\big(1 - (1 - h/\tau)^n\big)$, so Euler replaces $e^{-t/\tau}$ by $(1 - h/\tau)^{t/h} = 0.8^5 = 0.328$ at $t = \tau$ instead of 0.368 — a 6 % error in the voltage at one time constant. Halving h halves the error (first order). Notice also that $0 < 1 - h/\tau < 1$ is needed for the numerical solution to decay monotonically like the true one; this is a *stability* requirement, discussed below.

Runge–Kutta methods

Euler uses the slope only at the start of the step. Runge–Kutta (RK) methods sample the slope at several points within the step and combine the samples so that the Taylor expansion of the numerical solution matches the true one to higher order.

Heun's method (improved Euler, explicit trapezoid), order 2:

$$\mathbf{k}_1 = \mathbf{f}(t_n, \mathbf{y}_n), \quad \mathbf{k}_2 = \mathbf{f}(t_n + h, \mathbf{y}_n + h\mathbf{k}_1), \quad \mathbf{y}_{n+1} = \mathbf{y}_n + \tfrac{h}{2}(\mathbf{k}_1 + \mathbf{k}_2).$$

Explicit midpoint method, also order 2: $\mathbf{k}_2 = \mathbf{f}(t_n + \tfrac{h}{2}, \mathbf{y}_n + \tfrac{h}{2}\mathbf{k}_1)$, $\mathbf{y}_{n+1} = \mathbf{y}_n + h\mathbf{k}_2$.

Why order 2. For scalar $y' = f(t, y)$, the exact solution satisfies $y(t + h) = y + hf + \tfrac{h^2}{2}(f_t + f_y f) + O(h^3)$. Expanding Heun's $k_2 = f + h(f_t + f_y f) + O(h^2)$ gives $y_{n+1} = y + hf + \tfrac{h^2}{2}(f_t + f_y f) + O(h^3)$ — the two expansions agree through h^2, so the local error is $O(h^3)$.

The classical fourth-order Runge–Kutta method (RK4):

$$\begin{aligned} \mathbf{k}_1 &= \mathbf{f}(t_n,\ \mathbf{y}_n), & \mathbf{k}_2 &= \mathbf{f}\big(t_n + \tfrac{h}{2},\ \mathbf{y}_n + \tfrac{h}{2}\mathbf{k}_1\big), \\ \mathbf{k}_3 &= \mathbf{f}\big(t_n + \tfrac{h}{2},\ \mathbf{y}_n + \tfrac{h}{2}\mathbf{k}_2\big), & \mathbf{k}_4 &= \mathbf{f}(t_n + h,\ \mathbf{y}_n + h\mathbf{k}_3), \\ \mathbf{y}_{n+1} &= \mathbf{y}_n + \tfrac{h}{6}\left(\mathbf{k}_1 + 2\mathbf{k}_2 + 2\mathbf{k}_3 + \mathbf{k}_4\right). \end{aligned}$$

When $\mathbf{f}$ depends on t only, RK4 reduces to Simpson's rule (weights $\tfrac{1}{6}, \tfrac{4}{6}, \tfrac{1}{6}$, with the two midpoint samples sharing the middle weight). Four function evaluations per step buy fourth-order accuracy: halving h reduces the error by 16 for only twice the work.

```
def rk4_step(f, t, y, h):
    k1 = f(t, y)
    k2 = f(t + h/2, y + h/2 * k1)
    k3 = f(t + h/2, y + h/2 * k2)
    k4 = f(t + h,   y + h   * k3)
    return y + h/6 * (k1 + 2*k2 + 2*k3 + k4)
```

Worked Example 22.35 — One RK4 step, and observed orders

Solve $y' = y - t^2 + 1$, $y(0) = 0.5$, whose exact solution is $y = (t + 1)^2 - \tfrac{1}{2}e^t$.

One step with $h = 0.2$. $k_1 = f(0, 0.5) = 1.5$; $k_2 = f(0.1,\ 0.5 + 0.1 \cdot 1.5) = f(0.1, 0.65) = 0.65 - 0.01 + 1 = 1.64$; $k_3 = f(0.1,\ 0.5 + 0.1 \cdot 1.64) = f(0.1, 0.664) = 1.654$; $k_4 = f(0.2,\ 0.5 + 0.2 \cdot 1.654) = f(0.2, 0.8308) = 0.8308 - 0.04 + 1 = 1.7908$; $y_1 = 0.5 + \tfrac{0.2}{6}(1.5 + 3.28 + 3.308 + 1.7908) = 0.5 + 0.329293 = 0.829293$. Exact: $y(0.2) = 1.44 - 0.5e^{0.2} = 0.829299$. The one-step error is 5.3×10^{-6}.

Global errors at $t = 2$ (exact $y(2) = 5.305472$):

h	Euler	Heun	RK4
0.2	-0.440	-7.24×10^{-2}	-1.09×10^{-4}
0.1	-0.242	-1.89×10^{-2}	-6.99×10^{-6}
0.05	-0.127	-4.82×10^{-3}	-4.42×10^{-7}
ratio per halving	$\to 2$ (order 1)	3.9 (order 2)	15.8 (order 4)

To reach an error of 10^{-6}, Euler would need $h \approx 4 \times 10^{-7}$ (about five million steps and evaluations); RK4 needs $h \approx 0.06$ — about 33 steps, 130 evaluations.

Step-size control

A fixed step is wasteful: transients need small steps, quiescent intervals large ones. Production integrators (MATLAB `ode45`, SciPy `solve_ivp` with `RK45`) use **embedded Runge–Kutta pairs**, such as Dormand–Prince 5(4): two RK formulas of orders p and $p - 1$ share the same stage evaluations, and their difference estimates the local error err of the lower-order one. The step is accepted if $\text{err} \le \text{tol}$ and the next step is chosen as

$$h_{\text{new}} = h \cdot \min\left(f_{\max},\ \max\left(f_{\min},\ 0.9\left(\frac{\text{tol}}{\text{err}}\right)^{1/p}\right)\right),$$

where the exponent follows from err $\propto h^p$ and the safety factor 0.9 and limits $f_{\min}$, $f_{\max}$ (e.g. 0.2, 5) prevent oscillation. The tolerance is usually mixed, $\text{tol} = \text{atol} + \text{rtol} \cdot |y|$. Note that the controller bounds the *local* error per step; the global error is typically of the same order as the tolerance for well-behaved problems, but is not guaranteed by it.

Multistep methods

Instead of sampling within the step, **linear multistep methods** reuse past values. The second-order **Adams–Bashforth** method,

$$\mathbf{y}_{n+1} = \mathbf{y}_n + \frac{h}{2}\big(3\mathbf{f}_n - \mathbf{f}_{n-1}\big),$$

integrates the linear interpolant of the last two slopes and costs only *one* new evaluation per step. Implicit **Adams–Moulton** methods and the **backward differentiation formulas (BDF)**, e.g. BDF2 $\frac{3}{2}\mathbf{y}_{n+1} - 2\mathbf{y}_n + \frac{1}{2}\mathbf{y}_{n-1} = h\mathbf{f}_{n+1}$, are the workhorses for stiff problems (below). Multistep methods need a starting procedure (a few RK steps) and are more awkward to use with variable steps.

Absolute stability: the test equation

Convergence is a statement about $h \to 0$. In practice h is finite, and a method can produce wildly wrong, exponentially growing answers for a decaying problem if h is too large. The analysis uses the scalar **test equation**

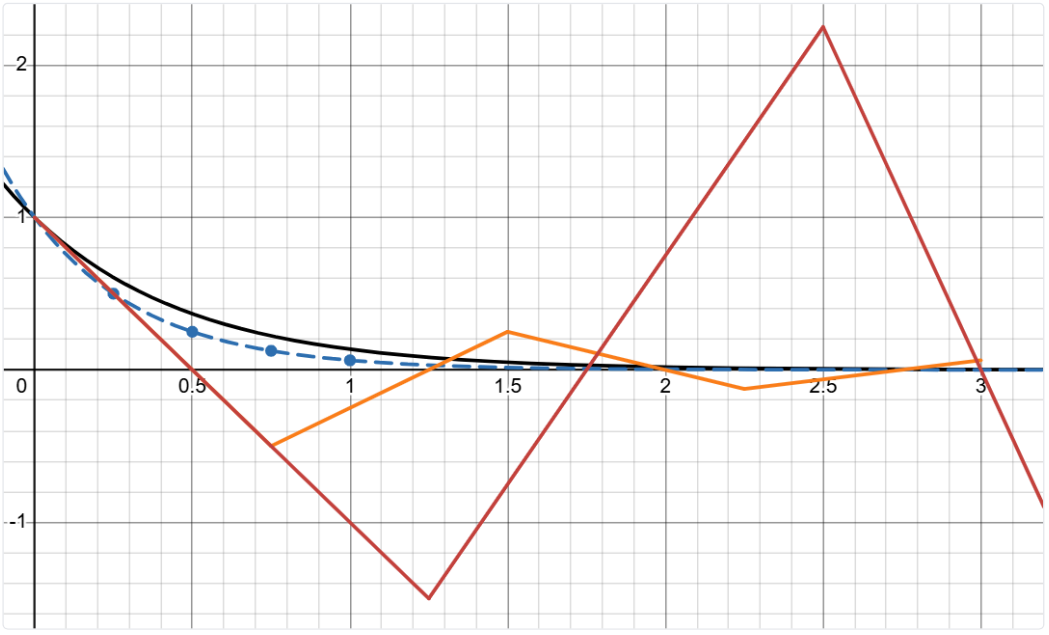
$$y' = \lambda y, \qquad \lambda \in \mathbb{C},\ \operatorname{Re}\lambda < 0,$$

whose solution decays. (It models each eigen-mode of a linear system $\mathbf{y}' = \mathbf{A}\mathbf{y}$, with λ an eigenvalue of $\mathbf{A}$ — Ch. 10.) Applied to it, every RK method gives $y_{n+1} = R(z)\,y_n$ with $z = h\lambda$, where R is the **stability function**:

Method	$R(z)$	Real stability interval
Euler (explicit)	$1 + z$	$-2 \le z \le 0$
Heun / midpoint (RK2)	$1 + z + \frac{z^2}{2}$	$-2 \le z \le 0$
RK4	$1 + z + \frac{z^2}{2} + \frac{z^3}{6} + \frac{z^4}{24}$	$-2.785 \le z \le 0$
backward (implicit) Euler	$\dfrac{1}{1 - z}$	all $z \le 0$
trapezoidal (Crank–Nicolson)	$\dfrac{1 + z/2}{1 - z/2}$	all $z \le 0$

> **Region of absolute stability; A-stability**
>
> The **region of absolute stability** of a method is $\{z \in \mathbb{C} : |R(z)| \le 1\}$. A method is **A-stable** if this region contains the entire left half-plane $\operatorname{Re} z \le 0$, so that the numerical solution decays whenever the true one does, for every step size.

For explicit Euler the region is the disk $|1 + z| \le 1$ of radius 1 centred at $z = -1$. For real $\lambda < 0$ the condition is $h \le 2/|\lambda|$; for monotone (non-oscillating) decay, $h \le 1/|\lambda|$. Explicit methods always have bounded stability regions (their R is a polynomial, which is unbounded); the implicit Euler and trapezoidal rules are A-stable.



Euler's method on $y' = -2y$, $y(0) = 1$ (exact e^{-2t}, black). With $h = 0.25$ ($z = -0.5$, blue) the numerical solution 0.5^n decays monotonically but too fast; with $h = 0.75$ ($z = -1.5$, orange) it oscillates in sign while decaying ($|R| = 0.5$); with $h = 1.25$ ($z = -2.5$, red) $|R| = 1.5 > 1$ and it grows without bound — outside the stability region.

Stiffness

Stiff problem (working definition)

An ODE system is **stiff** when it contains modes with very different time scales — eigenvalues of the Jacobian $\partial \mathbf{f}/\partial \mathbf{y}$ with $\operatorname{Re}\lambda < 0$ and $\max|\operatorname{Re}\lambda| \gg \min|\operatorname{Re}\lambda|$ — such that the step size of an explicit method is limited by **stability** for the fast, already-decayed modes rather than by **accuracy** for the slow mode of interest. The ratio $\max|\operatorname{Re}\lambda|/\min|\operatorname{Re}\lambda|$ is the stiffness ratio.

Stiffness is endemic in electronics: a circuit with a 1 ns parasitic time constant and a 1 ms thermal or bias time constant has stiffness ratio 10^6; an explicit method would need a million steps per millisecond merely to remain stable, long after the fast transient has died.

Implicit methods. Backward Euler,

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h\,\mathbf{f}(t_{n+1}, \mathbf{y}_{n+1}),$$

requires solving a (generally nonlinear) equation for $\mathbf{y}_{n+1}$ at every step — by Newton's method (Section 22.4) with Jacobian $\mathbf{I} - h\,\partial\mathbf{f}/\partial\mathbf{y}$ — but is A-stable, so h can be chosen for accuracy alone. Higher-order stiff solvers (BDF methods in `ode15s` and `solve_ivp(method='BDF')`, implicit RK methods such as Radau IIA) follow the same pattern. The **Dahlquist barrier** limits what is possible: no explicit linear multistep method is A-stable, and an A-stable linear multistep method has order at most 2 (the trapezoidal rule has the smallest error constant among them).

Worked Example 22.36 — A stiff scalar problem

$y' = -1000\,(y - \cos t)$, $y(0) = 0$. After a fast initial transient (e^{-1000t}, time constant 1 ms) the solution follows $y \approx \cos t$ closely. Exact value at $t = 0.1$: $y(0.1) = 0.9951030$. Here $\lambda = -1000$, so explicit Euler is stable only for $h \le 2/1000 = 0.002$.

h	steps to $t = 0.1$	explicit Euler $y(0.1)$	implicit Euler $y(0.1)$
0.001	100	0.9951035	0.9951025
0.0021	48	-96.0	0.9950226
0.01	10	-3.5×10^9	0.9950980

Implicit Euler step. Because f is linear in y, the implicit equation $y_{n+1} = y_n - 1000h\,(y_{n+1} - \cos t_{n+1})$ is solved in closed form: $y_{n+1} = \dfrac{y_n + 1000h\cos t_{n+1}}{1 + 1000h}$.

Lesson. Just 5% beyond the stability limit ($h = 0.0021$, $z = -2.1$, $|R| = 1.1$) explicit Euler explodes; implicit Euler gives a 0.0005 % accurate answer with ten steps. The interesting solution ($\cos t$) varies on a time scale of seconds; only the stability of the method forced explicit Euler to millisecond steps.

Common Pitfall — Energy drift in oscillators

For an undamped LC oscillator, $\ddot{x} + x = 0$, the eigenvalues are $\pm j$ — on the imaginary axis, which lies *outside* the stability region of explicit Euler except at $z = 0$. Euler multiplies the "energy" $x^2 + v^2$ by exactly $1 + h^2$ every step: with $h = 0.1$, after one period (62 steps) the amplitude has grown by a factor $\sqrt{1.853} = 1.36$. Backward Euler errs the other way, damping a lossless circuit. The trapezoidal rule ($|R(j\omega h)| = 1$ exactly) conserves amplitude, and *symplectic* methods (symplectic Euler, Störmer–Verlet/leapfrog) conserve a nearby energy for long times — the methods of choice for lossless systems such as orbits and particle accelerators.

Engineering Note — How SPICE integrates

SPICE's transient analysis uses implicit methods throughout — the **trapezoidal rule** by default and **Gear (BDF) methods** of order 1–2 as alternatives — with Newton iteration at every time point and step control based on a local-truncation-error estimate. The trapezoidal rule's tendency to produce a spurious point-to-point ringing on stiff modes (since $R(z) \to -1$ as $z \to -\infty$: the fast mode is not damped, just sign-flipped) is the reason SPICE offers `method=gear`, whose $R(z) \to 0$ ("L-stability") damps fast modes strongly. When a simulation shows ringing at the time-step frequency, switch the integration method before blaming the circuit.

22.10 Numerical solution of PDEs

Grids and notation

The three model PDEs of Ch. 13 — the **heat (diffusion)** equation, the **wave** equation and the **Laplace/Poisson** equation — are prototypes of the parabolic, hyperbolic and elliptic classes, and each class demands a different numerical strategy. EE instances abound: diffusion of dopants and heat in a chip, the telegrapher's equations on a transmission line, Maxwell's equations in an FDTD simulator, the potential in an electrostatic lens or around a microstrip.

The **finite-difference method** replaces the continuous domain by a grid $x_i = i\,\Delta x$, $t_n = n\,\Delta t$, the unknown function by grid values $u_i^n \approx u(x_i, t_n)$, and every derivative by a difference quotient from Section 22.7. Throughout we use

$$\delta_x^2 u_i^n = u_{i+1}^n - 2u_i^n + u_{i-1}^n, \qquad \frac{\delta_x^2 u_i^n}{\Delta x^2} = u_{xx}(x_i, t_n) + O(\Delta x^2).$$

The heat equation: explicit scheme (FTCS)

For $u_t = \alpha u_{xx}$ on $0 < x < L$ with boundary values $u(0,t)$, $u(L,t)$ and initial data $u(x,0)$, use a **f**orward difference in **t**ime and a **c**entral difference in **s**pace:

$$\frac{u_i^{n+1} - u_i^n}{\Delta t} = \alpha\,\frac{u_{i+1}^n - 2u_i^n + u_{i-1}^n}{\Delta x^2} \quad\Longleftrightarrow\quad u_i^{n+1} = u_i^n + r\left(u_{i+1}^n - 2u_i^n + u_{i-1}^n\right), \qquad r = \frac{\alpha\,\Delta t}{\Delta x^2}.$$

The dimensionless **mesh ratio** r controls everything. The scheme is explicit — each new value comes directly from three old ones — and its truncation error is $O(\Delta t) + O(\Delta x^2)$.

Stability by Fourier modes. Substitute a single grid Fourier mode $u_i^n = G^n e^{j\theta i}$ ($\theta = k\Delta x$) into the scheme:

$$G = 1 + r\left(e^{j\theta} - 2 + e^{-j\theta}\right) = 1 - 2r(1 - \cos\theta) = 1 - 4r\sin^2\frac{\theta}{2}.$$

The true solution mode decays, so we need $|G| \le 1$ for all θ. The worst case is the sawtooth mode $\theta = \pi$ ($u_i \propto (-1)^i$), where $G = 1 - 4r$, and $|1 - 4r| \le 1$ requires

$$\boxed{r = \frac{\alpha\,\Delta t}{\Delta x^2} \le \frac{1}{2}}.$$

This is a severe restriction: **halving Δx forces Δt to be quartered**, so refining the grid by 2 costs 8 times the work in one dimension. (Section 22.11 turns this calculation into the general von Neumann method.)

Worked Example 22.37 — One FTCS step

$u_t = u_{xx}$ on $[0, 1]$, $u = 0$ at both ends, $u(x, 0) = \sin \pi x$; exact solution $u = e^{-\pi^2 t}\sin \pi x$. Take $\Delta x = 0.25$ and $r = 0.25$, so $\Delta t = r\Delta x^2 = 0.015625$.

Initial values. $u^0 = (0,\ 0.707107,\ 1,\ 0.707107,\ 0)$.

Step. $u_1^1 = 0.707107 + 0.25(1 - 2\cdot 0.707107 + 0) = 0.603553$; $u_2^1 = 1 + 0.25(0.707107 - 2 + 0.707107) = 0.853553$; $u_3^1 = u_1^1$ by symmetry.

Compare. Exact: $e^{-\pi^2 \cdot 0.015625} = 0.857090$, so $u(0.25, \Delta t) = 0.606054$, $u(0.5, \Delta t) = 0.857090$. The numerical mode is multiplied by $G = 1 - 4(0.25)\sin^2(\pi/8) = 0.853553$ per step versus the exact factor 0.857090 — an error of 0.4 % per step from the coarse grid.

Worked Example 22.38 — Watching FTCS go unstable

Same problem with $\Delta x = 0.05$ (21 points), run to $t \approx 0.1$, with a tiny perturbation $10^{-6}(-1)^i$ (think rounding noise) added to the initial data.

r	steps	$\max_i \lvert u_i - u_{\text{exact}}\rvert$
0.50	80	1.5×10^{-3} (truncation error only)
0.60	67	3.9×10^{3}

At $r = 0.6$ the sawtooth mode has $G = 1 - 2.4 = -1.4$; after 67 steps it has grown by $1.4^{67} \approx 6 \times 10^9$, turning the 10^{-6} perturbation into thousands. Instability amplifies *whatever* high-frequency content is present — rounding error suffices — so an unstable scheme is useless however small the perturbation.

Implicit schemes: BTCS and Crank–Nicolson

Evaluating the spatial difference at the *new* time level gives the **backward-time (BTCS) scheme**

$$-r\,u_{i-1}^{n+1} + (1 + 2r)\,u_i^{n+1} - r\,u_{i+1}^{n+1} = u_i^n,$$

a **tridiagonal** linear system per step (solved in $O(N)$ by the Thomas algorithm, as for splines). Its amplification factor $G = 1/(1 + 4r\sin^2(\theta/2))$ satisfies $0 < G \le 1$ for *every* r: the scheme is **unconditionally stable**, though still only first order in time.

Averaging the explicit and implicit schemes gives **Crank–Nicolson**:

$$\frac{u_i^{n+1} - u_i^n}{\Delta t} = \frac{\alpha}{2}\left(\frac{\delta_x^2 u_i^{n+1}}{\Delta x^2} + \frac{\delta_x^2 u_i^n}{\Delta x^2}\right), \qquad G = \frac{1 - 2r\sin^2(\theta/2)}{1 + 2r\sin^2(\theta/2)},$$

second order in both Δt and Δx and unconditionally stable ($|G| \le 1$ always). It is the trapezoidal rule of Section 22.9 in disguise, and it inherits the trapezoidal rule's weakness: for large r the high-frequency modes have $G \to -1$ (at $r = 5$, $\theta = \pi$: $G = -9/11 = -0.82$), so sharp initial data (a step in temperature, a switched voltage) produce slowly decaying point-to-point oscillations. A few initial BTCS steps ("Rannacher smoothing") suppress them.

The method-of-lines view

Discretising *only in space* turns the PDE into a system of ODEs, $\dot{\mathbf{u}} = \frac{\alpha}{\Delta x^2}\mathbf{T}\mathbf{u}$, where $\mathbf{T} = \text{tridiag}(1, -2, 1)$. The eigenvalues of $\mathbf{T}$ (Ch. 10) are $-4\sin^2\left(\frac{k\pi}{2(N+1)}\right)$, so the ODE eigenvalues range from about $-\alpha\pi^2/L^2$ (the slow fundamental mode) to about $-4\alpha/\Delta x^2$ (the fast grid-scale mode). The system is therefore **stiff**, with stiffness ratio $\sim (2L/(\pi\Delta x))^2$, growing as the grid is refined. FTCS is explicit Euler on this system and its stability limit $\Delta t \cdot 4\alpha/\Delta x^2 \le 2$ is exactly $r \le \frac{1}{2}$; BTCS and Crank–Nicolson are implicit Euler and the trapezoidal rule. The method of lines thus lets any stiff ODE solver from Section 22.9 serve as a PDE solver — a common and powerful approach.

The wave equation and the CFL condition

For $u_{tt} = c^2 u_{xx}$, central differences in both variables give the explicit **leapfrog** scheme

$$u_i^{n+1} = 2u_i^n - u_i^{n-1} + C^2\left(u_{i+1}^n - 2u_i^n + u_{i-1}^n\right), \qquad C = \frac{c\,\Delta t}{\Delta x},$$

second order in both variables. C is the **Courant number**. The first step needs u^{-1}; with initial velocity $u_t(x, 0) = g(x)$, the central-difference condition $u_i^1 - u_i^{-1} = 2\Delta t\, g_i$ gives $u_i^1 = u_i^0 + \Delta t\, g_i + \frac{C^2}{2}\delta_x^2 u_i^0$.

Courant–Friedrichs–Lewy (CFL) condition

A necessary condition for the convergence of an explicit difference scheme for a hyperbolic equation is that the **numerical domain of dependence contain the physical domain of dependence**. For the leapfrog scheme for $u_{tt} = c^2 u_{xx}$ (and for upwind schemes for $u_t + c u_x = 0$) this is

$$C = \frac{c\,\Delta t}{\Delta x} \le 1,$$

and for leapfrog it is also sufficient for stability.

Reasoning. The exact solution at (x_i, t_n) depends on initial data in $[x_i - ct_n,\ x_i + ct_n]$ (d'Alembert, Ch. 13). The scheme's value u_i^n depends only on initial grid values in $[x_i - n\Delta x,\ x_i + n\Delta x]$ since information moves one cell per step. If $c\Delta t > \Delta x$ the numerical interval is smaller than the physical one, and changing the initial data in the gap changes the true solution but not the numerical one — so the scheme cannot converge. Von Neumann analysis confirms it: the amplification factors satisfy $G^2 - 2\big(1 - 2C^2\sin^2\tfrac{\theta}{2}\big)G + 1 = 0$, whose roots have $|G| = 1$ if $C \le 1$, while for $C > 1$ one root has $|G| > 1$ at $\theta = \pi$. $\square$

Worked Example 22.39 — The CFL limit in action

A plucked string: $c = 1$, $u = \sin \pi x$ at $t = 0$, $u_t = 0$, fixed ends, $\Delta x = 0.05$, run to $t = 2$ (one full period); exact $u = \cos(\pi t)\sin(\pi x)$. A 10^{-6} sawtooth perturbation is added to the initial data.

Courant number C	steps	max error at $t \approx 2$
1.00	40	1.0×10^{-6} (only the perturbation)
0.50	80	1.2×10^{-5}
1.05	38	7.2×10^{3}

Why $C = 1$ is exact. With $C = 1$ the scheme becomes $u_i^{n+1} = u_{i+1}^n + u_{i-1}^n - u_i^{n-1}$, which is satisfied exactly by any $F(x - ct) + G(x + ct)$ on the grid: the "magic time step" reproduces d'Alembert's solution. For $C < 1$ the scheme is stable but **dispersive** (different wavelengths travel at slightly wrong, different speeds). For $C = 1.05$, only 5 % over the limit, the sawtooth mode grows explosively.

First-order hyperbolic equations. For the advection equation $u_t + a\,u_x = 0$ ($a > 0$, a signal travelling along a lossless line), the natural explicit scheme takes the spatial difference **upwind** (from the side the information comes from):

$$u_i^{n+1} = u_i^n - C\left(u_i^n - u_{i-1}^n\right), \qquad C = \frac{a\Delta t}{\Delta x} \le 1.$$

It is stable for $0 \le C \le 1$, first order, and numerically diffusive (it smears sharp fronts). The tempting FTCS version with a central difference $u_{i+1}^n - u_{i-1}^n$ is **unconditionally unstable** ($|G|^2 = 1 + C^2\sin^2\theta > 1$) — a scheme that is perfectly consistent but useless, illustrating that consistency is not enough (Section 22.11). Second-order schemes (Lax–Wendroff, leapfrog) reduce diffusion at the cost of dispersive wiggles near discontinuities.

Engineering Note — FDTD and the Courant limit

The finite-difference time-domain (FDTD, Yee) method for Maxwell's equations is a staggered leapfrog scheme for $\mathbf{E}$ and $\mathbf{H}$. Its stability limit in 3-D on a cubic grid is $c\,\Delta t \le \Delta x/\sqrt{3}$ — the CFL condition with the 3-D domain of dependence. One consequence: halving the cell size to resolve a fine feature (a thin trace, a narrow slot) halves the allowable time step for the *whole* simulation, so run time scales like $(\Delta x)^{-4}$. This is why FDTD codes offer sub-gridding and why frequency-domain (FEM, MoM) solvers compete for electrically small fine structure.

Laplace's and Poisson's equations

Elliptic problems have no time variable: the potential in a region is determined all at once by its boundary values. For Poisson's equation $\nabla^2 V = -\rho/\varepsilon$ on a square grid with spacing h, the **five-point stencil**

$$\frac{V_{i+1,j} + V_{i-1,j} + V_{i,j+1} + V_{i,j-1} - 4V_{i,j}}{h^2} = -\frac{\rho_{i,j}}{\varepsilon}$$

has truncation error $O(h^2)$. For Laplace's equation ($\rho = 0$) it says each interior value is the **average of its four neighbours** — the discrete mean-value property, which also yields a discrete maximum principle (no interior extrema), mirroring the continuous theory of Ch. 13. Writing one equation per interior node gives a large, sparse, symmetric positive-definite linear system $\mathbf{A}\mathbf{V} = \mathbf{b}$, with boundary values moved into $\mathbf{b}$.

Worked Example 22.40 — Potential in a square trough

A square region has its top side at 100 V and the other three sides grounded. Use $h = \frac{1}{4}$ of the side, giving a 3×3 array of interior nodes.

Equations. For each interior node, $4V_{i,j} - (\text{sum of neighbours}) = (\text{sum of neighbouring boundary values})$. For example the top-left node: $4V_{1,1} - V_{1,2} - V_{2,1} = 100$; the centre: $4V_{2,2} - V_{1,2} - V_{3,2} - V_{2,1} - V_{2,3} = 0$.

Solution (by symmetry 6 unknowns, solved directly):

row	left	centre	right
top ($y = \frac{3}{4}$)	42.857	52.679	42.857
middle ($y = \frac{1}{2}$)	18.750	25.000	18.750
bottom ($y = \frac{1}{4}$)	7.143	9.821	7.143

Check. The centre value 25 V is exact even on this coarse grid: by superposition, the four problems with one side at 100 V sum to a box entirely at 100 V, so each contributes 25 V at the centre — and the discrete problem has the same symmetry. The Fourier-series solution (Ch. 13) gives 25.000 as well. Each value is also the average of its neighbours, e.g. $(100 + 18.75 + 52.679 + 0)/4 = 42.857$ for the top-left node.

Iterative solution. Real grids have 10^4–10^8 nodes, and direct elimination fills in the sparse matrix. The classical iterations sweep the grid repeatedly:

- **Jacobi:** replace every $V_{i,j}$ by the average of its neighbours' *old* values.
- **Gauss–Seidel:** use new values as soon as they are available (sweeping in order); converges twice as fast as Jacobi for this problem.
- **Successive over-relaxation (SOR):** $V_{i,j} \leftarrow (1-\omega)V_{i,j} + \omega \cdot (\text{Gauss–Seidel value})$ with $1 < \omega < 2$; for the square with N intervals per side the optimal factor is $\omega_{\text{opt}} = 2/(1 + \sin(\pi/N))$.

For the model problem the Jacobi iteration matrix has spectral radius $\cos(\pi h) \approx 1 - \frac{\pi^2 h^2}{2}$, so the number of iterations to reduce the error by a fixed factor grows like h^{-2} (Gauss–Seidel: same order, half the count); optimal SOR's radius $\approx 1 - 2\pi h$ makes it grow only like h^{-1}. In Example 22.40, reducing the error below 10^{-6} from a zero start takes 51 Jacobi, 25 Gauss–Seidel and 12 SOR sweeps ($\omega_{\text{opt}} = 2/(1+\sin(\pi/4)) = 1.172$). Modern solvers use preconditioned conjugate gradients and multigrid, whose cost is nearly proportional to the number of unknowns (Ch. 24).

```
import numpy as np
def laplace_sor(V, fixed, omega=1.8, tol=1e-8, maxit=10000):
    """V: 2-D array with boundary values set; fixed: boolean mask of Dirichlet nodes."""
    for it in range(maxit):
        delta = 0.0
        for i in range(1, V.shape[0] - 1):
            for j in range(1, V.shape[1] - 1):
                if fixed[i, j]:
                    continue
                gs = 0.25 * (V[i+1, j] + V[i-1, j] + V[i, j+1] + V[i, j-1])
                new = (1 - omega) * V[i, j] + omega * gs
                delta = max(delta, abs(new - V[i, j]))
                V[i, j] = new
        if delta < tol:
            return V, it + 1
    return V, maxit
```

Boundary conditions. Dirichlet values (fixed potentials, electrode voltages) enter $\mathbf{b}$ directly. A Neumann condition $\partial V/\partial n = g$ (a symmetry plane, an insulating boundary) is imposed with a **ghost point** outside the domain: at $x = 0$, the central difference $(V_{1,j} - V_{-1,j})/(2h) = g$ eliminates $V_{-1,j}$ from the stencil while keeping second-order accuracy. Curved boundaries and material interfaces (dielectric steps, where $\varepsilon\,\partial V/\partial n$ must be continuous) need modified stencils; this is where finite-element methods, which handle unstructured meshes naturally, usually take over.

Common Pitfall — Accuracy near corners and edges

The $O(h^2)$ error estimate assumes the solution is smooth. Near re-entrant corners and electrode edges, fields are singular (e.g. $E \propto r^{-1/3}$ near a 90° re-entrant corner, $r^{-1/2}$ near a thin conductor's edge) and convergence degrades sharply. Quantities computed from derivatives — fields, capacitance per unit length from surface charge — suffer most. Refine locally near singularities, or extract capacitance from a variational (energy) expression, which is less sensitive.

22.11 Stability and convergence

Three properties of a discretisation

Every section of this chapter has met the same pattern: a discretisation that looks accurate (small truncation error) may still produce garbage (Examples 22.9, 22.36, 22.38, 22.39). This final section isolates the concepts that explain the pattern and states the theorems that make them precise. We phrase them for a linear time-dependent problem $u_t = \mathcal{L}u$ (with $\mathcal{L}$ a spatial differential operator) discretised by a one-step scheme

$$\mathbf{u}^{n+1} = \mathbf{C}(\Delta t)\,\mathbf{u}^{n},$$

where $\mathbf{u}^n$ is the vector of grid values and $\mathbf{C}$ the **solution (amplification) operator** of the scheme, with the grid spacing Δx tied to Δt by a fixed rule (e.g. r or C held constant). The same ideas apply to ODE solvers ($\mathbf{C} = R(h\mathbf{A})$ for $\mathbf{y}' = \mathbf{A}\mathbf{y}$) and to elliptic problems.

Consistency, stability, convergence

- **Consistency.** The scheme is consistent if its **local truncation error** — the residual $\boldsymbol{\tau}^n = \left(\mathbf{u}_{\text{exact}}^{n+1} - \mathbf{C}\,\mathbf{u}_{\text{exact}}^{n}\right)/\Delta t$ obtained by inserting the exact solution — tends to zero as $\Delta t, \Delta x \to 0$. It is consistent **of order** (p, q) if $\|\boldsymbol{\tau}\| = O(\Delta t^p + \Delta x^q)$.
- **Stability.** The scheme is stable (in the sense of Lax–Richtmyer) if for every $T > 0$ there is a constant K_T, independent of Δt and Δx, such that

$$\|\mathbf{C}(\Delta t)^n\| \le K_T \qquad \text{for all } n \text{ with } n\Delta t \le T.$$

- **Convergence.** The scheme is convergent if, for every initial condition (in a suitable class), $\max_{n\Delta t \le T} \|\mathbf{u}^n - \mathbf{u}_{\text{exact}}(t_n)\| \to 0$ as $\Delta t, \Delta x \to 0$.

Consistency is a local, *one-step* property and is checked by Taylor expansion. Stability is a global property of *many steps*: errors introduced at any time (truncation, rounding, data) must not be amplified without bound. Convergence is what we actually want, but it is hard to verify directly, because it involves the unknown exact solution.

The Lax equivalence theorem

Lax equivalence theorem (Lax–Richtmyer, 1956)

For a consistent finite-difference approximation to a **well-posed linear** initial-value problem,

$$\text{stability} \iff \text{convergence}.$$

Moreover, a stable scheme that is consistent of order (p, q) converges with the same order: $\|\mathbf{e}^n\| = O(\Delta t^p + \Delta x^q)$.

Proof of the important direction (stability + consistency ⇒ convergence). Let $\mathbf{e}^n = \mathbf{u}_{\text{exact}}^n - \mathbf{u}^n$. By the definition of $\boldsymbol{\tau}$,

$$\mathbf{u}_{\text{exact}}^{n+1} = \mathbf{C}\,\mathbf{u}_{\text{exact}}^{n} + \Delta t\,\boldsymbol{\tau}^n, \qquad \mathbf{u}^{n+1} = \mathbf{C}\,\mathbf{u}^n \quad\Longrightarrow\quad \mathbf{e}^{n+1} = \mathbf{C}\,\mathbf{e}^n + \Delta t\,\boldsymbol{\tau}^n.$$

Unrolling with $\mathbf{e}^0 = \mathbf{0}$:

$$\mathbf{e}^n = \Delta t \sum_{k=0}^{n-1} \mathbf{C}^{\,n-1-k}\boldsymbol{\tau}^k \quad\Longrightarrow\quad \|\mathbf{e}^n\| \le \Delta t \sum_{k=0}^{n-1} K_T \|\boldsymbol{\tau}^k\| \le K_T\, T \max_k \|\boldsymbol{\tau}^k\|.$$

Consistency makes the right side tend to zero, at the rate of the truncation error. □

This is the same "local error × number of steps × bounded amplification" argument as for Euler's method in Section 22.9 — now in its general form. The converse (convergence ⇒ stability) uses the uniform boundedness principle of functional analysis.

The practical value of the theorem is enormous: **to prove that a linear scheme converges, check consistency (Taylor series) and stability (usually von Neumann analysis); you never need the exact solution.** It also explains the failures we saw — FTCS for the heat equation with $r > \tfrac{1}{2}$, leapfrog with $C > 1$, central-space FTCS for advection — all consistent, all unstable, therefore all non-convergent.

Common Pitfall — The scope of the Lax theorem

The theorem is for **linear** problems. For nonlinear PDEs (shock-forming conservation laws, nonlinear diffusion) stability of the linearised scheme is necessary but not sufficient, and convergence may be to a wrong (non-physical) weak solution unless the scheme is also *conservative* and satisfies an *entropy* condition (Lax–Wendroff theorem). Also, "stable" is relative to a norm: a scheme can be stable in ℓ^2 but produce overshoots in max-norm.

Von Neumann (Fourier) stability analysis

For linear constant-coefficient schemes on uniform grids (with periodic boundaries, or away from boundaries), Fourier modes $u_i^n = G^n e^{j\theta i}$ diagonalise the solution operator, and $\|\mathbf{C}^n\|_2 = \max_\theta |G(\theta)|^n$ by Parseval's theorem (Ch. 15–16).

Von Neumann stability condition

A one-step, constant-coefficient scheme with amplification factor $G(\theta, \Delta t)$ is stable in ℓ^2 if and only if

$$|G(\theta, \Delta t)| \le 1 + K\Delta t \qquad \text{for all } \theta \in [-\pi, \pi]$$

and some constant K independent of $\Delta t, \Delta x$. For problems whose exact solutions do not grow, the practical form is $|G| \le 1$.

The allowance $1 + K\Delta t$ permits physically growing solutions (e.g. $u_t = u_{xx} + u$): then $|G|^n \le e^{KT}$, still bounded. For multi-level schemes (leapfrog), one analyses the matrix amplification factor or the characteristic equation for G, requiring its roots to satisfy $|G| \le 1$ (and simple roots on the unit circle).

Recipe.

1. Substitute $u_i^n = G^n e^{j\theta i}$ into the homogeneous scheme.
2. Divide by $G^n e^{j\theta i}$ and solve for $G(\theta)$.
3. Find the conditions on the mesh ratios under which $\max_\theta |G| \le 1$.

Worked Example 22.41 — Von Neumann analysis of the upwind scheme

Scheme: $u_i^{n+1} = u_i^n - C(u_i^n - u_{i-1}^n)$ for $u_t + au_x = 0$, $C = a\Delta t/\Delta x$.

Step 1–2. $G = 1 - C\left(1 - e^{-j\theta}\right) = (1 - C) + Ce^{-j\theta}$.

Step 3. $|G|^2 = (1 - C + C\cos\theta)^2 + C^2\sin^2\theta = 1 - 2C(1 - C)(1 - \cos\theta)$. For $0 \le C \le 1$, $C(1 - C) \ge 0$ and $|G| \le 1$ for all θ: **stable**. For $C > 1$ (or $C < 0$, i.e. "downwind"), $C(1 - C) < 0$ and $|G| > 1$ for $\theta \ne 0$: **unstable**. The von Neumann condition reproduces the CFL condition.

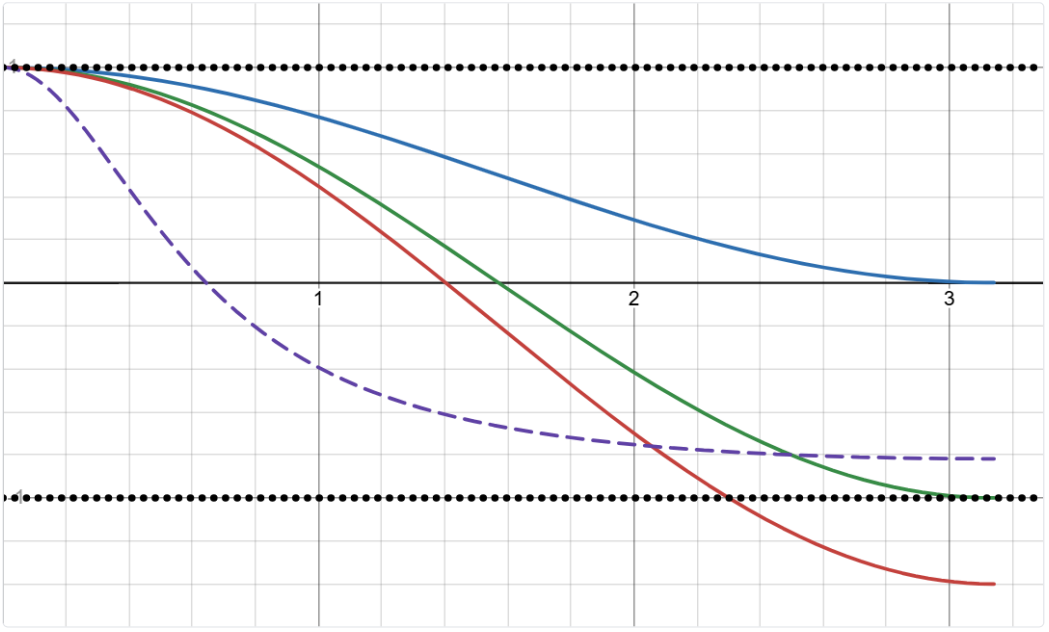
Numerical check ($C = 0.5$): $|G|^2 = 1,\ 0.854,\ 0.5,\ 0.146,\ 0$ at $\theta = 0,\ \pi/4,\ \pi/2,\ 3\pi/4,\ \pi$. The short-wavelength modes are strongly damped — the numerical diffusion of the upwind scheme.

Worked Example 22.42 — Stability of the heat-equation schemes compared

From Section 22.10, with $s = \sin^2(\theta/2) \in [0, 1]$:

Scheme	$G(\theta)$	Condition	Order
FTCS (explicit)	$1 - 4rs$	$r \le \frac{1}{2}$	$(1, 2)$
BTCS (implicit)	$\dfrac{1}{1 + 4rs}$	none (unconditional)	$(1, 2)$
Crank–Nicolson	$\dfrac{1 - 2rs}{1 + 2rs}$	none (unconditional)	$(2, 2)$

The exact amplification of mode θ over one step is $e^{-\alpha k^2 \Delta t} = e^{-r\theta^2}$; all three schemes match it for small θ (well-resolved modes), and differ only in how they treat grid-scale modes. Only FTCS can *amplify* them.



FTCS amplification factor $G(\theta) = 1 - 4r\sin^2(\theta/2)$ versus $\theta \in [0, \pi]$ for $r = 0.25$ (blue), 0.5 (green, just touching -1 at $\theta = \pi$) and 0.6 (red, dropping below -1: unstable), with Crank–Nicolson at $r = 5$ (purple dashed), which stays inside $[-1, 1]$ but approaches -1 for grid-scale modes.

Stability for ODE methods: zero-stability and absolute stability

For ODE solvers two different stability notions are needed, and it is important not to confuse them.

Zero-stability concerns $h \to 0$ on a *fixed* interval and is the ODE counterpart of Lax–Richtmyer stability. For a linear multistep method $\sum_{k=0}^{s} \alpha_k y_{n+k} = h\sum_{k=0}^{s} \beta_k f_{n+k}$, it is governed by the **first characteristic polynomial** $\rho(\zeta) = \sum \alpha_k \zeta^k$.

Dahlquist equivalence theorem

A linear multistep method is convergent if and only if it is **consistent** ($\rho(1) = 0$, $\rho'(1) = \sum \beta_k$) and **zero-stable**: all roots of $\rho(\zeta)$ satisfy $|\zeta| \le 1$, and roots on the unit circle are simple (the **root condition**). All one-step methods (Euler, RK) are automatically zero-stable.

Worked Example 22.43 — A high-order method that does not converge

The explicit two-step method

$$y_{n+2} + 4y_{n+1} - 5y_n = h\,(4f_{n+1} + 2f_n)$$

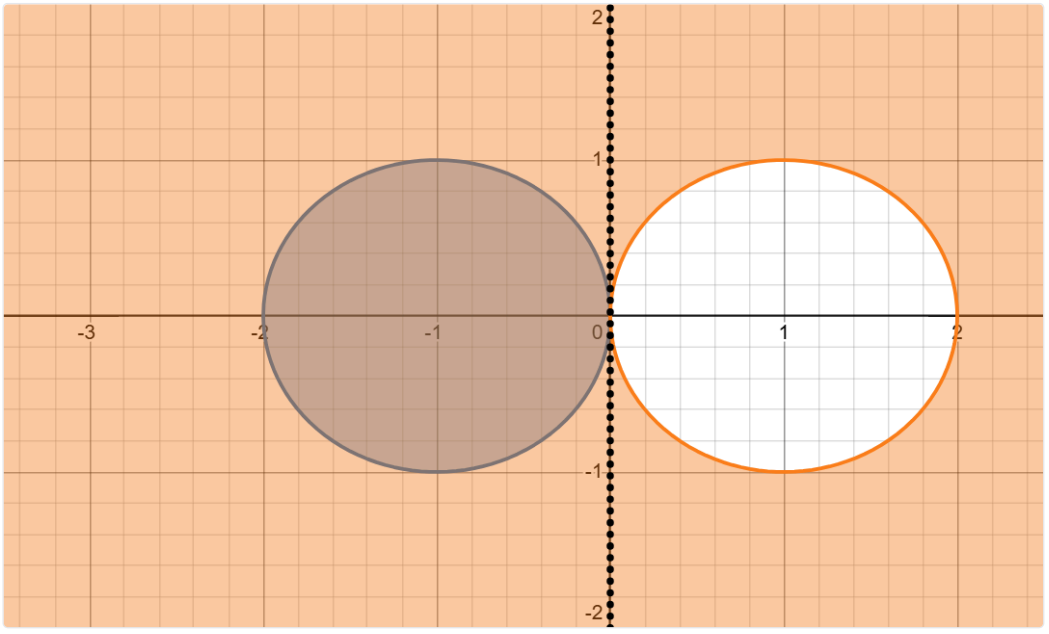
has the highest possible order (3) for its form — its truncation error is tiny. But $\rho(\zeta) = \zeta^2 + 4\zeta - 5 = (\zeta - 1)(\zeta + 5)$ has the root -5: the root condition fails.

Experiment on $y' = -y$, $y(0) = 1$, with exact starting values, integrating to $t = 1$ (exact $e^{-1} = 0.368$):

h	**0.1**	**0.05**	**0.025**
y_N	-6.68	-4.65×10^{6}	-2.88×10^{19}

The results get *worse* as h decreases: the parasitic solution $(-5)^n$ is excited by rounding and truncation errors and grows faster when there are more steps. Consistency with high order, yet no convergence — the Dahlquist (and Lax) theorems in action.

Absolute stability (Section 22.9) concerns a *fixed* step $h > 0$ applied to a decaying problem, and requires $h\lambda$ to lie in the stability region for every eigenvalue λ of the Jacobian. A method can be zero-stable and convergent but useless at practical step sizes on stiff problems because its absolute stability region is small.



Absolute stability regions in the complex $z = h\lambda$ plane: explicit Euler, $|1 + z| \le 1$ (blue disk centred at -1); implicit Euler, $|1 - z| \ge 1$ (orange, everything outside the disk centred at $+1$), which contains the whole left half-plane — A-stability. The imaginary axis (dotted) is where undamped oscillators live, outside the explicit Euler region.

Dissipation, dispersion and the modified equation

Stability guarantees that errors stay bounded; it says nothing about their *character*. Writing $G = |G|e^{-j\omega_{\text{num}}\Delta t}$ for a wave-like problem and comparing with the exact factor $e^{-j\omega\Delta t}$:

- $|G| < 1$ where the exact mode is undamped is **numerical dissipation** (amplitude error): sharp features are smeared;
- $\omega_{\text{num}} \neq \omega$ is **numerical dispersion** (phase error): different wavelengths travel at wrong and different speeds, producing trailing or leading wiggles.

The **modified equation** makes these effects quantitative: it is the PDE that the scheme solves *more accurately* than the original one, obtained by Taylor-expanding the scheme and eliminating time derivatives. For the upwind scheme,

$$u_t + a u_x = \frac{a\Delta x}{2}(1 - C)\,u_{xx} + O(\Delta x^2),$$

so upwinding is, to leading order, the advection equation plus an artificial diffusion with coefficient $\frac{a\Delta x}{2}(1 - C)$ — positive (hence stable) exactly when $0 \le C \le 1$, and zero at $C = 1$, the exact "magic" step. For leapfrog and Lax–Wendroff the leading error term is u_{xxx}, a dispersive term, which explains their oscillations near fronts. In FDTD simulations numerical dispersion makes waves travel slightly slower than c, with an error depending on direction and on the number of cells per wavelength — the reason for the rule of thumb of at least 10–20 cells per wavelength.

Verifying convergence in practice

The theorems tell us what *should* happen; verification checks that our code does it.

1. **Grid-refinement study.** Run on grids $h, h/2, h/4$; with a known exact solution, compute the observed order $p \approx \log_2(E_h/E_{h/2})$ (Section 22.2). Without one, use three grids: $p \approx \log_2 \dfrac{u_h - u_{h/2}}{u_{h/2} - u_{h/4}}$.
2. **Method of manufactured solutions.** Pick any smooth $u_{\text{m}}(x,t)$, compute the source term $f = (u_{\text{m}})_t - \mathcal{L}u_{\text{m}}$ symbolically, add f to the code, and check that the numerical solution converges to u_{m} at the design order. This tests every term, including boundary conditions.

3. **Richardson extrapolation** of the finest results to estimate the remaining discretisation error (as in Sections 22.7–22.8).
4. **Conservation checks.** Total charge, energy or mass that the PDE conserves should be conserved by the scheme to the expected accuracy.

> **Engineering Note — Reading a simulator's warnings**
>
> "Time step too small", "timestep reduced below minimum", "Courant number exceeded", "solution diverging" — these messages are the stability theory of this section surfacing in commercial tools. An explicit electromagnetic or thermal solver chooses its time step from the CFL or $r \le \frac{1}{2}$ condition applied to the *smallest* cell; an implicit solver chooses it for accuracy but may fail when its Newton iteration does not converge. Before trusting a simulation, perform at least one refinement study: halve the mesh size (and time step) and check that the quantity you care about changes by roughly the amount the method's order predicts.

Summary

Topic	Key formula or result	Notes
Floating point	$x = \pm(1.f)_2 \times 2^e$; $\mathrm{fl}(a \circ b) = (a \circ b)(1+\delta)$, $\lvert\delta\rvert \le u$	double: $u = 2^{-53} \approx 1.1 \times 10^{-16}$, $\varepsilon_M = 2^{-52}$
Cancellation	relative error of $a-b$ amplified by $\lvert a\rvert/\lvert a-b\rvert$	rewrite formulas (e.g. $1-\cos x = 2\sin^2\frac{x}{2}$)
Condition number	$\kappa_f = \lvert x f'(x)/f(x)\rvert$; $\kappa(\mathbf{A}) = \lVert\mathbf{A}\rVert\lVert\mathbf{A}^{-1}\rVert$	lose $\approx \log_{10}\kappa$ digits
Stability (algorithm)	forward error $\lesssim \kappa\times$ backward error	backward stable $\Rightarrow$ error $\approx \kappa u$
Observed order	$p \approx \ln(E_1/E_2)/\ln(h_1/h_2)$	the key debugging test
Bisection	$\lvert m_k - x^*\rvert \le (b-a)/2^{k+1}$	guaranteed, 1 bit per step
Fixed point	$x_{k+1} = g(x_k)$; converges if $\lvert g'\rvert \le L < 1$; $e_{k+1} \approx g'(x^*)e_k$	linear unless $g'(x^*) = 0$
Newton–Raphson	$x_{k+1} = x_k - f(x_k)/f'(x_k)$; $e_{k+1} \approx \frac{f''}{2f'}e_k^2$	quadratic; local; linear at multiple roots
Newton (systems)	$\mathbf{J}(\mathbf{x}_k)\Delta\mathbf{x} = -\mathbf{F}(\mathbf{x}_k)$	solve, never invert
Secant	$x_{k+1} = x_k - f_k\frac{x_k - x_{k-1}}{f_k - f_{k-1}}$	order $\varphi = 1.618$
Lagrange interpolation	$p_n = \sum y_i\ell_i$, $\ell_i = \prod_{j\ne i}\frac{x-x_j}{x_i-x_j}$	unique, degree $\le n$
Interpolation error	$f - p_n = \frac{f^{(n+1)}(\xi)}{(n+1)!}\prod(x-x_i)$	Runge phenomenon for equispaced nodes
Chebyshev nodes	$x_i = \cos\frac{(2i+1)\pi}{2(n+1)}$; $\max\lvert\omega_{n+1}\rvert = 2^{-n}$	near-optimal; $\Lambda_n \sim \frac{2}{\pi}\ln n$
Cubic spline	tridiagonal system for $M_i = S''(x_i)$; error $\frac{5}{384}h^4\lVert f^{(4)}\rVert$	minimum curvature
Least squares	$\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{a} = \mathbf{A}^{\mathsf{T}}\mathbf{y}$ (solve by QR)	orthogonal polynomials decouple coefficients
Minimax	error equioscillates at $n+2$ points	Remez; equiripple filters
Forward difference	$\frac{f(x+h)-f(x)}{h} = f' + \frac{h}{2}f''$	$h_{\text{opt}} \sim \sqrt{u}$
Central difference	$\frac{f(x+h)-f(x-h)}{2h} = f' + \frac{h^2}{6}f'''$	$h_{\text{opt}} \sim u^{1/3}$
Second difference	$\frac{f_1 - 2f_0 + f_{-1}}{h^2} = f'' + \frac{h^2}{12}f^{(4)}$	
Richardson	$R = \frac{2^p D(h/2) - D(h)}{2^p - 1}$	also gives error estimate
Composite trapezoid	$T_n = h[\frac{1}{2}f_0 + f_1 + \cdots + \frac{1}{2}f_n]$, $E = -\frac{(b-a)h^2}{12}f''$	spectral for periodic f
Composite Simpson	$S_n = \frac{h}{3}[f_0 + 4f_1 + 2f_2 + \cdots + f_n]$, $E = -\frac{(b-a)h^4}{180}f^{(4)}$	exact for cubics
Gauss–Legendre	n nodes = zeros of P_n; exact for degree $2n-1$	2-pt: $\pm 1/\sqrt{3}$, weights 1
Euler	$\mathbf{y}_{n+1} = \mathbf{y}_n + h\mathbf{f}(t_n, \mathbf{y}_n)$	order 1; stable for $\lvert 1 + h\lambda\rvert \le 1$
RK4	$\mathbf{y}_{n+1} = \mathbf{y}_n + \frac{h}{6}(\mathbf{k}_1 + 2\mathbf{k}_2 + 2\mathbf{k}_3 + \mathbf{k}_4)$	order 4; real stability limit $h\lambda \ge -2.785$
Implicit Euler / trapezoid	$R(z) = \frac{1}{1-z}$, $\frac{1+z/2}{1-z/2}$	A-stable; for stiff problems
Heat equation FTCS	$u_i^{n+1} = u_i^n + r\,\delta_x^2 u_i^n$, $r = \frac{\alpha\Delta t}{\Delta x^2} \le \frac{1}{2}$	BTCS, Crank–Nicolson unconditionally stable
Wave equation leapfrog	$u_i^{n+1} = 2u_i^n - u_i^{n-1} + C^2\delta_x^2 u_i^n$, $C = \frac{c\Delta t}{\Delta x} \le 1$	CFL condition
Laplace 5-point	$V_{i,j} = \frac{1}{4}(V_{i+1,j} + V_{i-1,j} + V_{i,j+1} + V_{i,j-1})$	Jacobi, Gauss–Seidel, SOR $\omega_{\text{opt}} = \frac{2}{1+\sin(\pi/N)}$
Lax equivalence	consistent + stable $\iff$ convergent (linear, well-posed)	order of convergence = order of consistency
Von Neumann	$u_i^n = G^n e^{ji\theta}$; need $\lvert G(\theta)\rvert \le 1 + K\Delta t$	Fourier modes diagonalise the scheme
Dahlquist	consistent + root condition $\iff$ convergent (multistep)	A-stable LMM has order ≤ 2

Chapter 23 — Optimization

> **Prerequisites:** Ch. 4 (single-variable extrema, §4.10), Ch. 6 (gradient, Hessian, constrained extrema and Lagrange multipliers, §6.10–6.11), Ch. 8–Ch. 10 (linear systems, least squares, positive-definite matrices, SVD), Ch. 22 (Newton's method for roots, convergence order). **Learning outcomes:** After this chapter you can
>
> - turn an engineering design question into a precise optimization problem: decision variables, objective, constraints, and scaling;
> - solve small linear programs graphically and by the simplex method, and read the dual variables as shadow prices;
> - state and apply the first- and second-order optimality conditions, including the Karush–Kuhn–Tucker (KKT) conditions for inequality constraints;
> - run and analyse gradient descent, Newton's method and the BFGS quasi-Newton method, choosing step sizes by line search;
> - recognise convex sets, functions and problems, and explain why convexity turns "a local minimum" into "the global minimum";
> - solve linear and nonlinear least-squares problems, with and without ridge (Tikhonov) regularization, and handle trade-offs between competing objectives with Pareto fronts, weighted sums and the ε-constraint method.

Optimization is the mathematics of *choosing well*. Every design an engineer signs off is the answer to an implicit optimization problem: the resistor values that meet a cutoff frequency at least cost, the generator outputs that meet a load at least fuel, the filter taps that best approximate an ideal response, the parameters of a model that best explain measured data. Chapter 4 handled the one-variable case with "set the derivative to zero", and Chapter 6 extended that to several variables and to equality constraints with Lagrange multipliers. This chapter takes the subject to the point where it becomes a working tool: many variables, inequality constraints, problems with no closed-form solution, and iterative algorithms that a computer runs for you — together with the theory that tells you whether the number the computer returns can be trusted.

Throughout, the standard problem is written

$$\begin{aligned} \min_{\mathbf{x}\in\mathbb{R}^n} \quad & f(\mathbf{x}) \\ \text{subject to} \quad & g_i(\mathbf{x}) \le 0, \quad i = 1,\dots,m, \\ & h_k(\mathbf{x}) = 0, \quad k = 1,\dots,p. \end{aligned}$$

Maximization of F is minimization of $f = -F$, and a constraint $g(\mathbf{x}) \ge 0$ is written $-g(\mathbf{x}) \le 0$, so this single template covers everything.

23.1 Objective functions

Motivation

The hardest step in optimization is usually not the algorithm; it is deciding *what you are optimizing*. "Design a good low-pass filter" is not a mathematical problem. "Choose R and C to minimise board area subject to a cutoff of $1\ \text{kHz} \pm 1\,\%$ and an output noise below $0.1\ \mu\text{V}$" is. The objective function encodes what "good" means, and a poorly chosen objective produces a design that is optimal for the wrong question — a perfect answer to a misstatement. This section sets up the vocabulary and shows how engineering goals become functions.

Definitions

Decision variables, objective, optimum

The **decision variables** $\mathbf{x} = (x_1, \dots, x_n)$ are the quantities the designer is free to choose. The **objective function** (cost, loss, or merit function) $f : D \subseteq \mathbb{R}^n \to \mathbb{R}$ assigns a single real number to each candidate design. A point $\mathbf{x}^*$ is a

- **global minimiser** if $f(\mathbf{x}^*) \le f(\mathbf{x})$ for every feasible $\mathbf{x}$;
- **local minimiser** if there is a $\delta > 0$ with $f(\mathbf{x}^*) \le f(\mathbf{x})$ for all feasible $\mathbf{x}$ with $\|\mathbf{x} - \mathbf{x}^*\| < \delta$;
- **strict** (local or global) minimiser if the inequality is strict for $\mathbf{x} \ne \mathbf{x}^*$.

The value $f^* = f(\mathbf{x}^*)$ is the **optimal value**. If the infimum of f is not attained (e.g. $f(x) = e^{-x}$ on $\mathbb{R}$) the problem has an optimal value $f^* = 0$ but no minimiser.

The distinction between local and global is the central difficulty of nonlinear optimization. Every practical algorithm in this chapter is *local*: it looks at f and its derivatives near the current point and moves downhill. Whether the point where it stops is the global answer depends on the global shape of f — which is why §23.7 on convexity matters so much.

Weierstrass extreme value theorem

If f is continuous on a nonempty, closed and bounded (compact) set $S \subset \mathbb{R}^n$, then f attains both a minimum and a maximum on S.

A useful variant for unbounded domains: if f is continuous on $\mathbb{R}^n$ and **coercive** — $f(\mathbf{x}) \to \infty$ whenever $\|\mathbf{x}\| \to \infty$ — then f has a global minimiser. (Proof sketch: pick any $\mathbf{x}_0$; coercivity means the sublevel set $\{\mathbf{x} : f(\mathbf{x}) \le f(\mathbf{x}_0)\}$ is bounded, it is closed by continuity, so Weierstrass applies to it, and nothing outside it can do better.) Quadratic losses $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 + \lambda\|\mathbf{x}\|^2$ with $\lambda > 0$ are coercive; this is one quiet reason regularization (§23.8) is popular.

Kinds of objective

Objective type	Form	Typical EE instance
Linear	$\mathbf{c}^{\mathsf{T}}\mathbf{x}$	fuel cost of generators with linear cost curves; total component cost
Quadratic	$\tfrac{1}{2}\mathbf{x}^{\mathsf{T}}\mathbf{Q}\mathbf{x} + \mathbf{c}^{\mathsf{T}}\mathbf{x}$	ohmic loss $\sum R_k I_k^2$; energy $\tfrac{1}{2}CV^2$; squared error

Objective type	Form	Typical EE instance
Sum of squares	$\sum_i r_i(\mathbf{x})^2$	curve fitting, filter design in the L^2 sense
Minimax	$\max_i \lvert r_i(\mathbf{x})\rvert$	equiripple (Chebyshev) filter design; worst-case tolerance
Ratio / log	$\log(\text{SNR})$, $\eta = P_{\text{out}}/P_{\text{in}}$	efficiency, noise figure, capacity $\log_2(1+\text{SNR})$
Expected value	$E[\ell(\mathbf{x}, \boldsymbol{\xi})]$	mean-square error of an estimator with random noise $\boldsymbol{\xi}$

The **norm** you put on an error vector $\mathbf{r}$ is a modelling choice with real consequences. The L^2 norm $\sum r_i^2$ is smooth and leads to linear equations (§23.8), but a few large errors dominate it. The L^1 norm $\sum \lvert r_i\rvert$ is robust to outliers and can be written as a linear program. The L^∞ norm $\max \lvert r_i\rvert$ controls the worst case, which is what a specification mask demands; it, too, becomes a linear program after an epigraph trick (§23.2).

Scaling and units

An objective must be a single number, so all its terms must share units. When the natural terms do not — dollars of capital and kilowatt-hours of loss, ohms and farads — you convert them to a common currency (cost per year) or nondimensionalise them by reference values. This is not cosmetic: gradient-based algorithms (§23.5) move in the direction of steepest descent *as measured in the units you chose*, and a variable measured in farads (10^{-9}) next to one measured in ohms (10^{4}) gives a problem that is numerically ill-conditioned by a factor of 10^{13}. Rescale every variable so that its plausible range is of order one before handing it to software.

Worked Example 23.1 — maximum power transfer as an optimization problem

A source with open-circuit voltage V_s and internal resistance R_s drives a load R_L. Choose $R_L > 0$ to maximise the power delivered.

Step 1 (variables and objective): the decision variable is R_L; the load current is $I = V_s/(R_s + R_L)$, so

$$P(R_L) = I^2 R_L = \frac{V_s^2 R_L}{(R_s + R_L)^2}.$$

Units: $\mathrm{V}^2\,\Omega/\Omega^2 = \mathrm{V}^2/\Omega = \mathrm{W}$. ✓

Step 2 (stationary point): by the quotient rule

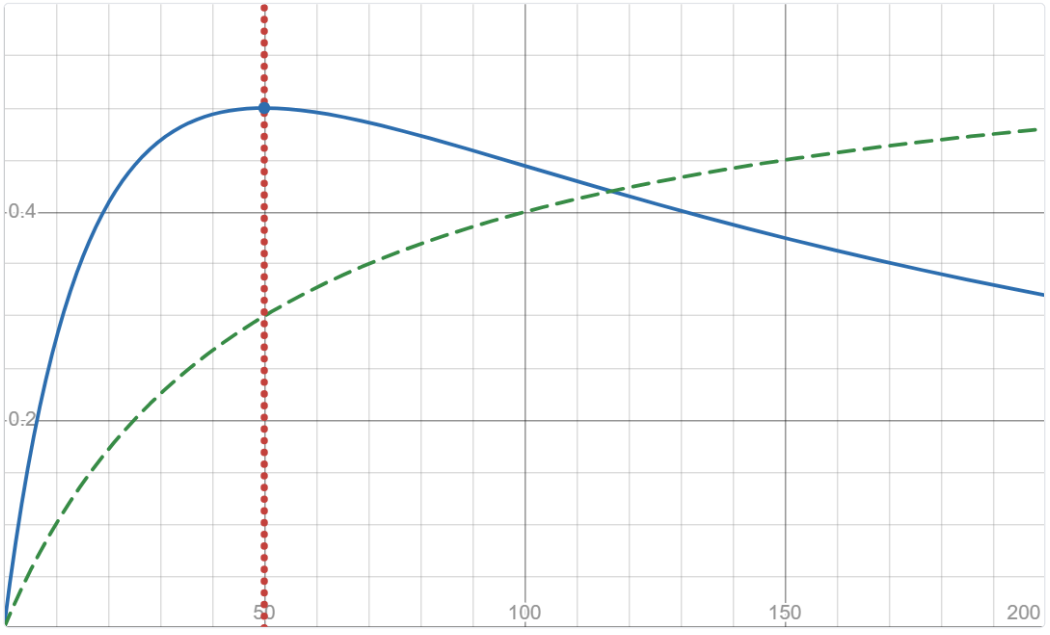
$$P'(R_L) = V_s^2 \frac{(R_s + R_L)^2 - 2R_L(R_s + R_L)}{(R_s + R_L)^4} = V_s^2 \frac{R_s - R_L}{(R_s + R_L)^3},$$

which vanishes only at $R_L = R_s$.

Step 3 (classify): $P' > 0$ for $R_L < R_s$ and $P' < 0$ for $R_L > R_s$, so $R_L = R_s$ is the global maximiser on $(0, \infty)$, with $P_{\max} = V_s^2/(4R_s)$.

Step 4 (check): $V_s = 10$ V, $R_s = 50\ \Omega$: $P(50) = 100 \cdot 50/100^2 = 0.5$ W $= V_s^2/(4R_s)$ ✓; $P(40) = 4000/8100 = 0.494$ W and $P(60) = 6000/12100 = 0.496$ W, both smaller ✓.

Step 5 (question the objective): at $R_L = R_s$ the efficiency is only $50\,\%$. A power utility, whose objective is efficiency, chooses $R_L \gg R_s$. Same circuit, different objective, opposite design.



Load power $P(R_L)$ (blue, watts) for $V_s = 10$ V, $R_s = 50\ \Omega$; the dashed green curve is efficiency $R_L/(R_s + R_L)$ scaled by 0.6. The two objectives peak in different places.

Worked Example 23.2 — Kelvin's law for conductor sizing

A feeder carries a steady current I for T hours per year. A conductor of cross-section A has annualised capital cost $c_1 A$ (cost per unit area per year) and resistance $\rho \ell / A$, so its yearly loss cost is $c_2 I^2 \rho \ell T / A$ with c_2 the price of energy. Find the economic cross-section.

Step 1 (objective): collect the constants $k = c_2 I^2 \rho \ell T$; the yearly cost is

$$f(A) = c_1 A + \frac{k}{A}, \qquad A > 0.$$

Step 2 (stationary point): $f'(A) = c_1 - k/A^2 = 0 \Rightarrow A^* = \sqrt{k/c_1}$.

Step 3 (classify): $f''(A) = 2k/A^3 > 0$ for all $A > 0$, so f is convex on its domain and A^* is the global minimiser. At the optimum $c_1 A^* = k/A^* = \sqrt{c_1 k}$: **the annual capital cost equals the annual loss cost** (Kelvin's law, 1881).

Step 4 (numbers): $I = 200$ A, $\ell = 1$ km, $\rho = 1.72 \times 10^{-8}\ \Omega\,\mathrm{m}$, $T = 8760$ h, energy 0.10 per kWh, capital $c_1 = 0.02$ per mm^2 per metre per year, i.e. 20 per mm^2 per year for the whole kilometre. Then the loss cost is

$$\frac{k}{A} = \frac{(200)^2 (1.72 \times 10^{-8})(1000)}{A\,[\mathrm{m}^2]}\ \mathrm{W} \times 8760\ \mathrm{h} \times \frac{0.10}{1000\ \mathrm{Wh}}.$$

With A in mm^2 ($1\ \mathrm{mm}^2 = 10^{-6}\ \mathrm{m}^2$): resistive loss $= 688/A$ kW, energy $= 6.03 \times 10^6 / A$ kWh, cost $= 6.03 \times 10^5 / A$. So $k = 6.03 \times 10^5$ and $A^* = \sqrt{6.03 \times 10^5 / 20} = 174$ mm^2. Check: capital $20 \times 174 = 3.47 \times 10^3$, loss $6.03 \times 10^5 / 174 = 3.47 \times 10^3$ ✓. One would then pick the next standard size (185 mm^2); the cost curve is flat near the optimum (f rises only 0.2 %), so rounding costs almost nothing.

That last remark is general and worth stating: near a smooth minimum, $f(\mathbf{x}^* + \boldsymbol{\delta}) \approx f^* + \tfrac{1}{2}\boldsymbol{\delta}^{\mathsf{T}} \nabla^2 f(\mathbf{x}^*) \boldsymbol{\delta}$, so a *first-order* error in the design costs only a *second-order* penalty in the objective. Optima are forgiving; this is why engineers can round to preferred values.

Worked Example 23.3 — writing a filter-design objective

We want a linear-phase FIR filter whose amplitude response $A(\omega; \mathbf{h}) = h_0 + 2\sum_{k=1}^{M} h_k \cos k\omega$ approximates an ideal low-pass $D(\omega)$ (1 in the passband $[0, \omega_p]$, 0 in the stopband $[\omega_s, \pi]$). Formulate three candidate objectives.

Step 1 (variables): $\mathbf{h} = (h_0, \dots, h_M) \in \mathbb{R}^{M+1}$. A is *linear* in $\mathbf{h}$: $A(\omega; \mathbf{h}) = \mathbf{a}(\omega)^{\mathsf{T}} \mathbf{h}$ with $\mathbf{a}(\omega) = (1, 2\cos\omega, \dots, 2\cos M\omega)$.

Step 2 (grid): sample $\omega_1, \dots, \omega_N$ in the bands (not in the transition band, which is left free) and form the error $e_i(\mathbf{h}) = W(\omega_i)\,[\mathbf{a}(\omega_i)^{\mathsf{T}}\mathbf{h} - D(\omega_i)]$ with a weight W (larger in the stopband if attenuation matters more).

Step 3 (objectives):

- $f_2(\mathbf{h}) = \sum_i e_i^2$: least squares — a quadratic, solved by one linear system (§23.8);
- $f_\infty(\mathbf{h}) = \max_i |e_i|$: minimax — the equiripple design; non-smooth, but an LP (§23.2–23.3);
- $f_1(\mathbf{h}) = \sum_i |e_i|$: least absolute error — also an LP.

All three are **convex** in $\mathbf{h}$ (§23.7), so each has a single global optimum that any correct algorithm finds. The choice between them is an engineering judgement about what the specification sheet actually penalises.

Common Pitfall — optimizing a proxy

Objectives are often proxies: "minimise component count" for cost, "minimise mean-square error" for audible distortion. An optimizer exploits every weakness of the proxy. If the optimal design looks strange — a resistor of 0.3 mΩ, a filter with huge gain in the transition band — the objective or the constraints are incomplete, not the algorithm.

Engineering Note — sensitivity of the optimal value

Once you have $\mathbf{x}^*(p)$ for a parameter p (a price, a load, a tolerance), the **envelope theorem** gives the sensitivity cheaply: $\dfrac{df^*}{dp} = \dfrac{\partial f}{\partial p}\Big|_{\mathbf{x}^*}$ — the indirect effect through $\mathbf{x}^*$ vanishes because $\nabla_{\mathbf{x}} f = \mathbf{0}$ there. In Example 23.2, $f^* = 2\sqrt{c_1 k}$ and indeed $\partial f / \partial c_1 = A^* = \sqrt{k/c_1} = df^*/dc_1$. With constraints the same role is played by the Lagrange multipliers (§23.4).

23.2 Constraints

Motivation

Unconstrained optimization is the exception in engineering. Resistances are positive, currents are bounded by fuse ratings, generator outputs lie between a technical minimum and a nameplate maximum, and the specification sheet is a list of inequalities: gain at least 40 dB, ripple at most 0.5 dB, power at most 2 W. Constraints change the character of the problem: the optimum is very often *on the boundary* of what is allowed, where the derivative of the objective is not zero at all. Learning to describe constraints precisely — and to see which ones actually matter — is the core of practical optimization.

Definitions

Feasible set, active constraints

For the standard problem with inequality constraints $g_i(\mathbf{x}) \le 0$ and equality constraints $h_k(\mathbf{x}) = 0$, the **feasible set** is

$$S = \{\mathbf{x} \in \mathbb{R}^n : \; g_i(\mathbf{x}) \le 0 \;\; (i = 1, \dots, m), \;\; h_k(\mathbf{x}) = 0 \;\; (k = 1, \dots, p)\}.$$

A point in S is **feasible**. At a feasible $\mathbf{x}$ the inequality g_i is **active** (binding, tight) if $g_i(\mathbf{x}) = 0$ and **inactive** if $g_i(\mathbf{x}) < 0$. The **active set** is $\mathcal{A}(\mathbf{x}) = \{i : g_i(\mathbf{x}) = 0\}$. Equality constraints are always active. If $S = \varnothing$ the problem is **infeasible**; if f is unbounded below on S it is **unbounded**.

Inactive constraints have no local influence: if $g_i(\mathbf{x}^*) < 0$, a small neighbourhood of $\mathbf{x}^*$ satisfies $g_i < 0$ too, so $\mathbf{x}^*$ would still be a local minimiser with g_i deleted. The difficulty of inequality-constrained optimization is that you do not know in advance *which* constraints will be active; the KKT conditions of §23.4 are, in effect, a systematic way to guess and verify the active set.

Common constraint types:

Type	Form	Example
Bound (box)	$\ell_j \le x_j \le u_j$	$P_{\min} \le P_g \le P_{\max}$ for a generator
Linear inequality	$\mathbf{a}_i^{\mathsf{T}}\mathbf{x} \le b_i$	total current from a supply $\le$ rating
Linear equality	$\mathbf{A}\mathbf{x} = \mathbf{b}$	Kirchhoff's current law at every node; power balance
Nonlinear	$g(\mathbf{x}) \le 0$	$RC = \tau$; $\lvert H(j\omega_s)\rvert \le 10^{-2}$; $\sqrt{kT/C} \le v_{\max}$
Integer / discrete	$x_j \in \mathbb{Z}$ or $x_j \in \{\text{E12 values}\}$	number of parallel cells; preferred resistor values

Discrete constraints make a problem combinatorial and are outside the scope of this chapter; the standard engineering practice is to solve the continuous relaxation and then round to the nearest available values, checking the specification afterwards (the forgiving-optimum argument of §23.1 says the penalty is second order).

Handling constraints: four techniques

1. Elimination. An equality constraint that can be solved for one variable removes that variable. For $\min f(x, y)$ subject to $h(x, y) = 0$ with $y = \varphi(x)$, minimise $F(x) = f(x, \varphi(x))$. This is the cleanest method when it applies, and it is exactly what Chapter 6 did before introducing multipliers (§6.10).

2. Change of variables. Simple inequality constraints can often be removed by a substitution: $x > 0$ becomes $x = e^u$ with $u \in \mathbb{R}$; $0 \le x \le 1$ becomes $x = \sin^2 u$ or $x = 1/(1 + e^{-u})$. The resulting problem is unconstrained. For positive physical quantities (resistances, capacitances, frequencies) the logarithmic substitution is particularly natural because tolerances and preferred-value series are logarithmic anyway; in §23.10 it turns a component-sizing problem into a convex one.

3. Slack variables. An inequality $g_i(\mathbf{x}) \le 0$ becomes an equality $g_i(\mathbf{x}) + s_i = 0$ with a new variable $s_i \ge 0$ (the **slack**). Linear programming uses this to put all constraints in equality form (§23.3). The slack is zero exactly when the constraint is active.

4. Penalty and barrier functions. Replace the constrained problem by a sequence of unconstrained ones:

- an *exterior penalty* adds $\mu\big(\sum_k h_k(\mathbf{x})^2 + \sum_i \max(0, g_i(\mathbf{x}))^2\big)$, with $\mu \to \infty$; iterates approach S from outside;
- an *interior (logarithmic) barrier* adds $-\frac{1}{t}\sum_i \ln(-g_i(\mathbf{x}))$, which is finite only strictly inside S; as $t \to \infty$ the minimiser approaches the constrained optimum from inside. Barrier methods with Newton steps are the **interior-point methods** that modern LP and convex solvers use.

The epigraph trick

A non-smooth objective such as $\max_i r_i(\mathbf{x})$ can be made smooth by adding one variable t:

$$\min_{\mathbf{x}} \; \max_i r_i(\mathbf{x}) \qquad \Longleftrightarrow \qquad \min_{\mathbf{x}, t} \; t \quad \text{subject to} \quad r_i(\mathbf{x}) \le t, \;\; i = 1, \dots, N.$$

At the optimum of the right-hand problem t is pushed down until it touches the largest r_i, so the two problems have the same solutions. With r_i linear in $\mathbf{x}$, minimax design becomes a linear program. Similarly $|r| \le t$ is the pair of linear inequalities $-t \le r \le t$, which turns L^1 and L^∞ fitting into LPs.

Worked Example 23.4 — a voltage divider: feasibility first

A divider R_1 (top), R_2 (bottom) from $V_{\text{in}} = 5$ V must give $V_{\text{out}} = 2$ V (ratio $\alpha = R_2/(R_1+R_2) = 0.4$), draw at most $I_{\max} = 100\ \mu$A, and have Thevenin output resistance $R_1 \parallel R_2 \le 10$ kΩ. Find the feasible designs.

Step 1 (eliminate the equality): with total resistance $R_T = R_1 + R_2$, the ratio gives $R_2 = \alpha R_T$, $R_1 = (1-\alpha)R_T$, so there is one free variable R_T.

Step 2 (rewrite the inequalities):

- current: $V_{\text{in}}/R_T \le I_{\max} \Rightarrow R_T \ge 5/10^{-4} = 50$ kΩ;
- output resistance: $R_1 R_2/R_T = \alpha(1-\alpha)R_T = 0.24 R_T \le 10$ kΩ $\Rightarrow R_T \le 41.7$ kΩ.

Step 3 (feasibility): $50 \le R_T \le 41.7$ is impossible: **the specification is infeasible.** No algorithm can fix that; the specification must change. (This is why solvers report "infeasible" as a legitimate outcome rather than an error.)

Step 4 (relax): allow $I_{\max} = 150\ \mu$A. Then $R_T \ge 33.3$ kΩ and the feasible set is the interval $[33.3,\ 41.7]$ kΩ.

Step 5 (optimise): to minimise quiescent power V_{in}^2/R_T, take the largest feasible $R_T = 41.7$ kΩ: $R_1 = 25.0$ kΩ, $R_2 = 16.7$ kΩ. The output-resistance constraint is **active**, the current constraint is **inactive**. Check: $5/41.7\text{k} = 120\ \mu\text{A} \le 150$ ✓; $25 \parallel 16.7 = 10.0$ kΩ ✓; ratio $16.7/41.7 = 0.40$ ✓.

Worked Example 23.5 — quadratic penalty converging to a constrained optimum

Minimise $f(x,y) = x^2 + y^2$ subject to $x + y = 1$ using the penalty function $P_\mu(x,y) = x^2 + y^2 + \mu(x+y-1)^2$.

Step 1 (exact answer, for reference): by elimination ($y = 1-x$), $F(x) = x^2 + (1-x)^2$, $F'(x) = 4x - 2 = 0$, so $(x^*, y^*) = (\tfrac12, \tfrac12)$, $f^* = \tfrac12$.

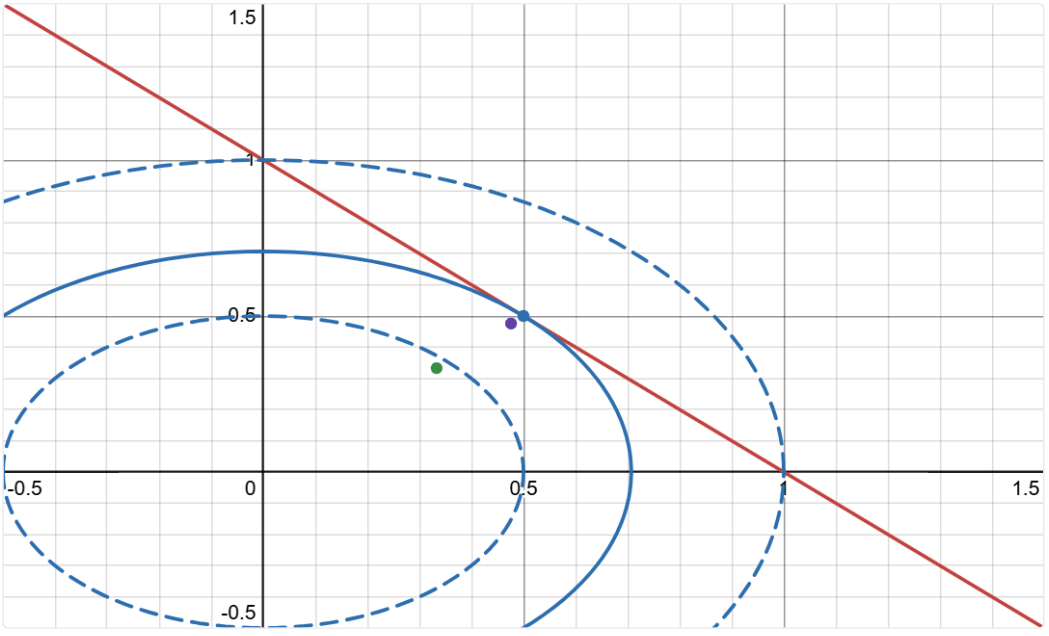
Step 2 (penalised problem): $\nabla P_\mu = \mathbf{0}$ gives $2x + 2\mu(x+y-1) = 0$ and $2y + 2\mu(x+y-1) = 0$. Subtracting, $x = y$; then $2x + 2\mu(2x-1) = 0$, so

$$x_\mu = y_\mu = \frac{\mu}{1+2\mu}.$$

Step 3 (behaviour): $\mu = 1$: $x_\mu = 0.333$; $\mu = 10$: 0.476; $\mu = 100$: 0.4975; $\mu = 10^4$: 0.499975. The constraint violation is $1 - 2x_\mu = 1/(1+2\mu)$, which goes to zero only as $\mu \to \infty$.

Step 4 (multiplier for free): the quantity $2\mu(x_\mu + y_\mu - 1) = -2\mu/(1+2\mu) \to -1$. Comparing with the Lagrange condition $\nabla f + \lambda \nabla h = \mathbf{0}$, i.e. $2x + \lambda = 0$ at $x = \tfrac12$, gives $\lambda^* = -1$: the penalty term's gradient converges to the multiplier term.

Step 5 (the catch): the Hessian of P_μ is $\begin{pmatrix} 2+2\mu & 2\mu \\ 2\mu & 2+2\mu \end{pmatrix}$ with eigenvalues 2 and $2+4\mu$; its condition number $1+2\mu$ grows without bound. Large penalties make the unconstrained subproblems ill-conditioned — the reason practical codes use *augmented Lagrangian* or barrier methods instead of a pure penalty.



Contours of $x^2 + y^2$ (blue) and the constraint line (red). The constrained optimum is where a contour is tangent to the line; penalty solutions approach it from the infeasible side as μ grows.

Worked Example 23.6 — minimax fitting as an LP

Fit a constant c to three measurements $1.0,\ 1.4,\ 2.0$ so that the worst-case error is as small as possible.

Step 1 (epigraph form): minimise t over (c, t) subject to $-t \le c - 1.0 \le t$, $-t \le c - 1.4 \le t$, $-t \le c - 2.0 \le t$ — six linear inequalities.

Step 2 (which constraints bind): only the extremes matter: $c - 1.0 \le t$ and $2.0 - c \le t$. Adding, $1.0 \le 2t$, so $t \ge 0.5$, with equality when $c - 1.0 = 2.0 - c$, i.e. $c = 1.5$.

Step 3 (compare): the minimax constant is the **midrange** 1.5 (worst error 0.5), the least-squares constant is the mean 1.467 (worst error 0.533), and the L^1 constant is the median 1.4 (worst error 0.6). Three norms, three answers; each is correct for its objective.

Common Pitfall — strict inequalities

Constraints in optimization are always non-strict ($\le$, not $<$). A feasible set defined by $x > 0$ is open, and $\min x$ over it has no minimiser. If a physical quantity must be strictly positive, impose $x \ge \varepsilon$ with a small physically meaningful ε (say $1\ \Omega$) or use the substitution $x = e^u$.

Engineering Note — constraint qualification in plain words

The optimality theory of §23.4 needs the active constraints to be "independent" at the optimum (their gradients linearly independent, or the feasible set having an interior). Redundant constraints — writing the same power-balance equation twice, or a bound that duplicates another — can break this and make solvers report spurious failures. Keep the constraint list minimal and non-redundant.

23.3 Linear programming

Motivation

When the objective and every constraint are linear, the problem is a **linear program** (LP). Linearity sounds restrictive, but LPs model a remarkable range of engineering decisions: dispatching generators with piecewise-linear cost curves, routing power or data flows through a network, allocating bandwidth, scheduling production, and — through the epigraph trick of §23.2 — minimax and L^1 fitting. LPs with millions of variables are solved routinely. More importantly for us, LP is the cleanest setting in which to see three ideas that run through all of optimization: the optimum lives on the boundary, an algorithm can walk along that boundary efficiently, and every problem has a **dual** whose variables are prices.

Standard and canonical forms

Linear program

A linear program in **inequality (canonical) form** is

$$\max_{\mathbf{x}} \ \mathbf{c}^{\mathsf{T}}\mathbf{x} \quad \text{subject to} \quad \mathbf{A}\mathbf{x} \le \mathbf{b},\ \ \mathbf{x} \ge \mathbf{0},$$

and in **standard (equality) form**

$$\min_{\mathbf{x}} \ \mathbf{c}^{\mathsf{T}}\mathbf{x} \quad \text{subject to} \quad \mathbf{A}\mathbf{x} = \mathbf{b},\ \ \mathbf{x} \ge \mathbf{0},$$

with $\mathbf{A} \in \mathbb{R}^{m \times n}$ and, in standard form, $\operatorname{rank} \mathbf{A} = m < n$. Vector inequalities hold componentwise.

Any LP can be brought to either form by these moves: maximise $\mathbf{c}^{\mathsf{T}}\mathbf{x} \leftrightarrow$ minimise $-\mathbf{c}^{\mathsf{T}}\mathbf{x}$; turn $\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b$ into $\mathbf{a}^{\mathsf{T}}\mathbf{x} + s = b$ with slack $s \ge 0$ (or $\mathbf{a}^{\mathsf{T}}\mathbf{x} \ge b$ into $\mathbf{a}^{\mathsf{T}}\mathbf{x} - s = b$ with surplus $s \ge 0$); replace a free variable x_j by $x_j^+ - x_j^-$ with both parts nonnegative.

Geometry: the optimum is at a vertex

The feasible set of an LP, $S = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b},\ \mathbf{x} \ge \mathbf{0}\}$, is an intersection of half-spaces — a **convex polyhedron** (a polygon in two dimensions). Its "corners" are **vertices** (extreme points): points of S that are not the midpoint of any two other points of S. Algebraically, in standard form a vertex is a **basic feasible solution**: choose m linearly independent columns of $\mathbf{A}$ (the *basis* $\mathbf{B}$), set the other $n - m$ variables to zero, and solve $\mathbf{B}\mathbf{x}_B = \mathbf{b}$; if $\mathbf{x}_B \ge \mathbf{0}$ the point is a vertex.

Fundamental theorem of linear programming

For an LP in standard form:

1. if the feasible set is nonempty, it has at least one basic feasible solution (vertex);
2. if the LP has an optimal solution, it has an optimal solution at a vertex.

Consequently an LP is either infeasible, unbounded, or attains its optimum at one of finitely many vertices (at most $\binom{n}{m}$ of them).

Proof sketch of part 2. Let $\mathbf{x}^*$ be optimal but not a vertex. Then $\mathbf{x}^* = \tfrac{1}{2}(\mathbf{y} + \mathbf{z})$ for distinct feasible $\mathbf{y}, \mathbf{z}$, so $\mathbf{d} = \mathbf{y} - \mathbf{x}^*$ is a direction along which one can move both ways and stay feasible for a while. Since $\mathbf{c}^{\mathsf{T}}(\mathbf{x}^* \pm t\mathbf{d}) = \mathbf{c}^{\mathsf{T}}\mathbf{x}^* \pm t\,\mathbf{c}^{\mathsf{T}}\mathbf{d}$ cannot drop below the optimum in either direction, $\mathbf{c}^{\mathsf{T}}\mathbf{d} = 0$. Move along $\mathbf{d}$ until one more variable hits zero; the objective is unchanged and the new point has strictly more zero components. Repeating at most n times ends at a vertex with the same optimal value. $\square$

The intuition: the objective $\mathbf{c}^{\mathsf{T}}\mathbf{x} = z$ is a family of parallel lines (planes). Slide the line in the improving direction $\mathbf{c}$ until it is about to leave S; the last contact is a vertex, or a whole edge if the line happens to be parallel to it.

The graphical method

For two variables:

1. draw each constraint boundary and shade the feasible side;
2. identify the feasible polygon and its vertices (intersections of pairs of active boundaries);
3. draw one objective contour $\mathbf{c}^{\mathsf{T}}\mathbf{x} = z_0$ and the direction $\mathbf{c}$ of improvement;
4. slide the contour in that direction to the last vertex touched — or, equivalently, evaluate the objective at every vertex and take the best.

Worked Example 23.7 — a production LP solved graphically

A small plant assembles two power-supply modules. Module 1 earns 4 units of profit, module 2 earns 3. Per batch, module 1 uses 1 hour of test time, 2 hours of assembly and 1 kg of copper; module 2 uses 1 hour of test, 1 hour of assembly and 3 kg of copper. Available per week: 8 test hours, 12 assembly hours, 18 kg copper. Maximise profit.

Step 1 (formulate): with x_1, x_2 batches,

$$\max\ z = 4x_1 + 3x_2 \quad \text{s.t.} \quad x_1 + x_2 \le 8,\ \ 2x_1 + x_2 \le 12,\ \ x_1 + 3x_2 \le 18,\ \ x_1, x_2 \ge 0.$$

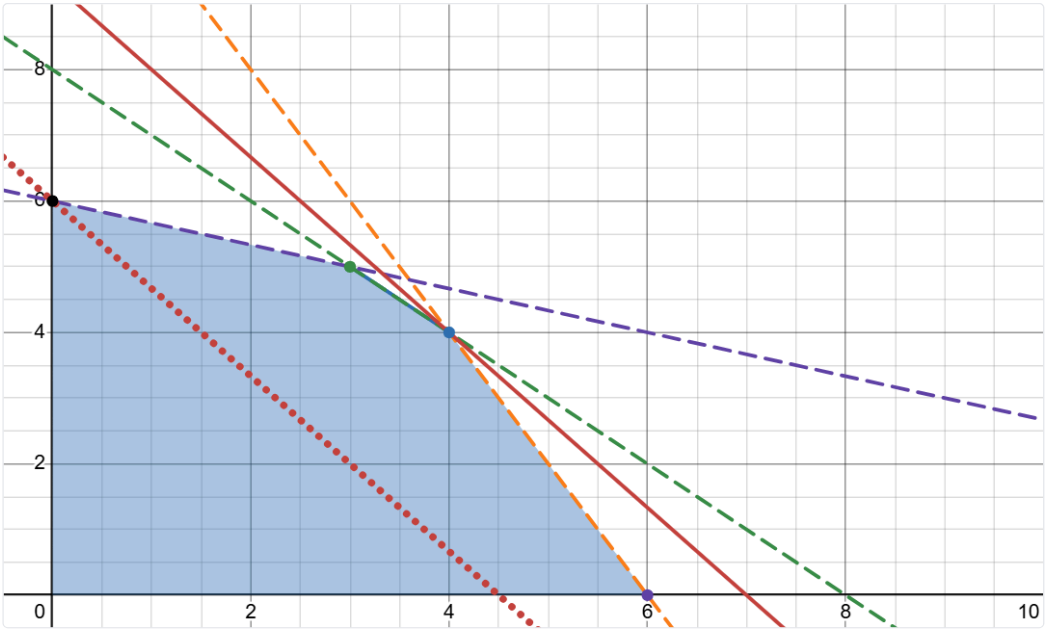
Step 2 (vertices): intersect pairs of boundaries and keep the feasible points:

Vertex	Active constraints	(x_1, x_2)	z
A	$x_1 = 0,\ x_2 = 0$	$(0, 0)$	0
B	$x_2 = 0$, assembly	$(6, 0)$	24
C	assembly, test	$(4, 4)$	**28**
D	test, copper	$(3, 5)$	27
E	copper, $x_1 = 0$	$(0, 6)$	18

(For C: subtract $x_1 + x_2 = 8$ from $2x_1 + x_2 = 12$ to get $x_1 = 4$, then $x_2 = 4$. For D: subtract $x_1 + x_2 = 8$ from $x_1 + 3x_2 = 18$ to get $x_2 = 5$, $x_1 = 3$.)

Step 3 (optimum): $x^* = (4, 4)$, $z^* = 28$. At C the test and assembly constraints are active; copper is inactive with slack $18 - (4 + 12) = 2$ kg.

Step 4 (contour check): the objective gradient $\mathbf{c} = (4, 3)$ has slope $-4/3$ for its contours. At C the two active edges have slopes -1 (test) and -2 (assembly); since $-2 < -4/3 < -1$, the contour $4x_1 + 3x_2 = 28$ touches the polygon only at C. ✓



Feasible region of Example 23.7 (blue) bounded by the test (green), assembly (orange) and copper (purple) constraints. The objective contour $z = 18$ (dotted) slides in the direction $(4, 3)$ until $z = 28$ (solid red) just touches vertex C.

Worked Example 23.8 — a minimisation LP, an unbounded region, and alternative optima

A utility must buy blocks from two contracts. A block from contract A supplies 1 MW of energy and 1 MW of reserve at cost 2; a block from B supplies 1 MW of energy and 3 MW of reserve at cost 3. It needs at least 4 MW of energy and 6 MW of reserve, and contract A is limited to 5 blocks.

Step 1 (formulate): $\min\ 2x + 3y$ s.t. $x + y \geq 4$, $x + 3y \geq 6$, $x \leq 5$, $x, y \geq 0$.

Step 2 (region): the feasible region is *unbounded* (any large y is allowed), but the objective increases in every feasible direction of escape, so a minimum exists. Its vertices are $(0, 4)$, $(3, 1)$ [from $x + y = 4$, $x + 3y = 6$], and $(5, \tfrac{1}{3})$ [from $x = 5$, $x + 3y = 6$].

Step 3 (evaluate): $2x + 3y$ gives 12, **9**, 11. Optimum $(3, 1)$ with cost 9: both the energy and reserve constraints are active.

Step 4 (alternative optima): change B's price so that the cost is $x + 3y$. Now the contours are parallel to the reserve edge $x + 3y = 6$; vertices give 12, 6, 6, and **every** point on the segment from $(3, 1)$ to $(5, \tfrac{1}{3})$ is optimal with cost 6. A solver will report one vertex; the existence of others is signalled by a zero reduced cost for a nonbasic variable in the final simplex tableau.

The simplex method

The fundamental theorem suggests an algorithm: start at a vertex, move along an edge to an adjacent vertex with a better objective, and stop when no edge improves. This is Dantzig's **simplex method** (1947). Adjacent vertices differ by exchanging one basic variable for one nonbasic variable, which is a single Gauss–Jordan pivot (Ch. 8).

Consider the canonical maximisation problem with $\mathbf{b} \geq \mathbf{0}$. Adding slacks $\mathbf{s}$ gives $\mathbf{A}\mathbf{x} + \mathbf{s} = \mathbf{b}$, and the point $\mathbf{x} = \mathbf{0},\ \mathbf{s} = \mathbf{b}$ is an immediate basic feasible solution (the slacks form the basis). Write the objective as a row $z - \mathbf{c}^{\mathsf{T}}\mathbf{x} = 0$. The **tableau** stores the constraint rows and this objective row.

Simplex iteration (maximisation, tableau form)

1. **Optimality test.** If every entry of the objective row (the **reduced costs**, here $-\bar{c}_j$) is ≥ 0, stop: the current vertex is optimal.
2. **Entering variable.** Otherwise choose a column q with a negative entry (Dantzig's rule: the most negative). Increasing x_q from zero increases z.
3. **Ratio test (leaving variable).** For each row i with positive entry $a_{iq} > 0$, compute b_i / a_{iq}. The smallest ratio identifies the row p whose basic variable first reaches zero as x_q grows. If no $a_{iq} > 0$, the LP is **unbounded**.
4. **Pivot.** Divide row p by a_{pq}, then subtract multiples of it from every other row (including the objective row) to zero column q. Return to step 1.

Why it works: in the current basis every basic variable is expressed in terms of the nonbasic ones; the objective row says how z changes per unit increase of each nonbasic variable. The ratio test increases the entering variable as far as possible *without making any basic variable negative*, so feasibility is preserved and z never decreases. With finitely many bases and strict improvement at each step (absent degeneracy), the method terminates.

Worked Example 23.9 — simplex on Example 23.7

Initial tableau (basis s_1, s_2, s_3; vertex A):

Basis	x_1	x_2	s_1	s_2	s_3	RHS
s_1	1	1	1	0	0	8
s_2	2	1	0	1	0	12
s_3	1	3	0	0	1	18
z	-4	-3	0	0	0	0

Iteration 1. Most negative reduced cost: x_1 (-4). Ratios: $8/1 = 8$, $12/2 = \mathbf{6}$, $18/1 = 18$; s_2 leaves. Pivot on the entry 2:

Basis	x_1	x_2	s_1	s_2	s_3	RHS
s_1	0	0.5	1	-0.5	0	2
x_1	1	0.5	0	0.5	0	6
s_3	0	2.5	0	-0.5	1	12
z	0	-1	0	2	0	24

This is vertex B $= (6, 0)$, $z = 24$.

Iteration 2. x_2 has reduced cost -1. Ratios: $2/0.5 = \mathbf{4}$, $6/0.5 = 12$, $12/2.5 = 4.8$; s_1 leaves. Pivot on 0.5:

Basis	x_1	x_2	s_1	s_2	s_3	RHS
x_2	0	1	2	-1	0	4
x_1	1	0	-1	1	0	4
s_3	0	0	-5	2	1	2
z	0	0	2	1	0	28

Optimality. All reduced costs are ≥ 0: optimum $x_1 = 4$, $x_2 = 4$, $s_3 = 2$ (spare copper), $z^* = 28$ — vertex C, as found graphically. The path was A → B → C: two pivots instead of examining all five vertices.

Bonus reading. The objective-row entries under the slack columns, $(2, 1, 0)$, are the **shadow prices** of test time, assembly time and copper — the dual solution, explained next.

Starting when the origin is infeasible. If some constraints are $\geq$ or equalities, $\mathbf{x} = \mathbf{0}$ is not feasible and there is no obvious initial basis. The **two-phase method** first minimises the sum of artificial variables added to those rows (phase I); a zero optimum gives a feasible vertex for phase II, a positive optimum proves the LP infeasible. The **big-M method** does both at once by charging each artificial variable a large cost M.

Degeneracy and cycling. If a ratio test ties, some basic variable becomes zero and the next pivot may not improve z. In rare constructed cases the method can then cycle forever; Bland's rule (always choose the lowest-indexed eligible variable) provably prevents this.

Complexity. The simplex method can take exponentially many pivots on contrived examples (Klee–Minty), but on practical problems it typically needs a small multiple of m pivots. **Interior-point methods** (Karmarkar 1984 and successors), which follow a smooth path through the interior using barrier functions (§23.2) and Newton steps (§23.6), have polynomial worst-case complexity and are preferred for very large sparse problems.

Duality

Every LP has a companion LP, its **dual**, obtained by asking: *what is the best upper bound on the primal objective that can be proved by combining the constraints?*

Take Example 23.7. Multiply the three constraints by nonnegative numbers y_1, y_2, y_3 and add:

$$(y_1 + 2y_2 + y_3)\,x_1 + (y_1 + y_2 + 3y_3)\,x_2 \;\leq\; 8y_1 + 12y_2 + 18y_3.$$

If the coefficients on the left are at least the profit coefficients, $y_1 + 2y_2 + y_3 \geq 4$ and $y_1 + y_2 + 3y_3 \geq 3$, then (because $x_1, x_2 \geq 0$) the left side is at least $4x_1 + 3x_2 = z$. So every such $\mathbf{y}$ gives the bound $z \leq 8y_1 + 12y_2 + 18y_3$. The tightest bound is the dual LP:

$$\min\; 8y_1 + 12y_2 + 18y_3 \quad \text{s.t.} \quad y_1 + 2y_2 + y_3 \geq 4,\;\; y_1 + y_2 + 3y_3 \geq 3,\;\; \mathbf{y} \geq \mathbf{0}.$$

Primal–dual pair

$$\text{(P)}\;\; \max\, \mathbf{c}^{\mathsf{T}}\mathbf{x} \;\text{ s.t. }\; \mathbf{A}\mathbf{x} \leq \mathbf{b},\; \mathbf{x} \geq \mathbf{0} \qquad\qquad \text{(D)}\;\; \min\, \mathbf{b}^{\mathsf{T}}\mathbf{y} \;\text{ s.t. }\; \mathbf{A}^{\mathsf{T}}\mathbf{y} \geq \mathbf{c},\; \mathbf{y} \geq \mathbf{0}.$$

Each primal constraint corresponds to a dual variable and each primal variable to a dual constraint. The dual of the dual is the primal.

LP duality

1. **Weak duality.** For any primal-feasible $\mathbf{x}$ and dual-feasible $\mathbf{y}$: $\mathbf{c}^{\mathsf{T}}\mathbf{x} \le \mathbf{b}^{\mathsf{T}}\mathbf{y}$.
2. **Strong duality.** If either problem has a finite optimum, so does the other, and $\mathbf{c}^{\mathsf{T}}\mathbf{x}^{*} = \mathbf{b}^{\mathsf{T}}\mathbf{y}^{*}$.
3. **Complementary slackness.** Feasible $\mathbf{x}$ and $\mathbf{y}$ are both optimal if and only if
$$y_i\,(b_i - \mathbf{a}_i^{\mathsf{T}}\mathbf{x}) = 0 \ \text{ for every } i, \qquad x_j\,\big((\mathbf{A}^{\mathsf{T}}\mathbf{y})_j - c_j\big) = 0 \ \text{ for every } j.$$
4. If the primal is unbounded the dual is infeasible, and vice versa (both can be infeasible).

Proof of weak duality and complementary slackness. For feasible $\mathbf{x}, \mathbf{y}$,
$$\mathbf{c}^{\mathsf{T}}\mathbf{x} \;\le\; (\mathbf{A}^{\mathsf{T}}\mathbf{y})^{\mathsf{T}}\mathbf{x} \;=\; \mathbf{y}^{\mathsf{T}}\mathbf{A}\mathbf{x} \;\le\; \mathbf{y}^{\mathsf{T}}\mathbf{b},$$
the first inequality using $\mathbf{x} \ge \mathbf{0}$ and $\mathbf{A}^{\mathsf{T}}\mathbf{y} \ge \mathbf{c}$, the second using $\mathbf{y} \ge \mathbf{0}$ and $\mathbf{A}\mathbf{x} \le \mathbf{b}$. Equality $\mathbf{c}^{\mathsf{T}}\mathbf{x} = \mathbf{b}^{\mathsf{T}}\mathbf{y}$ — which by weak duality certifies that both are optimal — holds exactly when both inequalities are equalities, i.e. when each product of a nonnegative variable and a nonnegative slack vanishes. Strong duality is deeper (it follows from Farkas' lemma, or from the fact that the simplex method terminates with a dual-feasible objective row); we state it without proof. □

Complementary slackness says: **a constraint with spare capacity has zero price, and a resource with positive price is fully used.**

Worked Example 23.10 — solving the dual by complementary slackness

Use the primal optimum $\mathbf{x}^{*} = (4, 4)$ of Example 23.7 to find the dual optimum.

Step 1 (inactive primal constraint): copper has slack 2, so $y_3 = 0$.

Step 2 (positive primal variables): $x_1, x_2 > 0$, so both dual constraints are tight: $y_1 + 2y_2 = 4$ and $y_1 + y_2 = 3$. Hence $y_2 = 1$, $y_1 = 2$.

Step 3 (verify): $\mathbf{y}^{*} = (2, 1, 0) \ge \mathbf{0}$ ✓ (dual feasible); dual objective $8(2) + 12(1) + 18(0) = 28 = z^{*}$ ✓. These are exactly the slack-column entries of the final simplex tableau.

Step 4 (interpret): one more test hour is worth 2 units of profit, one more assembly hour 1 unit, more copper nothing. Check with a re-solve: with 13 assembly hours the optimum moves to $(5, 3)$ and $z = 29 = 28 + 1$ ✓. With 8.4 test hours it moves to $(3.6, 4.8)$ and $z = 28.8 = 28 + 2(0.4)$ ✓.

Step 5 (range of validity): shadow prices are valid only while the optimal basis stays the same. Adding Δ test hours changes the basic variables by Δ times the s_1 column of the final tableau, $(2, -1, -5)$: copper slack becomes $2 - 5\Delta$, which hits zero at $\Delta = 0.4$. Beyond 8.4 test hours copper becomes binding and extra test time is worth nothing: with 8.5 hours the optimum is still 28.8.

Engineering Note — locational marginal prices

In an electricity market the operator solves an LP (or QP) that dispatches generators at minimum cost subject to power balance at each bus and line flow limits. The dual variable of the balance constraint at bus k is the **locational marginal price**: the cost of serving one more MW at that bus. When a transmission line is congested its limit constraint is active, its dual variable is positive, and prices on either side of the line differ — a direct, monetised reading of complementary slackness.

Common Pitfall — forgetting nonnegativity or sign conventions

Most LP software assumes $\mathbf{x} \ge \mathbf{0}$ by default (SciPy's `linprog` does). A variable that can be negative — a current direction, a voltage relative to ground — must be declared free, or the solver will silently clamp it at zero and return a wrong "optimum". Equally, solvers differ in the sign they report for dual values (marginals); check against a one-unit perturbation as in Example 23.10.

A minimal Python check of Examples 23.7 and 23.10 (`linprog` minimises, so the profit is negated):

```
from scipy.optimize import linprog
res = linprog(c=[-4, -3],
              A_ub=[[1, 1], [2, 1], [1, 3]], b_ub=[8, 12, 18],
              bounds=[(0, None), (0, None)])
print(res.x, -res.fun)          # [4. 4.] 28.0
print(-res.ineqlin.marginals)   # shadow prices [2. 1. 0.]
```

23.4 Nonlinear optimization

Motivation

Most engineering objectives are nonlinear: losses go as I^2R, gain as a ratio of polynomials in frequency, efficiency as a ratio of powers, model error as a sum of squared exponentials. Before choosing an algorithm we need to know what a solution *looks like* — which equations it satisfies and how to tell a minimum from a saddle. Those **optimality conditions** do double duty: for small problems they are solved by hand to give the answer, and for large ones they are the stopping test that every algorithm checks. This section collects them, first without constraints, then with equality constraints (Lagrange, already met in Ch. 6 §6.11), and finally with inequality constraints (Karush–Kuhn–Tucker).

Unconstrained optimality conditions

Let $f:\mathbb{R}^n\to\mathbb{R}$ be twice continuously differentiable, with gradient $\nabla f(\mathbf{x})$ and Hessian $\nabla^2 f(\mathbf{x})=\left[\partial^2 f/\partial x_i\partial x_j\right]$ (Ch. 6). Everything rests on the second-order Taylor expansion

$$f(\mathbf{x}^*+\mathbf{d})=f(\mathbf{x}^*)+\nabla f(\mathbf{x}^*)^{\mathsf T}\mathbf{d}+\tfrac12\,\mathbf{d}^{\mathsf T}\nabla^2 f(\mathbf{x}^*)\,\mathbf{d}+o(\|\mathbf{d}\|^2).$$

Optimality conditions without constraints

1. **First-order necessary condition (FONC).** If $\mathbf{x}^*$ is a local minimiser, then $\nabla f(\mathbf{x}^*)=\mathbf{0}$ ($\mathbf{x}^*$ is a **stationary point**).
2. **Second-order necessary condition (SONC).** If $\mathbf{x}^*$ is a local minimiser, then $\nabla^2 f(\mathbf{x}^*)$ is positive semidefinite.
3. **Second-order sufficient condition (SOSC).** If $\nabla f(\mathbf{x}^*)=\mathbf{0}$ and $\nabla^2 f(\mathbf{x}^*)$ is positive definite, then $\mathbf{x}^*$ is a strict local minimiser.

Proof. (1) If $\mathbf{g}=\nabla f(\mathbf{x}^*)\neq\mathbf{0}$, take $\mathbf{d}=-t\mathbf{g}$: $f(\mathbf{x}^*-t\mathbf{g})=f(\mathbf{x}^*)-t\|\mathbf{g}\|^2+O(t^2)<f(\mathbf{x}^*)$ for small $t>0$, contradicting minimality. (2) With $\nabla f=\mathbf{0}$, if some $\mathbf{d}$ had $\mathbf{d}^{\mathsf T}\nabla^2 f\,\mathbf{d}<0$, then $f(\mathbf{x}^*+t\mathbf{d})-f(\mathbf{x}^*)=\tfrac12 t^2\mathbf{d}^{\mathsf T}\nabla^2 f\,\mathbf{d}+o(t^2)<0$ for small t. (3) If $\nabla^2 f(\mathbf{x}^*)\succ 0$ with smallest eigenvalue $\lambda_{\min}>0$, then $\tfrac12\mathbf{d}^{\mathsf T}\nabla^2 f\,\mathbf{d}\geq\tfrac12\lambda_{\min}\|\mathbf{d}\|^2$, which beats the $o(\|\mathbf{d}\|^2)$ remainder for $\mathbf{d}$ small enough, so $f(\mathbf{x}^*+\mathbf{d})>f(\mathbf{x}^*)$ for small $\mathbf{d}\neq\mathbf{0}$. $\square$

Definiteness is checked by eigenvalues or, for small matrices, by leading principal minors (Ch. 10 §10.6). At a stationary point:

Hessian	Conclusion
positive definite (all $\lambda_i>0$)	strict local minimum
negative definite (all $\lambda_i<0$)	strict local maximum
indefinite (eigenvalues of both signs)	saddle point
semidefinite and singular	inconclusive — look at higher-order terms

Worked Example 23.11 — stationary points and their type

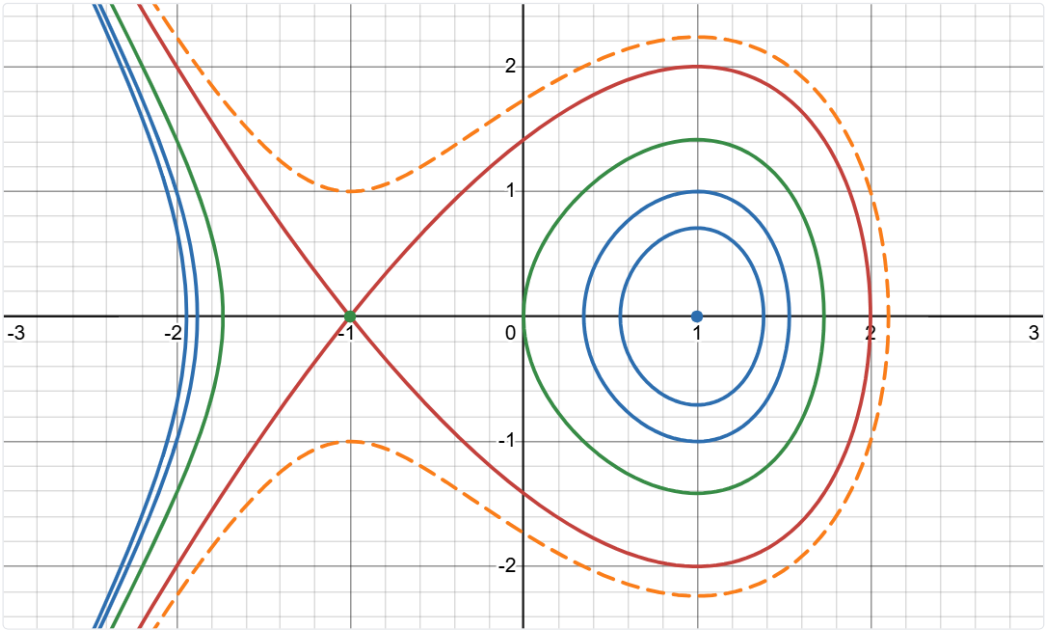
Classify the stationary points of $f(x,y)=x^3-3x+y^2$.

Step 1 (gradient): $\nabla f=(3x^2-3,\;2y)=\mathbf{0}$ gives $x=\pm1$, $y=0$.

Step 2 (Hessian): $\nabla^2 f=\begin{pmatrix}6x & 0\\ 0 & 2\end{pmatrix}$.

- At $(1,0)$: $\operatorname{diag}(6,2)\succ 0\to$ strict local minimum, $f=-2$.
- At $(-1,0)$: $\operatorname{diag}(-6,2)$ indefinite $\to$ saddle, $f=2$.

Step 3 (global?): along $y=0$, $f(x,0)=x^3-3x\to-\infty$ as $x\to-\infty$. The local minimum is **not** global; f is unbounded below. A descent algorithm started at $(-3,0)$ never finds $(1,0)$ — it runs off to $-\infty$.



Level curves of $f=x^3-3x+y^2$. Closed curves surround the local minimum at $(1,0)$; the red level $f=2$ crosses itself at the saddle $(-1,0)$, and to the left the function falls without bound.

Common Pitfall — a semidefinite Hessian proves nothing

$f_1=x^4+y^2$, $f_2=x^3+y^2$ and $f_3=-x^4+y^2$ all have $\nabla f=\mathbf{0}$ and Hessian $\operatorname{diag}(0,2)$ at the origin. The origin is a strict minimum of f_1, a degenerate saddle of f_2 and a saddle of f_3. When the Hessian is singular, the second-order test is silent; examine f along the null direction (here the x-axis).

Equality constraints: the Lagrange conditions

For $\min f(\mathbf{x})$ subject to $h_k(\mathbf{x}) = 0$ ($k = 1, \dots, p$), Chapter 6 showed that at a constrained extremum the gradient of f must be a linear combination of the constraint gradients, provided those gradients are linearly independent (Ch. 6 §6.11). With the **Lagrangian**

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \sum_{k=1}^{p} \lambda_k h_k(\mathbf{x}),$$

the conditions are $\nabla_{\mathbf{x}} \mathcal{L} = \mathbf{0}$ and $\nabla_{\boldsymbol{\lambda}} \mathcal{L} = \mathbf{h}(\mathbf{x}) = \mathbf{0}$: $n + p$ equations in $n + p$ unknowns. The geometric reason: any feasible direction $\mathbf{d}$ is tangent to every constraint surface, $\nabla h_k^{\mathsf{T}} \mathbf{d} = 0$, and at a minimum f cannot decrease along such directions, so $\nabla f \perp \mathbf{d}$ for all tangent $\mathbf{d}$ — that is, ∇f lies in the span of the ∇h_k. (Chapter 6 writes $\nabla f = \lambda \nabla h$; with our sign convention $\nabla f + \lambda \nabla h = \mathbf{0}$ the multiplier simply changes sign.)

The multiplier is a **sensitivity**: if the constraint is $h(\mathbf{x}) = b$ rather than 0, then $\dfrac{df^*}{db} = -\lambda^*$ in our convention. In Example 23.5, relaxing $x + y = 1$ to $x + y = b$ gives $f^* = b^2/2$ and $df^*/db = 1 = -\lambda^*$ at $b = 1$ ✓.

Inequality constraints: the KKT conditions

Now add inequalities $g_i(\mathbf{x}) \le 0$. At a candidate $\mathbf{x}^*$ only the active ones matter. For an active g_i, a direction $\mathbf{d}$ keeps us feasible to first order if $\nabla g_i^{\mathsf{T}} \mathbf{d} \le 0$ (we may move *into* the feasible side, not just along the boundary). At a minimum, no feasible direction may decrease f:

$$\nabla g_i(\mathbf{x}^*)^{\mathsf{T}} \mathbf{d} \le 0 \ \text{ for all active } i \quad \Longrightarrow \quad \nabla f(\mathbf{x}^*)^{\mathsf{T}} \mathbf{d} \ge 0.$$

By Farkas' lemma (the same theorem of alternatives that underlies LP duality), this implication holds exactly when $-\nabla f(\mathbf{x}^*)$ is a **nonnegative** combination of the active constraint gradients: $-\nabla f = \sum_{i \in \mathcal{A}} \mu_i \nabla g_i$ with $\mu_i \ge 0$. Geometrically: the downhill direction $-\nabla f$ points straight out of the feasible set, into the cone spanned by the outward normals of the active walls. If it pointed anywhere else, there would be a feasible downhill direction.

Setting $\mu_i = 0$ for inactive constraints and including equality constraints gives the central theorem of constrained optimization.

Karush–Kuhn–Tucker (KKT) conditions

Let $\mathbf{x}^*$ be a local minimiser of f subject to $g_i(\mathbf{x}) \le 0$ ($i = 1, \dots, m$) and $h_k(\mathbf{x}) = 0$ ($k = 1, \dots, p$), all continuously differentiable, and suppose a **constraint qualification** holds at $\mathbf{x}^*$ — for instance LICQ: the gradients of the active inequalities and of all equalities are linearly independent. Then there exist multipliers μ_i and λ_k such that

$$\begin{aligned}
&\text{stationarity:} && \nabla f(\mathbf{x}^*) + \sum_{i=1}^{m} \mu_i \nabla g_i(\mathbf{x}^*) + \sum_{k=1}^{p} \lambda_k \nabla h_k(\mathbf{x}^*) = \mathbf{0}, \\
&\text{primal feasibility:} && g_i(\mathbf{x}^*) \le 0, \quad h_k(\mathbf{x}^*) = 0, \\
&\text{dual feasibility:} && \mu_i \ge 0, \\
&\text{complementary slackness:} && \mu_i \, g_i(\mathbf{x}^*) = 0 \quad \text{for every } i.
\end{aligned}$$

If the problem is **convex** (f and all g_i convex, all h_k affine), the KKT conditions are also **sufficient**: any KKT point is a global minimiser (§23.7).

Remarks:

- **Complementary slackness** encodes the active-set logic: either a constraint is active ($g_i = 0$) or its multiplier is zero. It is the nonlinear version of the LP statement "spare capacity has zero price".
- **The sign of μ_i matters**, unlike λ_k. A negative multiplier on an active inequality says the objective would improve by moving *into* the interior, so the constraint should not be active — the guess of active set was wrong.
- **Sensitivity.** If $g_i(\mathbf{x}) \le b_i$, then $\partial f^*/\partial b_i = -\mu_i^*$: relaxing a constraint by one unit lowers the optimal cost by about μ_i^*. The multipliers are shadow prices, exactly as in LP; for an LP, the KKT conditions *are* primal feasibility, dual feasibility and complementary slackness.
- **Second-order conditions** for constrained problems test the Hessian of the Lagrangian, $\nabla^2_{\mathbf{xx}} \mathcal{L}$, only on directions tangent to the active constraints (the bordered-Hessian test of Ch. 6 is the two-variable special case).

A recipe for small problems

1. Write all constraints as $g_i \le 0$, $h_k = 0$ and form $\mathcal{L} = f + \sum \mu_i g_i + \sum \lambda_k h_k$.
2. Solve the unconstrained problem; if its minimiser is feasible and the problem is convex, you are done (all $\mu_i = 0$).
3. Otherwise, guess an active set $\mathcal{A}$. Solve stationarity together with $g_i = 0$ ($i \in \mathcal{A}$), $h_k = 0$, and $\mu_i = 0$ ($i \notin \mathcal{A}$).
4. Accept the guess if all inactive constraints are satisfied and all $\mu_i \ge 0$; otherwise try another active set. With m inequalities there are at most 2^m guesses — fine by hand for $m \le 3$; algorithms (active-set and interior-point methods) organise this search for large m.

Worked Example 23.12 — projection onto a half-plane

Minimise $f = (x - 2)^2 + (y - 1)^2$ subject to $g_1 = x + y - 2 \le 0$ and $g_2 = -x \le 0$.

Step 1 (unconstrained): the minimiser $(2, 1)$ has $g_1 = 1 > 0$: infeasible, so g_1 must be active.

Step 2 (guess $\mathcal{A} = \{1\}$): stationarity $\big(2(x - 2) + \mu_1,\ 2(y - 1) + \mu_1\big) = \mathbf{0}$ gives $x - 2 = y - 1$, i.e. $x = y + 1$. With $x + y = 2$: $y = \tfrac{1}{2}$, $x = \tfrac{3}{2}$, and $\mu_1 = -2(x - 2) = 1$.

Step 3 (verify): $\mu_1 = 1 \ge 0$ ✓; inactive $g_2 = -\tfrac{3}{2} < 0$ ✓ with $\mu_2 = 0$. KKT point $(1.5, 0.5)$, $f^* = 0.5$. The problem is convex, so this is the global minimum: the closest point to $(2, 1)$ in the region.

Step 4 (sensitivity): relax to $x + y \le 2 + \varepsilon$; the projection becomes $(1.5 + \varepsilon/2,\ 0.5 + \varepsilon/2)$ and $f^* = 2\big(\tfrac{1 - \varepsilon}{2}\big)^2 = \tfrac{1}{2}(1 - \varepsilon)^2$, so $df^*/d\varepsilon = -1 = -\mu_1$ at $\varepsilon = 0$ ✓.

Worked Example 23.13 — the minimum-norm point of a half-plane

Minimise $f = x^2 + y^2$ subject to $x + 2y \geq 2$.

Step 1 (standard form): $g = 2 - x - 2y \leq 0$. The unconstrained minimiser $(0, 0)$ has $g = 2 > 0$, infeasible.

Step 2 (active): stationarity $(2x - \mu,\ 2y - 2\mu) = \mathbf{0}$ gives $x = \mu/2$, $y = \mu$. Then $x + 2y = \frac{5}{2}\mu = 2 \Rightarrow \mu = \frac{4}{5}$, $(x, y) = (\frac{2}{5}, \frac{4}{5})$.

Step 3 (check): $\mu = 0.8 \geq 0$ ✓, $f^* = \frac{4}{25} + \frac{16}{25} = \frac{4}{5}$. Geometric check: the distance from the origin to the line $x + 2y = 2$ is $2/\sqrt{5}$, whose square is $\frac{4}{5}$ ✓. And $-\nabla f = (-0.8, -1.6) = \mu \nabla g = 0.8(-1, -2)$: the downhill direction points out of the feasible set along the outward normal, as the theory says.

Worked Example 23.14 — KKT with case analysis

Minimise $f = (x - 3)^2 + (y - 2)^2$ subject to $g_1 = x^2 + y^2 - 5 \leq 0$ (a disc) and $g_2 = x + 2y - 4 \leq 0$ (a half-plane).

Step 1 (unconstrained): $(3, 2)$ violates both ($13 > 5$, $7 > 4$).

Step 2 (only g_1 active): the closest point of the circle to $(3, 2)$ is $(3, 2)\sqrt{5}/\sqrt{13} = (1.861, 1.240)$. But $g_2 = 1.861 + 2.481 - 4 = 0.342 > 0$: infeasible, reject.

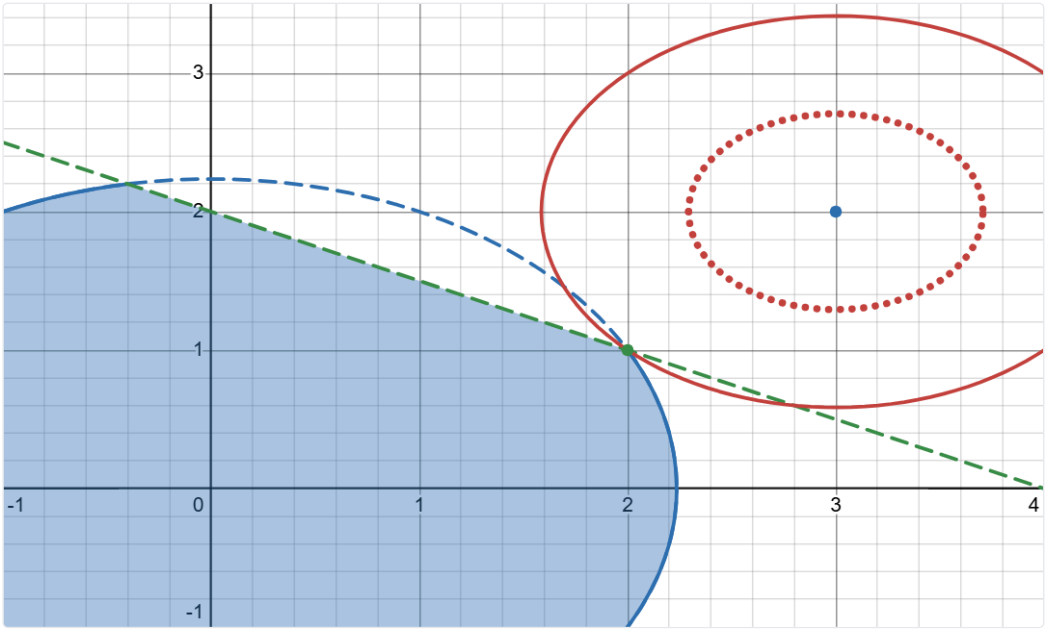
Step 3 (only g_2 active): the projection onto the line $x + 2y = 4$ is $(3, 2) - \frac{3+4-4}{5}(1, 2) = (2.4, 0.8)$. But $g_1 = 5.76 + 0.64 - 5 = 1.4 > 0$: infeasible, reject.

Step 4 (both active): $x = 4 - 2y$ in $x^2 + y^2 = 5$ gives $5y^2 - 16y + 11 = 0$, $y = 1$ or $y = \frac{11}{5}$. Take $(2, 1)$ (the other root $(-0.4, 2.2)$ is farther from $(3, 2)$; one can check its multipliers are not both nonnegative). Stationarity at $(2, 1)$:

$$\begin{pmatrix} -2 \\ -2 \end{pmatrix} + \mu_1 \begin{pmatrix} 4 \\ 2 \end{pmatrix} + \mu_2 \begin{pmatrix} 1 \\ 2 \end{pmatrix} = \mathbf{0} \ \Rightarrow\ 4\mu_1 + \mu_2 = 2,\ \ 2\mu_1 + 2\mu_2 = 2 \ \Rightarrow\ \mu_1 = \tfrac{1}{3},\ \mu_2 = \tfrac{2}{3}.$$

Step 5 (accept): both multipliers are positive ✓, so $(2, 1)$ is a KKT point with $f^* = 2$. The problem is convex (disc and half-plane are convex sets, f is convex), so it is the global minimum. A numerical solver (`scipy.optimize.minimize` with SLSQP) returns $(2.000, 1.000)$, $f = 2.000$ ✓.

Step 6 (sensitivity): enlarging the disc to radius^2 5.1 lowers f^* by about $\mu_1 \times 0.1 = 0.033$; the re-solved value is 1.968, a drop of 0.032 ✓.



Example 23.14: the feasible set (blue) is the part of the disc below the green line. The smallest contour of f (red) that touches it does so at the corner $(2, 1)$, where both constraints are active.

Engineering Note — water-filling

Allocating total power P across parallel channels with noise levels N_i to maximise capacity, $\max \sum_i \log(1 + p_i/N_i)$ s.t. $\sum p_i = P$, $p_i \geq 0$, is a convex problem whose KKT conditions give $p_i = \max(0,\ \nu - N_i)$ for a common "water level" ν. Channels whose noise exceeds the level get no power — their nonnegativity constraints are active. This one-line KKT result underlies power allocation in OFDM and MIMO systems.

23.5 Gradient-based methods

Motivation

The optimality conditions are equations, but for realistic problems — a 64-tap filter, a 20-parameter device model, a neural-network equaliser with 10^5 weights — they cannot be solved in closed form. Instead we **iterate**: start from a guess $\mathbf{x}_0$ and generate $\mathbf{x}_1, \mathbf{x}_2, \ldots$ with f decreasing at each step. The simplest and most widely used idea is to walk downhill along the negative gradient. Gradient descent is cheap (one gradient per step, no matrices), works in any dimension, and is the engine of adaptive filtering and machine learning. It is also slow on badly scaled problems, and understanding exactly why is the key to every faster method.

Descent directions and the generic iteration

All methods in this section and the next have the form

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{p}_k,$$

with a **search direction** $\mathbf{p}_k$ and a **step size** (learning rate) $\alpha_k > 0$.

Descent direction

$\mathbf{p}$ is a descent direction for f at $\mathbf{x}$ if $\nabla f(\mathbf{x})^{\mathsf T}\mathbf{p} < 0$. Then $f(\mathbf{x}+\alpha\mathbf{p}) < f(\mathbf{x})$ for all sufficiently small $\alpha > 0$, because $\dfrac{d}{d\alpha} f(\mathbf{x}+\alpha\mathbf{p})\Big|_{\alpha=0} = \nabla f(\mathbf{x})^{\mathsf T}\mathbf{p} < 0$.

Among unit vectors $\mathbf{p}$, the directional derivative $\nabla f^{\mathsf T}\mathbf{p} = \|\nabla f\|\cos\theta$ is most negative for $\theta = \pi$, i.e. $\mathbf{p} = -\nabla f/\|\nabla f\|$ (Ch. 6 §6.5). This gives **steepest descent** (gradient descent):

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k \nabla f(\mathbf{x}_k).$$

The negative gradient is perpendicular to the level curve through $\mathbf{x}_k$; each step leaves the contour at right angles. "Steepest" is relative to the Euclidean norm, i.e. to the units the variables are measured in — rescaling the variables changes the direction, which is the root of both the method's weakness and its cure (§23.6).

Fixed step sizes: when does it converge?

Suppose ∇f is **Lipschitz continuous** with constant L: $\|\nabla f(\mathbf{x}) - \nabla f(\mathbf{y})\| \le L\|\mathbf{x}-\mathbf{y}\|$ (for a C^2 function, L bounds the largest Hessian eigenvalue in magnitude). Then f lies below a quadratic upper bound,

$$f(\mathbf{y}) \le f(\mathbf{x}) + \nabla f(\mathbf{x})^{\mathsf T}(\mathbf{y}-\mathbf{x}) + \frac{L}{2}\|\mathbf{y}-\mathbf{x}\|^2,$$

and substituting $\mathbf{y} = \mathbf{x} - \alpha\nabla f(\mathbf{x})$ yields the **descent lemma**

$$f(\mathbf{x}_{k+1}) \le f(\mathbf{x}_k) - \alpha\Big(1 - \frac{L\alpha}{2}\Big)\|\nabla f(\mathbf{x}_k)\|^2.$$

Convergence of gradient descent with a fixed step

If f is bounded below and ∇f is L-Lipschitz, then for any fixed $0 < \alpha < 2/L$ the iterates satisfy $f(\mathbf{x}_{k+1}) < f(\mathbf{x}_k)$ whenever $\nabla f(\mathbf{x}_k) \neq \mathbf{0}$, and $\nabla f(\mathbf{x}_k) \to \mathbf{0}$. The choice $\alpha = 1/L$ maximises the guaranteed decrease, $f(\mathbf{x}_{k+1}) \le f(\mathbf{x}_k) - \frac{1}{2L}\|\nabla f(\mathbf{x}_k)\|^2$.

Proof sketch. The bracket $1 - L\alpha/2$ is positive for $\alpha < 2/L$, so f decreases by a positive multiple of $\|\nabla f\|^2$. Summing the inequality from $k=0$ to $N-1$ gives $c\sum_k \|\nabla f(\mathbf{x}_k)\|^2 \le f(\mathbf{x}_0) - f(\mathbf{x}_N) \le f(\mathbf{x}_0) - f_{\inf} < \infty$, so the gradient norms are square-summable and tend to zero. □

Note what is *not* claimed: convergence to a global minimum. Gradient descent finds a stationary point; convexity (§23.7) is what makes that point the answer.

The quadratic model problem

Everything about gradient descent can be seen on $f(\mathbf{x}) = \tfrac12 \mathbf{x}^{\mathsf T}\mathbf{A}\mathbf{x} - \mathbf{b}^{\mathsf T}\mathbf{x}$ with $\mathbf{A}$ symmetric positive definite, eigenvalues $0 < m = \lambda_{\min} \le \cdots \le \lambda_{\max} = L$. The minimiser solves $\mathbf{A}\mathbf{x}^* = \mathbf{b}$, and the gradient is $\mathbf{A}\mathbf{x} - \mathbf{b} = \mathbf{A}(\mathbf{x} - \mathbf{x}^*)$. The error $\mathbf{e}_k = \mathbf{x}_k - \mathbf{x}^*$ obeys

$$\mathbf{e}_{k+1} = (\mathbf{I} - \alpha\mathbf{A})\,\mathbf{e}_k.$$

Expanding $\mathbf{e}_0$ in the eigenvectors $\mathbf{v}_i$ of $\mathbf{A}$ (Ch. 10), each component is multiplied by $1 - \alpha\lambda_i$ per step. Hence:

- convergence for every start $\iff$ $|1-\alpha\lambda_i| < 1$ for all i $\iff$ $0 < \alpha < 2/L$;
- the slowest component decays like $\max_i |1-\alpha\lambda_i|^k$;
- minimising $\max(|1-\alpha m|, |1-\alpha L|)$ gives the **best fixed step** $\alpha^* = \dfrac{2}{m+L}$ and the **convergence factor**

$$\rho = \frac{L-m}{L+m} = \frac{\kappa - 1}{\kappa + 1}, \qquad \kappa = \frac{L}{m} = \operatorname{cond}(\mathbf{A}).$$

The **condition number** κ governs everything. To gain one decimal digit of accuracy needs about $\ln 10 / \ln(1/\rho) \approx 1.15\,\kappa$ iterations when κ is large. A problem with $\kappa = 10^4$ needs tens of thousands of gradient steps — while Newton's method (§23.6) would take one.

Worked Example 23.15 — fixed step on a one-dimensional quadratic

$f(x) = 2x^2$, so $f'(x) = 4x$, $L = 4$, $x^* = 0$, starting at $x_0 = 1$.

Step 1 (iteration): $x_{k+1} = x_k - 4\alpha x_k = (1-4\alpha)x_k$, so $x_k = (1-4\alpha)^k$.

Step 2 (cases):

- $\alpha = 0.1$: factor 0.6, monotone convergence; $x_{10} = 0.006$.
- $\alpha = 0.25 = 1/L$: factor 0, exact in one step (in one dimension $1/L$ is Newton's step).
- $\alpha = 0.4$: factor -0.6, convergence with sign flips (overshooting).
- $\alpha = 0.5 = 2/L$: factor -1, $x_k = (-1)^k$ oscillates forever.
- $\alpha = 0.6$: factor -1.4, divergence.

Step 3 (lesson): the stability limit $\alpha < 2/L$ is exactly the condition for a first-order discrete-time system $x_{k+1} = (1-\alpha L)x_k$ to have its pole inside the unit circle (Ch. 17). Gradient descent *is* a discrete-time feedback loop.

Worked Example 23.16 — step size on an anisotropic bowl

$f(x,y) = x^2 + 5y^2$, i.e. $\mathbf{A} = \operatorname{diag}(2, 10)$, $m = 2$, $L = 10$, $\kappa = 5$. Start at $(5, 1)$, $f_0 = 30$.

Step 1 (per-coordinate factors): $x_{k+1} = (1 - 2\alpha)x_k$ and $y_{k+1} = (1 - 10\alpha)y_k$.

Step 2 (stability): need $|1 - 10\alpha| < 1$, i.e. $\alpha < 0.2 = 2/L$. The *stiff* direction y (large curvature) sets the limit, while the *soft* direction x (small curvature) sets the speed.

Step 3 (compare after 20 steps):

α	x factor	y factor	$f(\mathbf{x}_{20})$
0.05	0.9	0.5	0.37
0.10	0.8	0	3.3×10^{-3}
1/6 (optimal)	$2/3$	$-2/3$	2.7×10^{-6}
0.18	0.64	-0.8	6.7×10^{-4}
0.21	0.58	-1.1	226 (diverging)

For the optimal step both factors have magnitude $\rho = (5-1)/(5+1) = 2/3$, so f falls by $\rho^2 = 4/9$ per step: $30(4/9)^{20} = 2.7 \times 10^{-6}$.

Step 4 (lesson): the best step is a compromise dictated by the two extreme curvatures. If the problem were rescaled so that $\kappa = 1$ (substitute $y = u/\sqrt{5}$), a single step would suffice.

Line search

Rather than a fixed α, choose α_k at each step by searching along the ray $\phi(\alpha) = f(\mathbf{x}_k + \alpha \mathbf{p}_k)$.

Exact line search minimises ϕ. For the quadratic, $\phi(\alpha) = f(\mathbf{x}_k) - \alpha \mathbf{g}_k^{\mathsf T}\mathbf{g}_k + \tfrac{1}{2}\alpha^2 \mathbf{g}_k^{\mathsf T}\mathbf{A}\mathbf{g}_k$ along $\mathbf{p}_k = -\mathbf{g}_k$, so

$$\alpha_k = \frac{\mathbf{g}_k^{\mathsf T}\mathbf{g}_k}{\mathbf{g}_k^{\mathsf T}\mathbf{A}\mathbf{g}_k}.$$

At the exact minimiser along the line, $\phi'(\alpha_k) = \nabla f(\mathbf{x}_{k+1})^{\mathsf T}\mathbf{p}_k = 0$: **the new gradient is orthogonal to the old search direction**. For steepest descent this means consecutive steps are at right angles — the notorious **zig-zag**. The classical bound (Kantorovich) is

$$f(\mathbf{x}_{k+1}) - f^\ast \le \left(\frac{\kappa - 1}{\kappa + 1}\right)^2 \big(f(\mathbf{x}_k) - f^\ast\big),$$

the same rate as the optimal fixed step: exact line search removes the need to know m and L, but does not beat the condition number.

Inexact line search is what real codes do, because each evaluation of f may be expensive. The aim is just "enough" decrease:

Armijo (sufficient decrease) and Wolfe conditions

For a descent direction $\mathbf{p}_k$ and constants $0 < c_1 < c_2 < 1$ (typically $c_1 = 10^{-4}$, $c_2 = 0.9$), a step α satisfies

- the **Armijo condition** if $f(\mathbf{x}_k + \alpha\mathbf{p}_k) \le f(\mathbf{x}_k) + c_1 \alpha \nabla f(\mathbf{x}_k)^{\mathsf T}\mathbf{p}_k$;
- the **curvature condition** if $\nabla f(\mathbf{x}_k + \alpha\mathbf{p}_k)^{\mathsf T}\mathbf{p}_k \ge c_2 \nabla f(\mathbf{x}_k)^{\mathsf T}\mathbf{p}_k$.

Both together are the **Wolfe conditions**. Armijo forbids steps that are too long (too little decrease for their length); the curvature condition forbids steps that are too short (the slope has not flattened enough).

Backtracking implements Armijo simply: try $\alpha = \alpha_0$ (say 1); while the Armijo condition fails, set $\alpha \leftarrow \beta\alpha$ (say $\beta = \tfrac{1}{2}$). Because $\mathbf{p}_k$ is a descent direction, a small enough α always passes, so the loop terminates.

Worked Example 23.17 — exact line search and the zig-zag

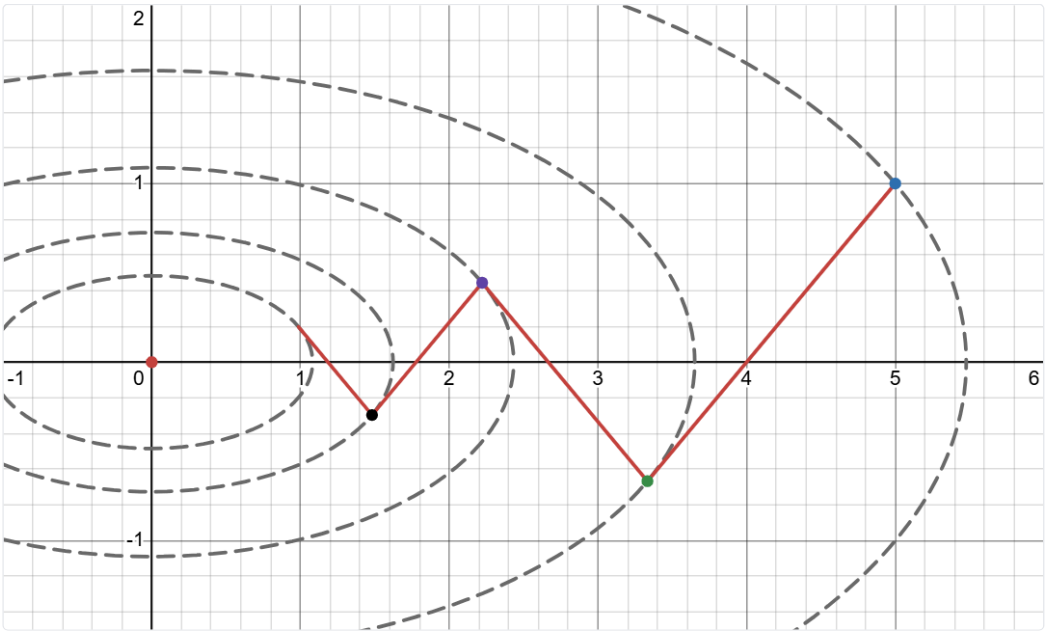
Apply steepest descent with exact line search to $f = x^2 + 5y^2$ from $(5, 1)$.

Step 1: $\mathbf{g}_0 = (2x, 10y) = (10, 10)$. $\mathbf{g}_0^{\mathsf T}\mathbf{g}_0 = 200$, $\mathbf{g}_0^{\mathsf T}\mathbf{A}\mathbf{g}_0 = 2(100) + 10(100) = 1200$, so $\alpha_0 = \tfrac{1}{6}$ and $\mathbf{x}_1 = (5, 1) - \tfrac{1}{6}(10, 10) = (\tfrac{10}{3}, -\tfrac{2}{3})$, $f_1 = \tfrac{100}{9} + \tfrac{20}{9} = 13.33$.

Step 2: $\mathbf{g}_1 = (\tfrac{20}{3}, -\tfrac{20}{3})$. Check orthogonality: $\mathbf{g}_1^{\mathsf T}\mathbf{g}_0 = \tfrac{200}{3} - \tfrac{200}{3} = 0$ ✓. Again $\alpha_1 = \tfrac{1}{6}$, giving $\mathbf{x}_2 = (\tfrac{20}{9}, \tfrac{4}{9})$, $f_2 = 5.93$.

Step 3 (pattern): $\mathbf{x}_3 = (\tfrac{40}{27}, -\tfrac{8}{27})$, $\mathbf{x}_4 = (\tfrac{80}{81}, \tfrac{16}{81})$, and $f_k = 30(\tfrac{4}{9})^k$: $30,\ 13.3,\ 5.93,\ 2.63,\ 1.17$. Each step multiplies f by exactly $(\tfrac{\kappa-1}{\kappa+1})^2 = \tfrac{4}{9}$: this starting point is the worst case of the Kantorovich bound.

Step 4 (picture): each step goes along $\pm 45^\circ$ and turns 90°; the path bounces across the narrow valley.



Steepest descent with exact line search on $f = x^2 + 5y^2$ (contours dashed). Every step leaves a contour at right angles and is orthogonal to the previous step, producing the characteristic zig-zag toward the minimum.

Worked Example 23.18 — backtracking on the Rosenbrock function

The Rosenbrock function $f(x, y) = (1 - x)^2 + 100(y - x^2)^2$ has its minimum $f = 0$ at $(1, 1)$ at the bottom of a long, curved, narrow valley. Take one backtracking step from the standard start $(-1.2, 1)$ with $\alpha_0 = 1$, $\beta = \tfrac{1}{2}$, $c_1 = 10^{-4}$.

Step 1 (gradient): $\partial f/\partial x = -2(1 - x) - 400x(y - x^2)$ and $\partial f/\partial y = 200(y - x^2)$. At $(-1.2, 1)$: $y - x^2 = -0.44$, so $\nabla f = (-4.4 - 211.2,\ -88) = (-215.6,\ -88)$, $\|\nabla f\|^2 = 54\,227$, $f_0 = 24.2$.

Step 2 (backtrack): trial f values for $\alpha = 1, \tfrac{1}{2}, \tfrac{1}{4}, \ldots$ are 2.1×10^{11}, 1.3×10^{10}, …, 543.5 ($\alpha = 2^{-6}$), 211.4, 149.6, 35.1 ($\alpha = 2^{-9}$) — all rejected; the Armijo bound $24.2 - 10^{-4}\alpha\,(54\,227)$ is about 24.2.

Step 3 (accept): $\alpha = 2^{-10} \approx 9.77 \times 10^{-4}$ gives $(-0.989,\ 1.086)$ with $f = 5.10 < 24.2$ ✓.

Step 4 (the long run): continuing with backtracking, gradient descent needs about 1.4×10^4 iterations to reach $\|\nabla f\| < 10^{-6}$. The Hessian at the minimum is $\begin{pmatrix} 802 & -400 \\ -400 & 200 \end{pmatrix}$, with condition number about 2500. Newton's method (§23.6) gets there in 6 iterations.

Beyond plain gradient descent

- **Momentum (heavy ball).** $\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha \nabla f(\mathbf{x}_k) + \beta(\mathbf{x}_k - \mathbf{x}_{k-1})$. The extra term is a low-pass filter on the step sequence that damps the zig-zag. On quadratics, optimally tuned α, β improve the convergence factor from $(\kappa - 1)/(\kappa + 1)$ to $(\sqrt{\kappa} - 1)/(\sqrt{\kappa} + 1)$, so the iteration count scales with $\sqrt{\kappa}$ instead of κ: for $\kappa = 10^4$, roughly 100 times fewer iterations. Nesterov's accelerated gradient achieves this rate for general smooth convex functions.
- **Conjugate gradient (CG).** For quadratics, choosing each direction to be $\mathbf{A}$-conjugate to the previous ones ($\mathbf{p}_i^{\mathsf{T}} \mathbf{A} \mathbf{p}_j = 0$) cures the zig-zag: CG reaches the exact minimiser in at most n steps and is the standard iterative solver for large sparse SPD systems (Ch. 24). Nonlinear variants (Fletcher–Reeves, Polak–Ribière) extend it to general f.
- **Stochastic gradient.** When $f = \frac{1}{N}\sum_i f_i$ is an average over many data points, use the gradient of one (or a few) f_i per step: noisy but N times cheaper.

Engineering Note — the LMS adaptive filter is stochastic gradient descent

An adaptive FIR filter with weights $\mathbf{w}$ and input vector $\mathbf{u}_n$ should minimise the mean-square error $E[e_n^2]$, $e_n = d_n - \mathbf{w}^{\mathsf{T}}\mathbf{u}_n$. The true gradient is $-2E[e_n \mathbf{u}_n]$; replacing the expectation by its instantaneous value gives Widrow's **least-mean-squares** update $\mathbf{w}_{n+1} = \mathbf{w}_n + \mu\, e_n \mathbf{u}_n$. The stability limit $\alpha < 2/L$ becomes the classical LMS bound $0 < \mu < 2/\lambda_{\max}(\mathbf{R})$, where $\mathbf{R} = E[\mathbf{u}_n \mathbf{u}_n^{\mathsf{T}}]$ is the input autocorrelation matrix (Ch. 21), and the convergence speed is governed by its eigenvalue spread — exactly the condition number story above.

Common Pitfall — stopping tests

"Stop when f stops changing" can halt in a flat region far from a minimum; "stop when $\|\nabla f\| < \varepsilon$" depends on the units of f and $\mathbf{x}$. Robust codes combine a *relative* gradient test, $\|\nabla f(\mathbf{x}_k)\| \le \varepsilon \max(1, |f(\mathbf{x}_k)|)$, with a small-step test and an iteration limit, and report which one fired.

A minimal implementation:

```
import numpy as np

def grad_descent(f, grad, x0, alpha0=1.0, beta=0.5, c1=1e-4, tol=1e-6, maxit=100000):
    x = np.asarray(x0, float)
    for k in range(maxit):
        g = grad(x)
        if np.linalg.norm(g) < tol:
            break
        a = alpha0
        while f(x - a*g) > f(x) - c1*a*(g @ g):   # Armijo backtracking
            a *= beta
        x = x - a*g
    return x, k
```

23.6 Newton and quasi-Newton methods

Motivation

Gradient descent uses only the slope; it does not know how curved the function is, so it cannot tell a gentle valley from a steep one and must use a step that is safe for the steepest direction. Newton's method also uses the **curvature** (the Hessian): it fits a quadratic bowl to f at the current point and jumps straight to the bottom of the bowl. Near a minimum this converges *quadratically* — the number of correct digits doubles every iteration — and is immune to bad scaling. The price is computing and factoring an $n \times n$ Hessian at every step. **Quasi-Newton** methods, BFGS above all, get most of the benefit while using only gradients, by learning the curvature from the history of steps. BFGS is the default unconstrained method in most scientific software, including SciPy's `minimize`.

Newton's method

At $\mathbf{x}_k$, with $\mathbf{g}_k = \nabla f(\mathbf{x}_k)$ and $\mathbf{H}_k = \nabla^2 f(\mathbf{x}_k)$, the quadratic model is

$$m_k(\mathbf{p}) = f(\mathbf{x}_k) + \mathbf{g}_k^{\mathsf T}\mathbf{p} + \tfrac{1}{2}\mathbf{p}^{\mathsf T}\mathbf{H}_k\mathbf{p}.$$

If $\mathbf{H}_k \succ 0$, the model has a unique minimiser where $\nabla m_k = \mathbf{g}_k + \mathbf{H}_k\mathbf{p} = \mathbf{0}$:

Newton step

$$\mathbf{H}_k\,\mathbf{p}_k^{\mathrm N} = -\mathbf{g}_k, \qquad \mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{p}_k^{\mathrm N},$$

with $\alpha_k = 1$ for the *pure* Newton method. The linear system is solved (never by forming $\mathbf{H}_k^{-1}$) by Cholesky factorisation, which also tests $\mathbf{H}_k \succ 0$ for free: the factorisation fails if it is not (Ch. 10 §10.6).

Two other views of the same iteration are useful:

- **Root-finding view.** Minimising f means solving $\nabla f(\mathbf{x}) = \mathbf{0}$. Newton's method for the nonlinear system $\mathbf{F}(\mathbf{x}) = \mathbf{0}$ uses the Jacobian of $\mathbf{F}$ (Ch. 6 §6.6, Ch. 22); with $\mathbf{F} = \nabla f$ the Jacobian is the Hessian, and we recover the Newton step. In one dimension: $x_{k+1} = x_k - f'(x_k)/f''(x_k)$.
- **Rescaling view.** If $\mathbf{H} \succ 0$, change variables to $\mathbf{u} = \mathbf{H}^{1/2}\mathbf{x}$. In $\mathbf{u}$ the local quadratic model is a perfectly round bowl ($\kappa = 1$) and steepest descent with unit step goes straight to its centre. Translating back gives the Newton step. Newton's method is **affine invariant**: a linear change of variables $\mathbf{x} = \mathbf{T}\mathbf{z}$ does not change the iterates (mapped back), so units and scaling do not matter — in sharp contrast to gradient descent.

A **descent property**: if $\mathbf{H}_k \succ 0$ then $\mathbf{g}_k^{\mathsf T}\mathbf{p}_k^{\mathrm N} = -\mathbf{g}_k^{\mathsf T}\mathbf{H}_k^{-1}\mathbf{g}_k < 0$, so the Newton direction is a descent direction and a line search can be applied. If $\mathbf{H}_k$ is indefinite, the "Newton step" heads for the stationary point of an indefinite quadratic — a saddle — and may go uphill.

Local quadratic convergence of Newton's method

Let $f \in C^2$ with Lipschitz-continuous Hessian near a point $\mathbf{x}^\ast$ where $\nabla f(\mathbf{x}^\ast) = \mathbf{0}$ and $\nabla^2 f(\mathbf{x}^\ast) \succ 0$. Then for $\mathbf{x}_0$ close enough to $\mathbf{x}^\ast$, pure Newton iterates are well defined, converge to $\mathbf{x}^\ast$, and satisfy

$$\|\mathbf{x}_{k+1} - \mathbf{x}^\ast\| \le C\,\|\mathbf{x}_k - \mathbf{x}^\ast\|^2$$

for a constant C (roughly $\tfrac{1}{2}\times$ Hessian Lipschitz constant $\times \|\nabla^2 f(\mathbf{x}^\ast)^{-1}\|$).

Proof sketch (one dimension). Write $e_k = x_k - x^\ast$. Taylor's theorem gives $0 = f'(x^\ast) = f'(x_k) - f''(x_k)e_k + \tfrac{1}{2}f'''(\xi)e_k^2$. Divide by $f''(x_k)$ and rearrange: $e_k - f'(x_k)/f''(x_k) = \frac{f'''(\xi)}{2f''(x_k)}e_k^2$. The left side is e_{k+1}. Hence $e_{k+1} \approx \dfrac{f'''(x^\ast)}{2f''(x^\ast)}e_k^2$. $\square$

Quadratic convergence is spectacular *once you are close*; far away the pure method may diverge, cycle or head for a maximum. The theorem says nothing about how close is close enough.

Worked Example 23.19 — quadratic convergence in one dimension

Minimise $f(x) = e^x - 2x$ (minimiser $x^* = \ln 2 = 0.693147$) from $x_0 = 0$.

Step 1 (iteration): $f'(x) = e^x - 2$, $f''(x) = e^x$, so $x_{k+1} = x_k - (e^{x_k} - 2)/e^{x_k} = x_k - 1 + 2e^{-x_k}$.

Step 2 (iterates):

k	x_k	error $e_k = x_k - \ln 2$	e_k / e_{k-1}^2
0	0	-0.693	—
1	1.000000	3.07×10^{-1}	0.64
2	0.735759	4.26×10^{-2}	0.45
3	0.694042	8.95×10^{-4}	0.49
4	0.6931476	4.00×10^{-7}	0.50
5	0.69314718056	8.0×10^{-14}	0.50

Step 3 (check the constant): the theory predicts $e_{k+1}/e_k^2 \to f'''(x^*)/(2f''(x^*)) = e^{x^*}/(2e^{x^*}) = \tfrac{1}{2}$ ✓. The number of correct digits goes 1, 1, 3, 6, 13: doubling each step.

Worked Example 23.20 — one Newton step solves a quadratic

For $f(\mathbf{x}) = \tfrac{1}{2}\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} - \mathbf{b}^{\mathsf{T}}\mathbf{x}$ with $\mathbf{A} \succ 0$, the Hessian is $\mathbf{A}$ everywhere and $\mathbf{p}^{\mathrm{N}} = -\mathbf{A}^{-1}(\mathbf{A}\mathbf{x}_0 - \mathbf{b}) = \mathbf{x}^* - \mathbf{x}_0$. One step lands exactly on $\mathbf{x}^*$ from any start, whatever κ. On $f = x^2 + 5y^2$ from $(5, 1)$: $\mathbf{g} = (10, 10)$, $\mathbf{H} = \operatorname{diag}(2, 10)$, $\mathbf{p} = -(5, 1)$, $\mathbf{x}_1 = (0, 0)$ ✓ — compared with the endless zig-zag of Example 23.17.

Worked Example 23.21 — pure Newton on the Rosenbrock function

From $(-1.2, 1)$, using the Hessian

$$\nabla^2 f = \begin{pmatrix} 2 - 400(y - x^2) + 800x^2 & -400x \\ -400x & 200 \end{pmatrix}:$$

k	(x_k, y_k)	$f(\mathbf{x}_k)$
0	$(-1.2000,\ 1.0000)$	24.2
1	$(-1.1753,\ 1.3807)$	4.73
2	$(0.7631,\ -3.1750)$	**1411.8**
3	$(0.7634,\ 0.5828)$	0.0560
4	$(0.999995,\ 0.9440)$	0.313
5	$(0.9999957,\ 0.9999914)$	1.9×10^{-11}
6	$(1,\ 1)$	3×10^{-20}

Observations: (i) six iterations versus about fourteen thousand for gradient descent (Example 23.18); (ii) the pure method is not a descent method — at step 2 the objective jumps from 4.7 to 1412 because the quadratic model is trusted far outside its region of validity; it happens to recover here, but on other problems such a jump diverges. (iii) The last two steps show the quadratic convergence. A line search (damped Newton) would have rejected the full step at iteration 2 and kept f monotone.

Making Newton's method robust

- **Damped Newton.** Use the Newton direction with a backtracking line search starting from $\alpha = 1$ (§23.5). Far from the solution, short steps keep f decreasing; near the solution $\alpha = 1$ is accepted and quadratic convergence is retained.
- **Hessian modification.** If $\mathbf{H}_k$ is not positive definite, replace it by $\mathbf{H}_k + \tau\mathbf{I}$ with $\tau > 0$ large enough that Cholesky succeeds. For small τ this is nearly Newton; for large τ it is a short gradient step $-\mathbf{g}/\tau$.
- **Trust region.** Minimise the model $m_k(\mathbf{p})$ only over $\|\mathbf{p}\| \le \Delta_k$, then compare the actual decrease with the predicted decrease. If they agree, accept and enlarge Δ; if not, shrink Δ. The KKT conditions of this subproblem give $(\mathbf{H}_k + \tau\mathbf{I})\mathbf{p} = -\mathbf{g}_k$ with $\tau \ge 0$ the multiplier of the radius constraint — so Hessian modification and trust regions are the same idea. For least squares this is the **Levenberg–Marquardt** method (§23.8).

Cost. Each Newton step needs the Hessian ($n(n+1)/2$ second derivatives) and a Cholesky factorisation ($\approx n^3/3$ flops). For n in the hundreds this is cheap; for $n = 10^5$ it is prohibitive unless the Hessian is sparse — which motivates quasi-Newton and, for very large problems, limited-memory variants.

Quasi-Newton methods and BFGS

The idea: maintain an approximation $\mathbf{B}_k \approx \nabla^2 f(\mathbf{x}_k)$ (or its inverse $\mathbf{H}_k \approx \nabla^2 f(\mathbf{x}_k)^{-1}$), take steps $\mathbf{p}_k = -\mathbf{H}_k\mathbf{g}_k$, and after each step update the approximation using only the gradient change.

With $\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k$ and $\mathbf{y}_k = \mathbf{g}_{k+1} - \mathbf{g}_k$, a first-order expansion of the gradient gives $\mathbf{y}_k \approx \nabla^2 f\, \mathbf{s}_k$ — exactly for a quadratic. So we require the new approximation to satisfy the

Secant (quasi-Newton) condition

$$\mathbf{B}_{k+1}\mathbf{s}_k = \mathbf{y}_k \qquad \Longleftrightarrow \qquad \mathbf{H}_{k+1}\mathbf{y}_k = \mathbf{s}_k.$$

This is n equations for the $n(n+1)/2$ entries of a symmetric matrix, so there is freedom. The Broyden–Fletcher–Goldfarb–Shanno (BFGS) update chooses the symmetric $\mathbf{H}_{k+1}$ satisfying the secant condition that is *closest* to $\mathbf{H}_k$ in a suitably weighted Frobenius norm. The result is a rank-two correction:

BFGS update

With $\rho_k = 1/(\mathbf{y}_k^{\mathsf T}\mathbf{s}_k)$,

$$\mathbf{H}_{k+1} = \left(\mathbf{I} - \rho_k \mathbf{s}_k \mathbf{y}_k^{\mathsf T}\right)\mathbf{H}_k\left(\mathbf{I} - \rho_k \mathbf{y}_k \mathbf{s}_k^{\mathsf T}\right) + \rho_k \mathbf{s}_k \mathbf{s}_k^{\mathsf T}.$$

Properties:

1. $\mathbf{H}_{k+1}$ is symmetric and satisfies $\mathbf{H}_{k+1}\mathbf{y}_k = \mathbf{s}_k$;
2. if $\mathbf{H}_k \succ 0$ and the **curvature condition** $\mathbf{y}_k^{\mathsf T}\mathbf{s}_k > 0$ holds, then $\mathbf{H}_{k+1} \succ 0$ — so every BFGS direction is a descent direction;
3. on a strictly convex quadratic with exact line searches, BFGS terminates in at most n steps with $\mathbf{H}_n = \mathbf{A}^{-1}$;
4. near a minimiser with $\nabla^2 f \succ 0$, BFGS with a Wolfe line search converges **superlinearly**: $\|\mathbf{x}_{k+1} - \mathbf{x}^*\| / \|\mathbf{x}_k - \mathbf{x}^*\| \to 0$.

Why property 1 holds. Multiply by $\mathbf{y}_k$: the right factor gives $(\mathbf{I} - \rho_k \mathbf{y}_k \mathbf{s}_k^{\mathsf T})\mathbf{y}_k = \mathbf{y}_k - \rho_k \mathbf{y}_k(\mathbf{s}_k^{\mathsf T}\mathbf{y}_k) = \mathbf{0}$, so only the last term survives: $\rho_k \mathbf{s}_k(\mathbf{s}_k^{\mathsf T}\mathbf{y}_k) = \mathbf{s}_k$ ✓. *Why property 2 holds.* For any $\mathbf{z} \neq \mathbf{0}$, put $\mathbf{w} = \mathbf{z} - \rho_k \mathbf{y}_k(\mathbf{s}_k^{\mathsf T}\mathbf{z})$; then $\mathbf{z}^{\mathsf T}\mathbf{H}_{k+1}\mathbf{z} = \mathbf{w}^{\mathsf T}\mathbf{H}_k\mathbf{w} + \rho_k(\mathbf{s}_k^{\mathsf T}\mathbf{z})^2$. Both terms are ≥ 0, and they cannot both vanish (if $\mathbf{s}_k^{\mathsf T}\mathbf{z} = 0$ then $\mathbf{w} = \mathbf{z} \neq \mathbf{0}$). The Wolfe curvature condition of §23.5 guarantees $\mathbf{y}_k^{\mathsf T}\mathbf{s}_k > 0$, which is why BFGS is always paired with a Wolfe line search.

Related methods: **DFP** is the same formula with the roles of $\mathbf{s}$ and $\mathbf{y}$ (and $\mathbf{B}$ and $\mathbf{H}$) swapped, and is less robust in practice; **SR1** is a symmetric rank-one update that need not stay positive definite (useful inside trust regions); **L-BFGS** stores only the last $m \approx 5$–20 pairs $(\mathbf{s}_i, \mathbf{y}_i)$ and applies $\mathbf{H}_k$ implicitly, using $O(mn)$ memory — the method of choice for large smooth problems.

Worked Example 23.22 — BFGS by hand on a quadratic

Minimise $f = x^2 + 5y^2$ ($\mathbf{A} = \operatorname{diag}(2, 10)$) from $\mathbf{x}_0 = (5, 1)$ with $\mathbf{H}_0 = \mathbf{I}$ and exact line search.

Step 1 (first step = steepest descent): $\mathbf{g}_0 = (10, 10)$, $\mathbf{p}_0 = -(10, 10)$, $\alpha_0 = \tfrac{1}{6}$ (as in Example 23.17), $\mathbf{x}_1 = (\tfrac{10}{3}, -\tfrac{2}{3})$, $\mathbf{g}_1 = (\tfrac{20}{3}, -\tfrac{20}{3})$.

Step 2 (update data): $\mathbf{s}_0 = (-\tfrac{5}{3}, -\tfrac{5}{3})$, $\mathbf{y}_0 = \mathbf{g}_1 - \mathbf{g}_0 = (-\tfrac{10}{3}, -\tfrac{50}{3})$, $\mathbf{y}_0^{\mathsf T}\mathbf{s}_0 = \tfrac{50}{9} + \tfrac{250}{9} = \tfrac{100}{3} > 0$ ✓, $\rho_0 = 0.03$.

Step 3 (BFGS update): evaluating the formula gives

$$\mathbf{H}_1 = \frac{1}{36}\begin{pmatrix} 53 & -7 \\ -7 & 5 \end{pmatrix}.$$

Secant check: $\mathbf{H}_1\mathbf{y}_0 = \tfrac{1}{36}\big(53(-\tfrac{10}{3}) + (-7)(-\tfrac{50}{3}),\ (-7)(-\tfrac{10}{3}) + 5(-\tfrac{50}{3})\big) = \tfrac{1}{36}(-60, -60) = (-\tfrac{5}{3}, -\tfrac{5}{3}) = \mathbf{s}_0$ ✓. Positive definite: trace > 0, determinant $(265 - 49)/36^2 > 0$ ✓.

Step 4 (second step): $\mathbf{p}_1 = -\mathbf{H}_1\mathbf{g}_1 = -\tfrac{20}{3} \cdot \tfrac{1}{36}(53 + 7,\ -7 - 5) = (-\tfrac{100}{9},\ \tfrac{20}{9})$. Exact line search: $\alpha_1 = -\mathbf{g}_1^{\mathsf T}\mathbf{p}_1 / (\mathbf{p}_1^{\mathsf T}\mathbf{A}\mathbf{p}_1) = 0.3$, so $\mathbf{x}_2 = (\tfrac{10}{3} - \tfrac{10}{3},\ -\tfrac{2}{3} + \tfrac{2}{3}) = (0, 0)$ — **the exact minimiser after $n = 2$ steps** ✓.

Step 5 (learned curvature): one more update gives $\mathbf{H}_2 = \operatorname{diag}(0.5,\ 0.1) = \mathbf{A}^{-1}$ exactly: BFGS has learned the inverse Hessian from two gradient differences.

Comparing the methods

On the Rosenbrock function from $(-1.2, 1)$ (tolerance about 10^{-5} on the gradient):

Method	Information used	Iterations	Function evaluations	Cost per iteration
Gradient descent + backtracking	$f, \nabla f$	$\approx 14\,000$	many more	$O(n)$
Nelder–Mead simplex (derivative-free)	f	85	159	$O(n)$
Nonlinear conjugate gradient	$f, \nabla f$	36	78	$O(n)$
BFGS	$f, \nabla f$	32	39	$O(n^2)$
Newton (pure)	$f, \nabla f, \nabla^2 f$	6	6	$O(n^3)$

(SciPy 1.18 defaults; exact counts depend on implementation and tolerances.) The rule of thumb: use Newton when Hessians are cheap and n is modest; BFGS when only gradients are available; L-BFGS or CG when n is large; derivative-free methods only when gradients are unavailable and n is small.

Common Pitfall — wrong gradients

Quasi-Newton methods trust the gradient you supply. A sign error or a missing factor of 2 produces failed line searches, "precision loss" warnings, or convergence to a non-stationary point. Always check an analytic gradient against central finite differences, $[f(\mathbf{x} + h\mathbf{e}_i) - f(\mathbf{x} - h\mathbf{e}_i)]/(2h)$ with $h \approx 10^{-6}|x_i|$, before optimising (`scipy.optimize.check_grad` does this).

Engineering Note — circuit simulators run Newton's method

SPICE's DC operating-point analysis solves the nonlinear nodal equations with Newton–Raphson and the device Jacobian; its convergence aids ("gmin stepping", "source stepping", step limiting on junction voltages) are exactly the damping and continuation ideas above. When a simulation reports "no convergence", the remedies are the optimiser's remedies: a better starting point, smaller steps, or a regularised Jacobian.

```
import numpy as np
from scipy.optimize import minimize

def f(v):    x, y = v; return (1 - x)**2 + 100*(y - x**2)**2
def grad(v): x, y = v; return np.array([-2*(1 - x) - 400*x*(y - x**2), 200*(y - x**2)])

res = minimize(f, x0=[-1.2, 1.0], jac=grad, method="BFGS")
print(res.x, res.nit, res.nfev)     # approx [1. 1.], 32, 39
```

23.7 Convex optimization fundamentals

Motivation

Sections 23.5–23.6 delivered algorithms that find *local* minima — points where no small move helps. For a general nonlinear problem that is all anyone can promise: a local method has no way to know whether a better valley exists somewhere else. There is, however, a large and very useful class of problems for which this worry disappears entirely. For **convex** problems every local minimum is global, the KKT conditions are sufficient as well as necessary, duality gives a certificate of optimality, and reliable algorithms find the solution in polynomial time. Least squares, linear programming, minimax and L^1 fitting, many filter-design problems, power allocation, economic dispatch with convex costs, and (after a change of variables) many component-sizing problems are all convex. The practical motto, due to Boyd and Vandenberghe, is that the great watershed in optimization is not between linear and nonlinear problems but between **convex and nonconvex** ones. Recognising convexity — or reformulating a problem until it is convex — is the most valuable modelling skill in this chapter.

Convex sets

Convex set

A set $C \subseteq \mathbb{R}^n$ is **convex** if for all $\mathbf{x}, \mathbf{y} \in C$ and all $\theta \in [0,1]$,

$$\theta \mathbf{x} + (1-\theta)\mathbf{y} \in C.$$

That is, the line segment joining any two points of C lies in C.

Standard examples:

- **hyperplanes** $\{\mathbf{x} : \mathbf{a}^{\mathsf T}\mathbf{x} = b\}$ and **half-spaces** $\{\mathbf{x} : \mathbf{a}^{\mathsf T}\mathbf{x} \le b\}$;
- **polyhedra** $\{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b},\ \mathbf{C}\mathbf{x} = \mathbf{d}\}$ (LP feasible sets);
- **norm balls** $\{\mathbf{x} : \|\mathbf{x} - \mathbf{x}_c\| \le r\}$ for any norm, and **ellipsoids** $\{\mathbf{x} : (\mathbf{x}-\mathbf{x}_c)^{\mathsf T}\mathbf{P}^{-1}(\mathbf{x}-\mathbf{x}_c) \le 1\}$, $\mathbf{P} \succ 0$;
- the **positive semidefinite cone** $\{\mathbf{X} = \mathbf{X}^{\mathsf T} : \mathbf{X} \succeq 0\}$;
- sublevel sets $\{\mathbf{x} : f(\mathbf{x}) \le c\}$ of a convex function f (shown below).

Non-examples: an annulus $1 \le x^2 + y^2 \le 4$ (the segment between opposite points passes through the hole); the set $\{(x,y) : xy \ge 1\}$ including both branches; any finite set of two or more points (e.g. E12 resistor values — which is why discrete design is hard).

Operations that preserve convexity of sets

Intersections (of any number) of convex sets are convex. Images and inverse images of convex sets under affine maps $\mathbf{x} \mapsto \mathbf{T}\mathbf{x} + \mathbf{t}$ are convex.

Proof for intersections. If $\mathbf{x}, \mathbf{y}$ lie in every C_i, so does each point of the segment between them, since each C_i is convex. $\square$

This is why a feasible set defined by many convex constraints — $g_i(\mathbf{x}) \le 0$ with each g_i convex, and affine equalities — is convex: it is an intersection of convex sublevel sets and hyperplanes. Note that a *nonlinear equality* $h(\mathbf{x}) = 0$ generally destroys convexity (a circle $x^2 + y^2 = 1$ is not convex, though the disc $x^2 + y^2 \le 1$ is).

Convex functions

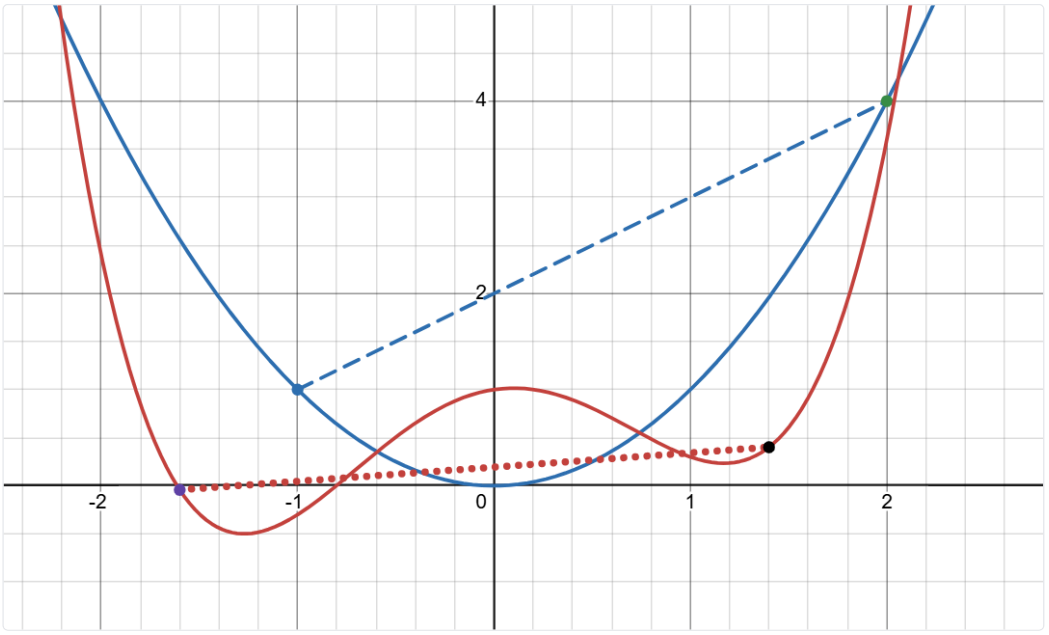
Convex function

$f : C \to \mathbb{R}$ on a convex set C is **convex** if for all $\mathbf{x}, \mathbf{y} \in C$ and $\theta \in [0,1]$,

$$f\big(\theta \mathbf{x} + (1-\theta)\mathbf{y}\big) \le \theta f(\mathbf{x}) + (1-\theta) f(\mathbf{y}),$$

i.e. the chord lies on or above the graph. It is **strictly convex** if the inequality is strict for $\mathbf{x} \ne \mathbf{y}$, $\theta \in (0,1)$, and **strongly convex** with parameter $m > 0$ if $f(\mathbf{x}) - \tfrac{m}{2}\|\mathbf{x}\|^2$ is convex. f is **concave** if $-f$ is convex.

Equivalently, f is convex iff its **epigraph** $\{(\mathbf{x}, t) : f(\mathbf{x}) \le t\}$ is a convex set — this is how the epigraph trick of §23.2 preserves convexity. The defining inequality extends by induction to **Jensen's inequality**: $f\big(\sum \theta_i \mathbf{x}_i\big) \le \sum \theta_i f(\mathbf{x}_i)$ for weights $\theta_i \ge 0$ summing to 1, and in probabilistic form $f(E[X]) \le E[f(X)]$ (Ch. 19).



Blue: $f = x^2$ is convex — every chord (dashed) lies above the graph. Red: a quartic with two local minima is not convex — the dotted chord between points near its two wells passes below the hump in the middle.

For differentiable functions there are two much more practical tests.

First- and second-order characterisations

Let C be open and convex.

1. **First order.** A differentiable f is convex on C iff for all $\mathbf{x}, \mathbf{y} \in C$

$$f(\mathbf{y}) \geq f(\mathbf{x}) + \nabla f(\mathbf{x})^{\mathsf{T}}(\mathbf{y} - \mathbf{x}),$$

i.e. every tangent plane is a global under-estimator. 2. **Second order.** A twice-differentiable f is convex on C iff $\nabla^2 f(\mathbf{x}) \succeq 0$ for all $\mathbf{x} \in C$. If $\nabla^2 f(\mathbf{x}) \succ 0$ everywhere, f is strictly convex; if $\nabla^2 f(\mathbf{x}) \succeq m\mathbf{I}$, it is m-strongly convex.

Proof sketch. (1, $\Rightarrow$) From the definition, $f(\mathbf{x} + \theta(\mathbf{y} - \mathbf{x})) \leq f(\mathbf{x}) + \theta(f(\mathbf{y}) - f(\mathbf{x}))$; rearrange to $\frac{f(\mathbf{x}+\theta(\mathbf{y}-\mathbf{x})) - f(\mathbf{x})}{\theta} \leq f(\mathbf{y}) - f(\mathbf{x})$ and let $\theta \to 0^+$: the left side tends to $\nabla f(\mathbf{x})^{\mathsf{T}}(\mathbf{y} - \mathbf{x})$. (1, $\Leftarrow$) Apply the inequality at $\mathbf{z} = \theta\mathbf{x} + (1-\theta)\mathbf{y}$ toward both $\mathbf{x}$ and $\mathbf{y}$, multiply by θ and $1-\theta$, add; the gradient terms cancel. (2) Restrict f to a line, $\varphi(t) = f(\mathbf{x} + t\mathbf{d})$; f is convex iff every such φ is, and a one-variable C^2 function is convex iff $\varphi''(t) = \mathbf{d}^{\mathsf{T}}\nabla^2 f\,\mathbf{d} \geq 0$. $\square$

The first-order condition is the heart of the matter. If $\nabla f(\mathbf{x}^*) = \mathbf{0}$, it says $f(\mathbf{y}) \geq f(\mathbf{x}^*)$ for **every** $\mathbf{y}$: a stationary point of a convex function is a global minimiser. Local information certifies a global fact.

A toolkit for recognising convex functions

Building blocks (convex on the stated domain):

Function	Domain	Note
$\mathbf{a}^{\mathsf{T}}\mathbf{x} + b$	$\mathbb{R}^n$	affine: both convex and concave
$\frac{1}{2}\mathbf{x}^{\mathsf{T}}\mathbf{Q}\mathbf{x}$	$\mathbb{R}^n$	iff $\mathbf{Q} \succeq 0$
$\lVert\mathbf{x}\rVert$ (any norm)	$\mathbb{R}^n$	triangle inequality
e^{ax}	$\mathbb{R}$	
x^p	$x > 0$	for $p \geq 1$ or $p \leq 0$; concave for $0 \leq p \leq 1$
$-\ln x$, $x \ln x$, $1/x$	$x > 0$	
$\log \sum_i e^{x_i}$	$\mathbb{R}^n$	smooth approximation of $\max_i x_i$
$\max_i (\mathbf{a}_i^{\mathsf{T}}\mathbf{x} + b_i)$	$\mathbb{R}^n$	piecewise-linear

Operations that preserve convexity of functions:

1. nonnegative weighted sums $\sum w_i f_i$, $w_i \geq 0$;
2. composition with an affine map, $f(\mathbf{A}\mathbf{x} + \mathbf{b})$ — so $\lVert\mathbf{A}\mathbf{x} - \mathbf{b}\rVert$ and $\lVert\mathbf{A}\mathbf{x} - \mathbf{b}\rVert^2$ are convex;
3. pointwise maximum (or supremum) of convex functions — so $\max_i |r_i(\mathbf{x})|$ with affine r_i is convex;
4. composition $h(g(\mathbf{x}))$ with h convex and nondecreasing and g convex (e.g. $e^{g(\mathbf{x})}$).

A product or ratio of convex functions is in general *not* convex (xy is not; x^2/y for $y > 0$ happens to be).

Worked Example 23.23 — testing convexity with the Hessian

Decide which are convex on $\mathbb{R}^2$: (a) $f = x^2 + xy + y^2$; (b) $f = xy$; (c) $f = x^2 + 4xy + y^2$; (d) $f = e^{x+y} + x^2$.

(a) $\nabla^2 f = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, eigenvalues $1, 3 > 0$: strictly (indeed 1-strongly) convex. ✓

(b) $\nabla^2 f = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, eigenvalues ± 1: indefinite, not convex (a saddle surface). Along $y = -x$, $f = -x^2$ is concave.

(c) $\nabla^2 f = \begin{pmatrix} 2 & 4 \\ 4 & 2 \end{pmatrix}$, eigenvalues 6 and -2: not convex, even though both "diagonal" terms are convex. Along $y = -x$: $f = x^2 - 4x^2 + x^2 = -2x^2$.

(d) $\nabla^2 f = e^{x+y}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} + \begin{pmatrix} 2 & 0 \\ 0 & 0 \end{pmatrix}$: a sum of two PSD matrices, so PSD — convex. (Or by the toolkit: e^u composed with the affine $u = x + y$, plus x^2.) Neither term alone is positive definite, but the sum has determinant $(e^{x+y} + 2)e^{x+y} - e^{2(x+y)} = 2e^{x+y} > 0$ and positive trace, so it is positive definite: f is strictly convex.

Worked Example 23.24 — convexity in engineering variables

(a) The conductor-cost function $f(A) = c_1 A + k/A$ of Example 23.2 has $f''(A) = 2k/A^3 > 0$ on $A > 0$: strictly convex, so the stationary point found there is the unique global optimum.

(b) The set of capacitances meeting a kT/C noise limit, $\{C > 0 : \sqrt{kT/C} \le v_{\max}\} = \{C \ge kT/v_{\max}^2\}$, is a half-line: convex.

(c) The power-transfer objective $P(R_L) = V_s^2 R_L/(R_s + R_L)^2$ of Example 23.1 is *not* concave on $(0, \infty)$: P'' changes sign at $R_L = 2R_s$ (check: $P'' \propto 2(R_L - 2R_s)/(R_s + R_L)^4$). It is, however, **unimodal**, so the stationary point is still the global maximum. Convexity is sufficient for "local = global", not necessary.

(d) The set $\{(x, y) : x > 0,\ y > 0,\ xy \ge 1\}$ (the region above one branch of a hyperbola) is convex: it is $\{-\ln x - \ln y \le 0\}$, a sublevel set of a convex function.

Convex optimization problems

Convex optimization problem

$$\min\ f(\mathbf{x}) \quad \text{s.t.} \quad g_i(\mathbf{x}) \le 0\ (i = 1, \dots, m), \qquad \mathbf{A}\mathbf{x} = \mathbf{b},$$

with f and every g_i convex. (Equality constraints must be affine.)

Local equals global

For a convex optimization problem:

1. every local minimiser is a global minimiser;
2. the set of global minimisers is convex (a point, a segment, a face…);
3. if f is strictly convex, there is at most one minimiser;
4. a feasible $\mathbf{x}^*$ is optimal iff $\nabla f(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{y} - \mathbf{x}^*) \ge 0$ for all feasible $\mathbf{y}$ (for differentiable f), and under Slater's condition iff it satisfies the KKT conditions.

Proof of 1. Suppose $\mathbf{x}^*$ is a local minimiser but some feasible $\mathbf{y}$ has $f(\mathbf{y}) < f(\mathbf{x}^*)$. The feasible set is convex, so $\mathbf{z}_\theta = \theta\mathbf{y} + (1-\theta)\mathbf{x}^*$ is feasible, and by convexity $f(\mathbf{z}_\theta) \le \theta f(\mathbf{y}) + (1-\theta) f(\mathbf{x}^*) < f(\mathbf{x}^*)$ for every $\theta \in (0, 1]$. As $\theta \to 0$, $\mathbf{z}_\theta$ comes arbitrarily close to $\mathbf{x}^*$ with a smaller value, contradicting local minimality. □

Proof of 3. If $\mathbf{x}_1 \ne \mathbf{x}_2$ were both minimisers with value f^*, strict convexity would give $f(\tfrac12\mathbf{x}_1 + \tfrac12\mathbf{x}_2) < f^*$ at a feasible point. □

Condition 4 says: at the optimum, no feasible direction goes downhill — the convex-set version of "the gradient is zero". In the interior of the feasible set it reduces to $\nabla f(\mathbf{x}^*) = \mathbf{0}$.

Lagrangian duality

LP duality (§23.3) is a special case of a construction that works for any problem. With the Lagrangian $\mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \sum \mu_i g_i(\mathbf{x}) + \sum \lambda_k h_k(\mathbf{x})$, define the **dual function**

$$q(\boldsymbol{\mu}, \boldsymbol{\lambda}) = \inf_{\mathbf{x}}\ \mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\lambda}).$$

For $\boldsymbol{\mu} \ge \mathbf{0}$ and any feasible $\mathbf{x}$, $\mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\lambda}) \le f(\mathbf{x})$ (the added terms are ≤ 0), so $q(\boldsymbol{\mu}, \boldsymbol{\lambda}) \le f^*$: every dual-feasible point gives a lower bound. The **dual problem** is to find the best bound, $\max_{\boldsymbol{\mu} \ge 0, \boldsymbol{\lambda}} q$. As an infimum of affine functions of $(\boldsymbol{\mu}, \boldsymbol{\lambda})$, q is always concave — the dual is a convex problem even when the primal is not.

Weak and strong duality

Weak duality $q^* \le f^*$ always holds. **Strong duality** $q^* = f^*$ holds for convex problems that satisfy **Slater's condition**: there is a strictly feasible point, $g_i(\mathbf{x}_0) < 0$ for all i (affine inequalities need only be satisfied), with $\mathbf{A}\mathbf{x}_0 = \mathbf{b}$. The gap $f(\mathbf{x}) - q(\boldsymbol{\mu}, \boldsymbol{\lambda}) \ge 0$ between any primal-feasible and dual-feasible pair bounds the suboptimality of $\mathbf{x}$ — a **certificate** that solvers use as their stopping test.

Worked Example 23.25 — the dual of a small QP

Primal (Example 23.13): $\min x^2 + y^2$ s.t. $2 - x - 2y \le 0$, with $f^\ast = \tfrac{4}{5}$ at $(\tfrac{2}{5}, \tfrac{4}{5})$.

Step 1 (Lagrangian): $\mathcal{L} = x^2 + y^2 + \mu(2 - x - 2y)$.

Step 2 (minimise over x, y): $\partial\mathcal{L}/\partial x = 2x - \mu = 0$, $\partial\mathcal{L}/\partial y = 2y - 2\mu = 0$, so $x = \mu/2$, $y = \mu$. Substituting,

$$q(\mu) = \frac{\mu^2}{4} + \mu^2 + 2\mu - \frac{\mu^2}{2} - 2\mu^2 = 2\mu - \frac{5}{4}\mu^2.$$

Step 3 (dual problem): maximise over $\mu \ge 0$: $q'(\mu) = 2 - \tfrac{5}{2}\mu = 0 \Rightarrow \mu^\ast = \tfrac{4}{5}$, $q^\ast = \tfrac{8}{5} - \tfrac{4}{5} = \tfrac{4}{5}$.

Step 4 (check): $q^\ast = f^\ast = 0.8$ — strong duality, as Slater predicts (the point $(2, 2)$ is strictly feasible). The dual optimum $\mu^\ast = 0.8$ is the KKT multiplier of Example 23.13. Any μ gives a bound: $\mu = 0.5$ gives $q = 0.6875 \le 0.8$, certifying that no feasible point beats 0.6875.

The standard convex problem classes

Class	Objective	Constraints	Typical EE use
LP	linear	linear	dispatch, flows, minimax / L^1 fitting
QP	convex quadratic	linear	least squares with bounds, MPC, portfolio-style allocation
SOCP	linear	$\|\mathbf{A}_i\mathbf{x} + \mathbf{b}_i\| \le \mathbf{c}_i^\mathsf{T}\mathbf{x} + d_i$	robust beamforming, FIR design with magnitude bounds
SDP	linear	$\sum x_i \mathbf{F}_i \preceq \mathbf{G}$	Lyapunov stability, LMI control design, relaxations
GP (after log)	posynomial	posynomial ≤ 1, monomial $= 1$	component and circuit sizing (§23.10)

Each class contains the one above it. Interior-point methods solve all of them to high accuracy in a few tens of Newton steps, nearly independent of problem size; modelling tools (CVX, CVXPY) let you write the problem in mathematical form and verify convexity automatically through the composition rules above ("disciplined convex programming").

Common Pitfall — "convex" in the wrong variables

Convexity depends on the parametrisation. The gain-bandwidth product of an amplifier, a monomial like $c\,W^{0.5}L^{-1}I^{0.5}$ in transistor width, length and current, is neither convex nor concave in (W, L, I), but its logarithm is *linear* in $(\ln W, \ln L, \ln I)$. Before concluding a problem is hopelessly nonconvex, try logarithmic variables, epigraph variables, or a different but equivalent objective (e.g. minimise $\|\cdot\|^2$ instead of a ratio).

Engineering Note — what to do with a nonconvex problem

Many real problems (filter design with free phase, AC optimal power flow, neural-network training) are nonconvex. Practical strategies: (i) find a convex reformulation or relaxation (AC power flow → SDP or DC power flow); (ii) run a local method from many starting points and keep the best; (iii) use the convex solution of a simplified model as the starting point for the full model; (iv) use the dual bound to judge how far from optimal a local solution might be.

23.8 Least-squares optimization

Motivation

Least squares is the most-used optimization problem in engineering. Fitting a calibration line to sensor readings, estimating a resistance from noisy voltage and current samples, identifying the parameters of a transfer function from a measured frequency response, designing an FIR filter, solving an overdetermined system of channel equations, training a linear equaliser — all are "minimise a sum of squared errors". It is so prevalent for good reasons: the problem is convex, its solution is given by a linear system, it is the maximum-likelihood estimator under Gaussian noise (Ch. 20), and it extends naturally to weighted, regularised and nonlinear versions. Chapter 9 (§9.11) treated least squares geometrically as orthogonal projection; here we treat it as an optimization problem, add regularization, and handle models that are nonlinear in their parameters.

Linear least squares and the normal equations

Given $\mathbf{A} \in \mathbb{R}^{N \times n}$ ($N \ge n$ measurements, n unknowns) and data $\mathbf{b} \in \mathbb{R}^N$, the system $\mathbf{A}\mathbf{x} = \mathbf{b}$ generally has no solution. We minimise the squared residual norm

$$f(\mathbf{x}) = \|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 = \mathbf{x}^\mathsf{T}\mathbf{A}^\mathsf{T}\mathbf{A}\mathbf{x} - 2\mathbf{b}^\mathsf{T}\mathbf{A}\mathbf{x} + \mathbf{b}^\mathsf{T}\mathbf{b}.$$

This is a quadratic with gradient $\nabla f = 2(\mathbf{A}^\mathsf{T}\mathbf{A}\mathbf{x} - \mathbf{A}^\mathsf{T}\mathbf{b})$ and Hessian $2\mathbf{A}^\mathsf{T}\mathbf{A} \succeq 0$, so it is convex and every stationary point is a global minimiser (§23.7).

Normal equations

$\mathbf{x}^\ast$ minimises $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$ if and only if

$$\mathbf{A}^\mathsf{T}\mathbf{A}\,\mathbf{x}^\ast = \mathbf{A}^\mathsf{T}\mathbf{b}.$$

The minimiser is unique iff $\mathbf{A}$ has full column rank ($\operatorname{rank}\mathbf{A} = n$), in which case $\mathbf{A}^\mathsf{T}\mathbf{A} \succ 0$ and $\mathbf{x}^\ast = (\mathbf{A}^\mathsf{T}\mathbf{A})^{-1}\mathbf{A}^\mathsf{T}\mathbf{b}$. The optimal residual $\mathbf{r}^\ast = \mathbf{b} - \mathbf{A}\mathbf{x}^\ast$ is orthogonal to every column of $\mathbf{A}$: $\mathbf{A}^\mathsf{T}\mathbf{r}^\ast = \mathbf{0}$.

Proof. Setting $\nabla f = \mathbf{0}$ gives the normal equations; convexity makes them sufficient. For uniqueness, $\mathbf{z}^\mathsf{T}\mathbf{A}^\mathsf{T}\mathbf{A}\mathbf{z} = \|\mathbf{A}\mathbf{z}\|^2$ vanishes only for $\mathbf{z} \in \operatorname{null}\mathbf{A}$, which is $\{\mathbf{0}\}$ exactly when the columns are independent. The orthogonality statement is the normal equations rewritten. □

The orthogonality $\mathbf{A}^{\mathsf{T}}\mathbf{r}^{*} = \mathbf{0}$ is the geometry of Chapter 9: $\mathbf{A}\mathbf{x}^{*}$ is the orthogonal projection of $\mathbf{b}$ onto the column space of $\mathbf{A}$, and the residual is what is left over, perpendicular to that space. It is also a cheap correctness check on any fit.

Worked Example 23.26 — fitting a resistor's V–I line

A resistor with a small offset in the measurement chain gives the readings

I (mA)	1	2	3	4	5
V (V)	2.3	4.4	6.8	8.9	11.1

Fit $V = RI + V_0$.

Step 1 (matrix form): unknowns $\mathbf{x} = (R, V_0)$; row i of $\mathbf{A}$ is $(I_i, 1)$, $\mathbf{b} = \mathbf{V}$.

Step 2 (normal equations):

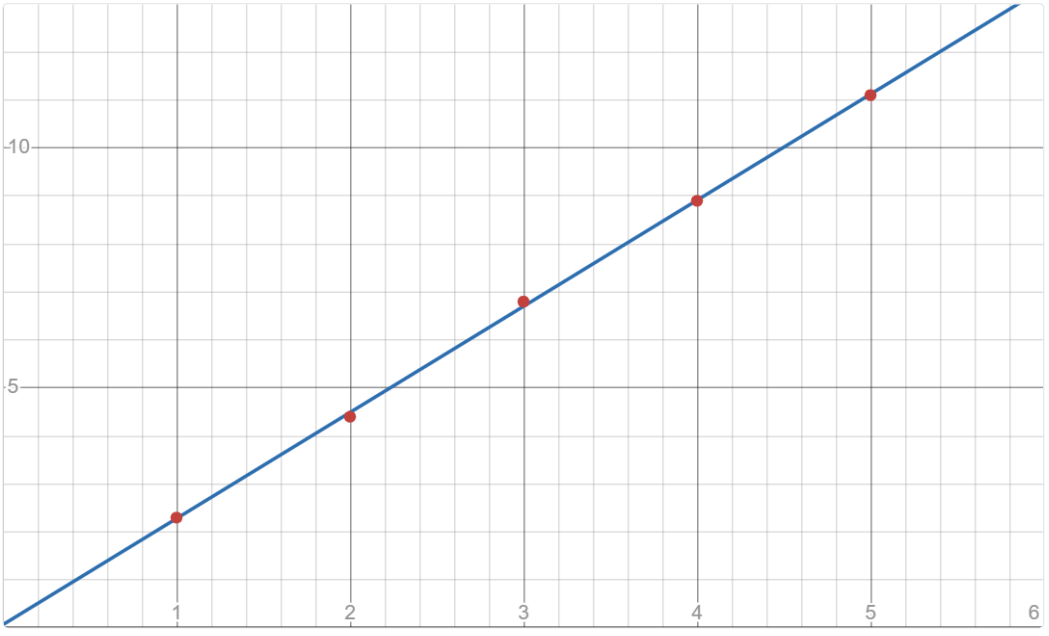
$$\mathbf{A}^{\mathsf{T}}\mathbf{A} = \begin{pmatrix} \sum I_i^2 & \sum I_i \\ \sum I_i & N \end{pmatrix} = \begin{pmatrix} 55 & 15 \\ 15 & 5 \end{pmatrix}, \qquad \mathbf{A}^{\mathsf{T}}\mathbf{b} = \begin{pmatrix} \sum I_i V_i \\ \sum V_i \end{pmatrix} = \begin{pmatrix} 122.6 \\ 33.5 \end{pmatrix}.$$

Step 3 (solve): determinant $55 \cdot 5 - 15^2 = 50$;

$$R = \frac{5(122.6) - 15(33.5)}{50} = 2.21, \qquad V_0 = \frac{55(33.5) - 15(122.6)}{50} = 0.07.$$

Units: R in V/mA $=$ kΩ, so $R = 2.21$ kΩ and $V_0 = 70$ mV.

Step 4 (check): residuals $V_i - (2.21 I_i + 0.07) = (0.02,\ -0.09,\ 0.10,\ -0.01,\ -0.02)$; $\sum r_i = 0$ ✓ and $\sum I_i r_i = 0.02 - 0.18 + 0.30 - 0.04 - 0.10 = 0$ ✓ (orthogonal to both columns). Sum of squares 0.019 V^2, so the rms residual is $\sqrt{0.019/3} = 80$ mV (dividing by $N - n = 3$ degrees of freedom).



Least-squares line $V = 2.21I + 0.07$ through the five measurements (current in mA, voltage in V). The fit minimises the sum of squared vertical distances.

Solving least squares reliably

The normal equations are perfect for derivations and for small, well-conditioned problems, but they have a numerical flaw: $\operatorname{cond}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \operatorname{cond}(\mathbf{A})^2$. If $\mathbf{A}$ has condition number 10^6, forming $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ in double precision (≈ 16 digits) leaves about 4 correct digits. Standard practice:

- **QR factorisation.** Write $\mathbf{A} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q}$ having orthonormal columns and $\mathbf{R}$ upper triangular (Gram–Schmidt or Householder, Ch. 9 §9.10). Since $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|$ is unchanged by orthogonal transformations, the problem reduces to the triangular system $\mathbf{R}\mathbf{x} = \mathbf{Q}^{\mathsf{T}}\mathbf{b}$, whose sensitivity is governed by $\operatorname{cond}(\mathbf{A})$, not its square.
- **SVD.** With $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}}$ (Ch. 10 §10.7), $\mathbf{x}^{*} = \sum_i \frac{\mathbf{u}_i^{\mathsf{T}}\mathbf{b}}{\sigma_i}\mathbf{v}_i$. Small singular values amplify the data component $\mathbf{u}_i^{\mathsf{T}}\mathbf{b}$ — including its noise — by $1/\sigma_i$. The SVD also gives the minimum-norm solution when $\mathbf{A}$ is rank deficient (the pseudoinverse $\mathbf{A}^{+}\mathbf{b}$), and it makes regularization transparent (below).

NumPy's `np.linalg.lstsq` uses the SVD; MATLAB's backslash uses QR.

Weighted least squares

If measurement i has noise variance σ_i^2, it deserves weight $w_i = 1/\sigma_i^2$:

$$\min_{\mathbf{x}} \sum_i w_i(\mathbf{a}_i^{\mathsf{T}}\mathbf{x} - b_i)^2 = (\mathbf{A}\mathbf{x} - \mathbf{b})^{\mathsf{T}}\mathbf{W}(\mathbf{A}\mathbf{x} - \mathbf{b}), \qquad \mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A}\,\mathbf{x}^{*} = \mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{b}.$$

More generally, with noise covariance $\boldsymbol{\Sigma}$, take $\mathbf{W} = \boldsymbol{\Sigma}^{-1}$. By the Gauss–Markov theorem this gives the minimum-variance linear unbiased estimator, with covariance $(\mathbf{A}^{\mathsf{T}}\mathbf{W}\mathbf{A})^{-1}$ — the formula that error bars on fitted parameters come from. Weighted LS is ordinary LS on the "whitened" data $\mathbf{W}^{1/2}\mathbf{A}$, $\mathbf{W}^{1/2}\mathbf{b}$.

Equality-constrained least squares

To minimise $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$ subject to $\mathbf{C}\mathbf{x} = \mathbf{d}$ (e.g. a filter with exactly unit DC gain, a fit forced through a known point), form the Lagrangian $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 + \boldsymbol{\lambda}^{\mathsf{T}}(\mathbf{C}\mathbf{x} - \mathbf{d})$. Its stationarity conditions are the linear **KKT system**

$$\begin{pmatrix} 2\mathbf{A}^{\mathsf{T}}\mathbf{A} & \mathbf{C}^{\mathsf{T}} \\ \mathbf{C} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} 2\mathbf{A}^{\mathsf{T}}\mathbf{b} \\ \mathbf{d} \end{pmatrix}.$$

Because the problem is convex with affine constraints, any solution of this system is the global constrained optimum.

Regularization: ridge (Tikhonov) least squares

When $\mathbf{A}$ is ill-conditioned — nearly collinear regressors, a high-order polynomial fit, deconvolution, an inverse problem in imaging or field reconstruction — the least-squares solution is extremely sensitive to noise. The cure is to add a penalty on the size of $\mathbf{x}$:

Ridge (Tikhonov) regression

For $\lambda > 0$,

$$\mathbf{x}_\lambda = \arg\min_{\mathbf{x}} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 + \lambda\|\mathbf{x}\|^2 \quad \Longleftrightarrow \quad (\mathbf{A}^{\mathsf{T}}\mathbf{A} + \lambda\mathbf{I})\,\mathbf{x}_\lambda = \mathbf{A}^{\mathsf{T}}\mathbf{b}.$$

More generally $\lambda\|\mathbf{L}\mathbf{x}\|^2$ with a matrix $\mathbf{L}$ (e.g. a difference operator, to penalise roughness rather than size).

Derivation. The gradient of the objective is $2(\mathbf{A}^{\mathsf{T}}\mathbf{A} + \lambda\mathbf{I})\mathbf{x} - 2\mathbf{A}^{\mathsf{T}}\mathbf{b}$. Since $\mathbf{A}^{\mathsf{T}}\mathbf{A} + \lambda\mathbf{I}$ has eigenvalues $\sigma_i^2 + \lambda \geq \lambda > 0$, it is always invertible — even if $\mathbf{A}$ is rank deficient — and the objective is 2λ-strongly convex, so $\mathbf{x}_\lambda$ exists and is unique. Equivalently, ridge is ordinary LS on the augmented system $\begin{pmatrix} \mathbf{A} \\ \sqrt{\lambda}\,\mathbf{I} \end{pmatrix}\mathbf{x} \approx \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix}$, which is how it is computed stably.

SVD view. Substituting $\mathbf{A} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\mathsf{T}}$,

$$\mathbf{x}_\lambda = \sum_i \underbrace{\frac{\sigma_i^2}{\sigma_i^2 + \lambda}}_{\text{filter factor } \phi_i} \frac{\mathbf{u}_i^{\mathsf{T}}\mathbf{b}}{\sigma_i}\,\mathbf{v}_i.$$

Components with $\sigma_i^2 \gg \lambda$ pass almost unchanged ($\phi_i \approx 1$); components with $\sigma_i^2 \ll \lambda$ — the ones that amplify noise — are suppressed ($\phi_i \approx \sigma_i^2/\lambda$). Ridge is a smooth low-pass filter in "singular-value space"; truncated SVD is the brick-wall version.

Trade-off. As λ grows, the residual $\|\mathbf{A}\mathbf{x}_\lambda - \mathbf{b}\|$ increases and the norm $\|\mathbf{x}_\lambda\|$ decreases monotonically: a bias–variance trade-off, and in fact a two-objective problem whose weighted-sum solutions trace a Pareto front (§23.9). The parameter is chosen by cross-validation, by the "corner" of the log–log plot of norm versus residual (the **L-curve**), or by the discrepancy principle (choose λ so that the residual matches the known noise level). Statistically, ridge is the MAP estimate when $\mathbf{x}$ has a Gaussian prior with variance $\sigma_{\text{noise}}^2/\lambda$.

Worked Example 23.27 — ridge stabilises a nearly collinear fit

Fit $\mathbf{x} = (x_1, x_2)$ to

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ 1 & 1.01 \\ 1 & 0.99 \end{pmatrix}, \qquad \mathbf{b} = \begin{pmatrix} 2 \\ 2.03 \\ 1.96 \end{pmatrix}.$$

The data were generated from $\mathbf{x}_{\text{true}} = (1, 1)$ with perturbations of order 0.02.

Step 1 (diagnose): singular values $\sigma_1 = 2.449$, $\sigma_2 = 0.0100$; $\operatorname{cond}(\mathbf{A}) = 245$ and $\operatorname{cond}(\mathbf{A}^{\mathsf{T}}\mathbf{A}) \approx 6 \times 10^4$. The second column is almost the first.

Step 2 (plain LS): $\mathbf{x}^* = (-1.503,\ 3.500)$ with residual norm 0.0041. The fit is excellent and the parameters are nonsense: the small noise has been amplified by $1/\sigma_2 = 100$ along $\mathbf{v}_2 \approx (1, -1)/\sqrt{2}$.

Step 3 (ridge):

λ	$\mathbf{x}_\lambda$	$\|\mathbf{A}\mathbf{x}_\lambda - \mathbf{b}\|$	$\phi_2 = \sigma_2^2/(\sigma_2^2 + \lambda)$
0	$(-1.503,\ 3.500)$	0.0041	1
10^{-3}	$(0.771,\ 1.226)$	0.0324	0.091
10^{-2}	$(0.972,\ 1.021)$	0.0357	0.0099
10^{-1}	$(0.979,\ 0.985)$	0.0669	0.001
1	$(0.855,\ 0.856)$	0.495	10^{-4}

Step 4 (interpret): a tiny $\lambda = 0.01$ (compared with $\sigma_1^2 = 6$) removes the unstable component and gives parameters within 3 % of the truth at the cost of a residual comparable to the noise level ($\|\mathbf{b} - \mathbf{A}\mathbf{x}_{\text{true}}\| = 0.028$). Too large a λ ($= 1$) starts shrinking the well-determined component as well — bias.

Nonlinear least squares

Many models are nonlinear in their parameters: an exponential decay $v(t) = a e^{-bt}$, a resonance $|H(j\omega)| = K/\sqrt{(1-\omega^2/\omega_0^2)^2 + (\omega/(Q\omega_0))^2}$, a diode law $I = I_s(e^{V/(nV_T)} - 1)$. With residuals $r_i(\mathbf{p}) = y_i - m(t_i;\mathbf{p})$ we minimise

$$F(\mathbf{p}) = \tfrac{1}{2}\sum_{i=1}^{N} r_i(\mathbf{p})^2 = \tfrac{1}{2}\|\mathbf{r}(\mathbf{p})\|^2.$$

With the residual Jacobian $\mathbf{J} = \partial \mathbf{r}/\partial \mathbf{p}$ ($N \times n$), the gradient and Hessian are

$$\nabla F = \mathbf{J}^{\mathsf T}\mathbf{r}, \qquad \nabla^2 F = \mathbf{J}^{\mathsf T}\mathbf{J} + \sum_i r_i \nabla^2 r_i.$$

The second Hessian term is small when the residuals are small (a good fit) or the model is nearly linear. Dropping it gives an approximation that needs only first derivatives and is automatically positive semidefinite.

Gauss–Newton and Levenberg–Marquardt

Gauss–Newton: solve the linear least-squares problem for the step,

$$(\mathbf{J}_k^{\mathsf T}\mathbf{J}_k)\,\boldsymbol{\delta}_k = -\mathbf{J}_k^{\mathsf T}\mathbf{r}_k, \qquad \mathbf{p}_{k+1} = \mathbf{p}_k + \boldsymbol{\delta}_k,$$

i.e. linearise the model about $\mathbf{p}_k$ and fit the linearised model exactly by least squares. **Levenberg–Marquardt:** $(\mathbf{J}_k^{\mathsf T}\mathbf{J}_k + \tau_k \mathbf{I})\boldsymbol{\delta}_k = -\mathbf{J}_k^{\mathsf T}\mathbf{r}_k$, with τ_k decreased after a successful step and increased after a failed one — a trust-region Gauss–Newton method (§23.6) that behaves like gradient descent far from the solution and like Gauss–Newton near it.

(If $\mathbf{r} = \mathbf{y} - \mathbf{m}$, then $\mathbf{J} = -\partial\mathbf{m}/\partial\mathbf{p}$; with the model Jacobian $\mathbf{J}_m = \partial\mathbf{m}/\partial\mathbf{p}$ the Gauss–Newton step reads $\mathbf{J}_m^{\mathsf T}\mathbf{J}_m\boldsymbol{\delta} = \mathbf{J}_m^{\mathsf T}\mathbf{r}$.) Gauss–Newton converges quadratically for zero-residual problems and linearly (often fast) for small-residual ones; it can fail on large-residual or badly initialised problems, which is when LM's damping matters. A good starting point is essential, and is often available from a linearising transformation.

Worked Example 23.28 — fitting an RC discharge by Gauss–Newton

A capacitor discharging through a resistor is sampled:

t (ms)	0	1	2	3	4
v (V)	5.0	3.0	1.9	1.1	0.7

Fit $v = a e^{-bt}$ (with $b = 1/\tau$).

Step 1 (starting guess by linearisation): $\ln v = \ln a - bt$ is linear. A straight-line LS fit of $\ln v_i$ against t_i gives $b = 0.4936\ \text{ms}^{-1}$, $\ln a = 1.6048$, $a = 4.977\ \text{V}$. (This minimises errors in $\ln v$, which over-weights the small late samples, so it is a starting point rather than the answer.)

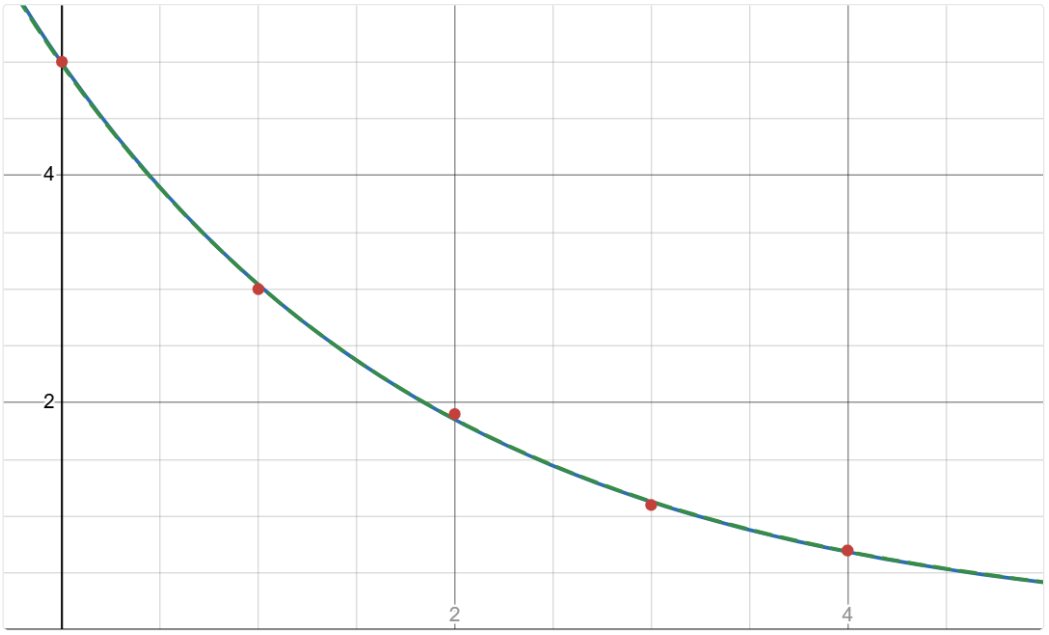
Step 2 (Jacobian): the model Jacobian has rows $\left(\partial m/\partial a,\ \partial m/\partial b\right) = \left(e^{-bt_i},\ -a t_i e^{-bt_i}\right)$.

Step 3 (iterate from a deliberately poor start $(a,b) = (4,\ 0.2)$):

k	a (V)	b (ms^{-1})	$\sum r_i^2$ (V^2)
0	4.0000	0.2000	4.09
1	4.8385	0.4319	0.142
2	4.9844	0.4920	0.00540
3	4.98933	0.495605	0.00496029
4	4.989372	0.4956304	0.00496027

Step 4 (result): $a = 4.989\ \text{V}$, $b = 0.4956\ \text{ms}^{-1}$, so $\tau = 1/b = 2.018\ \text{ms}$; residual rms $\sqrt{0.00496/3} = 41\ \text{mV}$. Starting from the log-linear guess, Gauss–Newton converges in two iterations.

Step 5 (check): at the solution $\mathbf{J}_m^{\mathsf T}\mathbf{r} = \mathbf{0}$ to machine precision — the nonlinear normal equations hold ✓.



RC discharge data (red), the nonlinear least-squares fit $4.989e^{-0.4956t}$ (blue) and the log-linear starting fit (green dashed); time in ms, voltage in V. The two curves nearly coincide here because the noise is small.

Common Pitfall — fitting in transformed coordinates

Fitting $\ln y$ instead of y, or $1/y$ instead of y, changes the error weighting: a 0.05 V error on a 0.7 V sample is a $7\,\%$ error in $\ln v$, but on a 5 V sample only $1\,\%$. Linearising transforms give excellent starting values; the final fit should minimise errors in the quantity that was actually measured with known noise (or use weights $w_i \propto y_i^2$ to compensate).

Engineering Note — system identification

Fitting a transfer function $H(s) = \frac{b_0 + b_1 s + \dots}{1 + a_1 s + \dots}$ to measured frequency-response data is nonlinear in the a_k. Levy's method multiplies through by the denominator to obtain a *linear* least-squares problem (an equation-error formulation); Sanathanan–Koerner iteration reweights it to approximate the true output-error criterion, and the result seeds a Levenberg–Marquardt refinement. Vector fitting, used for passive macromodels of interconnects, refines this idea with pole relocation.

```
import numpy as np
from scipy.optimize import least_squares

t = np.array([0, 1, 2, 3, 4.0]);  v = np.array([5.0, 3.0, 1.9, 1.1, 0.7])
res = least_squares(lambda p: v - p[0]*np.exp(-p[1]*t), x0=[4.0, 0.2], method="lm")
print(res.x)                                  # approx [4.989, 0.4956]

A = np.array([[1, 1], [1, 1.01], [1, 0.99]]);  b = np.array([2, 2.03, 1.96]);  lam = 1e-2
x_ridge = np.linalg.lstsq(np.vstack([A, np.sqrt(lam)*np.eye(2)]),
                          np.concatenate([b, np.zeros(2)]), rcond=None)[0]
print(x_ridge)                                # approx [0.972, 1.021]
```

23.9 Multi-objective optimization

Motivation

Real design specifications rarely reduce to one number. A low-noise amplifier should have low noise *and* low power consumption; a filter should have a sharp transition *and* low passband ripple *and* few taps; a power system should run at low cost *and* low emissions *and* high reliability; a regularised fit should have small residual *and* small parameter norm (§23.8). These goals conflict: improving one makes another worse. There is then no single "optimal" design but a family of best compromises, and the engineer's job is to *see* that family and choose from it. Multi-objective optimization provides the vocabulary (dominance, Pareto optimality) and the standard techniques (weighted sums, ε-constraints) that turn a vector of objectives back into ordinary single-objective problems.

Dominance and Pareto optimality

Consider $\min_{\mathbf{x} \in \mathcal{S}} \; \mathbf{F}(\mathbf{x}) = \big(f_1(\mathbf{x}), \dots, f_q(\mathbf{x})\big)$.

Pareto optimality

- A feasible $\mathbf{x}$ **dominates** $\mathbf{y}$ if $f_i(\mathbf{x}) \le f_i(\mathbf{y})$ for all i and $f_j(\mathbf{x}) < f_j(\mathbf{y})$ for at least one j: $\mathbf{x}$ is at least as good in every objective and strictly better in one.
- $\mathbf{x}^* \in S$ is **Pareto optimal** (efficient, non-dominated) if no feasible point dominates it. It is **weakly Pareto optimal** if no feasible point is strictly better in *every* objective.
- The **Pareto set** is the set of Pareto-optimal decisions; its image $\{\mathbf{F}(\mathbf{x}^*)\}$ in objective space is the **Pareto front** (trade-off curve).
- The **ideal (utopia) point** $\mathbf{F}^{\mathrm{id}}$ has components $f_i^{\mathrm{id}} = \min_S f_i$, each objective minimised on its own. It is usually not attainable.

At a Pareto-optimal point you cannot improve any objective without worsening another. A design that is *not* Pareto optimal is simply wasteful: some other design is better in at least one respect and worse in none. The first, uncontroversial, step of any trade-off study is therefore to discard dominated designs; only the choice *along* the front involves preferences.

The slope of a smooth two-objective front, $df_2/df_1 < 0$, is the **marginal rate of trade-off**: how many units of f_2 must be given up per unit of f_1 gained. Near the ends of the front this rate is often extreme — the last few percent of improvement in one objective is bought at great cost in the other — and a "knee" in the middle marks the region where a balanced compromise lives.

The weighted-sum method

Combine the objectives with nonnegative weights:

$$\min_{\mathbf{x}\in S} \sum_{i=1}^{q} w_i f_i(\mathbf{x}), \qquad w_i \ge 0, \;\; \sum w_i = 1.$$

Weighted sums and the Pareto front

1. If all $w_i > 0$, every minimiser of the weighted sum is Pareto optimal. (With some $w_i = 0$, it is at least weakly Pareto optimal.)
2. If the problem is **convex** (convex S and convex f_i), then for every Pareto-optimal $\mathbf{x}^*$ there are weights $w_i \ge 0$, not all zero, for which $\mathbf{x}^*$ minimises the weighted sum.
3. For nonconvex problems, Pareto-optimal points on non-convex parts of the front cannot be found by any choice of weights.

Proof of 1. If some $\mathbf{y}$ dominated a weighted-sum minimiser $\mathbf{x}^*$, then $\sum w_i f_i(\mathbf{y}) < \sum w_i f_i(\mathbf{x}^*)$ (strict because one f_j is strictly smaller and $w_j > 0$), contradicting minimality. □

Why 2 and 3 hold (two objectives). In the (f_1, f_2) plane the weighted sum $w_1 f_1 + w_2 f_2 = c$ is a straight line with slope $-w_1/w_2$. Minimising c slides this line toward the origin until it last touches the set of attainable objective vectors. The touching point is a point where the line **supports** the attainable set. For a convex problem the attainable set (plus everything dominated by it) is convex, and every boundary point of a convex set has a supporting line — so every front point is reachable. A part of the front that bulges *away* from the origin cannot be touched by a supporting line from below-left; the sliding line always jumps past it to the ends.

At a weighted-sum optimum on a smooth front, the line is tangent to the front, so the **front slope equals** $-w_1/w_2$: the weights *are* the trade-off rate one is willing to accept.

Common Pitfall — weights depend on units

$w_1 f_1 + w_2 f_2$ with f_1 in milliwatts and f_2 in $\mathrm{nV}^2/\mathrm{Hz}$ means nothing until the units are fixed; changing f_1 to watts changes the effective weight by 1000. Normalise each objective first, for example $\tilde{f}_i = (f_i - f_i^{\mathrm{id}})/(f_i^{\mathrm{nad}} - f_i^{\mathrm{id}})$ using the ideal point and the **nadir point** (worst value of f_i over the Pareto set), so that each normalised objective runs from 0 to 1 along the front. Even then, equal weights do not guarantee "equal importance"; sweep the weights and look at the front.

The ε-constraint method

Keep one objective and turn the others into constraints:

$$\min_{\mathbf{x}\in S} \; f_1(\mathbf{x}) \quad \text{subject to} \quad f_i(\mathbf{x}) \le \varepsilon_i, \;\; i = 2, \dots, q.$$

ε-constraint method

1. Every solution of the ε-constraint problem is weakly Pareto optimal; if it is unique, it is Pareto optimal.
2. Conversely, every Pareto-optimal $\mathbf{x}^*$ solves the ε-constraint problem with $\varepsilon_i = f_i(\mathbf{x}^*)$ — **convex or not**.
3. The KKT multiplier μ_i of the constraint $f_i \le \varepsilon_i$ gives the local trade-off rate: $\partial f_1^*/\partial \varepsilon_i = -\mu_i$.

Proof of 2. If some feasible $\mathbf{y}$ had $f_i(\mathbf{y}) \le f_i(\mathbf{x}^*)$ for $i \ge 2$ and $f_1(\mathbf{y}) < f_1(\mathbf{x}^*)$, it would dominate $\mathbf{x}^*$. □

The ε-constraint form is also how specifications are usually written ("minimise power subject to noise $\le$ spec"), so it connects directly to the design process: sweeping ε traces the front, and the multiplier tells the designer what each tightening of the specification costs. Its drawbacks are that it needs sensible ranges for ε_i and that each point requires a constrained solve.

Other scalarisations worth knowing: **goal programming / compromise programming** minimises the distance $\|\mathbf{F}(\mathbf{x}) - \mathbf{F}^{\mathrm{id}}\|$ (weighted, in some norm) to the ideal point; the **Chebyshev (min–max) scalarisation** $\min \max_i w_i(f_i - f_i^{\mathrm{id}})$ can reach every Pareto point even on nonconvex fronts. Population-based evolutionary algorithms (NSGA-II and relatives) approximate a whole front at once for difficult nonconvex problems.

Worked Example 23.29 — a convex front traced two ways

Objectives $f_1(x) = x^2$ and $f_2(x) = (x-2)^2$ over $x \in \mathbb{R}$ (two targets 0 and 2 that cannot both be met).

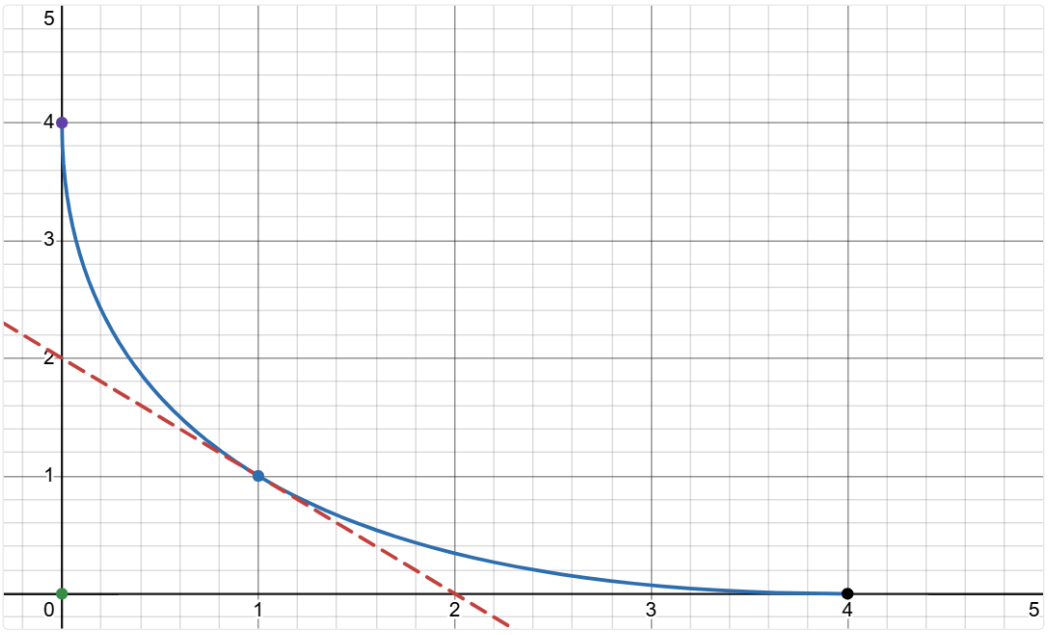
Step 1 (Pareto set): for $x < 0$, moving toward 0 improves both; for $x > 2$, moving toward 2 improves both. For $0 \le x \le 2$, increasing x helps f_2 and hurts f_1. Pareto set: $[0, 2]$. Ideal point $(0, 0)$, not attainable.

Step 2 (front): on $[0, 2]$, $x = \sqrt{f_1}$, so the front is $f_2 = (\sqrt{f_1} - 2)^2$, $0 \le f_1 \le 4$ — a convex curve from $(0, 4)$ to $(4, 0)$.

Step 3 (weighted sum): minimise $wx^2 + (1-w)(x-2)^2$: derivative $2wx + 2(1-w)(x-2) = 0$ gives $x^* = 2(1-w)$. As w runs from 1 to 0, x^* sweeps the whole Pareto set — every front point is reached, as the convex theory promises. For $w = \frac{1}{2}$: $x^* = 1$, $(f_1, f_2) = (1, 1)$.

Step 4 (ε-constraint): minimise x^2 s.t. $(x-2)^2 \le \varepsilon$. For $0 < \varepsilon < 4$ the constraint is active: $x^* = 2 - \sqrt{\varepsilon}$, $f_1^* = (2 - \sqrt{\varepsilon})^2$. With $\varepsilon = 1$: $x^* = 1$, $f_1^* = 1$ — the same point as $w = \frac{1}{2}$.

Step 5 (trade-off rate): $df_1^*/d\varepsilon = -(2 - \sqrt{\varepsilon})/\sqrt{\varepsilon} = -1$ at $\varepsilon = 1$, so $\mu = 1$. From KKT directly: $2x + \mu \cdot 2(x-2) = 0$ at $x = 1$ gives $\mu = 1$ ✓. And the weighted-sum tangent slope $-w/(1-w) = -1$ ✓: the multiplier and the weight ratio carry the same information.



Pareto front of $f_1 = x^2$, $f_2 = (x-2)^2$ (blue). The weighted-sum line for $w = \frac{1}{2}$ (red dashed, slope -1) is tangent to the front at $(1, 1)$; sweeping w rolls the tangent line along the whole convex front.

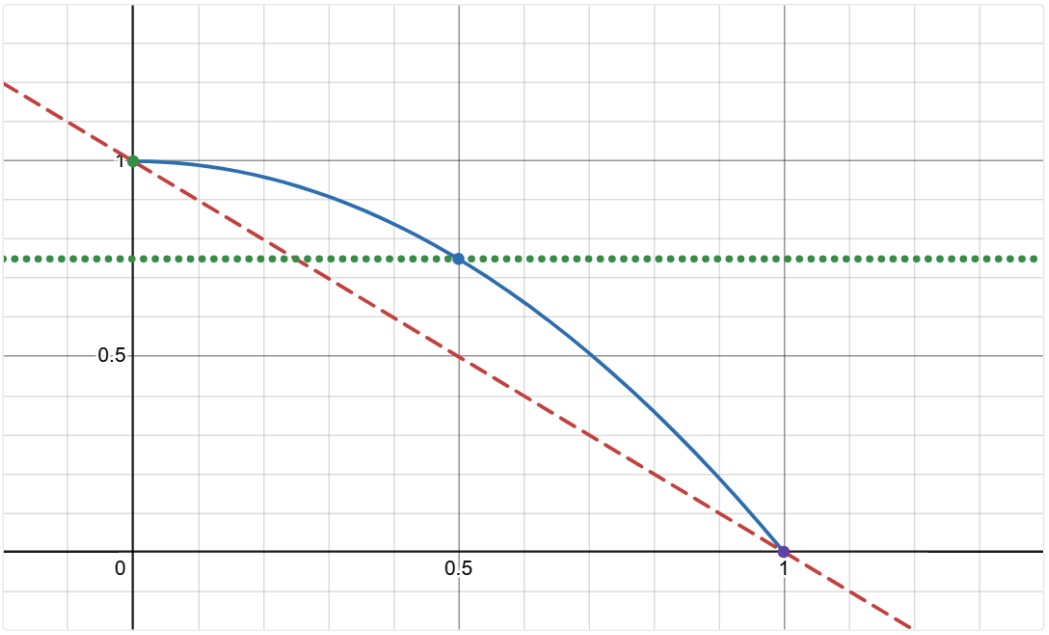
Worked Example 23.30 — a nonconvex front defeats the weighted sum

Objectives $f_1(x) = x$ and $f_2(x) = 1 - x^2$ on $S = [0, 1]$.

Step 1 (front): f_1 increases and f_2 decreases along S, so every $x \in [0, 1]$ is Pareto optimal and the front is $f_2 = 1 - f_1^2$, bulging *away* from the ideal point $(0, 0)$.

Step 2 (weighted sum): $\phi(x) = wx + (1-w)(1-x^2)$ has $\phi'' = -2(1-w) \le 0$: it is concave in x, so its minimum over $[0, 1]$ is at an endpoint. Comparing $\phi(0) = 1 - w$ and $\phi(1) = w$: the minimiser is $x = 1$ for $w < \frac{1}{2}$ and $x = 0$ for $w > \frac{1}{2}$. **Only the two end points of the front are ever found**, no matter how finely w is swept.

Step 3 (ε-constraint): minimise x s.t. $1 - x^2 \le \varepsilon$: $x^* = \sqrt{1 - \varepsilon}$. For $\varepsilon = 0.75$, $x^* = 0.5$ and $(f_1, f_2) = (0.5, 0.75)$, an interior front point unreachable by weights. Every front point is obtained as ε sweeps $[0, 1]$ ✓.



A nonconvex (concave-shaped) front $f_2 = 1 - f_1^2$. The equal-weight line (red dashed) touches only the end points; the ε-constraint $f_2 \le 0.75$ (green dotted) picks out the interior point $(0.5, 0.75)$.

Worked Example 23.31 — power versus noise in an amplifier stage

For a bipolar input stage biased at collector current I (mA) from a 3.3 V supply, model the power as $f_1 = 3.3I$ (mW) and the input voltage-noise density (shot-noise dominated) as $f_2 = 4/I$ (in nV^2/Hz), with $0.5 \le I \le 10$ mA.

Step 1 (front): f_1 rises and f_2 falls with I, so every feasible I is Pareto optimal. Eliminating I: $f_1 f_2 = 13.2$, a hyperbola from $(1.65, 8)$ to $(33, 0.4)$ — a convex front.

Step 2 (ε-constraint, the specification form): minimise $3.3I$ subject to $4/I \le 2$ (noise spec $\sqrt{2} = 1.41$ $\text{nV}/\sqrt{\text{Hz}}$). The constraint gives $I \ge 2$, so $I^* = 2$ mA and $f_1^* = 6.6$ mW.

Step 3 (multiplier): stationarity $3.3 + \mu(-4/I^2) = 0$ at $I = 2$ gives $\mu = 3.3$ mW per nV^2/Hz. Tightening the spec to $f_2 \le 1.9$ should cost about $0.1\mu = 0.33$ mW; the exact re-solve gives $I = 2.105$ mA, $f_1 = 6.95$ mW, an increase of 0.35 mW ✓.

Step 4 (weighted sum, normalised): with weights on the raw objectives, $w(3.3I) + (1-w)(4/I)$ is minimised at $I^* = \sqrt{4(1-w)/(3.3w)}$; $w = \frac{1}{2}$ gives $I^* = 1.10$ mA, $(f_1, f_2) = (3.63, 3.63)$ — a point that depends entirely on the arbitrary choice of units. Expressing the same requirement as a noise specification (Step 2) is usually more meaningful to the designer than choosing a weight.

Engineering Note — trade-off curves in design reviews

Presenting a Pareto front instead of a single "optimal" design changes design conversations: it makes explicit what each specification costs, reveals knees where a small concession buys a large gain, and exposes dominated legacy designs. Typical fronts in EE: noise figure versus power in LNAs, settling time versus overshoot in control loops, filter order versus transition width, conversion efficiency versus power density in converters, and residual versus solution norm (the L-curve) in regularised estimation.

23.10 Applications to engineering design

Motivation

The previous sections developed methods; this one shows how they fit together on problems that look like real design work. The pattern is always the same: (1) choose decision variables and put them in sensible units or logarithms; (2) write the objective and the specifications as functions; (3) recognise the problem class — LP, QP, convex, least squares, nonconvex; (4) solve with the matching method; (5) read the multipliers as sensitivities and check the design against the original, un-idealised requirements (discrete component values, tolerances, unmodelled effects). The three applications below — generator dispatch, component sizing, and FIR filter design — each exercise a different part of the chapter. They are motivation for the mathematics; the engineering details belong in power-systems, circuits and DSP texts.

Application 1: economic dispatch of generators

Generators $i = 1, \dots, G$ must together supply a demand D (MW). Each has a convex fuel-cost curve, commonly quadratic, $C_i(P_i) = a_i P_i^2 + b_i P_i + c_i$ (\$/\text{h}\$, with $a_i > 0$), and operating limits $P_i^{\min} \le P_i \le P_i^{\max}$. Losses are neglected here.

$$\min_{\mathbf{P}} \sum_{i=1}^{G} C_i(P_i) \quad \text{s.t.} \quad \sum_{i=1}^{G} P_i = D, \qquad P_i^{\min} \le P_i \le P_i^{\max}.$$

This is a convex QP: a convex separable objective, one affine equality and box constraints, so the KKT conditions are necessary and sufficient (§23.4, §23.7).

Without limits. The Lagrangian $\mathcal{L} = \sum C_i(P_i) + \lambda\big(D - \sum P_i\big)$ gives $\partial\mathcal{L}/\partial P_i = C_i'(P_i) - \lambda = 0$:

Equal incremental cost criterion

At the optimal unconstrained dispatch, every generator operates at the same **incremental cost** $dC_i/dP_i = \lambda$. For quadratic costs $P_i = (\lambda - b_i)/(2a_i)$, and the power balance gives

$$\lambda = \frac{D + \sum_i b_i/(2a_i)}{\sum_i 1/(2a_i)}.$$

The multiplier λ ($\$/\text{MWh}$) is the **system marginal cost**: $dC^*/dD = \lambda$.

The reason is the forgiving-optimum argument in reverse: if one unit had a lower incremental cost than another, shifting a little output from the expensive unit to the cheap one would lower total cost while keeping the balance.

With limits. With multipliers $\underline{\mu}_i, \overline{\mu}_i \ge 0$ for the lower and upper bounds, stationarity reads $C_i'(P_i) - \lambda - \underline{\mu}_i + \overline{\mu}_i = 0$. Complementary slackness then gives the textbook rule:

$$C_i'(P_i) = \lambda \text{ if } P_i^{\min} < P_i < P_i^{\max}, \qquad C_i'(P_i) \le \lambda \text{ if } P_i = P_i^{\max}, \qquad C_i'(P_i) \ge \lambda \text{ if } P_i = P_i^{\min}.$$

A unit at its maximum would *like* to produce more (its incremental cost is below the system price); the gap $\overline{\mu}_i = \lambda - C_i'(P_i^{\max})$ is the value of one more MW of its capacity.

Worked Example 23.32 — dispatching three units

Units with $a=(0.005,\ 0.008,\ 0.010)\ \$/\text{MW}^2\text{h}$, $b=(6.0,\ 6.5,\ 7.0)\ \$/\text{MWh}$ (fixed costs c_i do not affect the dispatch) supply $D = 700$ MW.

Step 1 (no limits): $\sum 1/(2a_i) = 100 + 62.5 + 50 = 212.5$ MW per $\$/\text{MWh}$, and $\sum b_i/(2a_i) = 600 + 406.25 + 350 = 1356.25$ MW. So

$$\lambda = \frac{700 + 1356.25}{212.5} = 9.676\ \$/\text{MWh}, \qquad P = \left(\frac{9.676 - 6}{0.01},\ \frac{9.676 - 6.5}{0.016},\ \frac{9.676 - 7}{0.02}\right) = (367.6,\ 198.5,\ 133.8)\ \text{MW}.$$

Check: sum $= 700.0$ ✓; incremental costs $2a_iP_i + b_i$ all equal 9.676 ✓. Variable cost $\sum(a_iP_i^2+b_iP_i)=5603.3\ \$/\text{h}$.

Step 2 (add the limit $P_1 \le 300$ MW): unit 1 violates it, so guess it is active: $P_1 = 300$ and units 2 and 3 share the remaining 400 MW at a common λ:

$$\lambda = \frac{400 + 406.25 + 350}{62.5 + 50} = 10.278\ \$/\text{MWh}, \qquad P_2 = 236.1,\ \ P_3 = 163.9\ \text{MW}.$$

Step 3 (verify KKT): unit 1's incremental cost at 300 MW is $2(0.005)(300) + 6 = 9.0 \le \lambda$ ✓, so $\overline\mu_1=10.278-9.0=1.278\ \$/\text{MWh}\ge0$ ✓. The limit raises the cost to $5646.5\ \$/\text{h}$ (+43.2) and raises the system marginal cost from 9.68 to 10.28 $\$/\text{MWh}$.

Step 4 (interpret): $\overline{\mu}_1$ says one more MW of capacity on unit 1 would save about $1.28 per hour — the information a planner needs to decide whether an uprate is worth it.

Worked Example 23.33 — linear costs give merit-order dispatch

If the same three units have *linear* costs $6.0,\ 6.5,\ 7.0\ \$/\text{MWh}$, each limited to 300 MW, and $D = 700$ MW, the problem is an LP. By the vertex theorem (§23.3) the optimum loads units fully in order of cost: $P = (300,\ 300,\ 100)$ MW, cost $1800+1950+700=4450\ \$/\text{h}$. The dual variable of the balance constraint is $\lambda=7.0\ \$/\text{MWh}$, the cost of the **marginal unit** (the only one not at a limit), and the capacity constraints of units 1 and 2 have shadow prices $7.0 - 6.0 = 1.0$ and $7.0-6.5=0.5\ \$/\text{MWh}$, by complementary slackness.

Application 2: sizing components — log variables and geometric programming

Component values are positive and span decades, and many circuit relationships are **monomials** $c\,x_1^{a_1}x_2^{a_2}\cdots$ (time constants RC, cutoff $1/(2\pi RC)$, kT/C noise, gain g_mR). Sums of monomials with positive coefficients are **posynomials**. A **geometric program** (GP) minimises a posynomial subject to posynomial ≤ 1 and monomial $= 1$ constraints. It is not convex as written, but in logarithmic variables $u_j = \ln x_j$:

- a monomial becomes $e^{\mathbf{a}^{\mathsf T}\mathbf{u} + \ln c}$, and the constraint "monomial $= 1$" becomes *linear*, $\mathbf{a}^{\mathsf T}\mathbf{u} + \ln c = 0$;
- a posynomial becomes a sum of exponentials of affine functions, which is convex; taking its logarithm gives the convex log-sum-exp form.

So every GP is a convex problem in disguise, with all the guarantees of §23.7. GP is used for sizing transistors in op-amps, wires in clock trees and gates in digital paths.

Worked Example 23.34 — sizing an RC low-pass filter

Choose R and C for a first-order low-pass with time constant $\tau = RC = 1$ ms (cutoff 159 Hz). Board area is modelled as $J = R/R_0 + C/C_0$ with $R_0 = 1\ \text{k}\Omega$ and $C_0 = 10$ nF (one unit of area per kilohm and per 10 nF). The integrated output noise $\sqrt{kT/C}$ at $T = 300$ K must not exceed 0.1 μV.

Step 1 (constraints in physical form): $kT = 4.14 \times 10^{-21}$ J, so $\sqrt{kT/C} \le 10^{-7}$ V $\iff C \ge kT/10^{-14} = 414$ nF.

Step 2 (log variables): let $u = \ln(R/R_0)$, $v = \ln(C/C_0)$. Then $RC = \tau$ becomes $u + v = \ln\big(\tau/(R_0C_0)\big) = \ln 100 = 4.605$, the noise constraint becomes $v \ge \ln 41.4 = 3.724$, and the objective is $J = e^u + e^v$ — convex. The problem is a convex program with one linear equality and one linear inequality.

Step 3 (ignore the noise constraint first): by symmetry of $e^u + e^v$ on the line $u + v = 4.605$, the optimum is $u = v = 2.303$: $R = 10\ \text{k}\Omega$, $C = 100$ nF, $J = 20$. But $C = 100$ nF violates $C \ge 414$ nF, so the noise constraint must be active.

Step 4 (active noise constraint): $v = 3.724$, $u = 4.605 - 3.724 = 0.881$: $C = 414$ nF, $R = \tau/C = 2.41\ \text{k}\Omega$, $J = 2.41 + 41.4 = 43.8$.

Step 5 (KKT check and sensitivity): with $\mathcal{L} = e^u + e^v + \lambda(u + v - 4.605) + \mu(3.724 - v)$: $\partial_u\mathcal{L} = e^u + \lambda = 0 \Rightarrow \lambda = -2.41$; $\partial_v\mathcal{L} = e^v + \lambda - \mu = 0 \Rightarrow \mu = 41.4 - 2.41 = 39.0 \ge 0$ ✓. In log variables μ is the cost per unit of $\ln C_{\min}$: a 1 % looser noise budget on $C_{\min}$ saves about 0.39 area units (re-solving with $C_{\min} = 410$ nF gives $J = 43.44$, a saving of 0.40 ✓). The noise specification is what drives the design.

Step 6 (round to preferred values): the nearest E12 capacitor not below 414 nF is 470 nF; then $R = \tau/C = 2.13\ \text{k}\Omega$, and the nearest E96 resistor 2.15 kΩ gives $\tau = 1.011$ ms (+1.1 %). The area becomes $2.15 + 47 = 49.2$ — 12 % above the continuous optimum, mostly because the E12 capacitor series is coarse. Rounding is a discrete optimisation; the continuous solution tells you where to look.

Application 3: FIR filter design by least squares and by linear programming

A linear-phase FIR low-pass filter of length $2M + 1$ has amplitude response $A(\omega) = h_0 + 2\sum_{k=1}^{M} h_k \cos k\omega$ (Example 23.3). Design means choosing $\mathbf{h}$ to approximate the ideal response $D(\omega)$.

Continuous least squares. Minimise $E(\mathbf{h}) = \int_0^\pi \big(A(\omega) - D(\omega)\big)^2 d\omega$. Because the functions $1, \cos\omega, \dots, \cos M\omega$ are orthogonal on $[0, \pi]$ — $\int_0^\pi \cos k\omega \cos l\omega\, d\omega = \frac{\pi}{2}\delta_{kl}$ for $k, l \ge 1$ and $\int_0^\pi 1\, d\omega = \pi$ — the normal equations are *diagonal*, and each coefficient is found independently:

$$h_0 = \frac{1}{\pi}\int_0^\pi D(\omega)\, d\omega, \qquad h_k = \frac{1}{\pi}\int_0^\pi D(\omega)\cos k\omega\, d\omega.$$

These are the Fourier-series coefficients of D (Ch. 15): **truncating a Fourier series is the least-squares approximation** by a trigonometric polynomial of that order. For an ideal low-pass with cutoff ω_c, $h_0 = \omega_c/\pi$ and $h_k = \sin(k\omega_c)/(k\pi)$ — the windowed-sinc design with a rectangular window.

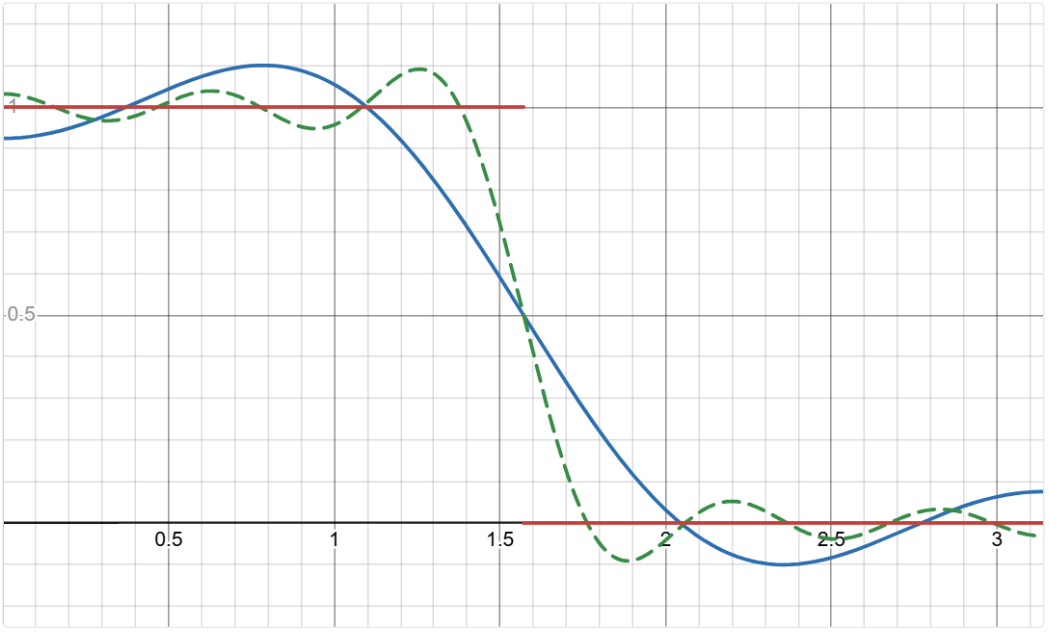
Worked Example 23.35 — a 7-tap least-squares half-band filter

Take $\omega_c = \pi/2$ and $M = 3$.

Step 1 (coefficients): $h_0 = \frac{1}{2}$, $h_1 = \sin(\pi/2)/\pi = 0.3183$, $h_2 = \sin\pi/(2\pi) = 0$, $h_3 = \sin(3\pi/2)/(3\pi) = -0.1061$. The impulse response is $(h_3, h_2, h_1, h_0, h_1, h_2, h_3) = (-0.106,\ 0,\ 0.318,\ 0.5,\ 0.318,\ 0,\ -0.106)$.

Step 2 (response): $A(\omega) = 0.5 + 0.6366\cos\omega - 0.2122\cos 3\omega$. Check $A(0) = 0.924$, $A(\pi/2) = 0.5$ (half amplitude at the cutoff, by symmetry), $A(\pi) = 0.076$.

Step 3 (error): the minimum integrated squared error is 0.078; the peak of A is 1.100 at $\omega = \pi/4$ — a 10 % overshoot. Raising M to 10 lowers the integrated error to 0.032 but the overshoot stays near 9 %: the **Gibbs phenomenon**. Least squares minimises average error, not peak error.



Least-squares approximations of an ideal half-band low-pass (red) by 7-tap (blue) and 21-tap (green dashed) linear-phase FIR filters, against normalised frequency ω in rad/sample. More taps sharpen the transition, but the overshoot near the edge (Gibbs) does not shrink.

Improving the formulation. Two changes to the *objective* do more than adding taps:

1. **Leave a transition band free.** Fit only on $[0, \omega_p] \cup [\omega_s, \pi]$ and solve the resulting discrete weighted least-squares problem on a frequency grid (§23.8). The jump disappears from the target, and with it most of the Gibbs overshoot.
2. **Change the norm.** Minimising the *peak* weighted error $\max_i |A(\omega_i) - D(\omega_i)|$ is an LP by the epigraph trick (§23.2); its solution is the **equiripple** (minimax) filter that the Parks–McClellan algorithm computes by a specialised exchange method.

Worked Example 23.36 — least squares versus minimax for a 21-tap filter

Specification: passband $[0, 0.4\pi]$, stopband $[0.6\pi, \pi]$, $M = 10$ (21 taps), 200 grid points in each band, equal weights.

Step 1 (least squares): `numpy.linalg.lstsq` on the 400×11 system gives a peak error of 0.0268, i.e. stopband peak $20 \log_{10} 0.0268 = -31.4$ dB.

Step 2 (minimax LP): minimise t over $(\mathbf{h}, t)$ subject to $-t \le A(\omega_i; \mathbf{h}) - D(\omega_i) \le t$ for all 400 grid points — 12 variables, 800 linear inequalities. `linprog` returns $t = 0.0114$: stopband peak -38.9 dB, about 7.5 dB better in the worst case, with the same number of taps.

Step 3 (moral): the minimax filter has larger *average* error and smaller *peak* error than the least-squares one. Which is "optimal" depends on whether the specification is an energy criterion or a mask — the point of §23.1.

A design-optimization checklist

1. **Variables.** What can actually be chosen? Use units of order one, or logarithms for positive quantities spanning decades.
2. **Objective.** What does "better" mean? Is it a proxy? If several goals conflict, plan a trade-off study (§23.9) rather than inventing weights.
3. **Constraints.** List every specification as $g \le 0$ or $h = 0$. Check feasibility first (Example 23.4). Remove redundant constraints.
4. **Classify.** Linear → LP; convex quadratic → QP; sum of squares → least squares; monomials → GP in log variables; otherwise check convexity with the toolkit of §23.7.
5. **Solve.** Use the matching solver. For nonconvex problems use several starting points, and seed them from a convex simplification.
6. **Verify.** Check KKT residuals, the sign of multipliers, and the duality gap. Perturb the data and re-solve: is the answer stable?
7. **Interpret.** Read multipliers as the price of each specification. Round to available values, re-check the specifications, and simulate the rounded design.

Common Pitfall — optimising the model, not the product

An optimizer drives the design to wherever the model is most flattering — often the edge of its validity (a transistor model used outside its fitted bias range, a linear cost curve far beyond the tested load). Add constraints that keep the design inside the model's domain of validity, and verify the final design with a higher-fidelity model or measurement.

Engineering Note — where these problems appear in tools

Optimal power flow and unit commitment in grid operation (LP/QP/MILP), automatic matching-network and filter synthesis in RF tools (nonlinear least squares and minimax), parameter extraction for device models (Levenberg–Marquardt), model predictive control running a QP every sample period, and analogue-circuit sizing by geometric programming are all direct applications of this chapter's methods.

Summary

Topic	Key result	Formula
Standard problem	minimise subject to inequalities and equalities	$\min f(\mathbf{x})$ s.t. $g_i(\mathbf{x}) \le 0,\ h_k(\mathbf{x}) = 0$
Existence	continuous f on a compact set, or coercive f	Weierstrass
Epigraph trick	minimax / L^1 to LP	$\min t$ s.t. $r_i(\mathbf{x}) \le t$
LP primal–dual	weak/strong duality	$\max \mathbf{c}^\mathsf{T}\mathbf{x},\ \mathbf{A}\mathbf{x} \le \mathbf{b},\ \mathbf{x} \ge \mathbf{0} \ \leftrightarrow\ \min \mathbf{b}^\mathsf{T}\mathbf{y},\ \mathbf{A}^\mathsf{T}\mathbf{y} \ge \mathbf{c},\ \mathbf{y} \ge \mathbf{0}$
Complementary slackness	spare capacity has zero price	$y_i(b_i - \mathbf{a}_i^\mathsf{T}\mathbf{x}) = 0,\ \mu_i g_i(\mathbf{x}) = 0$
Unconstrained optimality	FONC, SOSC	$\nabla f(\mathbf{x}^*) = \mathbf{0},\ \nabla^2 f(\mathbf{x}^*) \succ 0$
KKT stationarity	constrained optimality	$\nabla f + \sum \mu_i \nabla g_i + \sum \lambda_k \nabla h_k = \mathbf{0},\ \mu_i \ge 0$
Multiplier as sensitivity	shadow price	$\partial f^*/\partial b_i = -\mu_i$ for $g_i \le b_i$
Gradient descent	stable step, quadratic rate	$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha \nabla f,\ 0 < \alpha < 2/L,\ \rho = \dfrac{\kappa - 1}{\kappa + 1}$
Exact line search (quadratic)	step length	$\alpha_k = \dfrac{\mathbf{g}_k^\mathsf{T}\mathbf{g}_k}{\mathbf{g}_k^\mathsf{T}\mathbf{A}\mathbf{g}_k}$
Armijo condition	sufficient decrease	$f(\mathbf{x} + \alpha\mathbf{p}) \le f(\mathbf{x}) + c_1 \alpha \nabla f^\mathsf{T}\mathbf{p}$
Newton step	quadratic convergence	$\nabla^2 f(\mathbf{x}_k)\,\mathbf{p} = -\nabla f(\mathbf{x}_k)$
Secant condition	quasi-Newton	$\mathbf{H}_{k+1}\mathbf{y}_k = \mathbf{s}_k$
BFGS update	inverse Hessian	$\mathbf{H}_{k+1} = (\mathbf{I} - \rho \mathbf{s}\mathbf{y}^\mathsf{T})\mathbf{H}_k(\mathbf{I} - \rho \mathbf{y}\mathbf{s}^\mathsf{T}) + \rho \mathbf{s}\mathbf{s}^\mathsf{T},\ \rho = 1/\mathbf{y}^\mathsf{T}\mathbf{s}$
Convex function	chord above graph; tangent below	$f(\mathbf{y}) \ge f(\mathbf{x}) + \nabla f(\mathbf{x})^\mathsf{T}(\mathbf{y} - \mathbf{x});\ \nabla^2 f \succeq 0$
Convex problem	local = global; KKT sufficient	Slater ⇒ strong duality

Topic	Key result	Formula
Normal equations	linear least squares	$\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{A}^{\mathsf{T}}\mathbf{b}$, $\mathbf{A}^{\mathsf{T}}\mathbf{r}^{*} = \mathbf{0}$
Ridge regression	regularised LS	$(\mathbf{A}^{\mathsf{T}}\mathbf{A} + \lambda\mathbf{I})\mathbf{x} = \mathbf{A}^{\mathsf{T}}\mathbf{b}$, filter factors $\sigma_i^2/(\sigma_i^2+\lambda)$
Gauss–Newton	nonlinear LS	$\mathbf{J}^{\mathsf{T}}\mathbf{J}\boldsymbol{\delta} = -\mathbf{J}^{\mathsf{T}}\mathbf{r}$ (LM: $+\tau\mathbf{I}$)
Weighted sum	Pareto point (convex fronts only)	$\min \sum w_i f_i$, front slope $= -w_1/w_2$
ε-constraint	any Pareto point	$\min f_1$ s.t. $f_i \le \varepsilon_i$, $\partial f_1^{*}/\partial \varepsilon_i = -\mu_i$
Economic dispatch	equal incremental cost	$C_i'(P_i) = \lambda$ for units within limits

Chapter 24 — Computational Mathematics

> **Prerequisites:** Ch. 8 (elimination, LU, norms, condition number, sparse storage, Jacobi and Gauss–Seidel), Ch. 9 (least squares, QR), Ch. 10 (eigenvalues, SVD), Ch. 19–Ch. 20 (random variables, variance, estimation), Ch. 22 (floating point, numerical error, Newton's method). **Learning outcomes:** After this chapter you can
>
> - estimate the cost of an algorithm in flops and memory traffic, read and use big-O notation, and restructure a computation (reordering, vectorization) to change its cost;
> - decide when a symbolic computation is worth doing, recognise expression swell, and combine symbolic derivation with numerical evaluation;
> - compute QR and SVD factorisations, count their cost, and use backward error and the condition number to judge whether a computed answer can be trusted;
> - choose and tune iterative solvers (SOR, conjugate gradients, GMRES) and preconditioners, and predict their convergence from spectral information;
> - store and factor sparse matrices efficiently, controlling fill-in by reordering;
> - design Monte Carlo experiments with quantified error and variance reduction, fit nonlinear models by Gauss–Newton and Levenberg–Marquardt, propagate uncertainty by linearization (GUM), Monte Carlo and adjoint sensitivities, and make every such experiment reproducible.

Chapters 8 and 22 taught the *building blocks* of numerical computation: how a floating-point number is stored, how Gaussian elimination works, how Newton's method converges, how a system is ill-conditioned. This chapter is about *putting them together at scale*. A post-layout transistor-level simulation solves a sparse linear system with a million unknowns thousands of times; a finite-element model of a motor or an antenna produces systems with tens of millions; a yield study runs the same simulation ten thousand times with randomly perturbed component values; a device model is calibrated by fitting twenty parameters to a few thousand measured points. In every case the questions are the same. How much work will this take, and how does the work grow with problem size? Can I trust the answer, and how much of the error comes from the data, the model, the algorithm and the arithmetic? Could someone else — or I, in six months — get the same answer again?

The chapter therefore mixes three kinds of material: **cost** (Sections 24.1, 24.5), **algorithms with guaranteed accuracy** (24.2–24.4, 24.7) and **statistical computation** (24.6, 24.8), finishing with the discipline that ties them together, **reproducibility** (24.9). Short Python fragments using NumPy, SciPy and SymPy illustrate each idea; they are written to be read, not just run, and every number quoted in a worked example has been checked by such a script.

24.1 Algorithmic thinking

Motivation

Two programs that compute the same mathematical quantity can differ in running time by a factor of a million. The difference rarely comes from clever micro-optimisation; it comes from the *algorithm* — the sequence of operations chosen — and from how that sequence interacts with the hardware. A discrete Fourier transform of 2^{20} samples computed from the definition takes about 10^{12} complex multiply–adds; the FFT takes about 10^8 flops. Multiplying three matrices in the wrong order can cost a thousand times more than in the right order. Algorithmic thinking is the habit of asking, *before* writing code, "how does the work grow with n?" and "is there an equivalent formulation that does less?"

Measuring cost

Flop, cost model

A **flop** is one floating-point addition, subtraction, multiplication or division. The **arithmetic cost** of an algorithm is the number of flops it performs as a function of the problem size n (number of unknowns, samples, grid points). The **memory cost** is the number of words it stores; the **communication cost** is the number of words moved between levels of the memory hierarchy (main memory, cache, registers, or between processors).

Flop counts are the classical measure and remain the right first estimate. On modern hardware, however, moving a number from main memory costs far more time than an arithmetic operation on it — typically 10–100 flop-times. An algorithm whose ratio of flops to memory words (its **arithmetic intensity**) is high, like dense matrix–matrix multiplication ($2n^3$ flops on $3n^2$ words), runs near peak speed; one with intensity $O(1)$, like a sparse matrix–vector product (2 nnz flops on about nnz words), is limited by memory bandwidth no matter how fast the processor is.

Asymptotic notation

We usually care about how cost grows for large n, not about exact counts.

Big-O, big-Omega, big-Theta

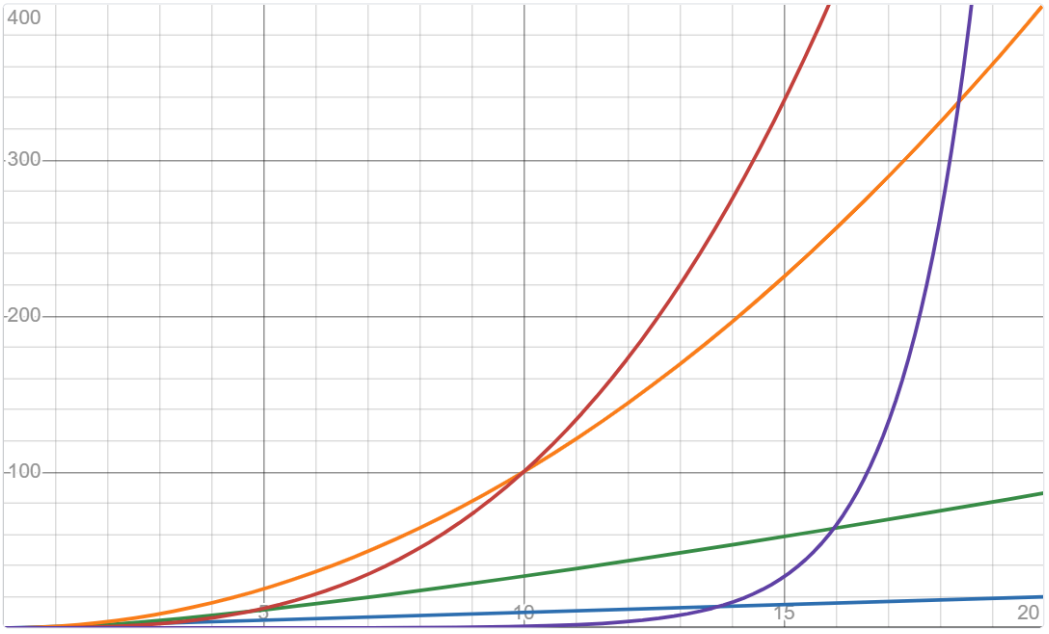
For positive functions $f(n)$, $g(n)$:

- $f = O(g)$ if there are constants $c > 0$, n_0 with $f(n) \le c\,g(n)$ for all $n \ge n_0$ (grows *no faster* than g);
- $f = \Omega(g)$ if $f(n) \ge c\,g(n)$ for $n \ge n_0$ (grows *at least as fast*);
- $f = \Theta(g)$ if both hold (grows *at the same rate*).

We also write $f \sim g$ if $f(n)/g(n) \to 1$; this keeps the leading constant, as in "LU costs $\sim \tfrac{2}{3}n^3$ flops".

Big-O hides constants, so it answers *scaling* questions ("if I double n, how much longer?") rather than *absolute* ones ("which of two $O(n^3)$ algorithms is faster?"). For the latter we keep the leading term with its constant, $\sim c\,n^p$. Typical growth classes in numerical work are:

Class	Example
$O(1)$	one evaluation of a closed-form formula
$O(\log n)$	bisection to fixed absolute accuracy on an interval of length n; binary search
$O(n)$	vector addition, inner product, tridiagonal (Thomas) solve, one sparse matrix–vector product
$O(n \log n)$	FFT, sorting, nested-dissection fill for 2-D grids
$O(n^2)$	dense matrix–vector product, triangular solve, direct DFT
$O(n^3)$	dense LU, QR, SVD, eigenvalues, matrix–matrix product
$O(2^n)$, $O(n!)$	exhaustive search over subsets or orderings; cofactor-expansion determinant



Growth of n (blue), $n \log_2 n$ (green), n^2 (orange), $n^3/10$ (red) and $2^n/1000$ (purple). The constants are deliberately chosen so that the "worse" algorithms start out faster: for small n any of them may win, but beyond a crossover the exponent (or the exponential) always dominates.

Empirical scaling exponent

If a cost behaves as $T(n) \approx c\, n^p$, then measurements at two sizes give

$$p \approx \frac{\ln\big(T(n_2)/T(n_1)\big)}{\ln(n_2/n_1)},$$

the slope of T against n on log–log axes. Predicting the time at a new size is then $T(n_3) \approx T(n_2)\,(n_3/n_2)^p$.

This is the single most useful back-of-envelope tool in computational work: time a code at two modest sizes, compute p, and you know whether the production run will take minutes or months — and whether the code really has the complexity you think it has.

Recurrences and divide-and-conquer

Many fast algorithms split a problem of size n into a subproblems of size n/b and combine the results with $O(n^d)$ extra work, giving the recurrence $T(n) = a\,T(n/b) + O(n^d)$.

Master theorem (simplified)

For $T(n) = a\,T(n/b) + \Theta(n^d)$ with $a \ge 1$, $b > 1$:

$$T(n) = \begin{cases} \Theta(n^d) & \text{if } d > \log_b a, \\ \Theta(n^d \log n) & \text{if } d = \log_b a, \\ \Theta(n^{\log_b a}) & \text{if } d < \log_b a. \end{cases}$$

Sketch. Unrolling the recursion gives $\log_b n$ levels; level ℓ has a^ℓ subproblems each costing $(n/b^\ell)^d$, i.e. total $n^d (a/b^d)^\ell$ at that level. This is a geometric series in ℓ with ratio a/b^d: if the ratio is below 1 the top level dominates, if it equals 1 all $\log_b n$ levels contribute equally, and if it exceeds 1 the $a^{\log_b n} = n^{\log_b a}$ leaves dominate. $\square$

The radix-2 FFT has $a = b = 2$, $d = 1$, so $T = \Theta(n \log n)$. Strassen's matrix multiplication replaces eight half-size products by seven, $a = 7$, $b = 2$, $d = 2$, giving $\Theta(n^{\log_2 7}) = \Theta(n^{2.807})$.

Worked Example 24.1 — Polynomial evaluation: naive versus Horner

Count the flops needed to evaluate $p(x) = a_0 + a_1 x + \cdots + a_n x^n$ (a) by computing each power x^k from scratch, (b) by accumulating powers, (c) by Horner's rule $p = a_0 + x(a_1 + x(a_2 + \cdots + x\,a_n))$.

(a) The term $a_k x^k$ needs k multiplications ($k-1$ for the power and one for the coefficient), so the total is $\sum_{k=1}^{n} k = \tfrac{1}{2}n(n+1)$ multiplications plus n additions: $\Theta(n^2)$.

(b) Keeping $x^k = x \cdot x^{k-1}$ costs one multiplication per power and one per coefficient: $2n$ multiplications and n additions, $3n$ flops.

(c) Horner performs one multiplication and one addition per coefficient: $2n$ flops — optimal, since any method must at least touch every coefficient.

Check, $n = 3$, $x = 2$, $p = 1 - 3x + 0x^2 + 2x^3$**.** Horner: $b_3 = 2$, $b_2 = 0 + 2 \cdot 2 = 4$, $b_1 = -3 + 2 \cdot 4 = 5$, $b_0 = 1 + 2 \cdot 5 = 11$; directly $1 - 6 + 0 + 16 = 11$ ✓. For a degree-20 filter polynomial the counts are 230, 60 and 40 flops. Horner is also the most accurate of the three in floating point, and its intermediate values b_k are the coefficients of the deflated polynomial $p(x)/(x - x_0)$ — two benefits for the price of one loop.

Worked Example 24.2 — Predicting a run time from two measurements

A dense solver takes 0.21 s for $n = 2000$ and 1.62 s for $n = 4000$. Estimate the scaling exponent and the time for $n = 20\,000$. Would $n = 10^6$ (a modest post-layout netlist) be feasible?

Exponent. $p = \ln(1.62/0.21)/\ln 2 = \ln 7.714/0.6931 = 2.043/0.6931 \approx 2.95$ — consistent with an $O(n^3)$ LU factorisation.

Prediction. $T(20\,000) \approx 1.62 \times (20\,000/4000)^{2.95} = 1.62 \times 5^{2.95} = 1.62 \times 115.5 \approx 187$ s, about three minutes.

Extrapolation to 10^6**.** $T \approx 1.62 \times (250)^3 \approx 2.5 \times 10^7$ s, about ten months — and the matrix alone would need $8n^2 = 8 \times 10^{12}$ bytes. Dense methods are out; the problem must be solved by exploiting sparsity (Section 24.5), where the cost for circuit matrices is typically close to $O(n^{1.1\text{–}1.5})$.

Reading. The measured $p = 2.95$ rather than exactly 3 is normal: at moderate n lower-order terms and cache effects still contribute. Always measure at sizes large enough that the leading term dominates, and treat the prediction as an order of magnitude.

Worked Example 24.3 — Associativity changes the cost

Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n \times n}$ and $\mathbf{x} \in \mathbb{R}^n$. Compare the cost of $(\mathbf{AB})\mathbf{x}$ and $\mathbf{A}(\mathbf{Bx})$ for $n = 1000$. Then consider $\mathbf{y} = (\mathbf{I} + \mathbf{u}\mathbf{v}^{\mathsf{T}})\mathbf{x}$.

Products. A matrix–matrix product costs $2n^3$ flops (n^2 entries, each an inner product of length n: n multiplications and $n-1$ additions); a matrix–vector product costs $2n^2$.

- $(\mathbf{AB})\mathbf{x}$: $2n^3 + 2n^2 \approx 2.002 \times 10^9$ flops.
- $\mathbf{A}(\mathbf{Bx})$: $2n^2 + 2n^2 = 4 \times 10^6$ flops.

The results are mathematically identical; the second is 500 times cheaper, and the ratio grows as $n/2$.

Rank-one update. Forming $\mathbf{I} + \mathbf{u}\mathbf{v}^{\mathsf{T}}$ explicitly and multiplying costs n^2 (outer product) $+ 2n^2$ (product) flops and n^2 words of memory. Writing instead $\mathbf{y} = \mathbf{x} + \mathbf{u}(\mathbf{v}^{\mathsf{T}}\mathbf{x})$ costs $2n$ (inner product) $+ 2n$ (scaled add) $= 4n$ flops and no extra storage. For $n = 10^6$ the explicit matrix would not even fit in memory.

Rule. Never form a matrix you only need to multiply by. The same rule appears as "never form $\mathbf{A}^{-1}$" (Ch. 8), "never form $\mathbf{A}^{\mathsf{T}}\mathbf{A}$" (Section 24.3) and "never form the dense Jacobian" (Section 24.8).

Vectorization and the memory hierarchy

Interpreted languages such as Python or MATLAB execute an explicit loop body at perhaps 10^7 iterations per second; the same operation expressed as a whole-array operation runs in compiled, cache-friendly library code at 10^9–10^{11} flops per second. **Vectorization** means expressing an algorithm in terms of whole-array operations — elementwise arithmetic, reductions, matrix products — so that the inner loops run inside optimised libraries (BLAS, LAPACK, FFTW).

```
import numpy as np
rng = np.random.default_rng(0)
t = np.linspace(0.0, 1e-3, 1_000_000)          # 1 ms, 1 M samples
# loop version: ~1 s in CPython
v = np.empty_like(t)
for k in range(t.size):
    v[k] = 5.0 * (1.0 - np.exp(-t[k] / 1e-4))
# vectorized version: ~10 ms
v = 5.0 * (1.0 - np.exp(-t / 1e-4))
```

The libraries are themselves organised in three levels. **Level-1 BLAS** (vector–vector, $O(n)$ work on $O(n)$ data), **level-2** (matrix–vector, $O(n^2)$ on $O(n^2)$) and **level-3** (matrix–matrix, $O(n^3)$ on $O(n^2)$). Only level-3 operations have enough arithmetic intensity to reuse data in cache, so high-performance LU, QR and Cholesky are written as **blocked algorithms**: the matrix is partitioned into $b \times b$ tiles (with b of order 100) and most of the work is recast as tile–tile products. This is why `numpy.linalg.solve` on a 4000×4000 matrix runs at a large fraction of the processor's peak, while a hand-written triple loop runs a thousand times slower *with the same flop count*.

Worked Example 24.4 — Direct DFT versus FFT, and a vectorized DFT

A spectrum is needed for a record of $N = 2^{20} \approx 1.05 \times 10^6$ samples. Compare the costs of the direct DFT $X_k = \sum_{n=0}^{N-1} x_n e^{-j2\pi kn/N}$ and the radix-2 FFT.

Direct DFT. N outputs, each a sum of N complex products: $N^2 \approx 1.1 \times 10^{12}$ complex multiply–adds, about 8×10^{12} real flops (a complex multiply–add is 4 real multiplications and 4 additions).

FFT. About $5N \log_2 N = 5 \times 2^{20} \times 20 \approx 1.05 \times 10^8$ real flops.

Ratio. $8N^2/(5N \log_2 N) = 8N/(5 \log_2 N) \approx 8.4 \times 10^4$. At 10^{10} flops per second the DFT takes about 13 minutes, the FFT about 10 ms.

Vectorization is not a substitute for a better algorithm. The DFT can be vectorized as a matrix–vector product, `X = np.exp(-2j*np.pi*np.outer(k, n)/N) @ x`, which is fast for $N = 1024$ — but the matrix has N^2 entries (16 TB in complex double precision for $N = 2^{20}$). Vectorization reduces the constant; only the FFT reduces the exponent.

Common Pitfall

Big-O comparisons hold only *asymptotically*. Insertion sort ($O(n^2)$) beats merge sort for $n \lesssim 20$, which is why library sorts switch to it for small subarrays; Strassen's algorithm only wins for n in the thousands and is less accurate; a sparse solver can be slower than a dense one for a 50×50 matrix. Conversely, a "fast" algorithm whose constant is small but whose exponent is large will lose eventually. Measure at realistic sizes, and report both the exponent and the constant.

Engineering Note

SPICE-class simulators spend most of their time in two places: evaluating device models (an $O(n)$ loop over transistors, vectorized and parallelized in modern simulators) and solving the sparse linear system at each Newton iteration. For large digital blocks the solve dominates; for analog blocks with complex transistor models the evaluation dominates. Profiling to find out *which* — before optimising anything — is itself part of algorithmic thinking. The same holds for an FPGA or DSP implementation: a filter whose coefficients are evaluated by Horner's rule needs n multipliers rather than $n(n+1)/2$, and an FFT-based convolution beats direct convolution once the filter length exceeds roughly 64 taps.

Accuracy is part of the algorithm

Cost is not the only property of an algorithm. Two algorithms with the same flop count can deliver very different accuracy: the textbook variance formula $\frac{1}{N}\sum x_i^2 - \bar{x}^2$ and the two-pass formula $\frac{1}{N}\sum (x_i - \bar{x})^2$ both cost $O(N)$, but the first suffers catastrophic cancellation when the mean is large compared with the spread (Ch. 22). An algorithm is judged by the triple **(cost, accuracy, robustness)** — and the next sections develop the tools (backward error, condition number, convergence rate) for the second and third.

Worked Example 24.5 — One-pass variance: cost versus accuracy

Ten resistor readings near 10 kΩ are recorded as $x_i = 10\,000 + \delta_i$ Ω with $\delta_i \in \{0.1, 0.2, \ldots, 1.0\}$. Compute the variance in single precision ($\varepsilon \approx 6 \times 10^{-8}$) by the one-pass and two-pass formulas.

Exact. The δ_i are $0.1k$, $k = 1, \ldots, 10$, with mean 0.55 and population variance $0.01 \times \mathrm{Var}(k) = 0.01 \times 8.25 = 0.0825\ \Omega^2$.

One-pass. $\frac{1}{N}\sum x_i^2 \approx 1.0000110 \times 10^8$; each x_i^2 is about 10^8, and single precision represents numbers near 10^8 only to the nearest multiple of 8. The difference $\frac{1}{N}\sum x_i^2 - \bar{x}^2$ is therefore a difference of two numbers each uncertain by several units, whose true value is 0.0825: the result is pure rounding noise. Run in NumPy `float32`, it returns -8.0 — a *negative* variance.

Two-pass. Subtracting $\bar{x} \approx 10\,000.55$ first leaves residuals between -0.45 and 0.45 with small relative error; the result is 0.08254, which agrees to five digits with the variance of the stored `float32` values computed in double precision. (It differs from 0.0825 in the fourth digit only because $10\,000.1$ etc. are themselves stored with errors up to 5×10^{-4}.)

Welford's algorithm obtains the two-pass accuracy in one pass by updating the mean and the sum of squared deviations recursively, $\bar{x}_k = \bar{x}_{k-1} + (x_k - \bar{x}_{k-1})/k$, $M_k = M_{k-1} + (x_k - \bar{x}_{k-1})(x_k - \bar{x}_k)$ — the method of choice for streaming data from an ADC.

24.2 Symbolic versus numerical computation

Motivation

A computer can manipulate mathematics in two quite different ways. A **computer algebra system** (CAS) such as SymPy, Mathematica or Maple manipulates *expressions*: it can differentiate $\ln(1 + e^{x/V_T})$, factor $s^3 + 2s^2 + 2s + 1$, or solve a nodal system with symbolic R and C and return a transfer function. A **numerical** library such as NumPy, SciPy or LAPACK manipulates *floating-point numbers*: it evaluates, factorises and integrates, quickly and approximately. Engineers need both, and the skill is knowing which to use for which part of a problem. Symbolic results give insight (which component controls the pole?), exactness (no rounding) and formulas that can be reused; numerical results give speed and scale. Each fails in characteristic ways, and the best workflows combine them.

Two models of computation

Symbolic and numerical computation

Symbolic computation represents mathematical objects exactly — integers of arbitrary length, rationals, algebraic numbers such as $\sqrt{2}$, symbols, and expression trees built from them — and transforms them by rewriting rules (expansion, simplification, differentiation, Gröbner bases, symbolic integration). **Numerical computation** represents real numbers by fixed-precision floating-point approximations (Ch. 22) and evaluates algorithms whose every step is a rounded arithmetic operation. **Exact numeric** (arbitrary-precision rational or integer) arithmetic and **arbitrary-precision floating point** (e.g. `mpmath` with 50 digits) are intermediate options.

The trade-off is between three resources:

	Symbolic / exact	Floating point
Cost per operation	grows with the *size* of the operands (digits, terms)	constant (one machine instruction)
Error	none (or explicit)	rounding, $\lesssim \varepsilon \approx 1.1 \times 10^{-16}$ per operation in double precision
Output	formula valid for all parameter values	number valid for one parameter value
Scale	tens of unknowns	millions of unknowns

Expression swell

The central failure mode of symbolic computation is that intermediate and final expressions can grow without bound even when the inputs are small.

Expression swell

Expression swell is the growth in size (number of terms, nesting depth, or number of digits) of the expressions produced during a symbolic or exact computation, so that time and memory grow much faster than the operation count of the corresponding floating-point algorithm.

Three sources recur.

1. **Combinatorial growth.** The determinant of a general symbolic $n \times n$ matrix has $n!$ terms in expanded form: 24 for $n = 4$, 3 628 800 for $n = 10$. Floating-point LU computes the numerical value in $\tfrac{2}{3}n^3 \approx 670$ flops for $n = 10$.
2. **Digit growth.** Exact rational arithmetic roughly doubles the number of digits at each multiplication. Gaussian elimination on an integer matrix, done naively over the rationals, can produce entries whose length grows exponentially with n (fraction-free Bareiss elimination keeps the growth polynomial, but still far from $O(1)$ per operation).
3. **Closed-form blow-up.** Formulas that exist in principle can be useless in practice. A quartic has closed-form roots, but SymPy's expression for a single root of $x^4 + x + 1$ already contains 72 operations of nested radicals; by the Abel–Ruffini theorem degree five and above have no general radical formula at all.

Worked Example 24.6 — Digit growth in exact Newton iteration

Apply Newton's method $x_{k+1} = \tfrac{1}{2}(x_k + 2/x_k)$ for $\sqrt{2}$ from $x_0 = 1$ in exact rational arithmetic, and compare with floating point.

Iterates. $x_1 = \tfrac{3}{2}$, $x_2 = \tfrac{17}{12}$, $x_3 = \tfrac{577}{408}$, $x_4 = \tfrac{665\,857}{470\,832}$, …

Errors and sizes.

k	1	2	3	4	5	6	7
digits in numerator	1	2	3	6	12	25	49
error $x_k - \sqrt{2}$	8.6×10^{-2}	2.5×10^{-3}	2.1×10^{-6}	1.6×10^{-12}	$\approx 10^{-24}$	$\approx 10^{-48}$	$\approx 10^{-97}$

Quadratic convergence doubles the number of correct digits each step; in exact arithmetic it *also* doubles the number of digits stored, so the cost of each step doubles too. In double precision the iteration reaches full accuracy at $k = 5$ and every step costs the same three flops.

Reading. Exactness was not buying anything: after step 5 the extra digits exceed any physical meaning. When the answer is going to be used as a number, use floating point (or arbitrary precision with a *fixed* number of digits) and control the error analytically.

Worked Example 24.7 — Exact versus floating-point inversion of Hilbert matrices

The Hilbert matrix $\mathbf{H}_n$, $h_{ij} = 1/(i + j - 1)$, is the classic ill-conditioned matrix of Ch. 8. Compare exact rational and floating-point inversion.

Exact. $\mathbf{H}_n^{-1}$ has *integer* entries, computable exactly in SymPy. Their size grows rapidly: the largest entry is 192 for $n = 3$, 179 200 for $n = 5$, 4.25×10^9 for $n = 8$ and 3.48×10^{12} for $n = 10$.

Floating point. The 2-norm condition numbers are $\kappa_2(\mathbf{H}_5) = 4.8 \times 10^5$, $\kappa_2(\mathbf{H}_8) = 1.5 \times 10^{10}$, $\kappa_2(\mathbf{H}_{10}) = 1.6 \times 10^{13}$. The worst-case rule of thumb "relative error $\lesssim \kappa\varepsilon$" allows about 2×10^{-6} for $n = 8$, 2×10^{-3} for $n = 10$ and order 1 for $n = 12$ ($\kappa_2 \approx 2 \times 10^{16}$); the measured relative errors of `numpy.linalg.inv` against the exact inverse are 2.1×10^{-9}, 8.8×10^{-5} and 3.1×10^{-2} — better than the bound, as is usual, but growing at the same exponential rate.

Which wins? If the matrix entries are *exact data* (as in a proof, or a combinatorial identity), exact arithmetic is the right tool for small n. If the entries come from measurements with three significant figures, exact inversion is meaningless: the problem itself amplifies data errors by κ, and no arithmetic can recover what the data do not contain. The cure is reformulation (an orthogonal polynomial basis instead of monomials, Section 24.3), not more digits.

What symbolic computation does well

- **Deriving formulas once, evaluating many times.** A symbolic transfer function, a Jacobian for Newton's method, or a sensitivity $\partial y/\partial p$ derived symbolically and then compiled to numerical code (SymPy `lambdify`, code generation to C) is exact in form and fast in evaluation.
- **Insight into parameter dependence.** A symbolic pole location shows which component moves it; a series expansion shows the leading behaviour.
- **Removing cancellation before it happens.** Rewriting an expression analytically (e.g. $1-\cos x = 2\sin^2(x/2)$) eliminates catastrophic cancellation that no amount of numerical care can fix afterwards.
- **Verification.** Symbolic results provide exact references against which numerical code is tested (Section 24.9).

What numerical computation does well

- Problems with **no closed form**: roots of degree-5 polynomials, nonlinear ODEs, most integrals of measured or tabulated data.
- **Large problems**: 10^6 unknowns, where any symbolic representation is hopeless.
- Problems whose **data are inexact anyway**: measurements, tolerances, fitted models.
- Problems whose answer is wanted **only as a number** at specific parameter values.

Worked Example 24.8 — Cancellation removed symbolically

Evaluate $f(x) = \dfrac{1-\cos x}{x^2}$ at $x = 10^{-4}$ and $x = 10^{-8}$ in double precision. Fix it with a symbolic rewrite.

Direct evaluation. At $x = 10^{-8}$, $\cos x = 1 - 5\times10^{-17}$ rounds to exactly 1 in double precision (the spacing of doubles just below 1 is 1.1×10^{-16}), so the numerator is 0 and $f = 0$. The true value is $\tfrac12$: 100% error. At $x = 10^{-4}$ the direct formula gives $0.499\,999\,996\,96$, relative error 6×10^{-9} — eight digits lost to cancellation.

Symbolic rewrite. $1-\cos x = 2\sin^2(x/2)$, so $f(x) = \dfrac{2\sin^2(x/2)}{x^2} = \dfrac12\left(\dfrac{\sin(x/2)}{x/2}\right)^2$. There is no subtraction; the evaluation gives 0.5 at $x = 10^{-8}$ and $0.499\,999\,999\,583$ at $x = 10^{-4}$, correct to all digits shown.

Series check. SymPy's `series((1-cos(x))/x**2, x, 0, 6)` returns $\tfrac12 - \tfrac{x^2}{24} + \tfrac{x^4}{720} + O(x^6)$; at $x = 10^{-4}$, $\tfrac12 - 4.17\times10^{-10} = 0.499\,999\,999\,583$ ✓.

Lesson. The symbolic step costs nothing at run time and removes the error at its source. This is the typical successful division of labour: algebra *before* the numbers.

Worked Example 24.9 — A hybrid workflow: symbolic transfer function, numerical evaluation

A two-section RC ladder (series R, shunt C, series R, shunt C) is driven by v_{in}. Derive $H(s) = V_2/V_{\text{in}}$ symbolically, then evaluate $|H(j\omega)|$ numerically over 1000 frequencies.

Symbolic nodal analysis. With node voltages V_1 (first capacitor) and V_2 (output) and $V_{\text{in}} = 1$,

$$\begin{bmatrix} \frac{2}{R}+sC & -\frac{1}{R} \\ -\frac{1}{R} & \frac{1}{R}+sC \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} \frac{1}{R} \\ 0 \end{bmatrix}.$$

```
import sympy as sp, numpy as np
s, R, C = sp.symbols('s R C', positive=True)
G = sp.Matrix([[2/R + s*C, -1/R], [-1/R, 1/R + s*C]])
V = G.LUsolve(sp.Matrix([1/R, 0]))
H = sp.factor(sp.simplify(V[1]))      # 1/(C**2*R**2*s**2 + 3*C*R*s + 1)
Hnum = sp.lambdify((s, R, C), H, 'numpy')
w = np.logspace(1, 6, 1000)
mag = np.abs(Hnum(1j*w, 1e3, 100e-9))  # vectorized over w
```

Result. $H(s) = \dfrac{1}{R^2C^2s^2 + 3RCs + 1}$. The symbolic form tells us immediately that the poles are at $s = -\dfrac{3\pm\sqrt{5}}{2RC}$, i.e. $-0.382/RC$ and $-2.618/RC$ (the same golden-ratio numbers that appear in infinite ladders): the loading of the first section by the second splits the double pole of two buffered sections apart by a factor $2.618^2 \approx 6.85$.

Numerical check. With $R = 1\ \text{k}\Omega$, $C = 100\ \text{nF}$ ($RC = 10^{-4}$ s), at $\omega = 10^4$ rad/s: $sRC = j$, so $H = 1/(-1+3j+1) = 1/(3j)$, $|H| = 1/3$ and the phase is -90° — what `Hnum(1j*1e4, 1e3, 100e-9)` returns.

Why hybrid? The symbolic solve of a 2×2 system is instant and gives insight; repeating it for a 40-node filter would produce an enormous rational function that is slower to evaluate, and less accurate, than a numerical sparse solve at each frequency. The rule: go symbolic for small subsystems whose *structure* you want to understand; go numerical for the full system.

Choosing between them

Engineering Note — a decision checklist

1. **Is a formula the deliverable** (a design equation, a sensitivity expression, a model to hand to someone else)? Use symbolic computation, on the smallest subsystem that captures the effect.
2. **Are there more than about ten coupled unknowns, or nonlinear equations without closed-form solution?** Use numerical methods.
3. **Will the expression be evaluated many times?** Derive symbolically, simplify, then generate numerical code (`lambdify` , `codegen`) — or use automatic differentiation (Section 24.8), which gives exact derivatives without symbolic expression swell.
4. **Is the computation losing digits to cancellation?** Rewrite symbolically first.
5. **Are the data exact integers or rationals and the size small** (combinatorics, coding theory, exact filter coefficients)? Exact arithmetic is appropriate.
6. **Is the problem ill-conditioned?** Neither exact arithmetic nor more digits fixes ill-conditioned *data*; reformulate.

Common Pitfall — floats leaking into symbolic code

In SymPy, `sp.Rational(1, 10)` is exactly $\frac{1}{10}$, but `0.1` is the binary float $0.1000000000000000055\ldots$ and turns the whole expression into floating-point arithmetic, silently losing exactness (and `sp.nsimplify` may not recover the intended rational). Similarly, `sp.sqrt(2)` is exact but `np.sqrt(2)` is not. Conversely, never call `simplify` inside a loop over thousands of parameter values: simplification is heuristic and can take seconds; derive once, `lambdify` , then loop numerically.

Common Pitfall — symbolic solutions with hidden assumptions

A CAS returns *generic* answers. Solving $ax = b$ symbolically gives $x = b/a$, valid only for $a \neq 0$; the symbolic inverse of a matrix ignores the parameter values at which the determinant vanishes. When a symbolic result will be evaluated across a parameter range, check the denominators (SymPy `fraction` , `solve(..., dict=True)` with assumptions) or verify numerically at the extremes of the range.

24.3 Numerical linear algebra

Motivation

Almost every large computation in engineering ends in linear algebra: Newton's method for a nonlinear circuit solves a linear system per iteration; a least-squares fit factorises a tall matrix; a modal analysis computes eigenvalues; a model-order reduction or a beamformer computes an SVD. Chapter 8 developed Gaussian elimination, LU and Cholesky factorisation, norms and the condition number; Chapter 9 introduced Gram–Schmidt and QR for least squares; Chapter 10 introduced the SVD. This section asks the computational questions those chapters postponed: *how* are QR and the SVD computed in floating point, what do they cost, and in what precise sense are the answers "correct"?

Forward error, backward error and stability

Let f be the exact map from data to answer (for a linear system, $\mathbf{b} \mapsto \mathbf{A}^{-1}\mathbf{b}$) and $\hat{f}$ the computed version.

Forward error, backward error

The **forward error** of a computed answer $\hat{\mathbf{y}} = \hat{f}(\mathbf{x})$ is $\|\hat{\mathbf{y}} - f(\mathbf{x})\|$ (absolute) or $\|\hat{\mathbf{y}} - f(\mathbf{x})\|/\|f(\mathbf{x})\|$ (relative). The **backward error** is the size of the smallest perturbation of the *data* that makes the computed answer exact:

$$\eta(\hat{\mathbf{y}}) = \min\left\{ \frac{\|\Delta\mathbf{x}\|}{\|\mathbf{x}\|} \;:\; \hat{\mathbf{y}} = f(\mathbf{x} + \Delta\mathbf{x}) \right\}.$$

An algorithm is **backward stable** if for every input its backward error is $O(\varepsilon)$ — that is, it computes the exact answer to a slightly perturbed problem, with the perturbation comparable to rounding the data.

The two are linked by the condition number κ of the *problem*:

Rule of thumb: forward error ≤ condition × backward error

To first order,

$$\frac{\|\hat{\mathbf{y}} - \mathbf{y}\|}{\|\mathbf{y}\|} \lesssim \kappa \cdot \eta.$$

In particular, a backward-stable algorithm applied to a problem with condition number κ delivers a relative forward error of about $\kappa\varepsilon$: roughly $\log_{10}\kappa$ significant digits are lost, and no algorithm can do systematically better with data known only to precision ε.

This separates responsibilities cleanly. **Conditioning** is a property of the problem — the circuit, the measurement geometry, the choice of basis — and is the engineer's business. **Stability** is a property of the algorithm and is the library writer's business. A backward-stable algorithm is "as good as the data deserve".

For linear systems the backward error has a computable formula (Rigal–Gaches): for an approximate solution $\hat{\mathbf{x}}$ with residual $\mathbf{r} = \mathbf{b} - \mathbf{A}\hat{\mathbf{x}}$, the smallest normwise perturbation $\Delta\mathbf{A}$ with $(\mathbf{A} + \Delta\mathbf{A})\hat{\mathbf{x}} = \mathbf{b}$ has

$$\eta_A(\hat{\mathbf{x}}) = \frac{\|\mathbf{r}\|}{\|\mathbf{A}\|\,\|\hat{\mathbf{x}}\|}.$$

A *small residual* therefore certifies a *small backward error* — but, as Ch. 8 showed, not a small forward error.

Worked Example 24.10 — Small residual, large error

$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.0001 \end{bmatrix}$, $\mathbf{b} = \begin{bmatrix} 2 \\ 2.0001 \end{bmatrix}$, exact solution $\mathbf{x} = (1, 1)^{\mathsf{T}}$. A candidate answer is $\hat{\mathbf{x}} = (2, 0)^{\mathsf{T}}$. Compute its residual, backward error and forward error in the ∞-norm, and check the rule of thumb.

Residual. $\mathbf{A}\hat{\mathbf{x}} = (2, 2)^{\mathsf{T}}$, so $\mathbf{r} = (0,\ 0.0001)^{\mathsf{T}}$, $\|\mathbf{r}\|_\infty = 10^{-4}$.

Backward error. $\|\mathbf{A}\|_\infty = 2.0001$, $\|\hat{\mathbf{x}}\|_\infty = 2$: $\eta = 10^{-4}/(2.0001 \times 2) = 2.5 \times 10^{-5}$. The wrong answer is the *exact* answer to a problem whose matrix differs from $\mathbf{A}$ in the fifth significant digit.

Forward error. $\hat{\mathbf{x}} - \mathbf{x} = (1, -1)^{\mathsf{T}}$, relative error $1/1 = 100\%$.

Condition number. $\mathbf{A}^{-1} = 10^4 \begin{bmatrix} 1.0001 & -1 \\ -1 & 1 \end{bmatrix}$, $\|\mathbf{A}^{-1}\|_\infty = 2.0001 \times 10^4$, so $\kappa_\infty = 4.0004 \times 10^4$. Then $\kappa\eta = 4.0 \times 10^4 \times 2.5 \times 10^{-5} = 1.0$ ✓ — the bound is attained.

Reading. If the matrix entries are resistor values known to 0.01%, both $(1, 1)$ and $(2, 0)$ are equally valid answers. The singular values $\sigma_1 = 2.00005$, $\sigma_2 = 5.0 \times 10^{-5}$ show why: the direction $\mathbf{v}_2 \approx (1, -1)/\sqrt{2}$ is almost in the null space.

Householder QR

Gram–Schmidt (Ch. 9) builds $\mathbf{Q}$ column by column by subtracting projections. In floating point, *classical* Gram–Schmidt loses orthogonality in proportion to $\kappa(\mathbf{A})^2\varepsilon$ and *modified* Gram–Schmidt in proportion to $\kappa(\mathbf{A})\varepsilon$. Production codes instead apply a sequence of orthogonal transformations to $\mathbf{A}$ that introduce zeros below the diagonal — orthogonal *triangularisation* rather than triangular *orthogonalisation*.

Householder reflector

For a nonzero vector $\mathbf{v} \in \mathbb{R}^m$, the **Householder reflector**

$$\mathbf{H} = \mathbf{I} - 2\frac{\mathbf{v}\mathbf{v}^{\mathsf{T}}}{\mathbf{v}^{\mathsf{T}}\mathbf{v}}$$

is symmetric and orthogonal ($\mathbf{H}^{\mathsf{T}}\mathbf{H} = \mathbf{H}^2 = \mathbf{I}$); it reflects vectors in the hyperplane orthogonal to $\mathbf{v}$. Given $\mathbf{a} \neq \mathbf{0}$, the choice

$$\mathbf{v} = \mathbf{a} + \operatorname{sign}(a_1)\|\mathbf{a}\|_2\,\mathbf{e}_1$$

gives $\mathbf{H}\mathbf{a} = -\operatorname{sign}(a_1)\|\mathbf{a}\|_2\,\mathbf{e}_1$: all entries but the first are zeroed.

Derivation. $\mathbf{H}\mathbf{a} = \mathbf{a} - 2\mathbf{v}(\mathbf{v}^{\mathsf{T}}\mathbf{a})/(\mathbf{v}^{\mathsf{T}}\mathbf{v})$. With $\mathbf{v} = \mathbf{a} + \alpha\mathbf{e}_1$, $\alpha = \operatorname{sign}(a_1)\|\mathbf{a}\|$, we have $\mathbf{v}^{\mathsf{T}}\mathbf{a} = \|\mathbf{a}\|^2 + \alpha a_1$ and $\mathbf{v}^{\mathsf{T}}\mathbf{v} = \|\mathbf{a}\|^2 + 2\alpha a_1 + \alpha^2 = 2(\|\mathbf{a}\|^2 + \alpha a_1)$, so $2\mathbf{v}^{\mathsf{T}}\mathbf{a}/\mathbf{v}^{\mathsf{T}}\mathbf{v} = 1$ and $\mathbf{H}\mathbf{a} = \mathbf{a} - \mathbf{v} = -\alpha\mathbf{e}_1$. The sign choice makes $|v_1| = |a_1| + \|\mathbf{a}\|$ a sum of same-signed quantities, avoiding cancellation when $\mathbf{a}$ is nearly parallel to $\mathbf{e}_1$. □

Applying reflectors $\mathbf{H}_1, \dots, \mathbf{H}_n$ to zero columns $1, \dots, n$ below the diagonal in turn gives $\mathbf{H}_n \cdots \mathbf{H}_1\mathbf{A} = \mathbf{R}$, i.e. $\mathbf{A} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q} = \mathbf{H}_1 \cdots \mathbf{H}_n$. The reflectors are never formed as matrices: $\mathbf{H}\mathbf{x} = \mathbf{x} - \beta\mathbf{v}(\mathbf{v}^{\mathsf{T}}\mathbf{x})$ with $\beta = 2/\mathbf{v}^{\mathsf{T}}\mathbf{v}$ costs $4m$ flops (Worked Example 24.3 again), and $\mathbf{Q}$ is stored implicitly as the list of vectors $\mathbf{v}_k$.

Cost and stability of Householder QR

For $\mathbf{A} \in \mathbb{R}^{m \times n}$, $m \geq n$, Householder QR costs $\sim 2mn^2 - \tfrac{2}{3}n^3$ flops ($\tfrac{4}{3}n^3$ for square $\mathbf{A}$, twice LU). It is backward stable: the computed $\hat{\mathbf{R}}$ is the exact triangular factor of $\mathbf{A} + \Delta\mathbf{A}$ with $\|\Delta\mathbf{A}\| \leq c\,mn\,\varepsilon\|\mathbf{A}\|$, and the computed $\hat{\mathbf{Q}}$ is orthogonal to working precision, $\|\hat{\mathbf{Q}}^{\mathsf{T}}\hat{\mathbf{Q}} - \mathbf{I}\| = O(\varepsilon)$, *independently of* $\kappa(\mathbf{A})$.

Cost sketch. Step k applies a reflector of length $m - k + 1$ to the remaining $n - k + 1$ columns, at $4(m - k + 1)(n - k + 1)$ flops. Summing, $\sum_{k=1}^{n} 4(m - k)(n - k) \approx 4\int_0^n (m - t)(n - t)\,dt = 4(mn^2 - \tfrac{1}{2}(m + n)n^2 + \tfrac{1}{3}n^3) = 2mn^2 - \tfrac{2}{3}n^3$. □

Givens rotations $\begin{bmatrix} c & s \\ -s & c \end{bmatrix}$ with $c^2 + s^2 = 1$ zero one entry at a time. They cost more for dense matrices (about $3mn^2 - n^3$) but are ideal when only a few entries need zeroing — sparse or banded matrices, or *updating* a QR factorisation when one new measurement row arrives (recursive least squares).

Worked Example 24.11 — Householder QR by hand

Compute the QR factorisation of $\mathbf{A} = \begin{bmatrix} 3 & 1 \\ 4 & 2 \end{bmatrix}$ with one Householder reflector.

Reflector. $\mathbf{a} = (3,4)^{\mathsf{T}}$, $\|\mathbf{a}\| = 5$, $\operatorname{sign}(a_1) = +1$, so $\mathbf{v} = (3+5,\ 4)^{\mathsf{T}} = (8,4)^{\mathsf{T}}$, $\mathbf{v}^{\mathsf{T}}\mathbf{v} = 80$, $\beta = 2/80 = 0.025$.

First column. $\mathbf{H}\mathbf{a} = -5\mathbf{e}_1 = (-5,0)^{\mathsf{T}}$ by construction. (Check: $\mathbf{v}^{\mathsf{T}}\mathbf{a} = 24 + 16 = 40$, $\mathbf{a} - 0.025 \times 40\,\mathbf{v} = (3,4) - (8,4) = (-5,0)$ ✓.)

Second column. $\mathbf{x} = (1,2)^{\mathsf{T}}$: $\mathbf{v}^{\mathsf{T}}\mathbf{x} = 8 + 8 = 16$, $\mathbf{H}\mathbf{x} = (1,2) - 0.025 \times 16\,(8,4) = (1 - 3.2,\ 2 - 1.6) = (-2.2,\ 0.4)$.

Result.

$$\mathbf{R} = \begin{bmatrix} -5 & -2.2 \\ 0 & 0.4 \end{bmatrix}, \qquad \mathbf{Q} = \mathbf{H} = \mathbf{I} - 0.025\,\mathbf{v}\mathbf{v}^{\mathsf{T}} = \begin{bmatrix} -0.6 & -0.8 \\ -0.8 & 0.6 \end{bmatrix}.$$

Checks. $\mathbf{QR}$: first row $(-0.6)(-5) = 3$, $(-0.6)(-2.2) + (-0.8)(0.4) = 1.32 - 0.32 = 1$ ✓; second row 4, $1.76 + 0.24 = 2$ ✓. $\det \mathbf{A} = 2$, $\det \mathbf{Q} \det \mathbf{R} = (-1)(-2) = 2$ ✓ (a reflector has determinant -1). `numpy.linalg.qr` returns exactly these factors; the negative diagonal of $\mathbf{R}$ is the Householder sign convention, not an error.

Worked Example 24.12 — Loss of orthogonality: Gram–Schmidt versus Householder

The Läuchli matrix with $\epsilon = 10^{-8}$,

$$\mathbf{L} = \begin{bmatrix} 1 & 1 & 1 \\ \epsilon & 0 & 0 \\ 0 & \epsilon & 0 \\ 0 & 0 & \epsilon \end{bmatrix},$$

has nearly parallel columns ($\kappa_2 \approx 1.7 \times 10^{8}$). Orthogonalise its columns by classical Gram–Schmidt (CGS), modified Gram–Schmidt (MGS) and Householder QR, and measure the loss of orthogonality $\|\hat{\mathbf{Q}}^{\mathsf{T}}\hat{\mathbf{Q}} - \mathbf{I}\|_F$ (Frobenius norm).

CGS by hand. $1 + \epsilon^2$ rounds to 1, so $\mathbf{q}_1 = (1,\epsilon,0,0)$. Then $\mathbf{a}_2 - (\mathbf{q}_1^{\mathsf{T}}\mathbf{a}_2)\mathbf{q}_1 = (0,-\epsilon,\epsilon,0)$, $\mathbf{q}_2 = (0,-1,1,0)/\sqrt{2}$. For $\mathbf{a}_3$ CGS projects the *original* column on each $\mathbf{q}_i$: $\mathbf{q}_1^{\mathsf{T}}\mathbf{a}_3 = 1$, $\mathbf{q}_2^{\mathsf{T}}\mathbf{a}_3 = 0$, giving $(0,-\epsilon,0,\epsilon)$, $\mathbf{q}_3 = (0,-1,0,1)/\sqrt{2}$. But $\mathbf{q}_2^{\mathsf{T}}\mathbf{q}_3 = \tfrac{1}{2}$ — the "orthonormal" vectors are at 60°!

MGS. Projects the *updated* vector: after removing $\mathbf{q}_1$, $\mathbf{a}_3$ becomes $(0,-\epsilon,0,\epsilon)$, and removing its component along $\mathbf{q}_2$ ($= \epsilon/\sqrt{2}$) gives $(0,-\epsilon/2,-\epsilon/2,\epsilon)$, orthogonal to $\mathbf{q}_2$.

Measured (NumPy, double precision):

Method	$\|\hat{\mathbf{Q}}^{\mathsf{T}}\hat{\mathbf{Q}} - \mathbf{I}\|_F$
classical Gram–Schmidt	0.71
modified Gram–Schmidt	1.2×10^{-8}
Householder	3.5×10^{-16}

MGS loses orthogonality like $\kappa\varepsilon$ ($1.7 \times 10^{8} \times 1.1 \times 10^{-16} \approx 2 \times 10^{-8}$ ✓); Householder is orthogonal to machine precision regardless of κ.

Least squares: normal equations versus QR

For the overdetermined problem $\min\|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2$ (Ch. 9), the normal equations $\mathbf{A}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \mathbf{A}^{\mathsf{T}}\mathbf{b}$ solved by Cholesky cost $\sim mn^2 + \tfrac{1}{3}n^3$ flops, about half of QR. But

$$\kappa_2(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \kappa_2(\mathbf{A})^2,$$

because the singular values of $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ are the squares of those of $\mathbf{A}$. Forming $\mathbf{A}^{\mathsf{T}}\mathbf{A}$ in floating point squares the condition number *before* any solving begins: if $\kappa(\mathbf{A}) = 10^{8}$, the normal equations have $\kappa = 10^{16}$ and no digits survive.

The QR route avoids this: with $\mathbf{A} = \mathbf{Q}\mathbf{R}$ (reduced, $\mathbf{Q} \in \mathbb{R}^{m\times n}$),

$$\|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 = \|\mathbf{R}\mathbf{x} - \mathbf{Q}^{\mathsf{T}}\mathbf{b}\|_2^2 + \|(\mathbf{I} - \mathbf{Q}\mathbf{Q}^{\mathsf{T}})\mathbf{b}\|_2^2,$$

so the solution is $\mathbf{R}\hat{\mathbf{x}} = \mathbf{Q}^{\mathsf{T}}\mathbf{b}$, a triangular solve whose sensitivity is governed by $\kappa(\mathbf{A})$ (plus a term $\kappa^2\|\mathbf{r}\|$ that only matters when the residual is large, and is intrinsic to the problem).

Worked Example 24.13 — A line fit by QR

Fit $V = x_1 + x_2 I$ to $(I, V) = (1, 2.1), (2, 3.9), (3, 6.2), (4, 7.8)$ by QR.

Factorisation. For $\mathbf{A} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 2 & 3 & 4 \end{bmatrix}^{\mathsf{T}}$, Householder QR gives

$$\mathbf{R} = \begin{bmatrix} -2 & -5 \\ 0 & -2.2361 \end{bmatrix}, \qquad \mathbf{Q}^{\mathsf{T}}\mathbf{b} = \begin{bmatrix} -10 \\ -4.3380 \end{bmatrix}.$$

(The first column of $\mathbf{Q}$ is $-\tfrac{1}{2}(1,1,1,1)$, so $(\mathbf{Q}^{\mathsf{T}}\mathbf{b})_1 = -\tfrac{1}{2}\sum V_i = -10$; the second is $\propto (-3,-1,1,3)$, the centred I values.)

Back substitution. $x_2 = -4.3380/-2.2361 = 1.940$; $x_1 = (-10 + 5 \times 1.940)/(-2) = 0.150$.

Check against the closed form. $\bar{I} = 2.5$, $\bar{V} = 5$, $\sum (I-\bar{I})(V-\bar{V}) = (-1.5)(-2.9) + (-0.5)(-1.1) + (0.5)(1.2) + (1.5)(2.8) = 9.7$, $\sum (I-\bar{I})^2 = 5$, slope 1.94 ✓, intercept $5 - 1.94 \times 2.5 = 0.15$ ✓.

Conditioning. $\kappa_2(\mathbf{A}) = 7.47$, $\kappa_2(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = 55.8 = 7.47^2$ ✓. Harmless here; the next example is not.

Worked Example 24.14 — Polynomial fitting: when the normal equations fail

Fit a degree-d polynomial in the monomial basis to $m = 50$ equally spaced points on $[0, 1]$, with data generated from the polynomial whose coefficients are all 1 (so the exact answer is known). Compare normal equations and QR.

degree d	$\kappa_2(\mathbf{V})$	rel. error, normal equations	rel. error, QR
6	2.0×10^{4}	2.7×10^{-9}	5.3×10^{-13}
10	2.0×10^{7}	1.0×10^{-3}	7.1×10^{-11}
14	2.3×10^{10}	6.0 (no correct digits)	1.4×10^{-6}

Reading. Each column follows the $\kappa\varepsilon$ rule: QR errors track $\kappa(\mathbf{V})\varepsilon$, normal-equation errors track $\kappa(\mathbf{V})^2\varepsilon$ (for $d = 14$, $\kappa^2\varepsilon \approx 6 \times 10^4$: hopeless). Even QR is losing ten digits at $d = 14$, which is a property of the *problem*: the monomials t^{13} and t^{14} are nearly parallel on $[0, 1]$. The real cure is a better basis — Chebyshev or Legendre polynomials on $[-1, 1]$, for which κ grows only slowly with d — exactly the reformulation advice of Worked Example 24.7.

The SVD computationally

The SVD $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\mathsf{T}}$ (Ch. 10) is computed in two phases. **Bidiagonalisation**: Householder reflectors applied alternately from the left and the right reduce $\mathbf{A}$ to upper bidiagonal form $\mathbf{B} = \mathbf{U}_1^{\mathsf{T}}\mathbf{A}\mathbf{V}_1$ (Golub–Kahan), at $\sim 4mn^2 - \frac{4}{3}n^3$ flops. **Diagonalisation**: an implicitly shifted QR iteration (or a divide-and-conquer method) drives the superdiagonal of $\mathbf{B}$ to zero, at $O(n^2)$ flops per sweep for the values. Forming $\mathbf{U}$ and $\mathbf{V}$ explicitly multiplies the cost several times.

Never compute the SVD from the eigenvalues of $\mathbf{A}^{\mathsf{T}}\mathbf{A}$: as with the normal equations this squares the condition number, and small singular values below $\sqrt{\varepsilon}\,\sigma_1$ are lost completely.

Accuracy of computed singular values

The computed singular values $\hat{\sigma}_i$ of a backward-stable SVD satisfy $|\hat{\sigma}_i - \sigma_i| \le c\,\varepsilon\,\sigma_1$. Singular values are perfectly conditioned in the *absolute* sense (Weyl's inequality: $|\sigma_i(\mathbf{A}+\mathbf{E}) - \sigma_i(\mathbf{A})| \le \|\mathbf{E}\|_2$), so large singular values are computed to high relative accuracy and singular values below $\varepsilon\sigma_1$ are indistinguishable from zero.

This makes the SVD the reliable tool for **numerical rank**: the number of singular values above a tolerance τ, typically $\tau = \max(m,n)\,\varepsilon\,\sigma_1$ for exact data, or the noise level $\|\mathbf{E}\|$ for measured data. The **truncated SVD** solution of a least-squares problem keeps only the k components with $\sigma_i > \tau$:

$$\hat{\mathbf{x}}_k = \sum_{i=1}^{k} \frac{\mathbf{u}_i^{\mathsf{T}}\mathbf{b}}{\sigma_i}\mathbf{v}_i.$$

Discarding the small σ_i removes the components that would divide noise by a tiny number — a form of *regularisation*.

Worked Example 24.15 — Truncated SVD stabilises a near-singular solve

Return to $\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1.0001 \end{bmatrix}$. The right-hand side is measured as $\mathbf{b} = (2,\ 2.0002)^{\mathsf{T}}$ — the true $(2, 2.0001)$ plus an error of 10^{-4} in the second entry. Compare the exact solve with the rank-1 truncated SVD.

Exact solve. $x_1 + x_2 = 2$, $x_1 + 1.0001x_2 = 2.0002$ give $0.0001x_2 = 0.0002$: $\mathbf{x} = (0, 2)^{\mathsf{T}}$, far from the true $(1, 1)$.

SVD. $\sigma_1 = 2.00005$, $\sigma_2 = 4.99988 \times 10^{-5}$; $\mathbf{v}_1 \approx (0.70709,\ 0.70712)$, $\mathbf{v}_2 \approx (-0.70712,\ 0.70709)$ (up to sign). The coefficients are $\mathbf{u}_1^{\mathsf{T}}\mathbf{b} = 2.82857$ and $\mathbf{u}_2^{\mathsf{T}}\mathbf{b} = 7.07 \times 10^{-5}$ (signs as returned by NumPy).

- Component 1 contributes $(2.82857/2.00005)\mathbf{v}_1 = (1.0000,\ 1.0000)$.
- Component 2 contributes $(7.07 \times 10^{-5}/5.0 \times 10^{-5})\mathbf{v}_2 \approx 1.414\,\mathbf{v}_2 = (-1,\ 1)$ — almost entirely the amplified measurement error.

Truncated. Keeping $k = 1$: $\hat{\mathbf{x}}_1 = (1.0000,\ 1.00005)$, within 5×10^{-5} of the truth.

Reading. With data error of order 10^{-4}, any singular value below about 10^{-4} cannot be trusted; here $\sigma_2 = 5 \times 10^{-5}$ is below that level and is discarded. Choosing the truncation level is a *modelling* decision based on the noise, not a numerical one.

Cost summary

Task	Algorithm	Flops (leading term)	Stable?
Solve $\mathbf{A}\mathbf{x}=\mathbf{b}$, general	LU, partial pivoting	$\frac{2}{3}n^3$	in practice (growth factor)
Solve, SPD	Cholesky	$\frac{1}{3}n^3$	yes
Solve, extra right-hand side	triangular solves with stored factors	$2n^2$	yes
Least squares $m \times n$	normal equations + Cholesky	$mn^2+\frac{1}{3}n^3$	no: κ^2
Least squares $m \times n$	Householder QR	$2mn^2-\frac{2}{3}n^3$	yes
Singular values only	Golub–Kahan + QR iteration	$4mn^2-\frac{4}{3}n^3$	yes
Full SVD, square	with $\mathbf{U},\mathbf{V}$	$\approx 21n^3$	yes
Symmetric eigenvalues	tridiagonalisation + QR/divide & conquer	$\frac{4}{3}n^3$ ($\approx 9n^3$ with vectors)	yes
Nonsymmetric eigenvalues	Hessenberg + shifted QR	$\approx 10n^3$ ($\approx 25n^3$ with vectors)	yes (but eigenvalues may be ill-conditioned)
Determinant	from LU	$\frac{2}{3}n^3$	yes (but beware overflow; use $\log\lvert\det\rvert$)

(Approximate counts from Golub and Van Loan; constants for the iterative phases depend on the matrix.)

Gaussian elimination with partial pivoting is backward stable in practice

GEPP computes $\hat{\mathbf{x}}$ with $(\mathbf{A}+\Delta\mathbf{A})\hat{\mathbf{x}}=\mathbf{b}$, $\|\Delta\mathbf{A}\|_\infty \le c\,n^3\rho_n\varepsilon\|\mathbf{A}\|_\infty$, where the **growth factor** $\rho_n=\max_{i,j,k}|a_{ij}^{(k)}|/\max_{i,j}|a_{ij}|$ measures how large the entries become during elimination. The worst case is $\rho_n=2^{n-1}$ — attained by Wilkinson's matrix (1 on the diagonal and in the last column, -1 below the diagonal), for which $n=20$ gives $\rho=2^{19}=524\,288$ — but matrices arising in practice almost never show growth beyond $\rho\approx 10$.

Eigenvalues: a computational note

Eigenvalues are roots of the characteristic polynomial, but **no one computes them that way**: polynomial roots are violently ill-conditioned functions of the coefficients (Wilkinson's polynomial $\prod_{k=1}^{20}(x-k)$: changing one coefficient by 2^{-23} moves roots into the complex plane). Instead the **QR algorithm** iterates $\mathbf{A}_k=\mathbf{Q}_k\mathbf{R}_k$, $\mathbf{A}_{k+1}=\mathbf{R}_k\mathbf{Q}_k$ (an orthogonal similarity) on a Hessenberg or tridiagonal form with shifts, converging to triangular (Schur) form. For one dominant eigenvalue of a huge sparse matrix the **power method** $\mathbf{v}_{k+1}=\mathbf{A}\mathbf{v}_k/\|\mathbf{A}\mathbf{v}_k\|$ suffices, converging at the rate $|\lambda_2/\lambda_1|$ per step; Lanczos and Arnoldi methods (the eigenvalue cousins of the CG and GMRES solvers of Section 24.4) find a few extreme eigenvalues of matrices with millions of rows.

Worked Example 24.16 — Power iteration

Apply the power method with Rayleigh quotient $\lambda^{(k)}=\mathbf{v}_k^{\mathsf T}\mathbf{A}\mathbf{v}_k$ to $\mathbf{A}=\begin{bmatrix}2&1\\1&3\end{bmatrix}$ from $\mathbf{v}_0=(1,0)$.

Iterates. The Rayleigh quotients (using the current normalised vector) are $2,\ 3,\ 3.5,\ 3.6,\ 3.6154,\ldots$, and the vectors $(0.894,0.447)$, $(0.707,0.707)$, $(0.6,0.8)$, $(0.555,0.832)$, $(0.537,0.844)$.

Exact. $\lambda=(5\pm\sqrt{5})/2=3.6180,\ 1.3820$; dominant eigenvector $\propto(0.526,0.851)$.

Rate. $|\lambda_2/\lambda_1|=0.382$: the vector error shrinks by 0.382 per step and, for a symmetric matrix, the Rayleigh-quotient error by $0.382^2=0.146$. The errors $0.118, 0.018, 0.0027$ in the last three quotients fall by about 0.15 per step ✓.

Common Pitfall

"The residual is tiny, so the answer is right" is false for ill-conditioned problems (Worked Example 24.10), and "the answer changed in the fifth digit when I switched libraries, so one of them is buggy" is usually false too — both may be backward stable answers to a problem with $\kappa\approx 10^{11}$. Before blaming an algorithm, estimate κ (`numpy.linalg.cond`, or the cheap LAPACK estimate from an existing factorisation) and compare the observed discrepancy with $\kappa\varepsilon$.

Engineering Note

Scaling matters. A modified nodal analysis matrix mixing conductances in siemens (10^{-3}) with unit entries for voltage sources, or a state-space model mixing millivolts and kiloamps, can have an enormous condition number that is purely an artefact of units. **Equilibration** — scaling rows and columns by diagonal matrices so that entries are of comparable size, $\mathbf{D}_r\mathbf{A}\mathbf{D}_c$ — often reduces κ by many orders of magnitude at negligible cost, and LAPACK's expert drivers (`dgesvx`) do it automatically. It is the matrix version of choosing sensible units, the topic of nondimensionalisation in Ch. 25.

24.4 Iterative solvers

Motivation

A direct solver (LU, Cholesky) delivers the solution of $\mathbf{A}\mathbf{x}=\mathbf{b}$ in a fixed number of operations. For a 3-D finite-element model of a transformer with $n=10^7$ unknowns, however, even the best fill-reducing ordering (Section 24.5) leaves factors with 10^{10} or more nonzeros — too much memory and too many flops. **Iterative methods** never factor $\mathbf{A}$. They need only the ability to compute $\mathbf{A}\mathbf{v}$ for a given vector $\mathbf{v}$ — $O(\text{nnz})$ work and no extra storage — and improve an approximate solution step by step. Their cost is (number of iterations) $\times$ (cost per iteration), and the whole art lies in making the first factor small. Chapter 8 introduced the Jacobi and Gauss–Seidel iterations and their convergence criterion; here we develop the general theory, over-relaxation, the Krylov methods (conjugate gradients and GMRES) that dominate modern practice, and preconditioning.

Stationary iterations: the general picture

Split $\mathbf{A} = \mathbf{M} - \mathbf{N}$ with $\mathbf{M}$ easy to invert. Then $\mathbf{A}\mathbf{x} = \mathbf{b}$ is equivalent to $\mathbf{M}\mathbf{x} = \mathbf{N}\mathbf{x} + \mathbf{b}$, suggesting

$$\mathbf{x}^{(k+1)} = \mathbf{M}^{-1}\big(\mathbf{N}\mathbf{x}^{(k)} + \mathbf{b}\big) = \mathbf{x}^{(k)} + \mathbf{M}^{-1}\mathbf{r}^{(k)}, \qquad \mathbf{r}^{(k)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(k)}.$$

The second form shows the structure: *correct the current iterate by an approximate solve of the residual equation*. With $\mathbf{A} = \mathbf{D} + \mathbf{L}_A + \mathbf{U}_A$ (diagonal, strictly lower, strictly upper), Jacobi is $\mathbf{M} = \mathbf{D}$ and Gauss–Seidel is $\mathbf{M} = \mathbf{D} + \mathbf{L}_A$.

Convergence of stationary iterations

The error $\mathbf{e}^{(k)} = \mathbf{x}^{(k)} - \mathbf{x}$ satisfies $\mathbf{e}^{(k+1)} = \mathbf{T}\mathbf{e}^{(k)}$ with **iteration matrix** $\mathbf{T} = \mathbf{M}^{-1}\mathbf{N} = \mathbf{I} - \mathbf{M}^{-1}\mathbf{A}$. The iteration converges for every $\mathbf{x}^{(0)}$ if and only if the spectral radius $\rho(\mathbf{T}) < 1$, and asymptotically

$$\|\mathbf{e}^{(k)}\| \approx C\,\rho(\mathbf{T})^k, \qquad k_\epsilon \approx \frac{\ln \epsilon}{\ln \rho(\mathbf{T})}$$

iterations reduce the error by a factor ϵ. The quantity $R = -\ln \rho(\mathbf{T})$ is the **asymptotic rate of convergence**.

(Proof in Ch. 8: $\mathbf{T}^k \to \mathbf{0}$ iff $\rho(\mathbf{T}) < 1$, which follows from the Jordan form of Ch. 10.) When ρ is close to 1, $R \approx 1 - \rho$ and the iteration count is $\approx \ln(1/\epsilon)/(1-\rho)$: halving $1 - \rho$ doubles the work.

Two caveats are worth stating. First, $\rho(\mathbf{T}) < 1$ controls the *asymptotic* rate; for non-normal $\mathbf{T}$ the error can grow for many steps before decaying. Second, the iteration stops on the residual, not the error: since $\mathbf{e} = -\mathbf{A}^{-1}\mathbf{r}$,

$$\frac{\|\mathbf{e}^{(k)}\|}{\|\mathbf{x}\|} \le \kappa(\mathbf{A})\,\frac{\|\mathbf{r}^{(k)}\|}{\|\mathbf{b}\|},$$

so a relative-residual tolerance of 10^{-8} guarantees only $10^{-8}\kappa$ in the error.

The model problem

The standard test case is the discrete Laplacian. In one dimension, $-u'' = f$ on $(0,1)$ with n interior points and spacing $h = 1/(n+1)$ gives the tridiagonal matrix $\mathbf{A} = \operatorname{tridiag}(-1, 2, -1)$ — also the nodal matrix of a uniform resistive ladder with grounded ends. Its eigenvalues are

$$\lambda_k = 2 - 2\cos(k\pi h) = 4\sin^2\!\Big(\frac{k\pi h}{2}\Big), \qquad k = 1, \dots, n,$$

with eigenvectors $\sin(k\pi i h)$. The Jacobi iteration matrix $\mathbf{I} - \tfrac{1}{2}\mathbf{A}$ has eigenvalues $\cos(k\pi h)$, so

$$\rho_J = \cos(\pi h) \approx 1 - \tfrac{1}{2}\pi^2 h^2.$$

The convergence factor approaches 1 as the grid is refined: the number of Jacobi iterations grows like $h^{-2} \propto n^2$. The slowest modes are the *smooth* ones (k small) — the iteration damps oscillatory errors quickly and smooth errors very slowly, an observation that is the starting point of **multigrid** methods.

Successive over-relaxation (SOR)

Gauss–Seidel moves each unknown to the value that satisfies its own equation. Over-relaxation moves it *further* in the same direction by a factor ω:

$$x_i^{(k+1)} = (1-\omega)x_i^{(k)} + \frac{\omega}{a_{ii}}\Big(b_i - \sum_{j<i} a_{ij}x_j^{(k+1)} - \sum_{j>i} a_{ij}x_j^{(k)}\Big).$$

In matrix form $\mathbf{M}_\omega = \frac{1}{\omega}\mathbf{D} + \mathbf{L}_A$ and

$$\mathbf{T}_\omega = (\mathbf{D} + \omega\mathbf{L}_A)^{-1}\big((1-\omega)\mathbf{D} - \omega\mathbf{U}_A\big).$$

$\omega = 1$ is Gauss–Seidel; $\omega > 1$ is over-relaxation, $\omega < 1$ under-relaxation.

SOR convergence (Kahan, Ostrowski–Reich, Young)

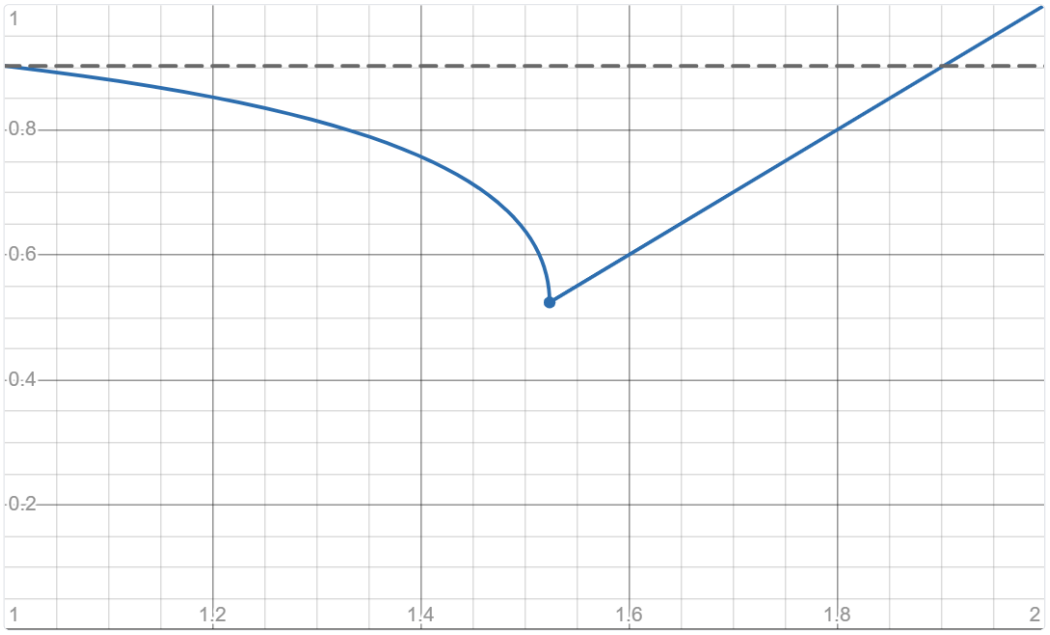
1. (**Kahan**) $\rho(\mathbf{T}_\omega) \ge |\omega - 1|$, so SOR can converge only for $0 < \omega < 2$.
2. (**Ostrowski–Reich**) If $\mathbf{A}$ is symmetric positive definite, SOR converges for every $0 < \omega < 2$.
3. (**Young**) If $\mathbf{A}$ is *consistently ordered* (true for tridiagonal matrices and for the 5-point Laplacian in natural or red–black ordering) and the Jacobi eigenvalues are real with $\rho_J < 1$, then the optimal relaxation factor and the resulting spectral radius are

$$\omega_{\text{opt}} = \frac{2}{1 + \sqrt{1 - \rho_J^2}}, \qquad \rho(\mathbf{T}_{\omega_{\text{opt}}}) = \omega_{\text{opt}} - 1.$$

Moreover $\rho(\mathbf{T}_1) = \rho_J^2$: Gauss–Seidel converges exactly twice as fast as Jacobi.

Sketch of 1. $\det \mathbf{T}_\omega = \det(\mathbf{D} + \omega\mathbf{L}_A)^{-1}\det((1-\omega)\mathbf{D} - \omega\mathbf{U}_A) = \det(\mathbf{D})^{-1}(1-\omega)^n \det \mathbf{D} = (1-\omega)^n$ because both factors are triangular. The determinant is the product of the eigenvalues, so at least one has modulus $\ge |1-\omega|$. $\square$

Sketch of 3. For consistently ordered matrices, each Jacobi eigenvalue μ and SOR eigenvalue λ are related by Young's equation $(\lambda + \omega - 1)^2 = \lambda\omega^2\mu^2$. Solving this quadratic in $\sqrt{\lambda}$ gives $\sqrt{\lambda} = \tfrac{1}{2}\big(\omega\mu \pm \sqrt{\omega^2\mu^2 - 4(\omega-1)}\big)$. For ω below the value making the discriminant zero for $\mu = \rho_J$, the largest $|\lambda|$ decreases with ω; above it the roots are complex with $|\lambda| = \omega - 1$, increasing with ω. The minimum is where the discriminant vanishes, $\omega^2\rho_J^2 = 4(\omega-1)$, whose root in $(1,2)$ is ω_{opt}. $\square$



Spectral radius of SOR against ω for a consistently ordered matrix with $\rho_J = 0.95$. At $\omega = 1$ (Gauss–Seidel) $\rho = 0.9025$ (dashed); the minimum $\rho = 0.524$ at $\omega_{\text{opt}} = 1.524$ is a sharp corner. Overestimating ω costs little (slope 1 on the right); underestimating it costs a lot (infinite slope on the left).

Worked Example 24.17 — SOR on the three-node network

Apply SOR with $\omega = 1.2$ to the nodal system of Ch. 8, Worked Example 8.39:

$$\begin{bmatrix} 4 & -2 & -1 \\ -2 & 4 & -1 \\ -1 & -1 & 4 \end{bmatrix} \mathbf{v} = \begin{bmatrix} 8 \\ 2 \\ 1 \end{bmatrix}, \qquad \mathbf{v} = (4, 3, 2)^{\mathsf{T}},$$

from $\mathbf{v}^{(0)} = \mathbf{0}$, and compare spectral radii.

Iteration 1.

- v_1: Gauss–Seidel value $\tfrac{1}{4}(8) = 2$; SOR $v_1 = -0.2 \cdot 0 + 1.2 \cdot 2 = 2.4$.
- v_2: GS value $\tfrac{1}{4}(2 + 2 \cdot 2.4 + 0) = 1.7$; $v_2 = 1.2 \times 1.7 = 2.04$.
- v_3: GS value $\tfrac{1}{4}(1 + 2.4 + 2.04) = 1.36$; $v_3 = 1.2 \times 1.36 = 1.632$.

Iterations 2 and 3. $\mathbf{v}^{(2)} = (3.6336,\ 2.8618,\ 1.9222)$, $\mathbf{v}^{(3)} = (3.9670,\ 2.9845,\ 2.0010)$. Maximum errors: 1.6, 0.366, 0.033 — against 2.0, 0.969, 0.456 for Gauss–Seidel.

Spectral radii (computed from $\mathbf{T}_\omega$):

ω	1.0	1.1	1.16	1.2	1.3	1.5
$\rho(\mathbf{T}_\omega)$	0.472	0.350	0.230	0.271	0.367	0.555

The optimum is near $\omega = 1.16$, where the iterations needed for 10^{-6} fall from 18 (GS) to 9.5. Young's formula with $\rho_J = 0.683$ would predict $\omega_{\text{opt}} = 1.155$; it applies only approximately because this matrix is not consistently ordered, but it is a good starting estimate.

Worked Example 24.18 — The model problem: Jacobi, Gauss–Seidel and optimal SOR

For the 1-D model problem with $n = 50$ interior points, how many iterations does each method need to reduce the error by 10^{-6}? Repeat for $n = 100$.

$n = 50$. $h = 1/51$, $\rho_J = \cos(\pi/51) = 0.998103$. Then

- Jacobi: $k = \ln 10^{-6} / \ln 0.998103 \approx 7277$;
- Gauss–Seidel: $\rho = \rho_J^2 = 0.996210$, $k \approx 3639$;
- SOR: $\omega_{\text{opt}} = 2/(1 + \sqrt{1 - \rho_J^2}) = 1.884$, $\rho = 0.884$, $k \approx 112$.

$n = 100$. $\rho_J = 0.999516$: Jacobi 28 554, Gauss–Seidel 14 277, SOR ($\omega_{\text{opt}} = 1.940$) 222.

Scaling. Doubling n multiplies Jacobi/GS work per unit accuracy by 4 (since $1 - \rho \propto h^2$) but optimal SOR only by 2 (since $1 - \rho_{\text{SOR}} \approx 2\pi h$). Optimal SOR turns an $O(n^2)$ iteration count into $O(n)$ — the same improvement, we shall see, that conjugate gradients achieve *without* needing to know ρ_J.

Krylov subspace methods

Stationary methods use only the latest residual. **Krylov methods** use the whole history: after k steps from $\mathbf{x}_0$ (residual $\mathbf{r}_0$) they choose the best approximation from the affine space $\mathbf{x}_0 + \mathcal{K}_k$, where

$$\mathcal{K}_k(\mathbf{A}, \mathbf{r}_0) = \operatorname{span}\{\mathbf{r}_0,\ \mathbf{A}\mathbf{r}_0,\ \mathbf{A}^2\mathbf{r}_0, \dots, \mathbf{A}^{k-1}\mathbf{r}_0\}$$

is the **Krylov subspace**. Every vector in it is $p(\mathbf{A})\mathbf{r}_0$ for a polynomial p of degree $< k$, so the error after k steps has the form $\mathbf{e}_k = q_k(\mathbf{A})\mathbf{e}_0$ with q_k a polynomial of degree k and $q_k(0) = 1$. Krylov methods differ in *which* q_k they choose — that is, in what "best" means.

Conjugate gradients

For SPD $\mathbf{A}$, solving $\mathbf{A}\mathbf{x} = \mathbf{b}$ is equivalent to minimising the quadratic "energy"

$$\phi(\mathbf{x}) = \tfrac{1}{2}\mathbf{x}^{\mathsf T}\mathbf{A}\mathbf{x} - \mathbf{b}^{\mathsf T}\mathbf{x}, \qquad \nabla\phi = \mathbf{A}\mathbf{x} - \mathbf{b} = -\mathbf{r}.$$

(For a resistive network, ϕ is half the dissipated power minus the power delivered by the sources, and the solution minimises it — Maxwell's minimum-heat theorem.) Steepest descent searches along $\mathbf{r}$ each time, which zigzags when the level sets are elongated. CG instead searches along directions $\mathbf{p}_0, \mathbf{p}_1, \dots$ that are **$\mathbf{A}$-conjugate**, $\mathbf{p}_i^{\mathsf T}\mathbf{A}\mathbf{p}_j = 0$ for $i \neq j$, so that minimising along a new direction never spoils the minimisation along the old ones.

Conjugate gradient algorithm

Given SPD $\mathbf{A}$, $\mathbf{b}$, $\mathbf{x}_0$: set $\mathbf{r}_0 = \mathbf{b} - \mathbf{A}\mathbf{x}_0$, $\mathbf{p}_0 = \mathbf{r}_0$. For $k = 0, 1, 2, \dots$:

$$\begin{aligned} \alpha_k &= \frac{\mathbf{r}_k^{\mathsf T}\mathbf{r}_k}{\mathbf{p}_k^{\mathsf T}\mathbf{A}\mathbf{p}_k}, & \mathbf{x}_{k+1} &= \mathbf{x}_k + \alpha_k \mathbf{p}_k, & \mathbf{r}_{k+1} &= \mathbf{r}_k - \alpha_k \mathbf{A}\mathbf{p}_k, \\ \beta_k &= \frac{\mathbf{r}_{k+1}^{\mathsf T}\mathbf{r}_{k+1}}{\mathbf{r}_k^{\mathsf T}\mathbf{r}_k}, & \mathbf{p}_{k+1} &= \mathbf{r}_{k+1} + \beta_k \mathbf{p}_k. \end{aligned}$$

Each iteration costs one matrix–vector product, two inner products and three vector updates — about $2\,\mathrm{nnz} + 10n$ flops — and stores four vectors.

Properties of CG

In exact arithmetic:

1. The residuals are mutually orthogonal and the directions mutually $\mathbf{A}$-conjugate.
2. $\mathbf{x}_k$ minimises the energy norm of the error $\|\mathbf{e}\|_{\mathbf{A}} = \sqrt{\mathbf{e}^{\mathsf T}\mathbf{A}\mathbf{e}}$ over $\mathbf{x}_0 + \mathcal{K}_k$; equivalently
$$\|\mathbf{e}_k\|_{\mathbf{A}} = \min_{q \in \mathcal{P}_k,\, q(0)=1} \|q(\mathbf{A})\mathbf{e}_0\|_{\mathbf{A}} \le \min_{q} \max_{\lambda \in \sigma(\mathbf{A})} |q(\lambda)|\, \|\mathbf{e}_0\|_{\mathbf{A}}.$$
3. CG terminates with the exact solution in at most n steps — in fact in at most d steps, where d is the number of distinct eigenvalues of $\mathbf{A}$.
4. With $\kappa = \lambda_{\max}/\lambda_{\min}$,
$$\frac{\|\mathbf{e}_k\|_{\mathbf{A}}}{\|\mathbf{e}_0\|_{\mathbf{A}}} \le 2\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^{k}.$$

Sketch. Property 2 follows because $\phi(\mathbf{x}) - \phi(\mathbf{x}^\ast) = \tfrac12\|\mathbf{x} - \mathbf{x}^\ast\|_{\mathbf{A}}^2$ and conjugacy makes the minimisation over the growing Krylov space separable, one direction at a time. Expanding $\mathbf{e}_0$ in eigenvectors, $\|q(\mathbf{A})\mathbf{e}_0\|_{\mathbf{A}}^2 = \sum_i \lambda_i q(\lambda_i)^2 c_i^2 \le \max_i q(\lambda_i)^2\, \|\mathbf{e}_0\|_{\mathbf{A}}^2$. Property 3: the polynomial $q(\lambda) = \prod_{i=1}^{d}(1 - \lambda/\lambda_i)$ vanishes on the spectrum. Property 4: choose q to be the Chebyshev polynomial on $[\lambda_{\min}, \lambda_{\max}]$ scaled so $q(0) = 1$; its maximum on the interval is $1/T_k\!\left(\frac{\kappa+1}{\kappa-1}\right) \le 2\big(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\big)^k$. $\square$

The bound gives an iteration count of about $k \approx \tfrac12\sqrt{\kappa}\ln(2/\epsilon)$, compared with $\tfrac12\kappa\ln(1/\epsilon)$ for steepest descent. For the 2-D model problem $\kappa \propto h^{-2}$, so CG needs $O(h^{-1}) = O(\sqrt{n})$ iterations — the same as optimal SOR, with no parameter to tune.

Worked Example 24.19 — Conjugate gradients by hand

Solve $\begin{bmatrix} 4 & 1 \\ 1 & 3 \end{bmatrix}\mathbf{x} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$ by CG from $\mathbf{x}_0 = \mathbf{0}$.

Step 0. $\mathbf{r}_0 = \mathbf{p}_0 = (1, 2)$, $\mathbf{r}_0^{\mathsf T}\mathbf{r}_0 = 5$, $\mathbf{A}\mathbf{p}_0 = (6, 7)$, $\mathbf{p}_0^{\mathsf T}\mathbf{A}\mathbf{p}_0 = 6 + 14 = 20$, $\alpha_0 = 0.25$. $\mathbf{x}_1 = (0.25,\ 0.5)$, $\mathbf{r}_1 = (1, 2) - 0.25(6, 7) = (-0.5,\ 0.25)$, $\mathbf{r}_1^{\mathsf T}\mathbf{r}_1 = 0.3125$, $\beta_0 = 0.3125/5 = 0.0625$, $\mathbf{p}_1 = (-0.5, 0.25) + 0.0625(1, 2) = (-0.4375,\ 0.375)$.

Step 1. $\mathbf{A}\mathbf{p}_1 = (-1.75 + 0.375,\ -0.4375 + 1.125) = (-1.375,\ 0.6875)$, $\mathbf{p}_1^{\mathsf T}\mathbf{A}\mathbf{p}_1 = 0.6016 + 0.2578 = 0.859375$, $\alpha_1 = 0.3125/0.859375 = 0.363636 = \tfrac{4}{11}$. $\mathbf{x}_2 = (0.25, 0.5) + \tfrac{4}{11}(-0.4375, 0.375) = (0.090909,\ 0.636364) = (\tfrac{1}{11}, \tfrac{7}{11})$, and $\mathbf{r}_2 = \mathbf{0}$.

Checks. $4/11 + 7/11 = 1$ ✓, $1/11 + 21/11 = 2$ ✓. Termination in $n = 2$ steps ✓. Orthogonality: $\mathbf{r}_0^{\mathsf T}\mathbf{r}_1 = -0.5 + 0.5 = 0$ ✓; conjugacy: $\mathbf{p}_0^{\mathsf T}\mathbf{A}\mathbf{p}_1 = (1, 2)\cdot(-1.375, 0.6875) = 0$ ✓.

Worked Example 24.20 — Iteration counts from the condition number

An SPD system from a capacitance extraction has $\kappa = 10^4$. Estimate the iterations for a 10^{-6} reduction of the energy-norm error with steepest descent and with CG.

Steepest descent. Error factor $\le \big(\frac{\kappa-1}{\kappa+1}\big)^k \approx e^{-2k/\kappa}$: $k \approx \frac{\kappa}{2}\ln 10^6 = 5000 \times 13.8 \approx 69\,000$.

CG. $k \approx \frac{\sqrt{\kappa}}{2}\ln(2 \times 10^6) = 50 \times 14.5 \approx 725$.

Reading. CG's dependence on $\sqrt{\kappa}$ rather than κ is worth a factor of 100 here. And the bound is pessimistic: if the eigenvalues are clustered (a few outliers and the rest close together), CG "removes" each outlier in about one iteration and then converges at the rate set by the cluster. That is exactly the effect a good preconditioner aims for.

GMRES

For nonsymmetric or indefinite matrices — modified nodal analysis with voltage sources, convection–diffusion models, integral-equation formulations of electromagnetic scattering — there is no energy to minimise. **GMRES** (generalised minimal residual) chooses $\mathbf{x}_k \in \mathbf{x}_0 + \mathcal{K}_k$ to minimise the residual norm $\|\mathbf{b} - \mathbf{A}\mathbf{x}_k\|_2$.

Arnoldi process and GMRES

The **Arnoldi process** builds an orthonormal basis $\mathbf{q}_1, \dots, \mathbf{q}_k$ of $\mathcal{K}_k$ by modified Gram–Schmidt: $\mathbf{q}_1 = \mathbf{r}_0/\beta$ with $\beta = \|\mathbf{r}_0\|$, and for each j, $\mathbf{w} = \mathbf{A}\mathbf{q}_j$ is orthogonalised against $\mathbf{q}_1, \dots, \mathbf{q}_j$ (coefficients h_{ij}) and normalised to give $\mathbf{q}_{j+1}$ ($h_{j+1,j} = \|\mathbf{w}\|$). In matrix form $\mathbf{A}\mathbf{Q}_k = \mathbf{Q}_{k+1}\tilde{\mathbf{H}}_k$ with $\tilde{\mathbf{H}}_k$ a $(k+1) \times k$ upper Hessenberg matrix. Writing $\mathbf{x}_k = \mathbf{x}_0 + \mathbf{Q}_k\mathbf{y}$,

$$\|\mathbf{b} - \mathbf{A}\mathbf{x}_k\|_2 = \|\beta\mathbf{e}_1 - \tilde{\mathbf{H}}_k\mathbf{y}\|_2,$$

a small $(k+1) \times k$ least-squares problem solved by Givens rotations. **GMRES** returns the minimising $\mathbf{y}$.

GMRES convergence

GMRES residuals are non-increasing and satisfy

$$\frac{\|\mathbf{r}_k\|}{\|\mathbf{r}_0\|} = \min_{q \in \mathcal{P}_k,\, q(0)=1} \frac{\|q(\mathbf{A})\mathbf{r}_0\|}{\|\mathbf{r}_0\|} \le \kappa(\mathbf{V}) \min_{q} \max_{\lambda \in \sigma(\mathbf{A})} |q(\lambda)|$$

for diagonalisable $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$. GMRES terminates in at most d steps if $\mathbf{A}$ has a minimal polynomial of degree d. Convergence is fast when the eigenvalues are clustered away from the origin and $\mathbf{V}$ is well conditioned.

The price of GMRES is that every step must orthogonalise against *all* previous basis vectors: step k costs $O(kn)$ flops and the method stores k vectors. In practice it is **restarted** every m steps (GMRES(m), with m typically 20–100), which bounds the memory but can slow or even stall convergence. Short-recurrence alternatives for nonsymmetric systems — BiCGSTAB, QMR, IDR(s) — have fixed cost per step but less predictable convergence.

Worked Example 24.21 — GMRES and the minimal polynomial

A 50×50 nonsymmetric matrix $\mathbf{A} = \mathbf{S}\mathbf{\Lambda}\mathbf{S}^{-1}$ is constructed with random $\mathbf{S}$ and eigenvalues 1 (25 times) and 3 (25 times). Predict, and then observe, the GMRES iteration count.

Prediction. $(\mathbf{A} - \mathbf{I})(\mathbf{A} - 3\mathbf{I}) = \mathbf{S}(\mathbf{\Lambda} - \mathbf{I})(\mathbf{\Lambda} - 3\mathbf{I})\mathbf{S}^{-1} = \mathbf{0}$, so the polynomial $q(\lambda) = (1-\lambda)(1-\lambda/3)$, with $q(0) = 1$, annihilates $\mathbf{A}$. GMRES must converge in 2 steps regardless of n.

Observation. SciPy's `gmres` reports relative residuals 0.988 after one step and 1.6×10^{-13} after two ✓.

Contrast. For a 1024-unknown convection–diffusion matrix (32×32 grid) with scattered eigenvalues, full GMRES needed 74 iterations for a 10^{-8} residual reduction while GMRES(20) needed 229 — restarting throws away the subspace that was making progress. This is why preconditioning, which clusters the spectrum, matters even more for GMRES than for CG.

Preconditioning

The convergence of every Krylov method depends on the spectrum of $\mathbf{A}$. **Preconditioning** replaces the system by an equivalent one with a better spectrum:

$$\text{left: } \mathbf{P}^{-1}\mathbf{A}\mathbf{x} = \mathbf{P}^{-1}\mathbf{b}, \qquad \text{right: } \mathbf{A}\mathbf{P}^{-1}\mathbf{y} = \mathbf{b},\ \ \mathbf{x} = \mathbf{P}^{-1}\mathbf{y},$$

where the preconditioner $\mathbf{P}$ satisfies two competing requirements: $\mathbf{P} \approx \mathbf{A}$ (so $\mathbf{P}^{-1}\mathbf{A} \approx \mathbf{I}$, eigenvalues clustered near 1) and $\mathbf{P}\mathbf{z} = \mathbf{r}$ cheap to solve. $\mathbf{P} = \mathbf{I}$ is cheap but useless; $\mathbf{P} = \mathbf{A}$ is perfect but as hard as the original problem. For CG, $\mathbf{P}$ must be SPD, and the preconditioned algorithm (PCG) is CG in the $\mathbf{P}$-inner product: the only change is that each iteration solves $\mathbf{P}\mathbf{z}_k = \mathbf{r}_k$ and uses $\mathbf{z}_k$ in place of $\mathbf{r}_k$ in the direction update and in α_k, β_k (via $\mathbf{r}_k^{\mathsf{T}}\mathbf{z}_k$).

Common preconditioners, in rough order of cost and power:

Preconditioner	$\mathbf{P}$	Comment
Jacobi (diagonal)	$\mathbf{D}$	removes bad *scaling*; free; weak otherwise
SSOR	$(\mathbf{D} + \omega\mathbf{L}_A)\mathbf{D}^{-1}(\mathbf{D} + \omega\mathbf{U}_A)$	symmetric version of SOR; no setup
Incomplete Cholesky IC(0) / incomplete LU ILU(0)	$\tilde{\mathbf{L}}\tilde{\mathbf{U}}$ with the sparsity of $\mathbf{A}$	elimination that discards all fill; workhorse of circuit and FEM codes
ILUT(τ, p)	incomplete LU keeping fill above threshold τ, at most p per row	tunable between ILU(0) and full LU
Multigrid / algebraic multigrid (AMG)	one V-cycle	$O(n)$ work and iteration count independent of h for elliptic problems
Domain decomposition	local solves on subdomains plus a coarse problem	parallel

Worked Example 24.22 — Diagonal scaling as a preconditioner

$\mathbf{A} = \begin{bmatrix} 10^4 & 1 \\ 1 & 1 \end{bmatrix}$ (a stiff spring coupled to a soft one, or a 10 kΩ and a 1 Ω branch sharing a node). Compare $\kappa_2(\mathbf{A})$ with that of the symmetrically Jacobi-preconditioned matrix $\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$.

Unpreconditioned. Eigenvalues $\approx 10^4$ and ≈ 0.9999: $\kappa_2 \approx 1.0 \times 10^4$.

Scaled. $\mathbf{D}^{-1/2} = \mathrm{diag}(10^{-2}, 1)$ gives $\begin{bmatrix} 1 & 0.01 \\ 0.01 & 1 \end{bmatrix}$, eigenvalues 1 ± 0.01, $\kappa_2 = 1.01/0.99 = 1.020$.

Reading. CG on the scaled system converges in 2 steps anyway ($n = 2$), but the iteration-count bound drops from about $\frac{1}{2}\sqrt{10^4}\ln(2/\epsilon)$ to essentially 1 step per digit. For large systems diagonal scaling never hurts and fixes purely unit-induced ill-conditioning; it cannot fix the *geometric* ill-conditioning of the model problem, whose diagonal is constant.

Worked Example 24.23 — Incomplete Cholesky on the 2-D Poisson problem

The 5-point Laplacian on a $k \times k$ grid ($n = k^2$ unknowns) is solved by CG to a relative residual of 10^{-8}, with and without an IC(0) preconditioner. Observed iteration counts:

grid	n	$\kappa(\mathbf{A})$	CG	PCG with IC(0)
16×16	256	116	28	17
32×32	1024	441	59	29
64×64	4096	1712	119	—

Reading. Without preconditioning the count doubles each time k doubles, tracking $\sqrt{\kappa} \propto k$ ($\sqrt{441} = 21$, $\sqrt{1712} = 41$); the bound $\frac{1}{2}\sqrt{\kappa}\ln(2/\epsilon) \approx 200$ for $k = 32$ is pessimistic by a factor of 3, as usual. IC(0) halves the count but does not change its growth rate (its preconditioned condition number still grows like h^{-2}, with a smaller constant). Each PCG iteration costs about twice a CG iteration (two triangular solves), so the net gain is modest here; it is much larger for problems with variable coefficients (materials with different permittivities or conductivities), where IC also corrects the scaling. Only multigrid makes the count independent of k.

Common Pitfall — wrong method for the matrix

CG requires $\mathbf{A}$ (and the preconditioner) to be symmetric positive definite. Applied to a nonsymmetric MNA matrix, or with a nonsymmetric ILU preconditioner, it may stall or diverge without any error message — in a test with an ILU preconditioner on the Poisson problem SciPy's `cg` ran to its iteration limit and returned garbage, while the same preconditioner inside GMRES worked. Check symmetry ($\|\mathbf{A} - \mathbf{A}^{\mathsf{T}}\|$) before choosing CG, use symmetric preconditioners (Jacobi, SSOR, IC) with it, and always check the returned convergence flag (`info` in SciPy).

Common Pitfall — stopping on the wrong quantity

A relative residual of 10^{-6} does not mean six correct digits: the error bound is κ times larger. Conversely, demanding 10^{-14} in a problem whose data are known to 10^{-3} wastes iterations. Choose the tolerance from the accuracy actually needed in the *output quantity* — often a single node voltage or a capacitance — and, if possible, monitor that quantity directly.

Engineering Note

In IC design, power-grid analysis (IR drop) solves SPD systems with 10^8 unknowns by PCG with algebraic multigrid or incomplete Cholesky preconditioners; full-wave EM solvers using integral equations (method of moments) solve dense complex systems by GMRES with matrix–vector products accelerated by the fast multipole method; transient circuit simulation, where each Newton step needs only a modest improvement on the previous solution, uses the previous LU factors as a preconditioner for a few GMRES steps. The common thread: the matrix–vector product and the preconditioner are designed together with the physics.

```
import numpy as np, scipy.sparse as sp, scipy.sparse.linalg as spla
k = 64
T = sp.diags([-1.0, 2.0, -1.0], [-1, 0, 1], shape=(k, k))
A = (sp.kron(sp.eye(k), T) + sp.kron(T, sp.eye(k))).tocsr()   # 2-D Laplacian
b = np.ones(k * k)
its = []
x, info = spla.cg(A, b, rtol=1e-8, callback=lambda xk: its.append(1))
print(info, len(its))          # 0 (converged), 119 iterations
```

24.5 Sparse computation

Motivation

The matrices of engineering are overwhelmingly **sparse**: a node in a circuit connects to a handful of others, a finite-element basis function overlaps only its neighbours, a bus in a power grid connects to a few lines. Chapter 8 introduced sparse storage (COO and CSR), fill-in and the effect of elimination order through the star-network example, and the Thomas algorithm for tridiagonal systems. This section makes those ideas quantitative: how the storage formats support the kernels that iterative and direct solvers need, how fill-in is predicted from the graph before any arithmetic is done, how reordering algorithms work, and how the cost of sparse factorisation scales with the geometry of the problem.

Storage formats and their kernels

CSR and CSC

For an $m \times n$ matrix with nnz nonzeros, **compressed sparse row** (CSR) stores three arrays: `data` (the nonzero values, row by row), `indices` (the column index of each value) and `indptr` (length $m+1$; row i occupies positions `indptr[i]` to `indptr[i+1]-1`). **Compressed sparse column** (CSC) stores the same information column by column: `indices` then holds row indices and `indptr` has length $n+1$. Both need $2\,\mathrm{nnz} + (\text{dimension} + 1)$ words.

The choice between them is dictated by the access pattern of the kernel:

Kernel	Natural format	Why
$\mathbf{y} = \mathbf{A}\mathbf{x}$	CSR	each y_i is an inner product of row i with $\mathbf{x}$
$\mathbf{y} = \mathbf{A}^{\mathsf{T}}\mathbf{x}$	CSC (or CSR of $\mathbf{A}$ read as CSC of $\mathbf{A}^{\mathsf{T}}$)	column access
left-looking LU, Cholesky, column pivoting	CSC	algorithms proceed column by column
row slicing, row-wise assembly	CSR	
assembly by stamping	COO	append (row, col, value) triplets; duplicates summed on conversion
ladder/1-D problems	banded / diagonal (DIA)	contiguous diagonals

The CSR matrix–vector product is the most executed loop in scientific computing:

```
def csr_matvec(data, indices, indptr, x):
    y = [0.0] * (len(indptr) - 1)
    for i in range(len(y)):
        s = 0.0
        for p in range(indptr[i], indptr[i + 1]):
            s += data[p] * x[indices[p]]      # indirect access to x
        y[i] = s
    return y
```

It performs $2\,\mathrm{nnz}$ flops and reads nnz values, nnz indices and (irregularly) entries of $\mathbf{x}$: an arithmetic intensity well below one flop per word, so its speed is set by memory bandwidth (Section 24.1). Orderings that cluster nonzeros near the diagonal improve cache reuse of $\mathbf{x}$ — a second, purely performance-related reason to reorder.

Worked Example 24.24 — CSR and CSC of a nonsymmetric matrix, and a product

Store

$$\mathbf{M} = \begin{bmatrix} 4 & 0 & -1 & 0 \\ 1 & 3 & 0 & -2 \\ 0 & 0 & 5 & 0 \\ 0 & -2 & 0 & 6 \end{bmatrix}$$

in CSR and CSC (0-based), and compute $\mathbf{M}\mathbf{x}$ for $\mathbf{x} = (1,2,3,4)^{\mathsf{T}}$ from the CSR arrays.

CSR. `data` $= [4,-1,\ 1,3,-2,\ 5,\ -2,6]$, `indices` $= [0,2,\ 0,1,3,\ 2,\ 1,3]$, `indptr` $= [0,2,5,6,8]$.

CSC. Reading down the columns: column 0 has 4 (row 0), 1 (row 1); column 1 has 3 (row 1), -2 (row 3); column 2 has -1 (row 0), 5 (row 2); column 3 has -2 (row 1), 6 (row 3). So `data` $= [4,1,\ 3,-2,\ -1,5,\ -2,6]$, `indices` $= [0,1,\ 1,3,\ 0,2,\ 1,3]$, `indptr` $= [0,2,4,6,8]$.

Product. Row 0: positions 0–1, $4\cdot x_0 + (-1)\cdot x_2 = 4 - 3 = 1$. Row 1: positions 2–4, $1\cdot 1 + 3\cdot 2 + (-2)\cdot 4 = -1$. Row 2: position 5, $5\cdot 3 = 15$. Row 3: positions 6–7, $-2\cdot 2 + 6\cdot 4 = 20$. So $\mathbf{M}\mathbf{x} = (1,-1,15,20)^{\mathsf{T}}$ — 16 flops for 8 nonzeros.

Check. A dense product gives the same result with 28 flops (16 multiplications, 12 additions), half of them on zeros. For a 10^6-node circuit with 5 nonzeros per row the ratio is $10^6/5 = 200\,000$.

The graph of a sparse matrix and the elimination game

Adjacency graph and fill

The **graph** $G(\mathbf{A})$ of a structurally symmetric $n \times n$ matrix has vertices $1,\dots,n$ and an edge $\{i,j\}$ whenever $a_{ij} \neq 0$, $i \neq j$. Eliminating vertex k (one step of Gaussian elimination) removes k and adds an edge between every pair of its remaining neighbours that were not already adjacent; these new edges are the **fill-in**. The **filled graph** $G^{+}(\mathbf{A})$ is $G(\mathbf{A})$ plus all fill edges; its edges are exactly the nonzeros of $\mathbf{L} + \mathbf{L}^{\mathsf{T}}$ (barring numerical cancellation).

This purely combinatorial description has three consequences that sparse direct solvers exploit.

1. **Symbolic factorisation.** The pattern of $\mathbf{L}$ can be computed from the graph alone, before any floating-point work, in time roughly proportional to $\mathrm{nnz}(\mathbf{L})$. Memory is allocated once.
2. **Reuse.** In Newton iterations, frequency sweeps, transient time steps and Monte Carlo runs, the *values* of the matrix change but its *pattern* does not. Ordering and symbolic factorisation are done once; only the numeric factorisation is repeated. SPICE has worked this way since the 1970s.
3. **The elimination tree.** Define the parent of column j as the row index of the first off-diagonal nonzero in column j of $\mathbf{L}$. The resulting tree encodes all dependencies: columns in disjoint subtrees can be factored independently, in parallel. Groups of consecutive columns with identical pattern (**supernodes**) are processed as dense blocks with level-3 BLAS, recovering the cache efficiency of dense code.

Reordering

The amount of fill depends on the elimination order, i.e. on the symmetric permutation $\mathbf{P}\mathbf{A}\mathbf{P}^{\mathsf{T}}$. Finding the order that minimises fill is NP-hard, so heuristics are used.

- **Bandwidth and profile reduction: (reverse) Cuthill–McKee.** Number the vertices by breadth-first search from a peripheral vertex, visiting neighbours in order of increasing degree; reversing the order (RCM) usually reduces the profile further. Elimination on a banded matrix creates fill only inside the band, so the fill is at most $n\times$(bandwidth).
- **Minimum degree** (and its fast approximation AMD): at each step eliminate the vertex with fewest neighbours in the current graph, since eliminating a degree-d vertex creates at most $d(d-1)/2$ fill edges. This is the greedy rule of the star example in Ch. 8 — leaves before hubs.
- **Nested dissection.** Find a small vertex **separator** S that splits the graph into two halves A and B with no edges between them; number A, then B, then S last; recurse on A and B. Since A and B are not connected, no fill ever links them; fill is confined to the separator blocks.
- **Column orderings for unsymmetric LU** (COLAMD) order the columns to limit fill in the factors of $\mathbf{A}^{\mathsf{T}}\mathbf{A}$'s pattern, leaving row pivoting free for numerical stability.

Fill and work for model grids

For the 5-point (2-D) and 7-point (3-D) Laplacians on grids with n unknowns, Cholesky factorisation costs, to leading order in n:

Ordering	2-D: $\operatorname{nnz}(\mathbf{L})$	2-D: flops	3-D: $\operatorname{nnz}(\mathbf{L})$	3-D: flops
natural (banded)	$n^{3/2}$	n^2	$n^{5/3}$	$n^{7/3}$
nested dissection	$n\log n$	$n^{3/2}$	$n^{4/3}$	n^2

Nested dissection is asymptotically optimal for these grids (George, 1973; Lipton–Rose–Tarjan).

Sketch, 2-D. A $k\times k$ grid ($n=k^2$) has a separator of k vertices (a grid line). After the two halves are eliminated the separator block is dense, $k\times k$, costing $O(k^3)=O(n^{3/2})$ flops to factor; the recursion $W(n)=4W(n/4)+O(n^{3/2})$ (splitting in both directions) gives $W=O(n^{3/2})$ by the master theorem (Section 24.1, $a=4$, $b=4$, $d=3/2>1$). The separators at level ℓ contribute 4^{ℓ} dense blocks of size $(k/2^{\ell})^2$, i.e. $O(n)$ fill per level over $\log n$ levels: $O(n\log n)$. With natural ordering the bandwidth is $k=\sqrt{n}$, the band fills completely ($n\cdot k=n^{3/2}$ entries) and the banded Cholesky costs $nk^2=n^2$. $\square$

In 3-D the separators are planes of $n^{2/3}$ vertices, and their dense blocks cost $(n^{2/3})^3=n^2$ — this is why 3-D field problems are the domain of iterative methods while 2-D problems and circuits (whose graphs have small separators) are routinely solved directly.

Worked Example 24.25 — Reverse Cuthill–McKee on a badly numbered chain

Six components form a chain whose nodes, in physical order along the chain, were numbered $0,3,5,1,4,2$ by a netlister. The nodal matrix has 2 on the diagonal and -1 for each link. Find its bandwidth, then renumber by RCM.

Original. The links are $\{0,3\},\{3,5\},\{5,1\},\{1,4\},\{4,2\}$, so the nonzero off-diagonals are in positions with $|i-j|=3,2,4,3,2$. The bandwidth is 4; banded elimination would treat the matrix as having up to 9 diagonals.

RCM. Start from a peripheral vertex (degree 1): vertex 2 or vertex 0. BFS from 0 visits $0,3,5,1,4,2$ — the physical order. Reversed: $2,4,1,5,3,0$. (SciPy's `reverse_cuthill_mckee` returns exactly this permutation.)

Result. In the new numbering consecutive chain nodes have consecutive numbers: the matrix is tridiagonal, bandwidth 1, and can be solved by the Thomas algorithm in $8n$ flops with zero fill.

Reading. For a chain this is obvious by eye; for a 10^5-node mesh it is not, and RCM does it in $O(\operatorname{nnz})$ time.

Worked Example 24.26 — Measured fill on a 2-D grid

The 2-D Laplacian on $k\times k$ grids is factored by SciPy's SuperLU with three column orderings. Nonzeros in $\mathbf{L}+\mathbf{U}$:

k	n	$\operatorname{nnz}(\mathbf{A})$	natural	COLAMD	minimum degree on $\mathbf{A}+\mathbf{A}^{\mathsf{T}}$
30	900	4 380	54 058	30 338	20 196
60	3 600	17 760	432 118	179 720	108 430
100	10 000	49 600	2 000 198	645 750	371 346

Check against theory. Natural ordering fills the band: $\operatorname{nnz}(\mathbf{L}+\mathbf{U})\approx 2nk=2k^3$, i.e. 54 000, 432 000, 2 000 000 ✓ — growing as $n^{3/2}$ (factor 8 per doubling of k). Minimum degree grows by a factor of 5.4 from $k=30$ to $k=60$, close to the $n\log n$ prediction $4\times\log(3600)/\log(900)\approx 4.8$.

Consequence. At $k=100$ the minimum-degree factors need 5.4 times less memory than natural ordering, and the flop savings are larger still (the flop count scales as the sum of squared column counts). At $k=1000$ ($n=10^6$) natural ordering would need 2×10^9 nonzeros (16 GB) and $\sim 10^{12}$ flops, nested dissection about $\frac{31}{4}n\log_2 n\approx 1.5\times 10^8$ nonzeros (1.2 GB) and $\frac{829}{84}n^{3/2}\approx 10^{10}$ flops (George's constants for the model grid).

Engineering Note — the circuit matrix is special

Circuit matrices differ from FEM matrices in ways that matter for solver choice: they are very sparse (often under 5 nonzeros per row), have a few dense rows and columns (supply rails, clock nets), are unsymmetric when controlled sources and voltage sources are present, and have small separators (circuits are "almost planar" locally). The KLU solver, designed for them, first permutes to **block triangular form** (each strongly connected component of the graph becomes a diagonal block, so only those blocks need factoring), then orders each block with AMD and factors it with partial pivoting. Power-grid analysis matrices, by contrast, are SPD and mesh-like, and are solved with sparse Cholesky (for $n \lesssim 10^7$) or PCG with multigrid.

Common Pitfall — accidental densification

Several innocent operations silently produce dense matrices: `A.toarray()` or `A.todense()` "for debugging"; `scipy.sparse.linalg.inv(A)` (the inverse of a sparse matrix is almost always dense — a node voltage depends on every source); `A + c` with a scalar $c \neq 0$; `numpy.linalg.solve(A.toarray(), b)` when a sparse solve was intended; or building a sparse matrix by element insertion into CSR (`A[i, j] = v` in a loop, quadratic cost — assemble in COO and convert once). Also beware of explicit zeros: a stamped matrix may store entries that cancel to exactly zero; call `eliminate_zeros()` only if the pattern will not change later (otherwise the stored zero keeps the symbolic factorisation valid).

Common Pitfall — ordering versus pivoting

For SPD matrices any symmetric ordering is numerically stable, so the ordering can be chosen purely for sparsity. For unsymmetric or indefinite matrices (MNA with voltage sources has zeros on the diagonal), the pivot sequence must also guard against small pivots. Sparse LU uses **threshold pivoting**: accept the sparsity-preferred pivot a_{kk} if $|a_{kk}| \geq u \max_i |a_{ik}|$ with u around 0.1 (or 0.001 in circuit simulators), otherwise pivot. Setting $u = 0$ for speed can give catastrophic growth.

Direct or iterative?

Putting Sections 24.4 and 24.5 together gives a practical rule:

Situation	Usual choice
circuits, 1-D and 2-D problems up to $\sim 10^6$–10^7 unknowns; many right-hand sides; need robustness	sparse direct (LU, Cholesky) with fill-reducing ordering
3-D field problems, $> 10^6$ unknowns	preconditioned Krylov (PCG for SPD, GMRES/BiCGSTAB otherwise), multigrid
matrix not available explicitly (only $\mathbf{A}\mathbf{v}$, e.g. fast multipole)	Krylov
sequence of slowly varying systems	direct factors of one reused as preconditioner for the others
low accuracy acceptable, cheap iterations	Krylov with loose tolerance

24.6 Monte Carlo methods

Motivation

Some quantities are expectations that are hard to compute any other way: the probability that a filter built from 5% components meets its specification, the bit-error rate of a receiver with a nonlinear equaliser, the average power absorbed by a randomly oriented antenna, an integral over a ten-dimensional parameter space. **Monte Carlo methods** estimate such quantities by *simulation*: draw random samples of the inputs, evaluate the quantity for each, and average. They are slow to converge — the error falls only as $1/\sqrt{N}$ — but that rate does not depend on the dimension of the problem or the smoothness of the function, and the method needs nothing more than the ability to evaluate the model. For high-dimensional problems, discontinuous pass/fail criteria, and black-box simulators, Monte Carlo is often the only practical method. Random variables, expectation, variance and the generation of samples from a given distribution (inverse transform) were developed in Ch. 19; sampling distributions and confidence intervals in Ch. 20.

The basic estimator

Monte Carlo estimator

To estimate $\mu = E[f(\mathbf{X})]$, where $\mathbf{X}$ is a random vector with known distribution, draw independent samples $\mathbf{X}_1, \dots, \mathbf{X}_N$ and form

$$\hat{\mu}_N = \frac{1}{N}\sum_{i=1}^{N} f(\mathbf{X}_i), \qquad s_N^2 = \frac{1}{N-1}\sum_{i=1}^{N} \bigl(f(\mathbf{X}_i) - \hat{\mu}_N\bigr)^2.$$

An integral $\int_\Omega g(\mathbf{x})\,d\mathbf{x}$ over a region of volume V is the special case $\mu = V\,E[g(\mathbf{X})]$ with $\mathbf{X}$ uniform on Ω. A probability $P(A)$ is the special case $f = \mathbf{1}_A$, the indicator of the event.

Convergence of Monte Carlo

If $\sigma^2 = \mathrm{Var}(f(\mathbf{X})) < \infty$, then

1. $\hat{\mu}_N$ is unbiased, $E[\hat{\mu}_N] = \mu$, with $\mathrm{Var}(\hat{\mu}_N) = \sigma^2/N$;
2. $\hat{\mu}_N \to \mu$ almost surely (strong law of large numbers);
3. $\sqrt{N}(\hat{\mu}_N - \mu)/\sigma \to \mathcal{N}(0,1)$ in distribution (central limit theorem), so for large N

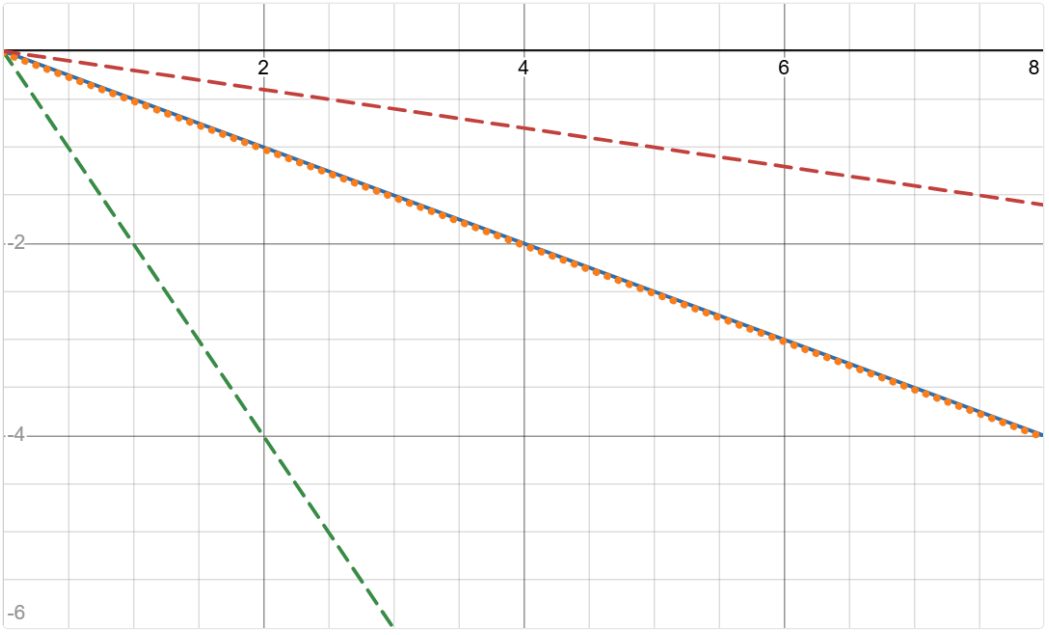
$$\mu \in \left[\hat{\mu}_N - z\frac{s_N}{\sqrt{N}},\ \hat{\mu}_N + z\frac{s_N}{\sqrt{N}}\right]$$

with confidence about 95% for $z = 1.96$ and 99.7% for $z = 3$.

The quantity $s_N/\sqrt{N}$ is the **standard error** of the estimate.

Proof of 1. Linearity of expectation gives $E[\hat{\mu}_N] = \frac{1}{N}\sum E[f(\mathbf{X}_i)] = \mu$; independence gives $\mathrm{Var}(\hat{\mu}_N) = \frac{1}{N^2}\sum \mathrm{Var}(f(\mathbf{X}_i)) = \sigma^2/N$. □

Three features stand out. The error decreases as $N^{-1/2}$: **each additional correct digit costs 100 times more samples**. The constant is σ, the standard deviation of the *integrand* — so reducing σ (variance reduction) is as good as increasing N. And neither the dimension d of $\mathbf{X}$ nor the smoothness of f appears. Compare a product trapezoidal rule in d dimensions, whose error is $O(h^2) = O(N^{-2/d})$ for N points: it beats Monte Carlo for $d < 4$, ties at $d = 4$, and loses for $d > 4$.



Log–log error versus number of function evaluations ($x = \log_{10} N$, $y = \log_{10}$ error, constants set to 1): Monte Carlo (blue, slope $-\frac{1}{2}$ in any dimension) against the trapezoidal rule in 1 dimension (green, slope -2), 4 dimensions (orange, slope $-\frac{1}{2}$, coinciding with Monte Carlo) and 10 dimensions (red, slope -0.2). In high dimension Monte Carlo wins.

Worked Example 24.27 — A one-dimensional integral and its error bar

Estimate $I = \int_0^1 e^x\,dx = e - 1 = 1.718\,282$ by Monte Carlo with $N = 10^4$ uniform samples, and predict the standard error.

Variance of the integrand. With $U \sim \mathcal{U}(0,1)$, $E[e^{2U}] = \frac{1}{2}(e^2 - 1) = 3.19453$, so $\sigma^2 = 3.19453 - (e-1)^2 = 0.242036$, $\sigma = 0.49197$.

Predicted standard error. $\sigma/\sqrt{N} = 0.49197/100 = 0.00492$.

One run (NumPy `default_rng(2024)`): $\hat{I} = 1.71993$, $s_N/\sqrt{N} = 0.00493$. The actual error 0.00165 is 0.33 standard errors — consistent with the CLT.

Reading. Three correct digits from 10^4 evaluations; the trapezoidal rule gets six digits with 40 points (error 9×10^{-5} with $n = 40$, Section 24.9). In one dimension Monte Carlo is a poor integrator; its value lies elsewhere.

Variance reduction

Since the error is $\sigma/\sqrt{N}$, any transformation that keeps the mean but reduces the variance of the averaged quantity by a factor r is equivalent to multiplying N by r. Four standard techniques:

Variance-reduction techniques

- **Antithetic variates.** Average f over pairs of negatively correlated samples, e.g. $\tfrac12\big(f(U)+f(1-U)\big)$. The variance of a pair mean is $\tfrac12\sigma^2(1+\rho)$, where $\rho=\operatorname{Corr}(f(U),f(1-U))$; it helps when f is monotone.
- **Control variates.** If $h(\mathbf{X})$ has *known* mean ν and is correlated with f, estimate $E[f-c(h-\nu)]$. The optimal coefficient and the resulting variance are

$$c^{*}=\frac{\operatorname{Cov}(f,h)}{\operatorname{Var}(h)},\qquad \operatorname{Var}\big(f-c^{*}(h-\nu)\big)=\sigma^2(1-\rho_{fh}^2).$$

- **Stratified sampling.** Partition the domain into strata, sample each stratum separately (proportionally to its probability) and combine. The between-strata component of the variance is eliminated.
- **Importance sampling.** Sample from a different density q that puts more mass where $|f|p$ is large, and reweight: $\mu=E_p[f(\mathbf{X})]=E_q\big[f(\mathbf{X})\,w(\mathbf{X})\big]$ with likelihood ratio $w=p/q$.

Derivation of the control-variate optimum. $\operatorname{Var}(f-ch)=\sigma_f^2-2c\operatorname{Cov}(f,h)+c^2\sigma_h^2$, a quadratic in c minimised at $c^{*}=\operatorname{Cov}(f,h)/\sigma_h^2$, where it equals $\sigma_f^2-\operatorname{Cov}(f,h)^2/\sigma_h^2=\sigma_f^2(1-\rho^2)$. A correlation of 0.99 reduces the variance 50-fold. □

Worked Example 24.28 — Three variance reductions on the same integral

Apply antithetic variates, a control variate and stratification to $I=\int_0^1 e^{x}\,dx$, at a cost of 10^4 evaluations of e^x each.

Antithetic. $\operatorname{Cov}(e^{U},e^{1-U})=E[e]-(e-1)^2=2.71828-2.95249=-0.23421$, so a pair mean has variance $\tfrac12(0.24204-0.23421)=0.003912$. Two independent samples averaged would have variance $0.24204/2=0.12102$: a reduction by a factor 30.9 for the same work. With 5000 pairs: $\hat I=1.71789\pm0.00088$.

Control variate $h(U)=U$ (mean $\tfrac12$, variance $\tfrac{1}{12}$). $\operatorname{Cov}(e^{U},U)=E[Ue^{U}]-\tfrac12(e-1)=1-0.85914=0.14086$, so $c^{*}=0.14086\times12=1.6903$ and the residual variance is $0.24204-0.14086^2\times12=0.003940$: a factor 61. With 10^4 samples: $\hat I=1.718462\pm0.00063$.

Stratified, one sample in each of 10^4 equal strata. $\hat I=1.718\,281\,80$, error 3×10^{-8} — the estimator is now essentially a randomised midpoint rule, whose error for smooth f falls as $N^{-3/2}$.

Reading. Variance reduction exploits knowledge of the integrand (monotonicity, a correlated function with known mean, smoothness). The cost is a little analysis; the gain can be orders of magnitude.

Rare events and importance sampling

Estimating a small probability p with plain Monte Carlo is expensive: the indicator has variance $p(1-p)$, so the *relative* standard error is

$$\frac{\sqrt{p(1-p)/N}}{p}\approx\frac{1}{\sqrt{Np}},$$

and a 10% relative error needs $N\approx100/p$ samples — about 100 *observed* events.

Worked Example 24.29 — A tail probability and a bit-error rate

(a) Estimate $p=P(X>4)$ for $X\sim\mathcal{N}(0,1)$ (exact $p=Q(4)=3.167\times10^{-5}$) with $N=10^4$ samples, plainly and by importance sampling from $\mathcal{N}(4,1)$. (b) How many simulated bits does a plain Monte Carlo BER measurement at $P_e=10^{-9}$ need?

(a) Plain. Relative standard error $\approx1/\sqrt{Np}=1/\sqrt{0.317}=1.78$ — with 10^4 samples we expect to see 0.3 events; the estimate is usually exactly zero. A 10% error would need 3.2×10^6 samples.

Importance sampling. Draw $Y_i\sim\mathcal{N}(4,1)$; the likelihood ratio is $w(y)=\dfrac{e^{-y^2/2}}{e^{-(y-4)^2/2}}=e^{-4y+8}$. The estimator $\frac1N\sum\mathbf{1}\{Y_i>4\}w(Y_i)$ is unbiased. Its second moment is $E_q[\mathbf{1}w^2]=e^{16}Q(8)=4.53\times10^{-9}$, giving a relative standard error $\sqrt{(4.53\times10^{-9}-p^2)/N}/p=2.1\%$ at $N=10^4$. One run: $\hat p=3.12\times10^{-5}\pm0.07\times10^{-5}$ ✓ — about 7000 times fewer samples than plain Monte Carlo for the same accuracy.

(b) BER. $N\approx100/P_e=10^{11}$ bits for a 10% error. At 10^6 simulated bits per second that is 28 hours per point on the BER curve. Importance sampling (biasing the noise variance or mean towards the decision boundary) or semi-analytic methods (simulate the noiseless waveform, compute the error probability analytically for each symbol) cut this to seconds.

Common Pitfall — importance sampling can make things worse

The variance of an importance-sampling estimator is $E_q[f^2w^2]-\mu^2$, which can be *infinite* if q has lighter tails than fp (e.g. sampling a heavy-tailed p from a Gaussian q). The estimator then converges erratically, with occasional enormous weights, and the sample standard error is meaningless. Always choose q with tails at least as heavy as p where $f\neq0$, and inspect the distribution of the weights; the **effective sample size** $(\sum w_i)^2/\sum w_i^2$ should not be tiny compared with N.

Quasi-Monte Carlo

Pseudo-random points cluster and leave gaps by chance. **Low-discrepancy sequences** (Halton, Sobol', lattice rules) fill the cube more evenly by design. For integrands of bounded variation the Koksma–Hlawka inequality bounds the error by the variation times the discrepancy of the point set, $O\big((\log N)^d/N\big)$ — asymptotically almost $1/N$ instead of $1/\sqrt{N}$. The points are deterministic, so error bars are obtained by **randomised QMC** (random shifts or scrambling,

repeated a few times). For smooth integrands in moderate dimension (up to tens), QMC routinely gains one to two orders of magnitude; for discontinuous indicators (pass/fail) the gain is smaller. SciPy provides `scipy.stats.qmc.Sobol`.

Monte Carlo tolerance analysis of a circuit

The most common engineering use of Monte Carlo is **statistical tolerance analysis**: components are manufactured with random deviations from their nominal values; what is the distribution of a circuit's performance, and what fraction of units (the **yield**) meets specification?

Tolerance analysis

Let a performance measure $y = g(p_1, \dots, p_m)$ depend on component values p_k with nominal values p_k^0 and tolerances $\pm t_k p_k^0$. **Worst-case analysis** finds the extreme values of y over the tolerance box. **Statistical analysis** models each p_k as a random variable (commonly uniform on the tolerance band for precision parts, or Gaussian with 3σ equal to the tolerance), and estimates the distribution of y; the **yield** is $Y = P(y \in [y_{\min}, y_{\max}])$.

The Monte Carlo procedure is:

1. Choose distributions (and correlations, e.g. resistors in the same thin-film network track each other) for all component values.
2. For $i = 1, \dots, N$: draw a component set, evaluate $y_i = g(\mathbf{p}_i)$ (a formula or a full circuit simulation).
3. Report $\hat{\mu}_y$, s_y, percentiles and the yield estimate $\hat{Y} = \frac{1}{N}\#\{y_i \text{ in spec}\}$ with standard error $\sqrt{\hat{Y}(1-\hat{Y})/N}$.

Worked Example 24.30 — Gain spread of a non-inverting amplifier

A non-inverting op-amp stage has gain $G = 1 + R_2/R_1$ with $R_1 = 1\ \text{k}\Omega$ and $R_2 = 9\ \text{k}\Omega$, both $\pm 1\%$ resistors modelled as independent and uniform on their tolerance bands. The specification is $G = 10 \pm 1\%$. Find the worst case, the standard deviation (by linearisation and by Monte Carlo) and the yield.

Worst case. $G_{\max} = 1 + 9 \times 1.01/0.99 = 10.1818$, $G_{\min} = 1 + 9 \times 0.99/1.01 = 9.8218$: $\pm 1.8\%$. Worst-case design says the spec cannot be guaranteed.

Linearisation. The relative sensitivities are $S^G_{R_2} = \dfrac{R_2}{G}\dfrac{\partial G}{\partial R_2} = \dfrac{R_2/R_1}{G} = 0.9$ and $S^G_{R_1} = -0.9$. A uniform $\pm 1\%$ deviation has standard deviation $\sigma_r = 0.01/\sqrt{3} = 0.5774\%$, so

$$\frac{\sigma_G}{G} \approx \sqrt{0.9^2 + 0.9^2}\,\sigma_r = 1.273 \times 0.5774\% = 0.735\%, \qquad \sigma_G \approx 0.0735.$$

Monte Carlo, $N = 10^5$:

```
rng = np.random.default_rng(12345)
N = 100_000
R1 = 1e3 * (1 + 0.01 * rng.uniform(-1, 1, N))
R2 = 9e3 * (1 + 0.01 * rng.uniform(-1, 1, N))
G = 1 + R2 / R1
yield_ = np.mean(np.abs(G - 10) <= 0.1)
```

Results: mean 10.0001, standard deviation 0.0738 (linearisation ✓), range $[9.8225,\ 10.1809]$ (inside the worst case, as it must be), yield within $\pm 1\%$: $\hat{Y} = 80.0\%$ (standard error 0.13%); within $\pm 1.5\%$: 97.2%.

Why not just use the Gaussian approximation? Treating G as Gaussian with $\sigma = 0.0735$ predicts a $\pm 1\%$ yield of $2\Phi(0.1/0.0735) - 1 = 82.6\%$. The true distribution of the sum of two uniform deviations is *triangular*, with thinner tails and more mass in the shoulders; the Gaussian overestimates the yield by 2.6 points. Monte Carlo makes no such assumption.

How many samples? With only $N = 1000$ samples, three seeds gave 78.6%, 79.3% and 80.2%, consistent with the standard error $\sqrt{0.8 \times 0.2/1000} = 1.3\%$. To quote yield to $\pm 0.5\%$ (one standard error) needs $N = 0.8 \times 0.2/0.005^2 = 6400$ runs.

Worked Example 24.31 — A nonlinear performance: RC cutoff frequency

An RC low-pass filter with $R = 10\ \text{k}\Omega \pm 5\%$ and $C = 10\ \text{nF} \pm 10\%$ (both uniform) has nominal $f_c = 1/(2\pi RC) = 1591.5$ Hz. The spec is f_c within $\pm 10\%$ of nominal. Compare linearised and Monte Carlo results.

Linearised. $S^{f_c}_R = S^{f_c}_C = -1$, so $\sigma_{f_c}/f_c = \sqrt{(0.05/\sqrt{3})^2 + (0.10/\sqrt{3})^2} = 6.45\%$, $\sigma_{f_c} = 102.7$ Hz, mean predicted 1591.5 Hz.

Monte Carlo ($N = 10^5$). Mean 1598.4 Hz, standard deviation 103.6 Hz, 0.5% and 99.5% percentiles 1396.7 and 1832.8 Hz, i.e. -12.2% and $+15.2\%$; yield within $\pm 10\%$: 87.4%.

Reading. Because $f_c \propto 1/(RC)$ is convex, the mean is *shifted upward* by 0.43% (second-order effect: $E[1/X] \approx \frac{1}{\mu}(1 + \sigma^2/\mu^2)$, and $(0.0645)^2 \approx 0.42\%$ ✓), and the distribution is skewed towards high frequencies. The linearised standard deviation is still accurate to 1%, but the asymmetric tails — which are what the yield depends on — are visible only in the simulation. Section 24.8 compares the two approaches systematically.

Engineering Note

SPICE simulators implement this directly (`.MC` analysis in many dialects; Monte Carlo with `mismatch` and `process` statistical models in foundry PDKs). Foundry models separate **global (process)** variation, common to all devices on a die, from **local (mismatch)** variation, independent per device and scaling as $1/\sqrt{\text{area}}$ (Pelgrom's law); a correct Monte Carlo draws one global sample per run and independent local samples per device. Because each run is a full circuit simulation, the techniques of this section — fewer runs through variance reduction, QMC, or importance sampling towards the failure region for high-sigma SRAM yield (failure probabilities of 10^{-6}–10^{-9} per cell) — translate directly into days of compute saved.

Common Pitfall — reporting Monte Carlo results without error bars

A Monte Carlo yield of "93.4%" from 200 runs has a standard error of 1.8%; the next digit is noise, and comparing it with "92.1%" from another design proves nothing. Always report the standard error (or a confidence interval), and when comparing two designs use **common random numbers** — the same random component deviations for both — so that the comparison is not swamped by sampling noise.

24.7 Parameter estimation

Motivation

Models contain parameters that must be learned from measurements: the time constant and final value of a charging capacitor, the saturation current and ideality factor of a diode, the ESR and inductance of a capacitor from an impedance sweep, the poles and zeros of a loudspeaker from its frequency response, the twenty parameters of a transistor compact model. When the model is linear in the parameters, the problem is linear least squares (Ch. 9), solved in one step by QR (Section 24.3). Most physical models are *nonlinear* in at least some parameters — τ in $e^{-t/\tau}$, n in $e^{V/(nV_T)}$, a resonance frequency — and need an iterative method. This section develops the Gauss–Newton and Levenberg–Marquardt algorithms, which exploit the least-squares structure far better than a general optimiser (Ch. 23), and shows how to attach uncertainties to the fitted parameters. The statistical justification — least squares is maximum likelihood under Gaussian noise — is in Ch. 20.

Problem statement

Nonlinear least squares

Given data (t_i, y_i), $i = 1, \dots, m$, and a model $y = \phi(t; \boldsymbol{\theta})$ with parameters $\boldsymbol{\theta} \in \mathbb{R}^n$ ($m > n$), define the **residuals** $r_i(\boldsymbol{\theta}) = y_i - \phi(t_i; \boldsymbol{\theta})$ and the cost

$$S(\boldsymbol{\theta}) = \tfrac{1}{2} \sum_{i=1}^{m} w_i \, r_i(\boldsymbol{\theta})^2 = \tfrac{1}{2} \, \mathbf{r}^{\mathsf{T}} \mathbf{W} \mathbf{r},$$

with weights $w_i = 1/\sigma_i^2$ (inverse noise variances; $\mathbf{W} = \mathbf{I}$ if the noise is uniform). The **Jacobian** $\mathbf{J} \in \mathbb{R}^{m \times n}$ of the model has entries $J_{ik} = \partial \phi(t_i; \boldsymbol{\theta}) / \partial \theta_k$, so that $\partial \mathbf{r} / \partial \boldsymbol{\theta} = -\mathbf{J}$.

The gradient and Hessian of S (with $\mathbf{W} = \mathbf{I}$) are

$$\nabla S = -\mathbf{J}^{\mathsf{T}} \mathbf{r}, \qquad \nabla^2 S = \mathbf{J}^{\mathsf{T}} \mathbf{J} - \sum_{i=1}^{m} r_i \nabla^2 \phi(t_i; \boldsymbol{\theta}).$$

The first Hessian term needs only first derivatives; the second is small when the residuals are small or the model is nearly linear. This structure is what the specialised methods exploit.

Gauss–Newton

Linearise the model about the current estimate $\boldsymbol{\theta}_k$: $\phi(t_i; \boldsymbol{\theta}_k + \boldsymbol{\delta}) \approx \phi(t_i; \boldsymbol{\theta}_k) + \mathbf{J}_i \boldsymbol{\delta}$. The residual becomes $\mathbf{r} - \mathbf{J}\boldsymbol{\delta}$, and minimising $\|\mathbf{r} - \mathbf{J}\boldsymbol{\delta}\|^2$ is a *linear* least-squares problem.

Gauss–Newton iteration

$$\boldsymbol{\theta}_{k+1} = \boldsymbol{\theta}_k + \boldsymbol{\delta}_k, \qquad \boldsymbol{\delta}_k = \arg\min_{\boldsymbol{\delta}} \|\mathbf{r}_k - \mathbf{J}_k \boldsymbol{\delta}\|_2, \quad \text{i.e.} \quad (\mathbf{J}_k^{\mathsf{T}} \mathbf{J}_k) \boldsymbol{\delta}_k = \mathbf{J}_k^{\mathsf{T}} \mathbf{r}_k.$$

The step should be computed by QR of $\mathbf{J}_k$, not by forming $\mathbf{J}_k^{\mathsf{T}} \mathbf{J}_k$ (Section 24.3), whenever $\mathbf{J}$ is ill-conditioned.

Gauss–Newton is Newton's method for $\nabla S = \mathbf{0}$ with the second Hessian term dropped. Consequently:

Local convergence of Gauss–Newton

Near a minimiser $\boldsymbol{\theta}^*$ with $\mathbf{J}(\boldsymbol{\theta}^*)$ of full rank, Gauss–Newton converges

- **quadratically** if the residuals at the solution are zero (the model fits exactly);
- **linearly** otherwise, with rate approximately $\rho\big((\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1} \sum_i r_i \nabla^2 \phi_i\big)$ evaluated at $\boldsymbol{\theta}^*$ — fast when the residuals are small relative to the model's curvature, and possibly divergent when they are large.

Far from the solution it may diverge: the linearised model can be a poor approximation, and the full step can overshoot.

Worked Example 24.32 — One Gauss–Newton step by hand

Fit $v(t) = a\,e^{-bt}$ to $(t, v) = (0, 5.0),\ (1, 3.1),\ (2, 1.8)$ starting from $(a, b) = (5,\ 0.5)$.

Model, residuals, Jacobian. $\phi = (5,\ 5e^{-0.5},\ 5e^{-1}) = (5,\ 3.03265,\ 1.83940)$; $\mathbf{r} = (0,\ 0.06735,\ -0.03940)$; $S_0 = \sum r_i^2 = 0.006088$ (we quote $\sum r_i^2$, i.e. $2S$). With $\partial\phi/\partial a = e^{-bt}$ and $\partial\phi/\partial b = -a\,t\,e^{-bt}$,

$$\mathbf{J} = \begin{bmatrix} 1 & 0 \\ 0.60653 & -3.03265 \\ 0.36788 & -3.67879 \end{bmatrix}.$$

Normal equations of the step.

$$\mathbf{J}^{\mathsf T}\mathbf{J} = \begin{bmatrix} 1.50321 & -3.19275 \\ -3.19275 & 22.73051 \end{bmatrix}, \qquad \mathbf{J}^{\mathsf T}\mathbf{r} = \begin{bmatrix} 0.02635 \\ -0.05930 \end{bmatrix}.$$

The determinant is $1.50321 \times 22.73051 - 3.19275^2 = 23.975$, so

$$\boldsymbol{\delta} = \frac{1}{23.975}\begin{bmatrix} 22.73051 & 3.19275 \\ 3.19275 & 1.50321 \end{bmatrix}\begin{bmatrix} 0.02635 \\ -0.05930 \end{bmatrix} = \begin{bmatrix} 0.01709 \\ -0.00021 \end{bmatrix}.$$

New estimate. $(a, b) = (5.01709,\ 0.49979)$, $\sum r_i^2 = 0.005625$. A library solver (`scipy.optimize.least_squares`) returns the same values to five digits and the same cost: one step has reached the minimum, because the starting point was close and the residuals small.

Contrast with the log-linear fit. Fitting $\ln v = \ln a - bt$ by linear least squares gives $(a, b) = (5.055,\ 0.511)$ — different, because the log transform reweights the data (small values gain influence). It is an excellent *starting point*, not the answer to the original problem (Ch. 9).

Levenberg–Marquardt

To make Gauss–Newton robust far from the solution, Levenberg (1944) and Marquardt (1963) added a damping term:

Levenberg–Marquardt step

$$\left(\mathbf{J}_k^{\mathsf T}\mathbf{J}_k + \lambda_k \mathbf{D}_k\right)\boldsymbol{\delta}_k = \mathbf{J}_k^{\mathsf T}\mathbf{r}_k,$$

with damping parameter $\lambda_k \ge 0$ and a positive diagonal scaling $\mathbf{D}_k$ (Levenberg: $\mathbf{D} = \mathbf{I}$; Marquardt: $\mathbf{D} = \operatorname{diag}(\mathbf{J}^{\mathsf T}\mathbf{J})$, which makes the method invariant to the units of the parameters). A typical update: if the step reduces S, accept it and decrease λ (e.g. $\lambda \leftarrow \lambda/10$); otherwise reject it, increase λ ($\lambda \leftarrow 10\lambda$) and recompute.

The damping interpolates between two methods:

- $\lambda \to 0$: the Gauss–Newton step (fast near the solution);
- $\lambda \to \infty$: $\boldsymbol{\delta} \approx \lambda^{-1}\mathbf{D}^{-1}\mathbf{J}^{\mathsf T}\mathbf{r} = -\lambda^{-1}\mathbf{D}^{-1}\nabla S$, a short (scaled) steepest-descent step, which always reduces S for λ large enough.

Equivalently, the LM step minimises the linearised cost $\|\mathbf{r} - \mathbf{J}\boldsymbol{\delta}\|^2$ subject to $\|\mathbf{D}^{1/2}\boldsymbol{\delta}\| \le \Delta$ for some trust radius Δ that decreases as λ increases: LM is a **trust-region** method, and modern implementations (MINPACK, `scipy.optimize.least_squares` with `method='lm'` or `'trf'`) adjust Δ directly by comparing the actual decrease of S with the decrease predicted by the linear model. The LM system is again best solved as an augmented least-squares problem $\min \left\| \begin{bmatrix} \mathbf{J} \\ \sqrt{\lambda}\,\mathbf{D}^{1/2} \end{bmatrix}\boldsymbol{\delta} - \begin{bmatrix} \mathbf{r} \\ \mathbf{0} \end{bmatrix} \right\|$ by QR.

Worked Example 24.33 — Fitting an RC charging curve: Gauss–Newton diverges, Levenberg–Marquardt converges

A capacitor charging through a resistor is sampled every 0.25 ms:

t (ms)	0.25	0.50	0.75	1.00	1.25	1.50	1.75	2.00
v (V)	1.342	2.330	3.036	3.550	3.943	4.213	4.440	4.616

(The data were synthesised from $V = 5$ V, $\tau = 0.8$ ms with Gaussian noise of $\sigma = 20$ mV.) Fit $v = V(1 - e^{-t/\tau})$ from the poor initial guess $V = 2$ V, $\tau = 5$ ms.

Jacobian. $\partial\phi/\partial V = 1 - e^{-t/\tau}$, $\partial\phi/\partial\tau = -V\,\dfrac{t}{\tau^2}e^{-t/\tau}$.

Gauss–Newton. The initial cost is $\sum r_i^2 = 80.3$ V^2. The first GN step jumps to $V = -42.4$ V, $\tau = -167$ ms — the linearisation about a nearly straight initial curve (with $\tau = 5$ ms the model is almost linear in t over the data) wildly extrapolates — and the iteration then diverges to $|V| \sim 10^{15}$.

Levenberg–Marquardt (Marquardt scaling, $\lambda_0 = 10^{-2}$, factor 10):

iter	V (V)	τ (ms)	$\sum r_i^2$ (V^2)	λ after step
0	2.000	5.000	80.27	10^{-2}
1	3.197	1.466	28.67	1
2	4.358	0.5445	0.4349	10^{-1}
3	4.644	0.6725	0.09904	10^{-2}
4	4.939	0.7815	0.004695	10^{-3}
5	5.0127	0.80667	0.0013139	10^{-4}
9	5.015855	0.807757	0.0013084	10^{-7}

In the first iteration three trial steps were rejected (λ raised to 10) before a short, safe step was accepted; thereafter λ falls by ten each iteration and the method becomes Gauss–Newton, converging rapidly. From the better start $(4\text{ V},\ 0.3\text{ ms})$ plain Gauss–Newton also converges, in about 6 iterations.

Reading. The final residual $\sqrt{0.0013084/6} = 14.8$ mV (dividing by $m - n = 6$ degrees of freedom) is consistent with the 20 mV noise. Fitted values: $V = 5.016$ V, $\tau = 0.808$ ms. How good are they? That needs the next subsection.

Uncertainty of the fitted parameters

Near the solution the model is approximately linear, $\mathbf{y} \approx \boldsymbol{\phi}(\boldsymbol{\theta}^*) + \mathbf{J}(\boldsymbol{\theta} - \boldsymbol{\theta}^*) + \text{noise}$, so the linear least-squares theory applies with $\mathbf{J}$ in place of the design matrix.

Asymptotic covariance of least-squares estimates

If the measurement errors are independent with variance σ^2 and the model is correct, the estimate $\hat{\boldsymbol{\theta}}$ has approximately

$$\operatorname{Cov}(\hat{\boldsymbol{\theta}}) \approx \sigma^2 (\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1}, \qquad \hat{\sigma}^2 = \frac{\sum_i r_i(\hat{\boldsymbol{\theta}})^2}{m - n},$$

with $\mathbf{J}$ evaluated at $\hat{\boldsymbol{\theta}}$. With weights $\mathbf{W} = \operatorname{diag}(1/\sigma_i^2)$ the covariance is $(\mathbf{J}^{\mathsf{T}}\mathbf{W}\mathbf{J})^{-1}$. Standard errors are the square roots of the diagonal; the **correlation** between $\hat{\theta}_j$ and $\hat{\theta}_k$ is $C_{jk}/\sqrt{C_{jj}C_{kk}}$. For small samples, approximate 95% intervals use Student's t_{m-n} quantile (Ch. 20).

Sketch. Linearising, $\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}^* \approx (\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1}\mathbf{J}^{\mathsf{T}}\boldsymbol{\epsilon}$, whose covariance is $(\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1}\mathbf{J}^{\mathsf{T}}(\sigma^2\mathbf{I})\mathbf{J}(\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1} = \sigma^2(\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1}$. This is the linear error propagation of Section 24.8 applied to the map from data to estimate. □

Worked Example 24.34 — Error bars and correlation for the RC fit

Continue Worked Example 24.33.

Covariance. With $\hat{\sigma} = 14.8$ mV and $\mathbf{J}$ at the solution, $\hat{\sigma}^2(\mathbf{J}^{\mathsf{T}}\mathbf{J})^{-1}$ gives standard errors $u(V) = 0.020$ V and $u(\tau) = 0.0077$ ms, and a correlation coefficient $+0.93$.

Intervals. With $t_{6,0.975} = 2.447$: $V = 5.016 \pm 0.049$ V, $\tau = 0.808 \pm 0.019$ ms (95%). Both contain the true values 5 V and 0.8 ms ✓.

The correlation matters. The data stop at $t = 2$ ms $= 2.5\tau$, before the curve has settled; a larger final value with a slower time constant fits almost as well as a smaller one with a faster time constant. The individual error bars understate how well the *combination* is determined, and any quantity derived from both (e.g. the initial slope V/τ) must be propagated with the full covariance (Section 24.8). Extending the record to 5τ would decorrelate them.

Scaling. In SI units the columns of $\mathbf{J}$ differ by a factor of order 10^3–10^4 (V per V versus V per second), and $\kappa(\mathbf{J}^{\mathsf{T}}\mathbf{J}) = 5.1 \times 10^7$. Measuring τ in milliseconds gives $\kappa = 65$. The answer is the same in exact arithmetic, but a well-scaled problem is kinder to every algorithm — Marquardt's diagonal scaling achieves the same effect automatically.

Identifiability and good formulations

Identifiability

A parameter vector is **(locally) identifiable** from an experiment if distinct parameter values near $\boldsymbol{\theta}^*$ produce distinct model outputs, i.e. $\mathbf{J}(\boldsymbol{\theta}^*)$ has full column rank. It is **practically identifiable** if, in addition, $\mathbf{J}^\mathsf{T}\mathbf{J}$ is well enough conditioned that the noise does not produce huge parameter uncertainties.

Practical non-identifiability is common and shows up as near-singular $\mathbf{J}^\mathsf{T}\mathbf{J}$, correlations near ± 1 and enormous standard errors. The remedies are experimental (measure over a wider range, excite the relevant dynamics) or mathematical (reparametrise, fix a parameter, add prior information as regularisation).

Worked Example 24.35 — Diode parameters: correlation by design

The forward diode law $I = I_s e^{V/(nV_T)}$ becomes linear after taking logarithms: $\ln I = \ln I_s + \dfrac{1}{nV_T} V$, with unknowns $\theta_1 = \ln I_s$ and $\theta_2 = 1/(nV_T)$. Measurements are taken at 11 equally spaced voltages from 0.5 V to 0.7 V. Find the correlation between the estimates, and fix it.

Correlation. The design matrix has columns $\mathbf{1}$ and $\mathbf{V}$. With equal noise, $\mathrm{Cov} \propto (\mathbf{X}^\mathsf{T}\mathbf{X})^{-1}$, and the correlation is $-\bar{V}/\sqrt{\overline{V^2}} = -0.6/\sqrt{0.36 + 0.004} = -0.994$. The intercept $\ln I_s$ is an extrapolation to $V = 0$, far outside the data; any error in the slope swings it strongly.

Reparametrisation. Write $\ln I = \ln I_0 + \theta_2 (V - 0.6)$, where I_0 is the current at the centre of the data. The columns $\mathbf{1}$ and $\mathbf{V} - \bar{V}$ are orthogonal, the correlation is exactly 0, and $\ln I_0$ is determined to the noise level divided by $\sqrt{11}$. $I_s = I_0 e^{-0.6\theta_2}$ can be computed afterwards — with its large but now honestly propagated uncertainty.

Reading. Parametrise models by quantities the data actually measure: a value at the centre of the data rather than an extrapolated intercept, log of scale parameters that span decades (like $I_s \sim 10^{-14}$ A), time constants rather than poles when the data are in the time domain.

Common Pitfall — local minima and bad starting values

Nonlinear least squares can have several local minima — fitting a sum of two exponentials, a resonance frequency, or a phase is notorious — and every method here finds only a local one. Get starting values from physics (the final value of a step response, the -3 dB point of a response), from a linearising transformation (Worked Example 24.32), or by a coarse grid search over the nonlinear parameters; and for models linear in some parameters, eliminate those analytically (**variable projection**: for each trial τ, the best V is a one-line linear least-squares solve), leaving a lower-dimensional search.

Engineering Note

Device-model extraction (BSIM transistor models, IBIS buffer models, battery equivalent circuits) is large-scale weighted nonlinear least squares, usually with LM and carefully staged parameter subsets so that each stage is identifiable. Impedance spectroscopy fits equivalent circuits to complex data by stacking real and imaginary residuals, $\mathbf{r} = [\mathrm{Re}\{\mathbf{Z}_\mathrm{meas} - \mathbf{Z}_\mathrm{model}\},\ \mathrm{Im}\{\cdots\}]$, often weighted by $1/|Z|$ so that every decade of frequency counts equally. Vector fitting, used to build rational macromodels of interconnects from S-parameter data, is an iterated *linear* least-squares method that relocates poles — an example of choosing a formulation that avoids nonlinear search altogether.

24.8 Sensitivity and uncertainty propagation

Motivation

Every computed result inherits uncertainty from its inputs: component tolerances, measured parameters, fitted model coefficients, environmental conditions. Two related questions follow. **Sensitivity analysis** asks how much the output changes per unit change of each input — which resistor sets the gain error, which permittivity dominates the resonance shift — and therefore where to spend money on tighter tolerances. **Uncertainty propagation** asks what the resulting uncertainty of the output is, so that a measurement or a simulation can be reported as "$y = \hat{y} \pm U$". Both depend on derivatives of the output with respect to the inputs, and computing those derivatives accurately and cheaply for large models is itself a computational problem. This section treats derivative computation (finite differences, complex step, automatic differentiation and the adjoint method), then linearised propagation in the framework of the *Guide to the Expression of Uncertainty in Measurement* (GUM), then Monte Carlo propagation and the conditions under which the two disagree.

Sensitivities

Sensitivity

For an output $y = f(p_1, \dots, p_m)$, the **absolute sensitivity** to p_k is $\partial y / \partial p_k$ and the **relative (normalised, Bode) sensitivity** is

$$S_{p_k}^{y} = \frac{p_k}{y}\frac{\partial y}{\partial p_k} = \frac{\partial \ln |y|}{\partial \ln |p_k|},$$

the percentage change in y per percent change in p_k. The vector of absolute sensitivities is the gradient $\nabla_{\mathbf{p}} y$; for several outputs it is the **sensitivity matrix** (Jacobian) $\mathbf{S} = \partial \mathbf{y} / \partial \mathbf{p}$.

Relative sensitivities are dimensionless and obey simple rules: $S_p^{y_1 y_2} = S_p^{y_1} + S_p^{y_2}$, $S_p^{1/y} = -S_p^{y}$, $S_p^{y^n} = n S_p^{y}$. For an RC cutoff $f_c = 1/(2\pi RC)$, $S_R^{f_c} = S_C^{f_c} = -1$; for an inverting amplifier $G = -R_2/R_1$, $S_{R_2}^{G} = 1$, $S_{R_1}^{G} = -1$.

Computing derivatives numerically

Finite differences. The forward difference $\big(f(x+h)-f(x)\big)/h$ has truncation error $\tfrac{1}{2}hf''$ and rounding error about $2\varepsilon|f|/h$ (Ch. 22). Balancing them gives $h_{\text{opt}} \approx \sqrt{\varepsilon}|x| \approx 10^{-8}|x|$ and a best relative accuracy of about $\sqrt{\varepsilon} \approx 10^{-8}$ — half the digits. The central difference $\big(f(x+h)-f(x-h)\big)/(2h)$ has truncation error $\tfrac{1}{6}h^2 f'''$, giving $h_{\text{opt}} \approx \varepsilon^{1/3}$ and accuracy about $\varepsilon^{2/3} \approx 10^{-11}$. Each gradient of m parameters costs m (forward) or $2m$ (central) extra evaluations of f.

Complex step. If f is real-analytic and implemented with operations that extend to complex arguments, Taylor expansion gives $f(x+jh) = f(x) + jhf'(x) - \tfrac{1}{2}h^2 f''(x) - \tfrac{1}{6}jh^3 f'''(x) + \cdots$, so

$$f'(x) = \frac{\operatorname{Im}\{f(x+jh)\}}{h} + O(h^2).$$

There is **no subtraction**, hence no cancellation: h can be made as small as 10^{-20} or 10^{-100} and the derivative is accurate to machine precision. The cost is one complex evaluation per parameter. Circuit and EM codes that already use complex arithmetic for phasors can often be differentiated this way with almost no change — but functions such as `abs`, `max` or comparisons must be redefined for complex arguments, and the code must not take the conjugate of the perturbed variable.

Worked Example 24.36 — Finite differences versus complex step

Differentiate $f(x) = \dfrac{e^{x}}{\sqrt{\sin^3 x + \cos^3 x}}$ at $x = 1.5$ (exact $f'(1.5) = 4.053\,427\,894$). Relative errors:

h	forward difference	central difference	complex step
10^{-2}	1.2×10^{-2}	1.3×10^{-4}	1.3×10^{-4}
10^{-4}	1.2×10^{-4}	1.3×10^{-8}	1.3×10^{-8}
10^{-6}	1.2×10^{-6}	1.4×10^{-10}	1.3×10^{-12}
10^{-8}	2.5×10^{-8}	8.4×10^{-9}	$< 10^{-16}$
10^{-10}	3.5×10^{-6}	2.0×10^{-7}	$< 10^{-16}$
10^{-12}	2.7×10^{-4}	5.4×10^{-5}	$< 10^{-16}$
10^{-20}	(meaningless)	(meaningless)	2.2×10^{-16}

Reading. Finite differences reach their best accuracy at an intermediate h (10^{-8} forward, about 10^{-6} central) and get *worse* as h decreases further — the V-shaped error curve of Ch. 22. The complex step improves monotonically and saturates at machine precision. For both large and small h, the central difference and complex step share the same $O(h^2)$ truncation error (identical first two rows).

Automatic differentiation (AD). A program is a composition of elementary operations whose derivatives are known. AD applies the chain rule to the *program*, operation by operation, producing derivatives exact to rounding error with no step size at all. **Forward mode** propagates, alongside each intermediate value v, its derivative $\dot v = \partial v/\partial p$ with respect to *one* input (dual numbers $v + \dot v\epsilon$ with $\epsilon^2 = 0$; the complex step is a close relative); a full gradient needs m passes. **Reverse mode** first evaluates the program and records it, then propagates *adjoints* $\bar v = \partial y/\partial v$ backwards from *one* output; a full gradient with respect to all m inputs costs a small constant multiple (typically 2–5) of one function evaluation, independent of m. Reverse-mode AD is "backpropagation" in neural networks and is what JAX, PyTorch and similar tools implement.

The adjoint method

The reverse-mode idea, applied to a model defined by a linear system, is the **adjoint method**. It is the key to sensitivity analysis of large circuits and field models, where there may be thousands of parameters but only a few outputs.

Let the state $\mathbf{x} \in \mathbb{R}^n$ be defined by $\mathbf{A}(\mathbf{p})\mathbf{x} = \mathbf{b}(\mathbf{p})$ and the output be $y = \mathbf{c}^{\mathsf T}\mathbf{x}$ (a node voltage, a port current). Differentiating the system with respect to p_k:

$$\mathbf{A}\frac{\partial \mathbf{x}}{\partial p_k} = \frac{\partial \mathbf{b}}{\partial p_k} - \frac{\partial \mathbf{A}}{\partial p_k}\mathbf{x}.$$

The **direct** method solves this for $\partial\mathbf{x}/\partial p_k$ — one solve per parameter — and forms $\partial y/\partial p_k = \mathbf{c}^{\mathsf T}\partial\mathbf{x}/\partial p_k$. The **adjoint** method notices that only the combination $\mathbf{c}^{\mathsf T}\mathbf{A}^{-1}$ is needed.

Adjoint sensitivity formula

Let $\boldsymbol{\lambda}$ solve the **adjoint system** $\mathbf{A}^{\mathsf T}\boldsymbol{\lambda} = \mathbf{c}$. Then for every parameter p_k

$$\frac{\partial y}{\partial p_k} = \boldsymbol{\lambda}^{\mathsf T}\Big(\frac{\partial \mathbf{b}}{\partial p_k} - \frac{\partial \mathbf{A}}{\partial p_k}\mathbf{x}\Big).$$

All m sensitivities of one output cost **one** extra solve (with the transposed matrix, whose LU factors are those of $\mathbf{A}$ transposed) plus m cheap inner products — instead of m solves.

Proof. $\dfrac{\partial y}{\partial p_k} = \mathbf{c}^{\mathsf T}\dfrac{\partial \mathbf{x}}{\partial p_k} = \mathbf{c}^{\mathsf T}\mathbf{A}^{-1}\Big(\dfrac{\partial \mathbf{b}}{\partial p_k} - \dfrac{\partial \mathbf{A}}{\partial p_k}\mathbf{x}\Big)$, and $\mathbf{c}^{\mathsf T}\mathbf{A}^{-1} = (\mathbf{A}^{-\mathsf T}\mathbf{c})^{\mathsf T} = \boldsymbol{\lambda}^{\mathsf T}$. $\square$

The rule of thumb: **direct** sensitivities when there are few parameters and many outputs; **adjoint** sensitivities when there are many parameters and few outputs (the common case in design optimisation and tolerance analysis).

For a conductance g connected between nodes a and b of a nodal matrix, $\partial\mathbf{G}/\partial g = (\mathbf{e}_a - \mathbf{e}_b)(\mathbf{e}_a - \mathbf{e}_b)^{\mathsf T}$ (the stamp of a unit conductance), so

$$\frac{\partial y}{\partial g} = -(\lambda_a - \lambda_b)(v_a - v_b)\,:$$

the product of the branch voltage in the original circuit and the branch voltage in the adjoint circuit. This is the classical **adjoint-network** result derived from Tellegen's theorem (Director and Rohrer, 1969). For a reciprocal (symmetric) network the adjoint network is the original network, driven by a unit current source at the output node.

Worked Example 24.37 — Sensitivities of a node voltage to every conductance with one extra solve

The three-node network of Worked Example 24.17 has conductances (in siemens) $g_{12}=2$, $g_{13}=1$, $g_{23}=1$ between nodes and $g_1=1$, $g_2=1$, $g_3=2$ from each node to ground, and source currents $\mathbf{b}=(8,2,1)$ A, giving $\mathbf{G}=\begin{bmatrix}4&-2&-1\\-2&4&-1\\-1&-1&4\end{bmatrix}$ and $\mathbf{v}=(4,3,2)$ V. Find $\partial v_3/\partial g$ for all six conductances and $\partial v_3/\partial b_k$ for all three sources.

Adjoint solve. $\mathbf{G}^{\mathsf T}\boldsymbol{\lambda}=\mathbf{e}_3$ ($\mathbf{G}$ is symmetric). Check that $\boldsymbol{\lambda}=(\tfrac16,\tfrac16,\tfrac13)$: row 1, $\tfrac46-\tfrac26-\tfrac13=0$ ✓; row 2 similarly 0 ✓; row 3, $-\tfrac16-\tfrac16+\tfrac43=1$ ✓.

Source sensitivities. $\partial\mathbf{b}/\partial b_k=\mathbf{e}_k$, so $\partial v_3/\partial b_k=\lambda_k$: $(\tfrac16,\tfrac16,\tfrac13)\ \Omega$ — these are transfer resistances, by reciprocity.

Conductance sensitivities $-(\lambda_a-\lambda_b)(v_a-v_b)$ (for a grounded element, $\lambda_b=v_b=0$):

element	$\lambda_a-\lambda_b$	v_a-v_b (V)	$\partial v_3/\partial g$ (V/S)	relative $S_g^{v_3}$
g_{12}	0	1	0	0
g_{13}	$-\tfrac16$	2	$+0.3333$	$+0.167$
g_{23}	$-\tfrac16$	1	$+0.1667$	$+0.083$
g_1	$\tfrac16$	4	-0.6667	-0.333
g_2	$\tfrac16$	3	-0.5000	-0.250
g_3	$\tfrac13$	2	-0.6667	-0.667

Check by finite difference. Increasing g_{13} by 10^{-6} and re-solving changes v_3 by 3.3333×10^{-7} ✓; every row agrees to six digits.

Reading. One factorisation, one extra (transposed) solve, and six inner products give every sensitivity; the direct method would need six solves, and for a circuit with 10^4 elements the adjoint saves a factor of 10^4. The table also explains the physics: g_{12} does not affect v_3 at all because nodes 1 and 2 are at the same potential in the adjoint circuit, and the shunt g_3 at the output node has the largest relative influence.

Linearised uncertainty propagation (GUM)

Standard uncertainty and the GUM law of propagation

The **standard uncertainty** $u(x)$ of an input estimate x is its estimated standard deviation — evaluated statistically from repeated observations (**Type A**) or from other information such as a datasheet tolerance or calibration certificate (**Type B**; a uniform interval $\pm a$ gives $u=a/\sqrt{3}$). For a measurement model $Y=f(X_1,\dots,X_n)$ with estimates x_i, the **combined standard uncertainty** of $y=f(x_1,\dots,x_n)$ is, to first order,

$$u_c^2(y)=\sum_{i=1}^{n}c_i^2u^2(x_i)+2\sum_{i<j}c_ic_j\,u(x_i,x_j),\qquad c_i=\left.\frac{\partial f}{\partial x_i}\right|_{\mathbf{x}},$$

where c_i are the **sensitivity coefficients** and $u(x_i,x_j)$ the covariances. In matrix form, for a vector output, $\mathbf{U}_y=\mathbf{J}\mathbf{U}_x\mathbf{J}^{\mathsf T}$. The **expanded uncertainty** is $U=k\,u_c(y)$ with **coverage factor** k, usually $k=2$ (about 95% coverage for a Gaussian output).

Derivation. Expand f to first order, $Y-y\approx\sum_i c_i(X_i-x_i)$; the variance of a linear combination is $\sum_{i,j}c_ic_j\,\mathrm{Cov}(X_i,X_j)$. $\square$

For products and quotients of powers, $y=\prod x_i^{a_i}$ with uncorrelated inputs, the rule takes the convenient relative form $\big(u_c(y)/y\big)^2=\sum_i a_i^2\big(u(x_i)/x_i\big)^2$ — the relative sensitivities are just the exponents.

Worked Example 24.38 — Power from voltage and resistance

The power dissipated in a resistor is computed as $P=V^2/R$ from $V=5.000$ V with $u(V)=0.020$ V and $R=100.0\ \Omega$ with $u(R)=0.50\ \Omega$ (independent). Find $u_c(P)$ and the expanded uncertainty.

Estimate. $P=25/100=0.2500$ W.

Relative form. Exponents 2 and -1: $\big(u_c/P\big)^2=(2\times0.004)^2+(0.005)^2=6.4\times10^{-5}+2.5\times10^{-5}=8.9\times10^{-5}$, so $u_c/P=0.943\%$ and $u_c(P)=2.36$ mW.

Budget. The voltage contributes $64/89=72\%$ of the variance despite its smaller relative uncertainty, because of the square. A better voltmeter is the cheaper improvement.

Result. $P=(250.0\pm4.7)$ mW with $k=2$.

Monte Carlo check (10^5 Gaussian draws): mean 250.00 mW, standard deviation 2.35 mW ✓. The model is nearly linear over $\pm1\%$, so linearisation is excellent.

Worked Example 24.39 — Correlated inputs: a quantity derived from fitted parameters

From the RC fit of Worked Example 24.34, compute the initial slope $s = V/\tau$ and its uncertainty, with and without the correlation $\rho = 0.931$.

Estimate. $s = 5.0159/0.80776 \times 10^{-3} = 6210$ V/s.

Sensitivities (relative). $s = V\tau^{-1}$: exponents $+1$ and -1. Relative uncertainties $u(V)/V = 0.398\%$, $u(\tau)/\tau = 0.949\%$.

Ignoring correlation. $\sqrt{0.398^2 + 0.949^2}\% = 1.03\%$, $u(s) = 64$ V/s.

With correlation. The cross term is $2 \times (+1)(-1) \times \rho \times 0.398\% \times 0.949\%$:

$$\left(\frac{u(s)}{s}\right)^2 = 0.398^2 + 0.949^2 - 2(0.931)(0.398)(0.949) = 0.1584 + 0.9006 - 0.7033 = 0.3557\ (\%)^2,$$

so $u(s)/s = 0.596\%$, $u(s) = 37$ V/s.

Reading. V and τ err in the *same* direction, so their ratio — which the early data points measure directly — is much better determined than either. Dropping the covariance overstates the uncertainty by 73% here; with $\rho < 0$ it would understate it. When propagating from fitted parameters, always use the full covariance matrix $\mathbf{J}_s \mathbf{C} \mathbf{J}_s^{\mathsf{T}}$.

Monte Carlo propagation and the limits of linearisation

The **GUM Supplement 1** approach replaces the first-order formula by simulation: assign a probability distribution to each input (Gaussian, uniform, triangular, or a joint distribution for correlated inputs), draw N samples (typically 10^5–10^6), evaluate the model for each, and summarise the output distribution by its mean, standard deviation and a *coverage interval* taken from the empirical quantiles (e.g. the 2.5% and 97.5% percentiles). It is exactly the tolerance analysis of Section 24.6, with measurement uncertainties in place of tolerances.

Linearisation and Monte Carlo agree when the model is approximately linear over the region where the input distributions have most of their mass, i.e. when second-order terms $\tfrac{1}{2} f'' u^2$ are small compared with $f' u$. They disagree when:

1. **The model is strongly nonlinear over the uncertainty range** (large relative uncertainties; exponentials, ratios with uncertain denominators near zero).
2. **The first derivative vanishes** at the estimate (an extremum: maximum power transfer, the peak of a resonance, a balanced bridge), so the linear formula predicts zero uncertainty.
3. **The output distribution is far from Gaussian** (bounded, skewed or bimodal), so that $y \pm 2u_c$ is not a 95% interval.
4. **The quantity of interest is a probability or a quantile** (yield, coverage) rather than a standard deviation.

For case 2 the GUM provides a second-order correction: for a single Gaussian input, $u_c^2 = c_1^2 u^2 + \tfrac{1}{2}\left(f''\right)^2 u^4$.

Worked Example 24.40 — Matched load: where linearisation predicts zero

A source with $R_s = 50\ \Omega$ drives a load R_L; the delivered power relative to the maximum is $\eta = \dfrac{4R_s R_L}{(R_s + R_L)^2}$. The load is nominally 50 Ω with a 5% Gaussian standard uncertainty. Find the uncertainty of η by GUM (first and second order) and by Monte Carlo.

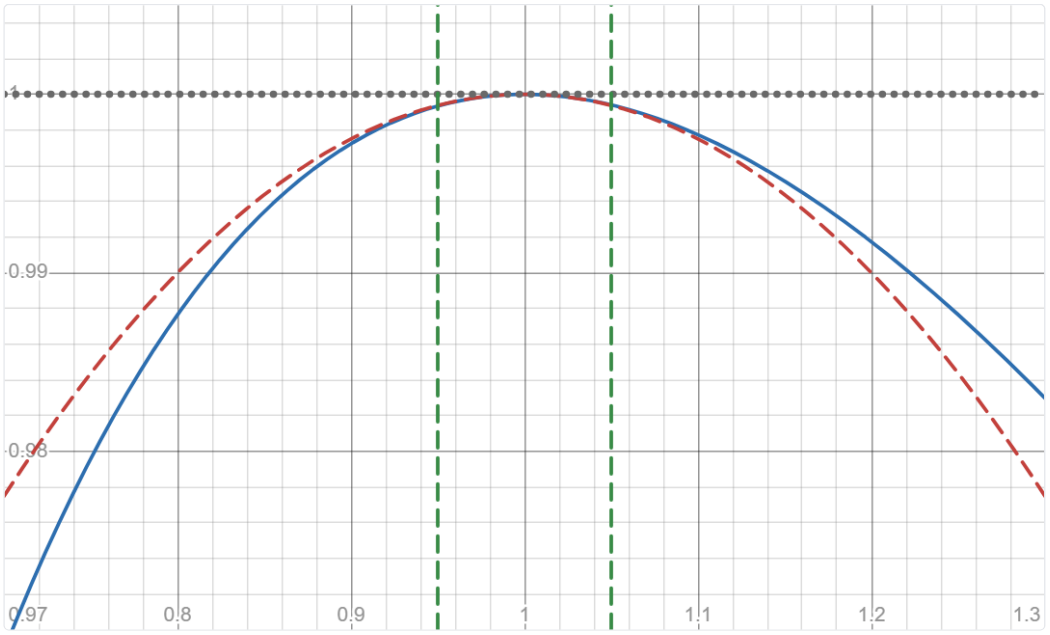
First order. With $x = R_L/R_s$, $\eta = 4x/(1+x)^2$, $d\eta/dx = 4(1-x)/(1+x)^3 = 0$ at $x = 1$. The linear law gives $u_c(\eta) = 0$: "the power is exactly 100%".

Second order. Expanding about $x = 1 + e$: $\eta = \dfrac{1+e}{(1+e/2)^2} \approx (1+e)(1 - e + \tfrac{3}{4}e^2) = 1 - \tfrac{1}{4}e^2$. So $\eta'' = -\tfrac{1}{2}$, and with $e \sim \mathcal{N}(0, 0.05^2)$:

$$E[\eta] \approx 1 - \tfrac{1}{4}(0.05)^2 = 0.999375, \qquad u(\eta) = \tfrac{1}{4}\sqrt{\mathrm{Var}(e^2)} = \tfrac{1}{4}\sqrt{2}(0.05)^2 = 0.000884.$$

Monte Carlo (10^5 samples). Mean 0.999373, standard deviation 0.000896, median 0.99972, 95% coverage interval $[0.99685,\ 0.99999]$.

Reading. The second-order GUM matches the mean and standard deviation, but the distribution is one-sided (it can never exceed 1) and strongly skewed: $\eta \pm 2u$ would include impossible values above 1. The Monte Carlo coverage interval is the honest answer. Mismatch is always a *loss*, never a gain — a qualitative fact the linear method cannot express.



Relative delivered power $\eta = 4x/(1+x)^2$ against $x = R_L/R_s$ (blue) with its quadratic approximation $1-(x-1)^2/4$ (red, dashed). The green lines mark ± 1 standard uncertainty of the load. At the maximum the tangent is horizontal, so a first-order propagation sees no uncertainty at all; the curvature maps a symmetric input spread into a one-sided output spread below 1.

	Linearised (GUM)	Monte Carlo (GUM-S1)
Cost	one evaluation plus m derivatives (one adjoint solve for many inputs)	10^4–10^6 evaluations
Nonlinearity	first order (second order with extra effort)	exact for the assumed input distributions
Output distribution	assumed Gaussian (or Student t)	estimated
Correlated inputs	covariance terms	joint sampling
Insight	uncertainty budget: contribution of each input	needs extra runs (one-at-a-time or variance-based indices)
Best for	small uncertainties, many inputs, design iterations	large uncertainties, extrema, yield and coverage questions, validation of the linear result

Engineering Note — global sensitivity

Derivatives describe *local* sensitivity at the nominal point. When inputs vary over wide ranges, **variance-based (Sobol') indices** quantify how much of $\mathrm{Var}(y)$ each input explains on its own ($S_i = \mathrm{Var}(E[y \mid X_i])/\mathrm{Var}(y)$) and through interactions. They are estimated by structured Monte Carlo designs and are the standard way to decide which of fifty process parameters actually matter for a circuit's yield. For a linear model with independent inputs they reduce to the normalised terms $c_i^2 u_i^2 / u_c^2$ of the GUM uncertainty budget.

Common Pitfall — tolerance is not standard uncertainty

A "$\pm 1\%$" resistor tolerance is a bound, not a standard deviation. Treating it as $u = 1\%$ overstates the uncertainty by $\sqrt{3}$ for a uniform distribution, and the true distribution of a purchased batch is often neither uniform nor Gaussian (parts near nominal may have been sorted into a tighter tolerance grade, leaving a bimodal distribution). State the assumed distribution explicitly, and where it matters, measure a sample.

24.9 Reproducible numerical experiments

Motivation

A numerical result is only useful if it can be trusted, and it can only be trusted if it can be checked. Six months after a tolerance study, someone asks why the yield was quoted as 87% when a re-run gives 85%. A colleague's filter-design script produces different coefficients on a new laptop. A regression test fails after a library upgrade, and nobody knows whether the old or the new answer is right. Each of these is a failure of **reproducibility**, and each has a mathematical component (random-number streams, floating-point non-associativity, ill-conditioning) as well as an organisational one (versions, environments, records). This section treats computations as *experiments* that must be designed, recorded and tested like laboratory measurements.

Levels of reproducibility

- **Repeatability (bitwise reproducibility):** the same code, data, parameters and environment produce bit-for-bit identical output.
- **Reproducibility:** a re-run by someone else, possibly on different hardware or library versions, produces results that agree *within a stated tolerance* justified by the numerical and statistical error analysis.
- **Replicability:** an independent implementation of the same method, or a new experiment, leads to the same scientific or engineering conclusion.

Bitwise repeatability is a debugging tool; reproducibility within tolerance is the engineering requirement.

Sources of irreproducibility

Source	Mechanism	Control
random numbers	different seeds, shared global generator, parallel streams overlapping	explicit seeded generators, independent spawned streams, seeds recorded
floating-point order	$(a+b)+c \neq a+(b+c)$; parallel reductions, multithreaded BLAS, vectorised loops, fused multiply–add, GPU atomics change the order	accept and bound the variation; deterministic modes where needed; compensated summation
library versions	changed algorithms, defaults (tolerances, orderings, pivoting thresholds), bug fixes	pinned versions, environment files, containers
ill-conditioning	tiny rounding differences amplified by κ	estimate κ; set test tolerances accordingly; reformulate
data and parameters	edited input files, manual steps, undocumented options	version control for code *and* inputs; configuration files; scripted pipelines
hardware and OS	different CPU instruction sets, math-library implementations of exp, sin	record platform; tolerance-based comparison

Floating-point non-associativity

Floating-point addition is commutative but not associative: each operation rounds, and the rounding depends on the operands' magnitudes (Ch. 22). Any change in the *order* of a reduction can therefore change the last few bits of the result — and multithreaded libraries choose the order dynamically, depending on the number of threads and on how the data are split.

Worked Example 24.41 — The order of a sum

(a) Compare $(0.1+0.2)+0.3$ with $0.1+(0.2+0.3)$, and $(10^{16}+1)-10^{16}$ with $(10^{16}-10^{16})+1$. (b) Sum 10^6 copies of 0.1 by a naive loop, by NumPy's `sum`, and by `math.fsum`. (c) Sum 10^6 standard-normal samples in forward, reversed and sorted order.

(a) $(0.1+0.2)+0.3 = 0.6000000000000001$ but $0.1+(0.2+0.3) = 0.6$. $(10^{16}+1)-10^{16} = 0$ (the spacing of doubles near 10^{16} is 2, so $10^{16}+1$ rounds back to 10^{16}), but $(10^{16}-10^{16})+1 = 1$.

(b) Naive loop: 100 000.000 001 332 88 (relative error 1.3×10^{-11}: each addition rounds, and errors accumulate roughly as $n\varepsilon$ in the worst case). NumPy `sum`: 100 000.000 000 000 03 — NumPy uses **pairwise summation**, whose error grows like $\varepsilon\log_2 n$. `math.fsum`: exactly 100 000.0, the correctly rounded sum of the stored values.

(c) Forward: 998.570 649 438 621 3; reversed: 998.570 649 438 621 4; sorted ascending: 998.570 649 438 654 1; `fsum`: 998.570 649 438 621 3. The results differ in the 12th–14th significant digit.

Reading. None of these is a bug. A test that compares such results with `==` will fail on another machine, or with a different thread count. Results that must agree should be compared with a tolerance derived from the error analysis — here about $n\varepsilon\max|x_i|/|\sum x_i|$, far larger than ε when there is cancellation. When bitwise repeatability matters (regression debugging, audit), fix the thread count, use deterministic library modes, or use compensated (Kahan) or exact summation in the few places that need it.

Random-number streams

Pseudo-random number generators (PRNGs) are deterministic: the same seed gives the same sequence. Reproducible Monte Carlo therefore requires that every random draw comes from a generator whose seed is chosen deliberately and recorded.

Seeded generators and independent streams

A **seed** is the initial state from which a PRNG's sequence is generated. A **stream** is the sequence produced by one generator. For parallel or multi-component simulations, each worker or component needs its own **statistically independent stream**, obtained not by seeds $1, 2, 3, \ldots$ chosen ad hoc but by a mechanism designed to avoid overlap and correlation — in NumPy, `SeedSequence.spawn`, which derives child seeds by hashing; in other libraries, jump-ahead or counter-based generators (Philox, Threefry).

```
import numpy as np
root = np.random.SeedSequence(20241021)          # record this number
children = root.spawn(8)                          # one per worker / per component group
rngs = [np.random.default_rng(s) for s in children]
# worker k draws only from rngs[k]; results are independent of scheduling
R1 = 1e3 * (1 + 0.01 * rngs[0].uniform(-1, 1, 10_000))
```

Three rules follow. Never use the legacy global generator (`np.random.seed`, `np.random.rand`): any library call that draws from it silently shifts every later draw. Never seed from the clock in production code (do it, if at all, once — and *log* the seed). And structure the draws so that adding a new random component does not change existing ones (give each component its own stream), so that a design change can be compared with the old design using **common random numbers** (Section 24.6).

Versions and environments

The result of a computation is a function of the code, its inputs and the environment — interpreter, libraries, compiler flags, hardware. All three must be pinned and recorded.

- **Version control** (git) for code, configuration and small input data. Every reported result should carry the commit hash of the code that produced it; a "dirty" working tree (uncommitted changes) should be flagged in the output.
- **Environment specification.** A `requirements.txt` with exact versions (`numpy==2.1.3`), a conda `environment.yml` or lock file, or a container image. Library defaults change: tolerances of iterative solvers, the default ordering of a sparse LU, the algorithm behind a random-number distribution. A pinned environment can be rebuilt; "latest" cannot.
- **Metadata with every output.** Write alongside each result file the parameters, the seeds, the commit hash, the library versions and the platform. This costs a few lines:

```
import json, platform, subprocess, numpy, scipy
meta = {
    "commit": subprocess.run(["git", "rev-parse", "HEAD"], capture_output=True, text=True).stdout.strip(),
    "numpy": numpy.__version__, "scipy": scipy.__version__,
    "python": platform.python_version(), "machine": platform.machine(),
    "seed": 20241021, "N": 100_000, "tolerance_model": "uniform, 1%",
}
json.dump(meta, open("results/mc_gain_meta.json", "w"), indent=2)
```

- **Scripted pipelines.** Figures and tables should be generated by scripts from raw data with a single command, not by interactive sessions or edits in a spreadsheet. A notebook is acceptable if it is run top to bottom from a clean kernel before results are recorded.

Testing numerical code

Numerical code fails silently: a wrong sign in a Jacobian slows Newton's method rather than crashing it; an off-by-one in a stencil changes the convergence order from 2 to 1 while still giving "reasonable" answers. Tests must therefore check *mathematical* properties, with tolerances justified by error analysis.

1. **Exact or analytic references.** Compare against cases with known solutions — a symbolic result (Section 24.2), a closed-form circuit response, a problem constructed so that the answer is known (data generated from known parameters, as in Worked Example 24.33).
2. **Convergence-order tests.** For a method of order p, the error behaves as Ch^p; halving h should divide it by 2^p. The **observed order** $p_{\text{obs}} = \log_2\big(e(h)/e(h/2)\big)$ is a far more sensitive check than the error itself.
3. **Method of manufactured solutions** (for ODE/PDE solvers): choose an arbitrary smooth solution $u^\ast$, substitute it into the equation to compute the source term that makes it exact, run the solver with that source, and verify both the error and its convergence order.
4. **Invariants and properties.** Kirchhoff's current law at every node (residual of $\mathbf{G}\mathbf{v} - \mathbf{i}$), symmetry and positive definiteness of matrices that must have them, reciprocity ($\mathbf{Z} = \mathbf{Z}^{\mathsf{T}}$ for passive networks), conservation of energy or charge, orthogonality of computed $\mathbf{Q}$. Property-based testing frameworks generate many random inputs and check such properties automatically.
5. **Regression tests.** Store reference outputs and compare future runs against them with a tolerance — catching unintended changes, not establishing correctness.
6. **Statistical tests for stochastic code.** A Monte Carlo estimate is a random variable; test that it lies within z standard errors of the known answer.

Worked Example 24.42 — An observed-order test for the trapezoidal rule

Test a trapezoidal-rule implementation on $\int_0^1 e^x\,dx = e - 1$ with $n = 10, 20, 40$ subintervals.

Errors. $T_{10} - I = 1.4317 \times 10^{-3}$, $T_{20} - I = 3.5796 \times 10^{-4}$, $T_{40} - I = 8.9493 \times 10^{-5}$.

Observed order. $\log_2(1.4317/0.35796) = \log_2(3.9996) = 1.9998$, and $\log_2(3.5796/0.89493) = 2.0000$ ✓ — the expected $p = 2$.

Leading constant. The Euler–Maclaurin formula predicts $T_n - I \approx \frac{h^2}{12}\big(f'(1) - f'(0)\big) = \frac{h^2}{12}(e - 1)$, i.e. 1.4319×10^{-3} for $h = 0.1$ ✓.

As a test. `assert abs(p_obs - 2) < 0.05`. A typical bug — weighting both end points by 1 instead of $\frac{1}{2}$ — gives an error of order h and $p_{\text{obs}} \approx 1$, which this test catches immediately even though T_{40} would still be correct to two digits.

Worked Example 24.43 — Setting tolerances for deterministic and stochastic tests

(a) A regression test checks the solution of a linear system with $\kappa(\mathbf{A}) \approx 10^6$ computed by LU. What relative tolerance is appropriate? (b) A Monte Carlo yield estimator is tested on a case with known yield $Y = 0.80$, using $N = 10^4$ samples. What acceptance band gives a false-failure probability below 10^{-4}?

(a) A backward-stable solver guarantees a relative error of about $\kappa\varepsilon \approx 10^6 \times 1.1 \times 10^{-16} \approx 10^{-10}$; differences between platforms or thread counts can be of this size. A tolerance of `rtol=1e-8` (a safety factor of 100) is appropriate; `rtol=1e-15` would fail spuriously, and `rtol=1e-3` would hide real bugs.

(b) The standard error is $\sqrt{0.8 \times 0.2/10^4} = 0.004$. Accepting $|\hat{Y} - 0.80| \le 4 \times 0.004 = 0.016$ has false-failure probability $2Q(4) = 6.3 \times 10^{-5}$ (a 3-standard-error band would fail spuriously 0.27% of the time — about once in every 370 runs of the test suite). With a fixed seed the test is also bitwise repeatable, but the band should still be set statistically, so that the test survives a legitimate change of seed or generator.

Rule. Tolerances come from error analysis: $\kappa\varepsilon$ for deterministic linear algebra, the truncation error Ch^p for discretisations, $z \cdot \mathrm{SE}$ for Monte Carlo. A tolerance chosen by trial and error ("1e-6 seemed to work") is a test that has not been designed.

```
import numpy as np
from numpy.testing import assert_allclose

def test_mc_gain_yield():
    rng = np.random.default_rng(7)
    N = 10_000
    R1 = 1e3 * (1 + 0.01 * rng.uniform(-1, 1, N))
    R2 = 9e3 * (1 + 0.01 * rng.uniform(-1, 1, N))
    G = 1 + R2 / R1
    Y = np.mean(np.abs(G - 10) <= 0.1)
    se = np.sqrt(Y * (1 - Y) / N)
    assert abs(Y - 0.80) < 4 * se          # reference 0.80 from a 10^6-sample run

def test_kcl_residual(G, v, i):
    assert_allclose(G @ v, i, rtol=1e-10, atol=1e-12)
```

Common Pitfall — the reference answer is also a computation

A regression test that compares a new result with an old one only shows that nothing *changed*. If the reference was produced by the same buggy code, the test enshrines the bug. Independent references — analytic results, a different algorithm (sparse versus dense solve, Monte Carlo versus linearisation), a published benchmark, or a measurement — are what establish correctness. Keep at least one independent check for every major result.

Common Pitfall — "it worked on my machine"

An analysis run in an interactive session with variables left over from earlier cells, a file edited by hand, a parameter changed and changed back, or an unrecorded library upgrade cannot be reproduced even by its author. The cure is mundane: scripts under version control, a pinned environment, a recorded seed, and a single command that regenerates every number in the report.

Engineering Note

In circuit design, reproducibility has an extra layer: the simulator version, the model files (PDK release), the simulator options (`reltol` , `abstol` , integration method, Gmin stepping) and the netlist all affect the numbers. Sign-off flows record all of them, and the same Monte Carlo seed is used for "before" and "after" runs of an engineering change so that differences reflect the design, not the sampling. Measurement laboratories accredited to ISO/IEC 17025 must document their uncertainty calculations (Section 24.8) and the software that performs them, which is validated like any other instrument.

Summary

Topic	Key formula or fact
Asymptotic cost	$f = O(g)$: $f \le cg$ for large n; scaling exponent $p \approx \ln(T_2/T_1)/\ln(n_2/n_1)$
Master theorem	$T = aT(n/b) + n^d$: n^d, $n^d \log n$ or $n^{\log_b a}$ as $d \gtrless \log_b a$
Typical costs	matrix–vector $2n^2$; matrix–matrix $2n^3$; LU $\tfrac{2}{3}n^3$; Cholesky $\tfrac{1}{3}n^3$; FFT $5N\log_2 N$; sparse matvec $2\,\mathrm{nnz}$
Expression swell	symbolic det has $n!$ terms; exact Newton doubles digits per step
Backward error (linear system)	$\eta = \|\mathbf{r}\|/(\|\mathbf{A}\|\|\hat{\mathbf{x}}\|)$; forward error $\lesssim \kappa\eta$
Householder reflector	$\mathbf{H} = \mathbf{I} - 2\mathbf{v}\mathbf{v}^{\mathsf{T}}/\mathbf{v}^{\mathsf{T}}\mathbf{v}$, $\mathbf{v} = \mathbf{a} + \operatorname{sign}(a_1)\|\mathbf{a}\|\mathbf{e}_1$
QR cost	$2mn^2 - \frac{2}{3}n^3$; backward stable; $\|\hat{\mathbf{Q}}^{\mathsf{T}}\hat{\mathbf{Q}} - \mathbf{I}\| = O(\varepsilon)$
Normal equations	$\kappa(\mathbf{A}^{\mathsf{T}}\mathbf{A}) = \kappa(\mathbf{A})^2$ — use QR or SVD
Truncated SVD	$\hat{\mathbf{x}}_k = \sum_{i\le k}(\mathbf{u}_i^{\mathsf{T}}\mathbf{b}/\sigma_i)\mathbf{v}_i$
Stationary iteration	$\mathbf{e}^{(k+1)} = \mathbf{T}\mathbf{e}^{(k)}$; converges iff $\rho(\mathbf{T}) < 1$; $k_\epsilon \approx \ln\epsilon/\ln\rho$
Model problem	$\rho_J = \cos\pi h$; $\rho_{GS} = \rho_J^2$
Optimal SOR	$\omega_{\text{opt}} = 2/(1+\sqrt{1-\rho_J^2})$, $\rho = \omega_{\text{opt}} - 1$
CG	$\|\mathbf{e}_k\|_{\mathbf{A}} \le 2\big(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\big)^k\|\mathbf{e}_0\|_{\mathbf{A}}$; $k \approx \frac{1}{2}\sqrt{\kappa}\ln(2/\epsilon)$
GMRES	minimises $\|\mathbf{r}_k\|_2$ over $\mathcal{K}_k$; exact in $\deg(\text{minimal polynomial})$ steps
Preconditioning	solve $\mathbf{P}^{-1}\mathbf{A}\mathbf{x} = \mathbf{P}^{-1}\mathbf{b}$ with $\mathbf{P} \approx \mathbf{A}$, $\mathbf{P}\mathbf{z} = \mathbf{r}$ cheap
Sparse storage	CSR/CSC: $2\,\mathrm{nnz} + n + 1$ words
Fill, 2-D grid	natural: $n^{3/2}$ fill, n^2 flops; nested dissection: $n\log n$ fill, $n^{3/2}$ flops
Monte Carlo	$\hat{\mu}_N = \frac{1}{N}\sum f(\mathbf{X}_i)$, $\mathrm{SE} = s_N/\sqrt{N}$
Control variate	$c^* = \mathrm{Cov}(f,h)/\mathrm{Var}(h)$; variance $\times(1-\rho^2)$
Importance sampling	$E_p[f] = E_q[f\,p/q]$
Rare event	relative SE $\approx 1/\sqrt{Np}$; $N \approx 100/p$ for 10%
Yield	$\hat{Y} = \#\text{pass}/N$, $\mathrm{SE} = \sqrt{\hat{Y}(1-\hat{Y})/N}$
Gauss–Newton	$(\mathbf{J}^{\mathsf{T}}\mathbf{J})\boldsymbol{\delta} = \mathbf{J}^{\mathsf{T}}\mathbf{r}$
Levenberg–Marquardt	$(\mathbf{J}^{\mathsf{T}}\mathbf{J} + \lambda\,\mathrm{diag}(\mathbf{J}^{\mathsf{T}}\mathbf{J}))\boldsymbol{\delta} = \mathbf{J}^{\mathsf{T}}\mathbf{r}$

Topic	Key formula or fact
Parameter covariance	$\hat{\sigma}^2(\mathbf{J}^\mathsf{T}\mathbf{J})^{-1}$, $\hat{\sigma}^2 = \sum r_i^2/(m-n)$
Relative sensitivity	$S_p^y = (p/y)\,\partial y/\partial p$
Complex step	$f'(x) \approx \mathrm{Im}\{f(x+jh)\}/h$, no cancellation
Adjoint sensitivity	$\mathbf{A}^\mathsf{T}\boldsymbol{\lambda} = \mathbf{c}$; $\partial y/\partial p = \boldsymbol{\lambda}^\mathsf{T}(\partial_p \mathbf{b} - \partial_p \mathbf{A}\,\mathbf{x})$; branch: $-(\lambda_a - \lambda_b)(v_a - v_b)$
GUM propagation	$u_c^2 = \sum c_i^2 u_i^2 + 2\sum_{i<j} c_i c_j u_{ij}$; $\mathbf{U}_y = \mathbf{J}\mathbf{U}_x\mathbf{J}^\mathsf{T}$; $U = k u_c$
Uniform tolerance	$\pm a \Rightarrow u = a/\sqrt{3}$
Observed order	$p_{\text{obs}} = \log_2\left(e(h)/e(h/2)\right)$
Test tolerances	$\kappa\varepsilon$ (linear algebra), Ch^p (discretisation), $z \cdot \mathrm{SE}$ (Monte Carlo)

Chapter 25 — Mathematical Modeling

> **Prerequisites:** Ch. 1 (Mathematical Language and Algebra), Ch. 4 (Differential Calculus), Ch. 6 (Multivariable Calculus), Ch. 8 (Matrices and Linear Systems), Ch. 11–12 (Ordinary and Linear Differential Equations), Ch. 14 (Laplace Transforms), Ch. 20 (Statistical Analysis), Ch. 22–23 (Numerical Methods, Optimization) **Learning outcomes:** After this chapter you can …
>
> - run the modeling cycle deliberately: state the purpose, choose the system boundary, write conservation laws and constitutive relations, and decide what to neglect;
> - separate state variables, parameters, inputs, disturbances and outputs, and put a lumped model into state-space form;
> - apply the Buckingham Pi theorem to reduce the number of variables in a problem and to obtain scaling laws without solving any equation;
> - nondimensionalize a model (RLC circuit, thermal network, heat equation, nonlinear oscillator) so that its behaviour is governed by a minimal set of dimensionless groups such as ζ, ω_n, Biot and Fourier numbers;
> - linearize a nonlinear model about an operating point, compute small-signal parameters, and estimate the amplitude range over which the linear model is trustworthy;
> - validate a model with residual analysis, goodness-of-fit measures and cross-validation, identify its parameters from step responses or by least squares, test identifiability, and choose between analytical and numerical solution.

Every chapter of this book has taken a mathematical problem as given: *solve this differential equation*, *invert this transform*, *minimize this function*. In engineering practice the problem is almost never given. Someone hands you a circuit board that oscillates when it should not, a sensor whose reading drifts with temperature, a transmission line whose losses are higher than the datasheet suggests, and the first and hardest step is to decide **which mathematics describes it**. That step is *mathematical modeling*.

Modeling is a craft as much as a science, but it is not mysterious. It has a recognisable cycle (Section 25.1), a vocabulary (25.2), a set of tools that extract information *before* any equation is solved (dimensional analysis and scaling, 25.3–25.4), a standard way to make hard problems tractable (linearization, 25.5), a discipline of stating and checking assumptions (25.6), and a way to confront the model with data — validating its structure (25.7) and estimating its numbers (25.8). The chapter ends with the choice every modeller faces between closed-form and computed solutions (25.9), and a short synthesis that ties the methods of the whole book together.

Because this is the final chapter, it leans on almost everything before it. Cross-references are given where a technique is used; the emphasis here is on *when* and *why* to use each one, not on re-deriving it.

25.1 Model formulation

What a model is, and what it is for

> **Mathematical model**
>
> A **mathematical model** of a system is a set of mathematical relations — algebraic equations, differential or difference equations, probability distributions, inequalities — together with a statement of the variables they relate, the assumptions under which they hold, and the purpose for which they are intended.

The last clause is the one most often forgotten. A model is a tool built for a job, and "Is the model correct?" is the wrong question; the right one is "Is the model *adequate for this purpose* over *this range of conditions*?" The same resistor is

- an ideal $v = Ri$ for a DC bias calculation,
- $v = R(T)\,i$ with $R(T) = R_0\,[1 + \alpha(T - T_0)]$ for a precision current shunt,
- R in series with a lead inductance L_s and in parallel with a pad capacitance C_p for a 2 GHz matching network,
- R plus a Johnson noise source with power spectral density $4kTR$ for a low-noise amplifier front end (Ch. 21).

None of these is "the" model of a resistor. Each is the simplest model that answers a particular question. George Box's often-quoted remark that all models are wrong but some are useful expresses exactly this point.

> **Engineering Note — the purpose fixes the fidelity**
>
> Before writing an equation, write one sentence: *"This model must predict ____ to within ____ for inputs in the range ____."* For example: "predict the junction temperature of Q3 to within 5 °C for dissipations from 0 to 25 W, on time scales longer than 1 s." That sentence decides the boundary, the time scale, the variables to keep and the accuracy needed from every parameter. Models built without it tend to be either too crude to answer the question or too elaborate to be understood, calibrated or trusted.

The modeling cycle

Modeling is iterative. A widely used description has six stages:

1. **Problem statement and purpose.** What question must the model answer? What accuracy, what operating range, what time scale?
2. **Conceptualization.** Choose the system boundary, identify the inputs crossing it and the outputs of interest, and decide which physical effects matter. Sketch an idealized system (a circuit diagram, a lumped thermal network, a free-body diagram).
3. **Mathematical formulation.** Write the governing equations: conservation laws plus constitutive relations, with initial and boundary conditions.
4. **Analysis and solution.** Simplify (dimensional analysis, scaling, linearization), then solve — analytically or numerically.
5. **Validation.** Compare predictions with independent measurements. Are the residuals consistent with measurement noise? Does the model work on data not used to build it?

6. **Use and refinement.** Use the model for design or prediction; when it fails, return to stage 2 or 3 with what the failure taught.

$$\text{purpose} \;\to\; \text{concept} \;\to\; \text{equations} \;\to\; \text{solution} \;\to\; \text{validation} \;\to\; \text{use} \;\circlearrowleft$$

The loop back is essential. The first model is rarely the last; but a *documented* first model, with explicit assumptions, is the only thing that can be systematically improved.

Building blocks: conservation laws and constitutive relations

Almost every physical model in electrical engineering is assembled from two kinds of equation.

Balance (conservation) law and constitutive relation

A **balance law** states that the rate of change of an extensive quantity inside a boundary equals its net inflow plus its internal production:

$$\frac{d}{dt}(\text{amount inside}) = (\text{rate in}) - (\text{rate out}) + (\text{rate generated}).$$

A **constitutive relation** characterises a particular material or component: it links the *flow* of the conserved quantity to the *effort* (potential difference) that drives it, or links the stored amount to the effort.

Balance laws are universal and exact (within classical physics); constitutive relations are empirical, approximate and valid over limited ranges. That asymmetry tells you where model error usually lives: in the constitutive relations and in what was left out, rather than in the conservation laws themselves.

Domain	Conserved quantity	Effort (potential)	Flow	Storage relation	Dissipation relation
Electrical	charge q	voltage v	current i	$q = Cv$	$v = Ri$
Magnetic (flux linkage)	flux linkage λ	—	—	$\lambda = Li$	—
Thermal	heat Q	temperature T	heat flow P	$Q = C_{\text{th}}T$	$\Delta T = R_{\text{th}}P$
Mechanical (translation)	momentum p	velocity v	force F	$p = mv$	$F = bv$
Mechanical (rotation)	angular momentum	angular velocity ω	torque τ	$J\omega$	$\tau = b\omega$
Fluid	volume V	pressure p	volume flow Q	$V = C_f\,p$	$p = R_f\,Q$

Kirchhoff's current law is charge conservation at a node; Kirchhoff's voltage law is energy conservation around a loop (in the quasi-static, lumped regime of Section 25.6). The *analogy* across domains is not decorative: it lets an electrical engineer write the thermal model of a heat sink or the mechanical model of a motor shaft as an equivalent circuit, and reuse every circuit-analysis technique of Ch. 12 and Ch. 14.

Levels of description

Models can be classified along several independent axes. Choosing a position on each axis is part of formulation.

Axis	Choices	Mathematics that results
Spatial	lumped / distributed	ODEs (Ch. 11–12) / PDEs (Ch. 13)
Time	static / dynamic; continuous / discrete	algebraic / differential / difference equations (Ch. 17)
Linearity	linear / nonlinear	superposition, transforms (Ch. 14–17) / iteration, simulation (Ch. 22)
Time dependence of parameters	time-invariant / time-varying	constant-coefficient / variable-coefficient equations
Certainty	deterministic / stochastic	ODEs / random processes (Ch. 21)
Origin	white-box (physics) / grey-box / black-box (data)	first-principles equations / fitted structure / regression, ARX, neural nets

A **white-box** model is derived entirely from physical laws with parameters known from geometry and material data. A **black-box** model is a flexible input–output relation fitted to data with no physical interpretation of its coefficients. Most useful engineering models are **grey-box**: the structure comes from physics (a first-order thermal lag, a second-order mechanical resonance), and the parameter values come from measurement (Section 25.8).

Worked Example 25.1 — An RC charging model from first principles

Problem. A sensor node draws its supply from a capacitor $C = 100\ \mu\text{F}$ charged through a resistor $R = 1\ \text{k}\Omega$ from a source $V_s = 5\ \text{V}$ that is switched on at $t = 0$. The load draws a constant current $I_L = 1\ \text{mA}$. Formulate a model for the capacitor voltage $v(t)$ and find its steady state and time constant.

Step 1 — purpose. Predict $v(t)$ to a few percent over the first second after switch-on, to check the node can start when $v > 3\ \text{V}$.

Step 2 — concept. Boundary: the capacitor node. Inputs: V_s (switched), I_L. Neglect capacitor leakage and equivalent series resistance (justified later if the leakage current is $\ll I_L$).

Step 3 — equations. Charge balance at the node (KCL):

$$C\frac{dv}{dt} = \frac{V_s - v}{R} - I_L, \qquad v(0) = 0.$$

Rearranged:

$$RC\,\frac{dv}{dt} + v = V_s - RI_L.$$

Step 4 — solution. This is the standard first-order linear equation of Ch. 11 with time constant $\tau = RC = 10^3 \times 10^{-4} = 0.1\ \text{s}$ and steady state $v_\infty = V_s - RI_L = 5 - 1 = 4\ \text{V}$:

$$v(t) = v_\infty\left(1 - e^{-t/\tau}\right) = 4\left(1 - e^{-t/0.1}\right)\ \text{V}.$$

Step 5 — use. The node reaches 3 V when $1 - e^{-t/\tau} = 0.75$, i.e. $t = \tau \ln 4 = 0.139\ \text{s}$.

Dimensional check. $[RC] = (\text{V/A})(\text{A s/V}) = \text{s}$ and $[RI_L] = \text{V}$, so every term has the right units.

The example is elementary on purpose: notice that the mathematics (Step 4) occupied one line, while purpose, boundary and assumptions occupied the rest. That proportion is typical of real modeling.

Worked Example 25.2 — A lumped thermal model of a power transistor

Problem. A MOSFET dissipating $P = 20\ \text{W}$ is mounted on a heat sink in ambient air at $T_a = 40\ ^\circ\text{C}$. Datasheets give the junction-to-case resistance $R_{jc} = 1.5\ \text{K/W}$, the interface (thermal pad) resistance $R_{cs} = 0.5\ \text{K/W}$ and the sink-to-ambient resistance $R_{sa} = 2.0\ \text{K/W}$. The heat sink (aluminium, $m = 0.25\ \text{kg}$, $c_p = 900\ \text{J/(kg K)}$) has much larger heat capacity than the transistor package. Formulate a model for the junction temperature after power is applied.

Concept. Heat flows junction → case → sink → ambient through three series resistances. Heat is *stored* mainly in the sink, with thermal capacitance $C_s = mc_p = 0.25 \times 900 = 225\ \text{J/K}$. Neglect the package's own capacitance (it charges in seconds, while the sink takes minutes).

Equations. Energy balance on the sink, with sink temperature T_s:

$$C_s\frac{dT_s}{dt} = P - \frac{T_s - T_a}{R_{sa}},$$

and, because the package stores negligible heat, the full P flows through $R_{jc} + R_{cs}$ at every instant:

$$T_j = T_s + (R_{jc} + R_{cs})P.$$

Solution. With $T_s(0) = T_a$, the sink equation is first order with $\tau = R_{sa}C_s = 2.0 \times 225 = 450\ \text{s}$ and

$$T_s(t) = T_a + PR_{sa}\left(1 - e^{-t/\tau}\right).$$

Hence

$$T_j(t) = T_a + (R_{jc} + R_{cs})P + R_{sa}P\left(1 - e^{-t/\tau}\right) = 40 + 40 + 40\left(1 - e^{-t/450}\right)\ ^\circ\text{C}.$$

At switch-on the junction jumps (on the model's time scale) to 80 °C, and it approaches 120 °C with a 7.5-minute time constant.

What the model omits. The instantaneous jump is an artefact of neglecting the package capacitance; on a millisecond time scale the junction rises smoothly. That is acceptable for the stated purpose (steady state and minutes-scale warm-up) but would be wrong for a 10 ms overload pulse — there the package capacitance is the *only* thing that matters. Same device, different purpose, different model.

Worked Example 25.3 — An electromechanical model: the DC motor

Problem. Formulate a model for a permanent-magnet DC motor driven by voltage $v_a(t)$ and loaded by torque $\tau_L(t)$, suitable for designing a speed controller.

Concept. Two coupled domains. Electrical: armature resistance R_a, inductance L_a, and back-EMF proportional to speed. Mechanical: rotor and load inertia J, viscous friction b. Coupling: the torque constant K_t (torque per ampere) and back-EMF constant K_e (volts per rad/s). Energy conservation across the air gap (electrical power $e\,i$ converted equals mechanical power $\tau\omega$) forces $K_t = K_e \equiv K$ in SI units.

Equations. KVL round the armature and Newton's law for rotation:

$$L_a \frac{di}{dt} = v_a - R_a i - K\omega,$$
$$J \frac{d\omega}{dt} = K i - b\omega - \tau_L.$$

If shaft position θ is also wanted, add $\dot{\theta} = \omega$.

Check. Units: $[K\omega] = (\mathrm{V\,s/rad})(\mathrm{rad/s}) = \mathrm{V}$; $[Ki] = (\mathrm{N\,m/A})(\mathrm{A}) = \mathrm{N\,m}$; and $\mathrm{V\,s} = \mathrm{N\,m/A}$ since $1\ \mathrm{V\,A} = 1\ \mathrm{W} = 1\ \mathrm{N\,m/s}$. Steady state with $\tau_L = 0$: $\omega_\infty = K v_a / (R_a b + K^2)$, which is the familiar no-load speed when b is small, $\omega_\infty \approx v_a / K$.

This model is linear only because friction was taken viscous. Real gearboxes add Coulomb friction $\tau_c\,\mathrm{sgn}(\omega)$, which is nonlinear and discontinuous at $\omega = 0$ — the reason speed controllers behave poorly near standstill. Whether to include it depends, once again, on the purpose.

Common Pitfall — modeling the device instead of the question

A frequent failure is to start from "let us model everything about the motor": winding temperature, magnetic saturation, brush arcing, cogging torque, shaft flexibility. The result has dozens of parameters, most unknown, and no-one can tell which effects drive the answer. Start with the simplest model that could possibly answer the question; add an effect only when validation (Section 25.7) shows the simple model fails *in a way that effect explains*.

25.2 State variables and parameters

Five kinds of quantity

Once a model is written down, every symbol in it plays one of a small number of roles. Getting the roles straight is what turns a page of equations into something that can be simulated, identified and controlled.

Roles of quantities in a model

- **State variables** $\mathbf{x}(t) \in \mathbb{R}^n$: the minimal set of quantities whose present values, together with future inputs, determine all future behaviour. They carry the system's *memory*.
- **Inputs** $\mathbf{u}(t)$: externally imposed signals that the modeller (or a controller) chooses — a drive voltage, a commanded current, a heater power.
- **Disturbances** $\mathbf{w}(t)$: external signals that act on the system but are *not* chosen — ambient temperature, load torque, supply ripple, noise.
- **Parameters** $\mathbf{p}$: quantities that characterise the system and are constant (or vary much more slowly than the states) over the time scale of interest — R, L, C, J, K, R_{th}.
- **Outputs** $\mathbf{y}(t)$: quantities that are measured or are of interest; functions of the states and inputs.

The general lumped, continuous-time model is

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, \mathbf{w}; \mathbf{p}, t), \qquad \mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u}; \mathbf{p}, t), \qquad \mathbf{x}(t_0) = \mathbf{x}_0.$$

Constants that are *universal* — π, the Boltzmann constant k, the elementary charge q — are sometimes called **constants** to distinguish them from parameters, which belong to a particular device.

The distinction between a parameter and a state is a matter of *time scale*, not of physics. The temperature of a resistor is a parameter in a circuit simulation lasting a microsecond, because it cannot change appreciably in that time; it is a state in a thermal simulation lasting an hour. The same goes for battery state of charge, capacitor ageing, or a slowly drifting oscillator frequency. A useful rule:

Engineering Note — parameter or state?

If a quantity changes by less than the required model accuracy over the time window of interest, treat it as a parameter. If it changes by more, it must be a state with its own equation, or the model must be re-identified as it drifts (adaptive or gain-scheduled models).

The distinction between an input and a disturbance is a matter of *control*. Ambient temperature is a disturbance for an amplifier, but an input for the environmental chamber used to test it.

Why states: the state-space form

The state-space form $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$ is the standard because

- it is first order, so every numerical ODE solver of Ch. 22 accepts it directly;
- its linear version $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ is analysed by the eigenvalue methods of Ch. 10 (modes, stability) and the matrix exponential;
- the initial condition $\mathbf{x}(t_0)$ is exactly the information needed — no more, no less.

For linear time-invariant (LTI) systems,

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}, \qquad \mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u},$$

with solution

$$\mathbf{x}(t) = e^{\mathbf{A}t}\mathbf{x}(0) + \int_0^t e^{\mathbf{A}(t-\tau)}\mathbf{B}\mathbf{u}(\tau)\,d\tau$$

and transfer function (Ch. 14), for zero initial state,

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}.$$

The poles of $\mathbf{G}(s)$ are among the eigenvalues of $\mathbf{A}$; they coincide with all of them when the realization is minimal (controllable and observable).

Choosing state variables

Natural state variables for lumped physical systems

In a lumped network of ideal elements, a natural choice of states is one *energy variable per independent energy-storage element*: the capacitor voltages (or charges) and inductor currents (or flux linkages) in a circuit; the masses' velocities and springs' deflections in a mechanism; the node temperatures of thermal capacitances. The stored energy is then a quadratic form in the states, e.g. $E = \tfrac{1}{2}\sum C_k v_k^2 + \tfrac{1}{2}\sum L_m i_m^2$.

Why it works (sketch). The constitutive relations of storage elements are the only ones involving derivatives ($i = C\,dv/dt$, $v = L\,di/dt$). Resistive elements and Kirchhoff's laws are algebraic. Solving the algebraic equations for the capacitor currents and inductor voltages in terms of the capacitor voltages, inductor currents and sources gives exactly $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$.

The word *independent* matters. Two capacitors directly in parallel share one voltage and contribute one state; a loop consisting only of capacitors and voltage sources, or a cut-set consisting only of inductors and current sources, removes a state. Such configurations are called **degenerate**; the order of the network is

$$n = n_C + n_L - n_{\text{C-loops}} - n_{\text{L-cutsets}},$$

where $n_{\text{C-loops}}$ counts independent loops of capacitors (and voltage sources only) and $n_{\text{L-cutsets}}$ counts independent cut-sets of inductors (and current sources only).

States are not unique. Any invertible linear transformation $\mathbf{z} = \mathbf{T}\mathbf{x}$ gives an equally valid state vector, with

$$\dot{\mathbf{z}} = \mathbf{T}\mathbf{A}\mathbf{T}^{-1}\mathbf{z} + \mathbf{T}\mathbf{B}\mathbf{u}, \qquad \mathbf{y} = \mathbf{C}\mathbf{T}^{-1}\mathbf{z} + \mathbf{D}\mathbf{u}.$$

The eigenvalues ($\mathbf{T}\mathbf{A}\mathbf{T}^{-1}$ is similar to $\mathbf{A}$, Ch. 10) and the transfer function are unchanged: $\mathbf{C}\mathbf{T}^{-1}(s\mathbf{I} - \mathbf{T}\mathbf{A}\mathbf{T}^{-1})^{-1}\mathbf{T}\mathbf{B} = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$. What changes is interpretability and numerical conditioning — physical states with similar magnitudes are usually the best-conditioned choice.

Worked Example 25.4 — State-space model of the series RLC circuit

Problem. A series RLC circuit with $R = 10\ \Omega$, $L = 1$ mH, $C = 1\ \mu$F is driven by $v_s(t)$. The output is the capacitor voltage. Write the state-space model, find the eigenvalues and interpret them.

States. One capacitor and one inductor, no degeneracy: $n = 2$, $\mathbf{x} = [v_C,\ i]^{\mathsf{T}}$.

Equations. Capacitor: $C\dot{v}_C = i$. KVL: $L\dot{i} = v_s - Ri - v_C$. Hence

$$\frac{d}{dt}\begin{bmatrix} v_C \\ i \end{bmatrix} = \begin{bmatrix} 0 & 1/C \\ -1/L & -R/L \end{bmatrix}\begin{bmatrix} v_C \\ i \end{bmatrix} + \begin{bmatrix} 0 \\ 1/L \end{bmatrix} v_s, \qquad y = \begin{bmatrix} 1 & 0 \end{bmatrix}\mathbf{x}.$$

Eigenvalues. $\det(\lambda\mathbf{I} - \mathbf{A}) = \lambda^2 + (R/L)\lambda + 1/(LC) = 0$. Numerically $R/L = 10^4\ \text{s}^{-1}$ and $1/(LC) = 10^9\ \text{s}^{-2}$, so

$$\lambda = -5000 \pm j\sqrt{10^9 - 2.5\times 10^7} = -5000 \pm j\,31\,225\ \text{s}^{-1}.$$

The real part gives an envelope decay time $1/5000 = 0.2$ ms; the imaginary part gives a ringing frequency $31\,225/(2\pi) = 4.97$ kHz.

Transfer function. $G(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} = \dfrac{1/(LC)}{s^2 + (R/L)s + 1/(LC)}$, the standard second-order low-pass form whose dimensionless parameters are extracted in Section 25.4.

Worked Example 25.5 — Counting states in a degenerate circuit

Problem. A voltage source v_s feeds a resistor R_1 into node A. Node A has capacitor C_1 to ground and capacitor C_2 to node B; node B has C_3 to ground and R_2 to ground. How many states? Now suppose R_1 is removed so the source connects directly to node A. How many states?

Case 1. Three capacitors. Is there a loop of capacitors only? The loop ground–C_1–A–C_2–B–C_3–ground contains only capacitors, so $n_{\text{C-loops}} = 1$ and $n = 3 - 1 = 2$. Indeed $v_{C_1} = v_{C_2} + v_{C_3}$ (KVL round the loop), so only two capacitor voltages are independent; choose $\mathbf{x} = [v_{C_1}, v_{C_3}]^{\mathsf{T}}$.

Case 2. With the source wired straight to node A, $v_{C_1} = v_s$ is now forced: the loop source–C_1 is a second loop of capacitors and voltage sources only. So $n = 3 - 2 = 1$, with state v_{C_3} (and $v_{C_2} = v_s - v_{C_3}$).

Consequence. In case 2 a step in v_s produces an *impulse* of current into C_1 and C_2 — the ideal model predicts infinite current. A circuit simulator will either fail or insert a tiny series resistance. The degeneracy is a symptom of an idealization (zero source resistance) that is invalid on short time scales, and is a reminder that assumptions must be checked (Section 25.6).

Worked Example 25.6 — Changing state coordinates for the DC motor

Problem. For the DC motor of Example 25.3 with $\tau_L = 0$, the states $\mathbf{x} = [i,\ \omega]^{\mathsf{T}}$ give

$$\mathbf{A} = \begin{bmatrix} -R_a/L_a & -K/L_a \\ K/J & -b/J \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 1/L_a \\ 0 \end{bmatrix}.$$

Use instead the momentum-like states $\mathbf{z} = [\lambda,\ h]^{\mathsf{T}} = [L_a i,\ J\omega]^{\mathsf{T}}$ (flux linkage and angular momentum). Find the new matrices and confirm the eigenvalues are unchanged. Use $R_a = 2\ \Omega$, $L_a = 5$ mH, $K = 0.05$ V s/rad, $J = 2 \times 10^{-5}$ kg m^2, $b = 10^{-5}$ N m s/rad.

Transformation. $\mathbf{T} = \operatorname{diag}(L_a, J)$, so

$$\mathbf{T}\mathbf{A}\mathbf{T}^{-1} = \begin{bmatrix} -R_a/L_a & -K/J \\ K/L_a & -b/J \end{bmatrix}, \qquad \mathbf{T}\mathbf{B} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}.$$

In the new coordinates the input enters with unit gain ($\dot\lambda = v_a - \dots$), which is the energy-based (port-Hamiltonian) form preferred in some control designs.

Eigenvalues. Trace $= -R_a/L_a - b/J = -400 - 0.5 = -400.5\ \text{s}^{-1}$; determinant $= (R_a b + K^2)/(L_a J) = (2 \times 10^{-5} + 2.5 \times 10^{-3})/(10^{-7}) = 25\,200\ \text{s}^{-2}$. Both matrices share trace and determinant, so both give

$$\lambda^2 + 400.5\lambda + 25\,200 = 0 \ \Rightarrow\ \lambda = \frac{-400.5 \pm \sqrt{400.5^2 - 4(25\,200)}}{2} = \frac{-400.5 \pm 244.1}{2},$$

that is $\lambda_1 \approx -78.2\ \text{s}^{-1}$ and $\lambda_2 \approx -322.3\ \text{s}^{-1}$. The slow mode (time constant 12.8 ms) is essentially mechanical, related to $JR_a/K^2 = 16$ ms; the fast mode (3.1 ms) is essentially electrical, related to $L_a/R_a = 2.5$ ms. Because the domains are coupled through K, neither eigenvalue equals the naive single-domain estimate — a small but genuine lesson about decoupled "back-of-envelope" models.

Common Pitfall — treating a derivative of an input as a state

In a model like $\ddot y + a\dot y + by = c\dot u + du$, it is tempting to take $\mathbf{x} = [y, \dot y]^{\mathsf{T}}$. Then $\ddot y$ contains $\dot u$, and the "state equation" needs the derivative of the input — which does not exist for a step input. The fix is a proper realization (e.g. controllable canonical form, Ch. 14) in which the states are internal variables and u enters without differentiation; the output is then $y = \mathbf{C}\mathbf{x}$ with $\mathbf{C} = [d,\ c]$.

Algebraic variables and DAEs

Many models contain variables that obey *algebraic* rather than differential equations: node voltages with no capacitor, currents through resistors, a junction temperature determined by an instantaneous heat flow (Example 25.2). The full model is then a **differential-algebraic equation** (DAE)

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{z}, \mathbf{u}), \qquad \mathbf{0} = \mathbf{g}(\mathbf{x}, \mathbf{z}, \mathbf{u}),$$

with differential states $\mathbf{x}$ and algebraic variables $\mathbf{z}$. If $\partial \mathbf{g}/\partial \mathbf{z}$ is invertible (an *index-1* DAE), the implicit function theorem (Ch. 6) lets us eliminate $\mathbf{z}$ locally and recover an ODE. Circuit simulators of the SPICE family solve the DAE form directly using modified nodal analysis, because eliminating every algebraic variable by hand would destroy the sparsity of the network equations.

Discrete-time states

Sampled-data systems and digital filters have states that evolve by a difference equation,

$$\mathbf{x}[n+1] = \mathbf{A}_d\mathbf{x}[n] + \mathbf{B}_d\mathbf{u}[n], \qquad \mathbf{y}[n] = \mathbf{C}\mathbf{x}[n] + \mathbf{D}\mathbf{u}[n].$$

For a continuous plant whose input is held constant between samples (zero-order hold) at period T, the exact discretization is $\mathbf{A}_d = e^{\mathbf{A}T}$ and $\mathbf{B}_d = \int_0^T e^{\mathbf{A}\sigma}\,d\sigma\,\mathbf{B}$; the eigenvalues map as $z = e^{sT}$ (Ch. 17). The states of a digital filter are its delay-line contents; the parameters are its coefficients.

25.3 Dimensional analysis

Motivation: information for free

Before solving a single equation — sometimes before even knowing the equations — one can deduce the *form* of a physical relation from the requirement that it be dimensionally consistent. Dimensional analysis

- detects errors (an equation that adds volts to amperes is wrong, full stop);
- reduces the number of variables an experiment or simulation must sweep, often dramatically;
- yields **scaling laws** ("double the length, quadruple the radiated power") that guide design before detailed analysis;
- organises results into dimensionless groups that are universal across sizes and materials.

Chapter 1 introduced dimensional consistency as an error check. This section turns it into a method.

Dimensions, units and homogeneity

Dimension, base dimensions, dimensional formula

A **dimension** is a physical kind of quantity (length, mass, time…); a **unit** is a particular standard amount of it (metre, kilogram, second). The SI uses seven **base dimensions**; for electrical engineering four or five suffice: mass M, length L, time T, current I, and temperature Θ. Every derived quantity Q has a **dimensional formula**

$$[Q] = \mathrm{M}^{a_1}\mathrm{L}^{a_2}\mathrm{T}^{a_3}\mathrm{I}^{a_4}\Theta^{a_5},$$

and the exponent vector $(a_1, \dots, a_5)$ is its **dimension vector**. A quantity is **dimensionless** if all exponents are zero.

Some dimension vectors used constantly in EE:

Quantity	SI unit	M	L	T	I	Θ
Voltage V	V	1	2	−3	−1	0
Resistance R	Ω	1	2	−3	−2	0
Capacitance C	F	−1	−2	4	2	0
Inductance L	H	1	2	−2	−2	0
Permittivity ε	F/m	−1	−3	4	2	0
Permeability μ	H/m	1	1	−2	−2	0
Conductivity σ	S/m	−1	−3	3	2	0
Power P	W	1	2	−3	0	0
Thermal resistance R_{th}	K/W	−1	−2	3	0	1
Thermal conductivity k	W/(m K)	1	1	−3	0	−1
Heat-transfer coefficient h	W/(m² K)	1	0	−3	0	−1

Principle of dimensional homogeneity

A physically meaningful equation must have the same dimensions in every additive term. Consequently, the arguments of transcendental functions (exp, ln, sin, …) must be dimensionless, and any relation among physical quantities can be rearranged so that it relates dimensionless combinations only.

The first sentence is the error check of Ch. 1. The second is the seed of the Pi theorem: a law of nature cannot depend on whether we measure in metres or feet, so it must be expressible in quantities that do not change when units change — dimensionless groups.

The Buckingham Pi theorem

Buckingham Pi theorem

Suppose a physical relation involves n quantities $Q_1, \dots, Q_n$,

$$f(Q_1, Q_2, \dots, Q_n) = 0,$$

and is dimensionally homogeneous. Let $\mathbf{D}$ be the $k \times n$ **dimension matrix** whose column i is the dimension vector of Q_i, and let $r = \operatorname{rank}\mathbf{D}$. Then the relation is equivalent to one among $n - r$ independent dimensionless products

$$F(\Pi_1, \Pi_2, \dots, \Pi_{n-r}) = 0, \qquad \Pi_m = Q_1^{a_{1m}} Q_2^{a_{2m}} \cdots Q_n^{a_{nm}},$$

where the exponent vectors $\mathbf{a}_m = (a_{1m}, \dots, a_{nm})^{\mathsf{T}}$ form a basis of the null space of $\mathbf{D}$.

Proof sketch. A product $\Pi = \prod Q_i^{a_i}$ has dimension vector $\mathbf{D}\mathbf{a}$, so it is dimensionless exactly when $\mathbf{D}\mathbf{a} = \mathbf{0}$. By the rank–nullity theorem (Ch. 9) the null space has dimension $n - r$, so there are exactly $n - r$ independent dimensionless products; any other dimensionless product is a product of powers of these. Now pick r of the quantities whose dimension vectors are linearly independent (the **repeating variables**). Changing the size of each base unit rescales every Q_i by a factor, and because the repeating variables span the dimension space, units can be chosen so that each repeating variable has numerical value 1. In those units the relation $f = 0$ depends only on the remaining $n - r$ quantities, whose numerical values are now precisely the Π groups. Since the physical relation cannot depend on the choice of units, it must be a relation among the Π's alone. $\square$

The theorem's power lies in the count: a relation among n quantities becomes one among $n - r$ groups. A function of one variable needs one curve to describe it; a function of zero variables is just a constant.

Procedure — applying the Pi theorem

1. **List** every quantity that could influence the result, including the result itself. Omitting a relevant quantity is the main way the method fails.
2. **Write** the dimension matrix $\mathbf{D}$ and find its rank r.
3. **Choose** r repeating variables with independent dimensions, preferably those that are "given" (geometry, material constants), not the unknown.
4. **Form** each remaining quantity into a Π by multiplying by powers of the repeating variables and solving the linear equations for the exponents that make it dimensionless. (Equivalently: compute a null-space basis of $\mathbf{D}$.)
5. **Write** the result as $\Pi_1 = \Phi(\Pi_2, \dots, \Pi_{n-r})$ with the unknown in Π_1, and determine Φ by theory, simulation or experiment.

Worked Example 25.7 — The period of a pendulum

Problem. A simple pendulum has bob mass m, length ℓ, release angle θ_0, in gravity g. Find the form of the period T_p.

List. $T_p, m, \ell, g, \theta_0$: $n = 5$.

Dimension matrix (rows M, L, T):

$$\mathbf{D} = \begin{array}{c|ccccc} & T_p & m & \ell & g & \theta_0 \\ \hline \mathrm{M} & 0 & 1 & 0 & 0 & 0 \\ \mathrm{L} & 0 & 0 & 1 & 1 & 0 \\ \mathrm{T} & 1 & 0 & 0 & -2 & 0 \end{array}$$

The columns of m, ℓ, g are independent, so $r = 3$ and there are $5 - 3 = 2$ groups.

Groups. θ_0 (an angle, radians, is already dimensionless): $\Pi_2 = \theta_0$. For T_p, try $\Pi_1 = T_p\, m^a \ell^b g^c$: M: $a = 0$; L: $b + c = 0$; T: $1 - 2c = 0$. So $c = \tfrac{1}{2}$, $b = -\tfrac{1}{2}$:

$$\Pi_1 = T_p \sqrt{\frac{g}{\ell}}, \qquad T_p = \sqrt{\frac{\ell}{g}}\, \Phi(\theta_0).$$

Conclusions without solving anything. (i) The period is independent of the mass — no dimensionless group can contain m, because m is the only quantity carrying M. (ii) It scales as $\sqrt{\ell}$: a pendulum four times longer swings half as fast. (iii) Only one curve $\Phi(\theta_0)$ need be measured. Solving the ODE (Section 25.5) gives $\Phi(0) = 2\pi$ and $\Phi(\theta_0) = 4K(\sin(\theta_0/2))$ in terms of the complete elliptic integral K; dimensional analysis cannot find the constant 2π, but it found everything else.

Worked Example 25.8 — Dimensionless groups of the RLC circuit

Problem. The free response of a series RLC circuit is characterised by a frequency ω (any characteristic frequency). Which dimensionless groups govern it?

List. ω, L, C, R: $n = 4$. **Dimension matrix** (rows M, L, T, I):

$$\mathbf{D} = \begin{array}{c|cccc} & \omega & L & C & R \\ \hline \mathrm{M} & 0 & 1 & -1 & 1 \\ \mathrm{L} & 0 & 2 & -2 & 2 \\ \mathrm{T} & -1 & -2 & 4 & -3 \\ \mathrm{I} & 0 & -2 & 2 & -2 \end{array}$$

Rows M, L and I are proportional (each component appears only through the combination $\mathrm{ML^2I^{-2}}$), so $r = 2$ and there are $4 - 2 = 2$ groups even though four base dimensions appear. This is why the rank, not the number of base dimensions, must be used.

Null space. Solving $\mathbf{D}\mathbf{a} = \mathbf{0}$ gives basis vectors $(2, 1, 1, 0)$ and $(0, -1, 1, 2)$ for (ω, L, C, R) — the second equivalent, after taking a square root, to $(0, -\tfrac{1}{2}, \tfrac{1}{2}, 1)$. Hence

$$\Pi_1 = \omega^2 LC \;\to\; \omega\sqrt{LC}, \qquad \Pi_2 = R\sqrt{\frac{C}{L}}.$$

Any characteristic frequency is therefore $\omega = \Phi\!\left(R\sqrt{C/L}\right)/\sqrt{LC}$. Section 25.4 shows these are exactly $\omega_n = 1/\sqrt{LC}$ and $\zeta = \tfrac{1}{2}R\sqrt{C/L}$; the damped frequency $\omega_d = \omega_n\sqrt{1-\zeta^2}$ is one instance of the general form.

Worked Example 25.9 — Skin depth from dimensions alone

Problem. At angular frequency ω, current in a conductor of conductivity σ and permeability μ concentrates in a surface layer of thickness δ. Assuming δ depends only on ω, μ, σ, find its form and estimate the scaling with frequency.

List and matrix. $n = 4$: $\delta, \omega, \mu, \sigma$. Rows M, L, T, I:

$$\mathbf{D} = \begin{array}{c|cccc} & \delta & \omega & \mu & \sigma \\ \hline \mathrm{M} & 0 & 0 & 1 & -1 \\ \mathrm{L} & 1 & 0 & 1 & -3 \\ \mathrm{T} & 0 & -1 & -2 & 3 \\ \mathrm{I} & 0 & 0 & -2 & 2 \end{array}$$

Rank $r = 3$, so a single group exists. Try $\delta^2 \omega^a \mu^b \sigma^c$. M: $b - c = 0$; I: $-2b + 2c = 0$; L: $2 + b - 3c = 0 \Rightarrow c = 1, b = 1$; T: $-a - 2b + 3c = 0 \Rightarrow a = 1$. So

$$\Pi = \delta^2 \omega \mu \sigma = \text{const} \quad\Longrightarrow\quad \delta = \frac{c_0}{\sqrt{\omega\mu\sigma}}.$$

With one group and no other, Φ is a pure constant. Solving the diffusion equation for the field in the conductor (Ch. 13) gives $c_0 = \sqrt{2}$, i.e. $\delta = \sqrt{2/(\omega\mu\sigma)}$.

Numbers. For copper, $\sigma = 5.8 \times 10^7$ S/m, $\mu = \mu_0$: $\delta = 8.53$ mm at 60 Hz, 66 μm at 1 MHz, 2.09 μm at 1 GHz — every factor of 100 in frequency shrinks δ by 10, exactly as $\delta \propto \omega^{-1/2}$ demands.

Worked Example 25.10 — Radiated power of a short dipole (two groups)

Problem. A short wire antenna of length ℓ carries a uniform sinusoidal current of amplitude I_0 at angular frequency ω in free space (μ_0, ε_0). Find the form of the time-averaged radiated power P.

List. $P, I_0, \ell, \omega, \mu_0, \varepsilon_0$: $n = 6$. **Matrix** (rows M, L, T, I):

$$\mathbf{D} = \begin{array}{c|cccccc} & P & I_0 & \ell & \omega & \mu_0 & \varepsilon_0 \\ \hline \mathrm{M} & 1 & 0 & 0 & 0 & 1 & -1 \\ \mathrm{L} & 2 & 0 & 1 & 0 & 1 & -3 \\ \mathrm{T} & -3 & 0 & 0 & -1 & -2 & 4 \\ \mathrm{I} & 0 & 1 & 0 & 0 & -2 & 2 \end{array}$$

Rank $r = 4$, so $6 - 4 = 2$ groups.

Null space. A basis is $\mathbf{a}_1 = (-1, 2, 1, 1, 1, 0)$ and $\mathbf{a}_2 = (1, -2, 1, 1, 0, 1)$, i.e.

$$\Pi_a = \frac{I_0^2\, \ell\, \omega\, \mu_0}{P}, \qquad \Pi_b = \frac{P\, \ell\, \omega\, \varepsilon_0}{I_0^2}.$$

These are correct but not illuminating. Any products of powers are equally valid groups, so recombine: $\Pi_a \Pi_b = \omega^2 \ell^2 \mu_0 \varepsilon_0 = (k\ell)^2$ with $k = \omega\sqrt{\mu_0 \varepsilon_0} = 2\pi/\lambda$, and $\sqrt{\Pi_b / \Pi_a} = (P/I_0^2)\sqrt{\varepsilon_0/\mu_0} = P/(\eta_0 I_0^2)$, with $\eta_0 = \sqrt{\mu_0/\varepsilon_0} \approx 377\ \Omega$. Therefore

$$P = \eta_0 I_0^2\, \Phi(k\ell).$$

Physics fills in Φ. For a short dipole ($k\ell \ll 1$) the field solution gives $\Phi = (k\ell)^2/(12\pi)$, i.e. $P = \eta_0 I_0^2 (k\ell)^2/(12\pi) = 40\pi^2 (\ell/\lambda)^2 I_0^2$ watts. For $\ell = 1$ m, $f = 10$ MHz ($\lambda = 30$ m), $I_0 = 1$ A: $P = 40\pi^2/900 = 0.439$ W. Dimensional analysis alone already told us the answer is $\eta_0 I_0^2$ times a function of electrical length, and that a geometrically similar antenna scaled together with the wavelength radiates the same power for the same current.

Choice of groups. The lesson of the recombination step: the null space is unique, its basis is not. Choose groups that have recognised physical meanings (electrical length $k\ell$, power normalised to $\eta_0 I_0^2$).

Worked Example 25.11 — Forced-air cooling of a heat sink: Nusselt, Reynolds and Prandtl

Problem. The convective heat-transfer coefficient h of a heat-sink fin in an air stream depends on air speed V, fin length ℓ, and the air's thermal conductivity k, density ρ, viscosity μ and specific heat c_p. Reduce the problem.

List. $n = 7$; base dimensions M, L, T, Θ, and the dimension matrix has rank $r = 4$. So there are $7 - 4 = 3$ groups. A null-space computation gives the basis (after recombination):

$$\mathrm{Nu} = \frac{h\ell}{k}, \qquad \mathrm{Re} = \frac{\rho V \ell}{\mu}, \qquad \mathrm{Pr} = \frac{\mu c_p}{k}.$$

Check one: $[h\ell/k] = (\mathrm{MT}^{-3}\Theta^{-1})(\mathrm{L})/(\mathrm{MLT}^{-3}\Theta^{-1}) = 1$.

Result. $\mathrm{Nu} = \Phi(\mathrm{Re}, \mathrm{Pr})$. A seven-variable problem has become a two-variable one; for air $\mathrm{Pr} \approx 0.71$ is essentially fixed, so a *single curve* $\mathrm{Nu}(\mathrm{Re})$ — measured once in a wind tunnel on any convenient size of fin — serves every fin and every fan speed. Laminar flat-plate theory gives $\mathrm{Nu} = 0.664\, \mathrm{Re}^{1/2} \mathrm{Pr}^{1/3}$, from which $h \propto \sqrt{V/\ell}$: doubling the fan speed raises h by only $\sqrt{2}$.

Common Pitfall — the missing variable

Dimensional analysis is only as good as the list of variables. Leave out g in the pendulum and no group containing T_p can be formed — the method then "proves" that the period is meaningless. Worse, leave out a variable whose dimensions happen to be expressible through the others (say, the wire radius a in the dipole problem, which has the same dimension as ℓ) and the method silently returns a wrong, incomplete answer: the true result would contain the additional group a/ℓ. Physical insight decides what goes in the list; the algebra only processes it.

Common Pitfall — dimensionless is not the same as negligible

Angles, ratios such as a/ℓ, and numbers like Pr are dimensionless but may matter enormously. Dimensional analysis never tells you which groups can be dropped; that comes from scaling (Section 25.4) or experiment.

Engineering Note — scaling laws in electronics

Dennard's MOSFET scaling rules are dimensional reasoning applied to a device: scale all lengths and the supply voltage by $1/\kappa$ and doping by κ, so that every electric field — and therefore every dimensionless group in the device equations — is unchanged. Then current scales as $1/\kappa$, capacitance as $1/\kappa$, gate delay CV/I as $1/\kappa$, and power density stays constant. When threshold-voltage and leakage effects (which introduce the thermal voltage kT/q, a quantity that does *not* scale) became important, the rules broke down — a dimensional argument explaining why the "free lunch" of scaling ended.

25.4 Scaling and nondimensionalization

From dimensionless groups to dimensionless equations

Dimensional analysis (Section 25.3) works on a *list of variables* and tells us which combinations can appear. **Nondimensionalization** works on the *equations themselves*: every dependent and independent variable is divided by a characteristic scale, and the equation is rewritten in the new variables. The parameters then collapse into a handful of dimensionless groups, each of which can be read as a ratio of competing effects. When the scales are chosen well, the size of each group tells us which terms dominate and which can be neglected.

Characteristic scale, scaled variable

For a variable q with characteristic magnitude q_c (a constant built from the model's parameters, inputs or geometry), the **scaled variable** is $q^* = q/q_c$. For time, $t^* = t/t_c$, and derivatives transform by the chain rule:

$$\frac{dq}{dt} = \frac{q_c}{t_c}\frac{dq^*}{dt^*}, \qquad \frac{d^2q}{dt^2} = \frac{q_c}{t_c^2}\frac{d^2q^*}{dt^{*2}}.$$

A scaling is **good** when, for the behaviour of interest, the scaled variables and their derivatives are of order one, so that the size of each dimensionless coefficient directly measures the importance of its term.

The procedure is mechanical:

1. Identify dependent variables, independent variables and parameters.
2. Introduce scaled variables with *unknown* scales q_c, t_c, x_c.
3. Substitute and divide through by the coefficient of one chosen term (usually the one that must always be present).
4. Choose the scales to make as many coefficients as possible equal to 1.
5. The coefficients that remain are the governing dimensionless groups.

The number of groups that survive equals the number predicted by the Pi theorem for the quantities in the equation — the two methods are consistent, but scaling also tells you *where* in the equation each group sits.

The series RLC circuit: ω_n and ζ

The capacitor voltage of a series RLC circuit driven by $v_s(t)$ obeys

$$LC\frac{d^2v}{dt^2} + RC\frac{dv}{dt} + v = v_s(t).$$

Let $v = V_0\, y$ (with V_0 the size of the input, e.g. the step height) and $t = t_c\,\tau$:

$$\frac{LC}{t_c^2}\,y'' + \frac{RC}{t_c}\,y' + y = u(\tau), \qquad u = v_s/V_0,$$

with primes denoting $d/d\tau$. Choosing t_c so that the first coefficient is 1 gives $t_c = \sqrt{LC}$, and the middle coefficient becomes $RC/\sqrt{LC} = R\sqrt{C/L}$. Writing it as 2ζ:

Standard form of a second-order system

With $\omega_n = 1/\sqrt{LC}$, $\tau = \omega_n t$ and

$$\zeta = \frac{R}{2}\sqrt{\frac{C}{L}} = \frac{1}{2Q},$$

the series RLC circuit becomes

$$y'' + 2\zeta y' + y = u(\tau).$$

Every series RLC circuit — every mass–spring–damper, every second-order servo — with the same ζ has the *same* scaled response; ω_n only stretches the time axis and V_0 only stretches the voltage axis.

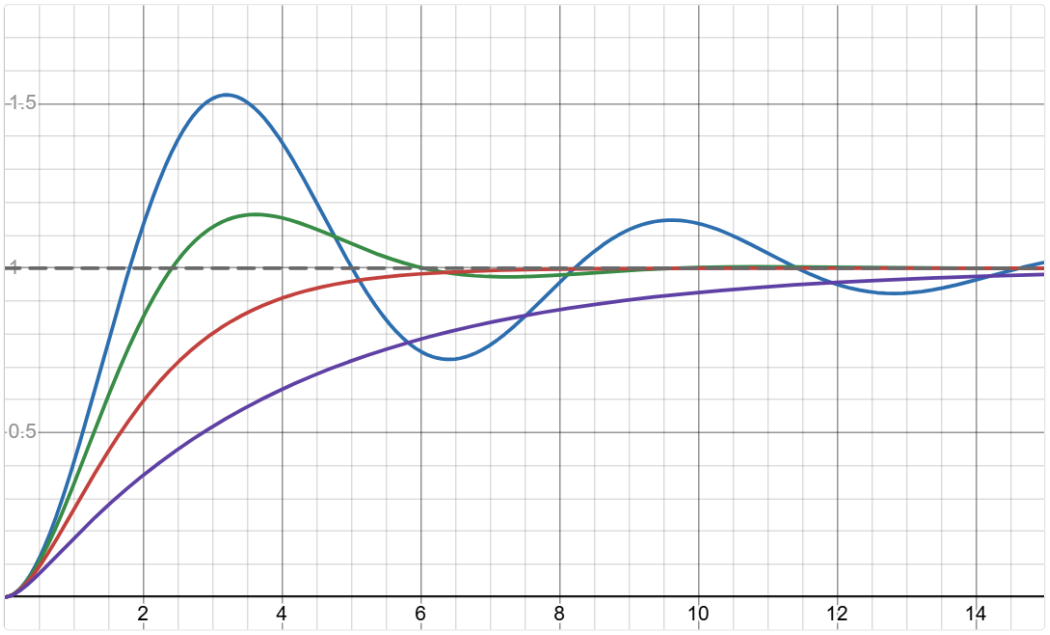
Three parameters (R, L, C) have become one (ζ) plus two scales. Equivalently, the physical step response is

$$v(t) = V_0\, S_\zeta(\omega_n t),$$

where S_ζ is the universal unit-step response of the standard form. For $0 < \zeta < 1$,

$$S_\zeta(\tau) = 1 - e^{-\zeta\tau}\left[\cos\!\left(\sqrt{1-\zeta^2}\,\tau\right) + \frac{\zeta}{\sqrt{1-\zeta^2}}\sin\!\left(\sqrt{1-\zeta^2}\,\tau\right)\right],$$

for $\zeta = 1$, $S_1(\tau) = 1 - (1+\tau)e^{-\tau}$, and for $\zeta > 1$ it is the sum of two decaying real exponentials with rates $\zeta \pm \sqrt{\zeta^2 - 1}$.



Universal step responses $S_\zeta(\tau)$ of $y''+2\zeta y'+y=u$ for $\zeta=0.2$ (blue), 0.5 (green), 1 (red, critically damped) and 2 (purple, overdamped); the horizontal axis is $\tau=\omega_n t$.

The dimensionless figures of merit follow directly: percent overshoot $\mathrm{PO}=100\,e^{-\pi\zeta/\sqrt{1-\zeta^2}}$, peak time $\tau_p=\pi/\sqrt{1-\zeta^2}$, and 2 % settling time $\tau_s\approx 4/\zeta$. Each is a function of ζ only; physical times are recovered by dividing by ω_n.

Worked Example 25.12 — Reading the RLC circuit of Example 25.4 in scaled form

Problem. For $R=10\ \Omega$, $L=1$ mH, $C=1\ \mu$F, find ω_n, ζ, Q, overshoot, peak time and settling time of the capacitor voltage after a 1 V step. What resistance gives critical damping?

Scales. $\omega_n=1/\sqrt{10^{-3}\times 10^{-6}}=1/\sqrt{10^{-9}}=31\,623$ rad/s ($f_n=5.03$ kHz). $\zeta=\frac{10}{2}\sqrt{10^{-6}/10^{-3}}=5\times 0.031\,62=0.158$; $Q=1/(2\zeta)=3.16$.

Figures of merit. $\sqrt{1-\zeta^2}=0.9874$.

$$\mathrm{PO}=100\exp\!\left(-\frac{\pi\times 0.158}{0.9874}\right)=100\,e^{-0.503}=60.5\,\%.$$

Peak time $t_p=\pi/(\omega_n\sqrt{1-\zeta^2})=\pi/31\,225=100.6\ \mu$s; settling time $t_s\approx 4/(\zeta\omega_n)=4/5000=0.8$ ms.

Critical damping. $\zeta=1$ requires $R=2\sqrt{L/C}=2\sqrt{1000}=63.2\ \Omega$. The quantity $\sqrt{L/C}=31.6\ \Omega$ is the **characteristic impedance** of the resonator — the natural resistance scale of the circuit — and ζ is simply R measured in units of $2\sqrt{L/C}$.

Check against Example 25.4. There the eigenvalues were $-5000\pm j\,31\,225$: real part $-\zeta\omega_n=-0.158\times 31\,623=-5000$ ✓, imaginary part $\omega_n\sqrt{1-\zeta^2}=31\,225$ ✓.

Thermal models: lumped scaling

The sink equation of Example 25.2, $C_s\dot T_s=P-(T_s-T_a)/R_{sa}$, scales with temperature-rise scale $\Delta T_c=PR_{sa}$ and time scale $t_c=R_{sa}C_s$. Setting $\theta=(T_s-T_a)/(P_0R_{sa})$ and $\tau=t/(R_{sa}C_s)$,

$$\frac{d\theta}{d\tau}+\theta=p(\tau),\qquad p=P/P_0.$$

There is *no* dimensionless parameter left: every first-order lag is the same system, and its only "parameters" are the two scales. This is why one plot of $1-e^{-\tau}$ serves RC filters, thermometers and heat sinks alike.

Distributed thermal models: Biot and Fourier numbers

The lumped model assumes the body is at a uniform temperature. Whether that is reasonable is itself answered by scaling. Consider a plate of half-thickness ℓ, conductivity k, diffusivity $\alpha=k/(\rho c_p)$, initially at T_0, suddenly exposed on both faces to a fluid at T_∞ with heat-transfer coefficient h. By symmetry, on $0\le x\le \ell$:

$$\frac{\partial T}{\partial t}=\alpha\frac{\partial^2 T}{\partial x^2},\qquad \frac{\partial T}{\partial x}(0,t)=0,\qquad -k\frac{\partial T}{\partial x}(\ell,t)=h\,\big(T(\ell,t)-T_\infty\big),\qquad T(x,0)=T_0.$$

Scale with $\xi=x/\ell$, $\theta=(T-T_\infty)/(T_0-T_\infty)$ and an as-yet-free time scale t_c:

$$\frac{\ell^2}{\alpha t_c}\frac{\partial\theta}{\partial\tau}=\frac{\partial^2\theta}{\partial\xi^2},\qquad \frac{\partial\theta}{\partial\xi}(1,\tau)=-\frac{h\ell}{k}\,\theta(1,\tau).$$

Choosing $t_c=\ell^2/\alpha$ (the diffusion time) makes the scaled time the **Fourier number** and leaves a single group in the boundary condition, the **Biot number**:

$$\mathrm{Fo}=\frac{\alpha t}{\ell^2},\qquad \mathrm{Bi}=\frac{h\ell}{k}=\frac{\ell/k}{1/h}=\frac{\text{internal conduction resistance}}{\text{surface convection resistance}}.$$

The lumped-capacitance criterion

If $\mathrm{Bi} \ll 1$ (in practice $\mathrm{Bi} < 0.1$), the temperature inside the body is uniform to within about 5 % of the overall temperature difference, and the distributed model reduces to the lumped first-order model

$$\frac{d\theta}{dt} = -\frac{hA}{\rho c_p V}\,\theta, \qquad \tau_{\text{lumped}} = \frac{\rho c_p V}{hA} = \frac{\ell^2}{\alpha\,\mathrm{Bi}} \quad (\text{plate: } V/A = \ell).$$

Sketch. With $\mathrm{Bi} \to 0$ the boundary condition says $\partial\theta/\partial\xi \approx 0$ at both faces, so to leading order θ is independent of ξ. Integrating the PDE over $0 \le \xi \le 1$ and using the boundary conditions gives $d\bar\theta/d\mathrm{Fo} = -\mathrm{Bi}\,\theta(1) \approx -\mathrm{Bi}\,\bar\theta$, i.e. decay on the slow time $\mathrm{Fo} \sim 1/\mathrm{Bi}$, which is the lumped model. The internal profile relaxes on the fast time $\mathrm{Fo} \sim 1$; when $\mathrm{Bi} \ll 1$ these two time scales are well separated. □

Worked Example 25.13 — Is the heat sink really lumped?

Problem. The heat sink of Example 25.2 has a 5 mm thick aluminium base ($k = 200$ W/(m K), $\alpha = 8.4 \times 10^{-5}$ m²/s), cooled by natural convection, $h \approx 10$ W/(m²K) (effective, per unit fin area, $h_{\text{eff}} \approx 100$ W/(m²K) referred to the base area). A second design uses a 1.6 mm FR-4 board as the "sink" ($k = 0.3$ W/(m K)). Compute Biot numbers and diffusion times.

Aluminium. Heated from one side, the relevant length is the full thickness $\ell = 5$ mm:

$$\mathrm{Bi} = \frac{100 \times 0.005}{200} = 2.5 \times 10^{-3} \ll 0.1,$$

and the diffusion time $\ell^2/\alpha = 2.5 \times 10^{-5}/8.4 \times 10^{-5} = 0.30$ s, versus a lumped time constant of 450 s. Lumped model: excellent.

FR-4. $\mathrm{Bi} = 100 \times 0.0016/0.3 = 0.53$. The lumped model is *not* valid: the board surface far from the component runs much cooler than the copper under it, and the heat spreads laterally over a distance comparable to the board thickness times $1/\sqrt{\mathrm{Bi}}$. A distributed (PDE or finite-element) model, or at least a multi-node RC ladder, is required.

Moral. The *same equation* (first-order lag) is a superb model in one case and a poor one in the other; the dimensionless number tells which, before any simulation is run.

Time-scale separation and small parameters

A good scaling often exposes a **small parameter** $\varepsilon \ll 1$ multiplying one term. Neglecting that term gives a **reduced model**; the conditions under which this is legitimate are the subject of perturbation theory.

- If ε multiplies a term that is *not* the highest derivative, setting $\varepsilon = 0$ is a **regular** perturbation: the solution changes smoothly, by $O(\varepsilon)$.
- If ε multiplies the *highest* derivative, setting $\varepsilon = 0$ lowers the order of the equation and some initial conditions can no longer be satisfied: a **singular** perturbation. The neglected dynamics act in a fast **boundary layer** of duration $O(\varepsilon)$ in scaled time, after which the reduced model is accurate.

The RLC circuit with very small inductance is the canonical example. Scaling time on the *slow* scale $t_c = RC$ instead of $\sqrt{LC}$:

$$\varepsilon\, y'' + y' + y = u, \qquad \varepsilon = \frac{L/R}{RC} = \frac{L}{R^2 C} = \frac{1}{4\zeta^2}.$$

When $\zeta \gg 1$, $\varepsilon \ll 1$ and the circuit behaves as an RC circuit with time constant RC, except for a brief initial interval of order L/R during which the inductor current builds up. The two time constants are approximately RC and L/R, and their ratio is ε — a direct measure of the **stiffness** that will matter for numerical solution (Section 25.9).

Worked Example 25.14 — A nonlinear oscillator reduced to one parameter

Problem. A negative-resistance LC oscillator (for example, a tunnel-diode or cross-coupled-pair oscillator) is modelled by an inductor L and capacitor C in parallel with a nonlinear element drawing current $i_N(v) = -av + bv^3$ ($a > 0$ is the small-signal negative conductance, $b > 0$ models gain compression). Nondimensionalize and predict amplitude and frequency for $L = 10\ \mu\text{H}$, $C = 1\ \text{nF}$, $a = 1\ \text{mS}$, $b = 1\ \text{mA/V}^3$.

Equations. KCL at the top node with inductor current i_L: $C\dot{v} + i_L + i_N(v) = 0$, $L\,\dot{i}_L = v$. Differentiate the first and substitute the second:

$$C\ddot{v} - a\left(1 - \frac{3b}{a}v^2\right)\dot{v} + \frac{v}{L} = 0.$$

Scaling. Let $t = \sqrt{LC}\,\tau$ and $v = V_c\,x$. Multiplying by L:

$$x'' - a\sqrt{\frac{L}{C}}\left(1 - \frac{3bV_c^2}{a}x^2\right)x' + x = 0.$$

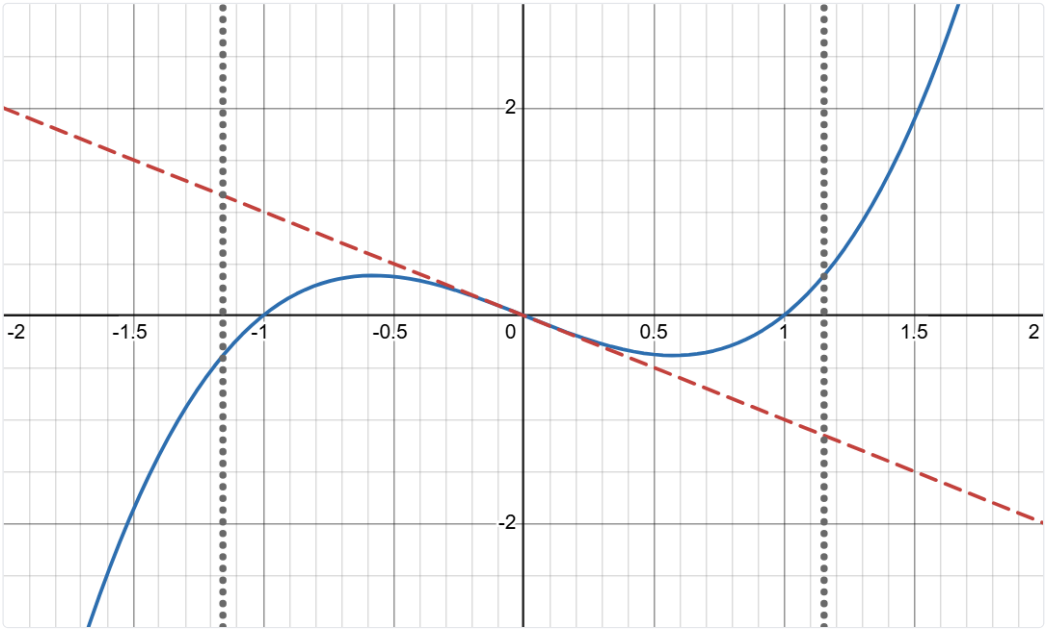
Choose $V_c = \sqrt{a/(3b)}$ to make the bracket $1 - x^2$. The result is the **Van der Pol equation**

$$x'' - \mu\,(1 - x^2)\,x' + x = 0, \qquad \mu = a\sqrt{\frac{L}{C}}.$$

Five physical parameters (L, C, a, b) plus time and voltage units have collapsed into *one* number μ, the ratio of the negative conductance to the tank's characteristic admittance $\sqrt{C/L}$.

Numbers. $\sqrt{L/C} = \sqrt{10^{-5}/10^{-9}} = 100\ \Omega$, so $\mu = 10^{-3} \times 100 = 0.1$. $V_c = \sqrt{10^{-3}/(3 \times 10^{-3})} = 0.577$ V. For small μ the Van der Pol limit cycle is nearly sinusoidal with amplitude $x \approx 2$ and scaled angular frequency ≈ 1; numerical integration gives amplitude 2.000 and period $1.0006 \times 2\pi$ for $\mu = 0.1$. Hence $v(t) \approx 1.155\cos(\omega_0 t)$ V with $f_0 = 1/(2\pi\sqrt{LC}) = 1.59$ MHz.

The parameter's meaning. For $\mu = 1$ the scaled amplitude is 2.01 and the period $1.06 \times 2\pi$; for $\mu = 5$ the oscillation becomes a *relaxation* oscillation with period $1.85 \times 2\pi$ and sharp transitions — a square-ish rather than sinusoidal waveform. A designer wanting a clean sine wave therefore wants $\mu \ll 1$, i.e. just enough negative conductance to sustain oscillation; this design rule is invisible in the five-parameter form and obvious in the one-parameter form.



Nonlinear element current $i_N(v) = -av + bv^3$ in mA against v in volts ($a = 1$ mS, $b = 1$ mA/V³): the small-signal slope $-a$ (red dashed) supplies energy near $v = 0$, the cubic term absorbs it at large swing, and the dotted lines mark the predicted oscillation amplitude $2V_c = 1.155$ V.

Common Pitfall — scaling with the wrong scale

A scaling is a *hypothesis* about which balance dominates. Scaling the RLC circuit with $t_c = \sqrt{LC}$ when $\zeta = 50$ produces a coefficient $2\zeta = 100$ in front of y' and hides the fact that the response has two widely separated time scales; scaling with $t_c = RC$ instead reveals $\varepsilon = 1/(4\zeta^2) = 10^{-4}$. If a scaled solution produces derivatives far from order one, the chosen scales were wrong for that regime — rescale.

Engineering Note — normalized design charts

Filter tables (Butterworth, Chebyshev), Smith charts, universal resonance curves and heat-sink design charts are all products of nondimensionalization. A Butterworth table lists poles for $\omega_c = 1$ rad/s and $R = 1\ \Omega$; *frequency scaling* and *impedance scaling* then produce any physical design. Recognising that a design problem is a scaled version of a tabulated one is often the fastest route to an answer.

25.5 Linearization

Why linearize

Almost every real device is nonlinear: diodes and transistors are exponential or square-law, magnetic cores saturate, pendulums follow $\sin\theta$, power is quadratic in voltage. Yet the overwhelming majority of engineering analysis — transfer functions, Bode plots, phasors, eigenvalue stability, Kalman filters, linear control — is linear. The bridge is **linearization**: replacing a nonlinear model by its first-order Taylor approximation about an **operating point**, and treating the deviations from that point as small signals. Small-signal analysis of amplifiers, the "AC analysis" of every circuit simulator, and the stability analysis of every power converter and control loop rest on it.

The price is a **regime of validity**: the linear model is accurate only for deviations small enough that the neglected second-order terms are negligible. An honest linear model states how small "small" is.

Operating points and the Jacobian

Operating point and linearized model

For the model $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$, $\mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u})$, an **operating point** (equilibrium) is a pair $(\bar{\mathbf{x}}, \bar{\mathbf{u}})$ with $\mathbf{f}(\bar{\mathbf{x}}, \bar{\mathbf{u}}) = \mathbf{0}$; the corresponding output is $\bar{\mathbf{y}} = \mathbf{h}(\bar{\mathbf{x}}, \bar{\mathbf{u}})$. Writing $\mathbf{x} = \bar{\mathbf{x}} + \delta\mathbf{x}$, $\mathbf{u} = \bar{\mathbf{u}} + \delta\mathbf{u}$, $\mathbf{y} = \bar{\mathbf{y}} + \delta\mathbf{y}$, the **linearized (small-signal) model** is

$$\delta\dot{\mathbf{x}} = \mathbf{A}\,\delta\mathbf{x} + \mathbf{B}\,\delta\mathbf{u}, \qquad \delta\mathbf{y} = \mathbf{C}\,\delta\mathbf{x} + \mathbf{D}\,\delta\mathbf{u},$$

with Jacobian matrices evaluated at the operating point:

$$\mathbf{A} = \left.\frac{\partial \mathbf{f}}{\partial \mathbf{x}}\right|_{\bar{\mathbf{x}},\bar{\mathbf{u}}}, \quad \mathbf{B} = \left.\frac{\partial \mathbf{f}}{\partial \mathbf{u}}\right|_{\bar{\mathbf{x}},\bar{\mathbf{u}}}, \quad \mathbf{C} = \left.\frac{\partial \mathbf{h}}{\partial \mathbf{x}}\right|_{\bar{\mathbf{x}},\bar{\mathbf{u}}}, \quad \mathbf{D} = \left.\frac{\partial \mathbf{h}}{\partial \mathbf{u}}\right|_{\bar{\mathbf{x}},\bar{\mathbf{u}}}.$$

Derivation. Taylor's theorem in several variables (Ch. 6) gives

$$\mathbf{f}(\bar{\mathbf{x}} + \delta\mathbf{x}, \bar{\mathbf{u}} + \delta\mathbf{u}) = \underbrace{\mathbf{f}(\bar{\mathbf{x}}, \bar{\mathbf{u}})}_{=\mathbf{0}} + \mathbf{A}\,\delta\mathbf{x} + \mathbf{B}\,\delta\mathbf{u} + \mathbf{r}(\delta\mathbf{x}, \delta\mathbf{u}),$$

and since $\dot{\bar{\mathbf{x}}} = \mathbf{0}$, $\delta\dot{\mathbf{x}} = \dot{\mathbf{x}}$. Dropping the remainder $\mathbf{r}$ gives the linear model. If $\mathbf{f}$ is twice continuously differentiable, the remainder is bounded by

$$\|\mathbf{r}\| \le \tfrac{1}{2} M \left(\|\delta\mathbf{x}\| + \|\delta\mathbf{u}\|\right)^2,$$

where M bounds the second derivatives of $\mathbf{f}$ near the operating point. The linear terms are of size $\|\mathbf{A}\|\|\delta\mathbf{x}\|$, so the *relative* error of linearization grows in proportion to the signal amplitude.

Linearization and local stability (Lyapunov's indirect method)

Let $\bar{\mathbf{x}}$ be an equilibrium of $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ with $\mathbf{f}$ continuously differentiable and Jacobian $\mathbf{A}$.

1. If every eigenvalue of $\mathbf{A}$ has negative real part, $\bar{\mathbf{x}}$ is locally asymptotically stable for the nonlinear system.
2. If some eigenvalue has positive real part, $\bar{\mathbf{x}}$ is unstable for the nonlinear system.
3. If no eigenvalue has positive real part but some lie on the imaginary axis, linearization is **inconclusive**; the nonlinear terms decide.

Moreover (Hartman–Grobman), when no eigenvalue lies on the imaginary axis (a *hyperbolic* equilibrium), the nonlinear trajectories near $\bar{\mathbf{x}}$ are a continuous deformation of the linear ones.

The theorem is the formal licence for small-signal stability analysis — and case 3 is its fine print.

Small-signal model of a diode

Worked Example 25.15 — The diode small-signal resistance and its range of validity

Problem. A silicon diode obeys the Shockley equation $i = I_S\left(e^{v/(nV_T)} - 1\right)$ with $n = 1$ and $V_T = kT/q = 25.85$ mV at 300 K. It is biased at $I_D = 1$ mA. Find the small-signal resistance and determine how large a voltage excursion the linear model tolerates for 2 %, 10 % and 20 % accuracy in the current change.

Linearization. At the bias point $\bar{v} = V_D$, with $I_D \gg I_S$,

$$g_d = \left.\frac{di}{dv}\right|_{V_D} = \frac{I_S}{nV_T}e^{V_D/(nV_T)} \approx \frac{I_D}{nV_T}, \qquad r_d = \frac{1}{g_d} = \frac{nV_T}{I_D} = \frac{25.85\ \text{mV}}{1\ \text{mA}} = 25.85\ \Omega.$$

Remarkably, r_d depends only on the bias current, not on I_S — an unknown, process-dependent parameter has dropped out.

Exact versus linear. The exact current change for a voltage step δv is $\delta i = I_D\left(e^{\delta v/V_T} - 1\right)$; the linear prediction is $\delta i_{\text{lin}} = \delta v / r_d = I_D\,\delta v/V_T$. With $x = \delta v/V_T$, the relative error is

$$\frac{\delta i_{\text{lin}} - \delta i}{\delta i} = \frac{x}{e^{x}-1} - 1 \approx -\frac{x}{2} \quad (|x| \ll 1).$$

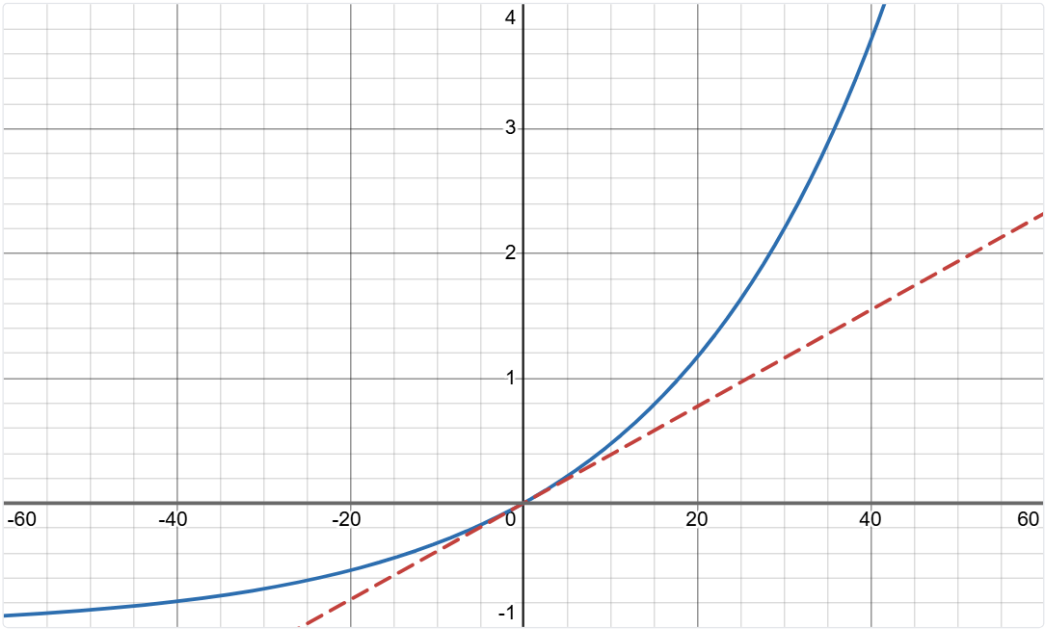
δv	exact δi (µA)	linear δi (µA)	error
$+1$ mV	39.44	38.68	−1.9 %
$+5$ mV	213.4	193.4	−9.4 %
$+10$ mV	472.3	386.8	−18.1 %
-10 mV	−320.8	−386.8	+20.6 %
$+20$ mV	1167.6	773.6	−33.7 %

Regime of validity. Since the error is about $|\delta v|/(2V_T)$, an accuracy e requires $|\delta v| \lesssim 2eV_T$: about 1 mV for 2 %, 5 mV for 10 %, 10 mV for 20 %. The often-quoted rule "small signal means $|v_d| \ll V_T$" is this calculation in words. Note the asymmetry between ± 10 mV: the linear model *underestimates* forward excursions and *overestimates* reverse ones, which is the origin of even-order distortion.

The second-order Taylor term gives that distortion quantitatively. For $\delta v = \hat{V}\cos\omega t$,

$$\delta i \approx I_D\left[\frac{\hat{V}}{V_T}\cos\omega t + \frac{1}{2}\left(\frac{\hat{V}}{V_T}\right)^2\cos^2\omega t\right] = I_D\left[\frac{\hat{V}}{V_T}\cos\omega t + \frac{\hat{V}^2}{4V_T^2} + \frac{\hat{V}^2}{4V_T^2}\cos 2\omega t\right],$$

so the second-harmonic distortion is $\text{HD}_2 \approx \hat{V}/(4V_T)$: 0.97 % at $\hat{V} = 1$ mV and 4.8 % at 5 mV (the exact Bessel-function result, $I_2(\hat{V}/V_T)/I_1(\hat{V}/V_T)$, agrees to three digits). The constant term $\hat{V}^2/(4V_T^2)$ is a shift of the operating point — **rectification** — and is exactly what the linear model misses entirely.



Diode current change $\delta i/I_D = e^{\delta v/V_T} - 1$ (blue) and its tangent-line linearization $\delta v/V_T$ (red dashed), with δv in mV; they agree only within a few millivolts of the operating point.

The nonlinear pendulum (and every oscillator with a $\sin$)

The pendulum $\ddot{\theta} + \omega_0^2 \sin\theta = 0$, $\omega_0^2 = g/\ell$, is the prototype for a whole class of EE models: the swing equation of a synchronous generator ($M\ddot{\delta} + D\dot{\delta} = P_m - P_{\max}\sin\delta$), the phase-locked loop with a sinusoidal phase detector, and the Josephson junction all have the same sin nonlinearity.

With $\mathbf{x} = [\theta,\ \dot{\theta}]^{\mathsf{T}}$, $\mathbf{f} = [\dot{\theta},\ -\omega_0^2\sin\theta]^{\mathsf{T}}$, equilibria satisfy $\sin\bar{\theta} = 0$: $\bar{\theta} = 0$ (hanging) and $\bar{\theta} = \pi$ (inverted). The Jacobian is

$$\mathbf{A}(\bar\theta) = \begin{bmatrix} 0 & 1 \\ -\omega_0^2 \cos\bar\theta & 0 \end{bmatrix}.$$

Worked Example 25.16 — Linearizing the pendulum about both equilibria

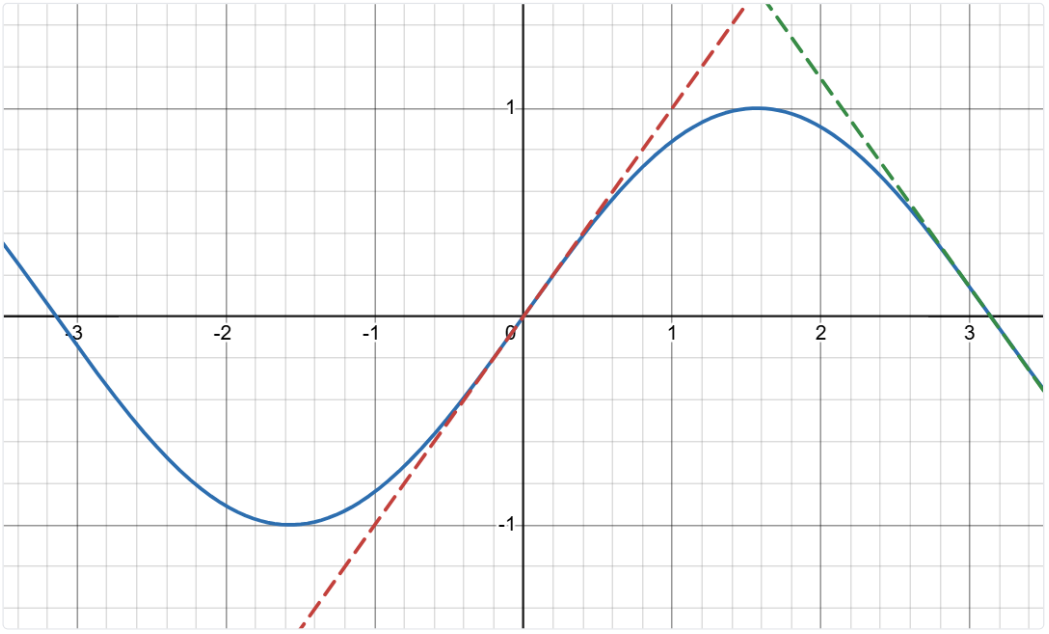
Hanging, $\bar\theta = 0$. $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -\omega_0^2 & 0 \end{bmatrix}$, eigenvalues $\pm j\omega_0$. Linearization predicts a centre (undamped oscillation at ω_0) — but by the theorem this is case 3, *inconclusive*. Here energy conservation, $E = \tfrac{1}{2}\dot\theta^2 + \omega_0^2(1 - \cos\theta)$, settles it: level curves of E near the bottom are closed, so the nonlinear system also has a centre.

Inverted, $\bar\theta = \pi$. $\cos\pi = -1$, so $\mathbf{A} = \begin{bmatrix} 0 & 1 \\ \omega_0^2 & 0 \end{bmatrix}$, eigenvalues $\pm\omega_0$: a saddle, hyperbolic, so the nonlinear equilibrium is genuinely unstable, with small deviations growing as $e^{\omega_0 t}$. For $\ell = 1$ m, $\omega_0 = 3.13$ s^{-1}: an error doubles every $\ln 2/\omega_0 = 0.22$ s, which sets the bandwidth an inverted-pendulum balancing controller must have.

How good is the hanging linearization? The linear model predicts a period $T_0 = 2\pi/\omega_0$ independent of amplitude. The exact period is $T = (2/\pi)\,K(\sin(\theta_0/2))\,T_0$, with K the complete elliptic integral of the first kind; its series is $T/T_0 = 1 + \theta_0^2/16 + \dots$

Amplitude θ_0	exact T/T_0	$1 + \theta_0^2/16$	linear-model error
10°	1.0019	1.0019	0.19 %
20°	1.0077	1.0076	0.77 %
30°	1.0174	1.0171	1.7 %
45°	1.0400	1.0386	4.0 %
90°	1.1803	1.1542	18 %
150°	1.7622	1.4284	76 %

The "small-angle approximation" is good to 1 % up to about 23° and fails completely as $\theta_0 \to 180^\circ$, where the period diverges.



The pendulum nonlinearity $\sin\theta$ (blue) and its linearizations about $\bar\theta = 0$ (red, slope $+1$) and $\bar\theta = \pi$ (green, slope -1): the sign of the slope decides between oscillation and exponential divergence.

A multivariable example: magnetic levitation

Worked Example 25.17 — Linearizing an electromagnet suspension

Problem. A steel ball of mass m hangs below an electromagnet. With gap x (measured downward from the magnet face) and coil current i, the magnetic force is approximately $k\,i^2/x^2$ upward, so

$$m\ddot{x} = mg - k\frac{i^2}{x^2}.$$

For $m = 0.05$ kg, $k = 10^{-4}$ N m^2/A^2, find the current that holds the ball at $x_0 = 10$ mm, linearize, and classify the equilibrium.

Operating point. $mg = ki_0^2/x_0^2 \Rightarrow i_0 = x_0\sqrt{mg/k} = 0.01\sqrt{0.4905/10^{-4}} = 0.700$ A.

Jacobian. With $\mathbf{x} = [x,\ \dot{x}]^{\mathsf{T}}$ and input i, $f_2 = g - (k/m)\,i^2/x^2$:

$$\frac{\partial f_2}{\partial x} = \frac{2ki_0^2}{mx_0^3} = \frac{2g}{x_0}, \qquad \frac{\partial f_2}{\partial i} = -\frac{2ki_0}{mx_0^2} = -\frac{2g}{i_0},$$

where the equilibrium condition was used to simplify. So

$$\delta\ddot{x} = \frac{2g}{x_0}\,\delta x - \frac{2g}{i_0}\,\delta i = 1962\,\delta x - 28.0\,\delta i.$$

Classification. Open loop ($\delta i = 0$), $\lambda = \pm\sqrt{2g/x_0} = \pm 44.3$ s^{-1}: an unstable saddle with time constant $1/44.3 = 23$ ms. The linearized model, with transfer function $\delta X/\delta I = -28.0/(s^2 - 1962)$, is the starting point for designing the stabilizing feedback loop.

Validity. The second-order term in δx is $\tfrac{1}{2}(\partial^2 f_2/\partial x^2)\delta x^2 = -(3g/x_0^2)\,\delta x^2$; compared with the linear term $(2g/x_0)\delta x$, the ratio is $1.5\,|\delta x|/x_0$. For 10 % accuracy the ball must stay within about ± 0.7 mm of the set point — the linear controller design is valid only if the controller keeps it there.

Beyond equilibria

Two extensions are worth knowing by name:

- **Linearization about a trajectory.** If $\bar{\mathbf{x}}(t)$ is a nominal solution (e.g. a switching converter's periodic steady state), the deviations obey a *time-varying* linear system $\delta\dot{\mathbf{x}} = \mathbf{A}(t)\delta\mathbf{x} + \mathbf{B}(t)\delta\mathbf{u}$, with Jacobians evaluated along $\bar{\mathbf{x}}(t)$. For periodic trajectories this leads to Floquet theory and to state-space averaging in power electronics.
- **Quasi-linearization (describing functions).** For a sinusoidal signal of amplitude A through a static nonlinearity, replace the nonlinearity by the gain of its fundamental Fourier component (Ch. 15), $N(A)$. This amplitude-dependent "linearization" predicts limit cycles, as in the Van der Pol oscillator, where it gives amplitude $x = 2$ exactly.

Common Pitfall — linearizing what is not differentiable

Saturation, dead zones, ideal switches, Coulomb friction $\tau_c\,\mathrm{sgn}(\omega)$ and absolute-value detectors have no derivative at the critical point. A Jacobian taken "on one side" describes only that side, and small-signal analysis at the corner is meaningless: an amplifier biased exactly at the edge of saturation has *no* well-defined small-signal gain. Either bias away from the corner or use describing-function, piecewise-linear or simulation methods.

Engineering Note — what SPICE "AC analysis" actually does

A circuit simulator's AC analysis first solves the nonlinear DC operating-point equations by Newton's method (Ch. 22), then replaces every nonlinear device by its Jacobian — g_m, r_π, r_o, junction capacitances evaluated at the bias point — and solves the resulting *linear* phasor equations at each frequency. An AC analysis therefore reports a gain of, say, 40 dB for a 10 V input signal without complaint; it is the user's responsibility to remember that the result is valid only for signals small enough to keep the operating point fixed.

25.6 Model assumptions

Assumptions are part of the model

Every model in this chapter so far rested on assumptions: the capacitor had no leakage (Example 25.1), the package stored no heat (25.2), friction was viscous (25.3), the source had zero resistance (25.5), the diode signal was small (25.15). An assumption is not a weakness to be hidden; it is the *specification* of the model's domain of validity. A model without stated assumptions cannot be checked, cannot be trusted outside the conditions it was tested in, and cannot be improved systematically.

Assumption and regime of validity

A **modeling assumption** is a statement that some effect, quantity or interaction is negligible, constant, ideal or of a particular form. Its **regime of validity** is the set of operating conditions — usually expressible as an inequality on a dimensionless group — under which the error it introduces is below the accuracy required by the model's purpose.

The key move is the second sentence: turning a qualitative assumption ("the wire is short") into a quantitative inequality ("$\ell < \lambda/10$"). Sections 25.3–25.5 provide the tools; this section collects the standard assumptions of EE modeling and the inequalities that police them.

A catalogue of standard assumptions

Assumption	What it buys	Regime of validity (typical)	When it fails
Lumped (quasi-static) circuit	ODEs instead of PDEs; Kirchhoff's laws	size $\ell \ll \lambda$, say $\ell < \lambda/10$; or edge rise time $t_r > 6\,t_{pd}$	long cables, fast digital edges, RF
Lumped thermal body	one temperature per body	$\mathrm{Bi} = h\ell/k < 0.1$	thin, poorly conducting boards (Ex. 25.13)
Linearity	superposition, transforms, eigenvalues	deviations small vs. nonlinearity scale, e.g. $\lvert v_d\rvert \ll V_T$	large signals, saturation, clipping
Time invariance	constant coefficients, transfer functions	parameters drift less than accuracy over the window	warm-up, ageing, battery discharge
Ideal op-amp	virtual short, infinite input impedance	loop gain $\lvert A\beta\rvert \gg 1$, i.e. $f \ll f_{\mathrm{GBW}}\beta$	high frequency, high closed-loop gain
Ideal capacitor	$Z = 1/(j\omega C)$	f well below self-resonance $1/(2\pi\sqrt{L_{\mathrm{ESL}}C})$	decoupling at hundreds of MHz
Constant resistance	R fixed	$\alpha\,\Delta T \ll$ accuracy	windings, filaments, current shunts
Deterministic	no noise terms	signal $\gg$ noise (SNR large)	low-level sensing, receivers
Neglect of a time constant	lower-order model	that time constant $\ll$ time scale of interest (Sec. 25.4)	stiff, closely spaced modes
Continuum / Ohm's law	$\mathbf{J} = \sigma\mathbf{E}$	dimensions $\gg$ mean free path; fields moderate	nanoscale devices, breakdown

Making an assumption quantitative

The pattern is always the same: identify the neglected term, estimate its size relative to the retained terms using the scales of Section 25.4, and require the ratio to be below the tolerated error.

Worked Example 25.18 — Is a PCB trace a lumped wire or a transmission line?

Problem. A 10 cm trace on FR-4 (effective relative permittivity $\varepsilon_{\mathrm{eff}} \approx 4$) carries (a) a 100 MHz sinusoid, (b) a digital signal with 0.5 ns rise time. Is the lumped assumption valid?

Propagation. $v_p = c/\sqrt{\varepsilon_{\mathrm{eff}}} = 1.5 \times 10^8$ m/s, so the one-way delay is $t_{pd} = 0.1/1.5 \times 10^8 = 0.67$ ns.

(a) Sinusoid. $\lambda = v_p/f = 1.5$ m, $\ell/\lambda = 0.067 < 0.1$. The phase shift along the trace is $360^\circ \times 0.067 = 24^\circ$ — borderline. For a rough amplitude estimate the lumped model is acceptable; for a phase-critical path it is not.

(b) Digital edge. The relevant comparison is rise time versus delay. With $t_r = 0.5$ ns $< t_{pd} = 0.67$ ns, the edge has fully risen at the driver before it reaches the load: reflections will be seen as distinct steps. Equivalently, the signal's "knee" frequency $0.35/t_r = 700$ MHz has wavelength 0.21 m, and $\ell/\lambda \approx 0.5$. The trace must be modelled as a transmission line (Ch. 13, telegrapher's equations) and terminated.

Moral. "Is the circuit lumped?" has no answer until the *signal* is specified. The assumption belongs to the combination of system and input.

Worked Example 25.19 — When is an op-amp ideal?

Problem. A non-inverting amplifier with ideal gain $1/\beta = 100$ uses an op-amp with DC gain $A_0 = 10^5$ and a single pole giving gain–bandwidth product $f_{\mathrm{GBW}} = 1$ MHz (pole at 10 Hz). Over what frequency range is the ideal-op-amp model (gain exactly 100) accurate to 1 %? To 3 dB?

Model. The closed-loop gain is

$$G = \frac{A}{1 + A\beta} = \frac{1}{\beta}\cdot\frac{1}{1 + 1/(A\beta)}, \qquad A(f) = \frac{A_0}{1 + jf/10\ \mathrm{Hz}}.$$

The ideal model sets $1/(A\beta) = 0$; the neglected term is the reciprocal of the loop gain.

DC. $A_0\beta = 1000$, error $\approx 0.1\,\%$: excellent.

Frequency dependence. For $f \gg 10$ Hz, $A \approx -jf_{\mathrm{GBW}}/f$, so $1/(A\beta) \approx jf/(f_{\mathrm{GBW}}\beta) = jf/10$ kHz, and

$$|G| \approx \frac{100}{\sqrt{1 + (f/10\ \mathrm{kHz})^2}}.$$

A 1 % magnitude error requires $(f/10\ \mathrm{kHz})^2 < 0.02$, i.e. $f < 1.4$ kHz. The 3 dB point is $f = f_{\mathrm{GBW}}\beta = 10$ kHz. A direct computation gives $|G| = 99.41$ at 1 kHz, 89.4 at 5 kHz and 70.7 (−3.0 dB) at 10 kHz, confirming the estimate.

Moral. The "ideal op-amp" assumption is not a property of the op-amp; it is a condition, $|A\beta| \gg 1$, on the op-amp *in this circuit at this frequency*. An op-amp that is ideal for an audio buffer is far from ideal at gain 100 in the same band.

Worked Example 25.20 — Hidden parasitics: the capacitor that becomes an inductor

Problem. A 100 nF ceramic decoupling capacitor has equivalent series inductance $L_{\text{ESL}} = 1$ nH and equivalent series resistance $R_{\text{ESR}} = 10$ mΩ. Over what frequency range is it "a capacitor"?

Model. $Z(\omega) = R_{\text{ESR}} + j\left(\omega L_{\text{ESL}} - \dfrac{1}{\omega C}\right)$, a series RLC. Its self-resonant frequency is

$$f_{\text{SRF}} = \frac{1}{2\pi\sqrt{L_{\text{ESL}}C}} = \frac{1}{2\pi\sqrt{10^{-9}\times 10^{-7}}} = 15.9\ \text{MHz}.$$

At 1 MHz, $|Z| = 1.585\ \Omega$ versus the ideal $1/(\omega C) = 1.592\ \Omega$ — the ideal model is within 0.4 %. At 15.9 MHz the reactances cancel and $|Z| = R_{\text{ESR}} = 10\ \text{m}\Omega$. At 100 MHz, $|Z| = 0.61\ \Omega$ and the part is *inductive*: an ideal-capacitor model would predict 0.016 Ω, wrong by a factor of 38.

Regime. The ideal model holds for $f \ll f_{\text{SRF}}$; the inequality comes from the ratio of the neglected to the retained reactance, $\omega^2 L_{\text{ESL}} C = (f/f_{\text{SRF}})^2$.

Checking assumptions a posteriori

Many assumptions can only be checked after the model has been solved, because the size of the neglected term depends on the solution. The discipline is:

1. Solve the simplified model.
2. Use the solution to *evaluate* every neglected term.
3. Confirm each is small compared with the retained terms, by the margin the purpose requires.
4. If not, restore the term and re-solve.

Worked Example 25.21 — A posteriori check of a constant-resistance assumption

Problem. In the DC motor model of Example 25.3, $R_a = 2\ \Omega$ was taken constant. The copper winding has temperature coefficient $\alpha = 0.003\,93\ \text{K}^{-1}$. A thermal model of the motor shows that at rated load the winding settles 40 K above the temperature at which R_a was measured. The speed model must be accurate to 5 %. Is the assumption acceptable?

Evaluate the neglected effect. $R_a(T) = R_a(1 + \alpha\Delta T) = 2(1 + 0.157) = 2.31\ \Omega$ — a 15.7 % change.

Effect on the output. At load torque τ_L the steady speed (with b small) is $\omega \approx v_a/K - R_a\tau_L/K^2$. The *speed droop* term is proportional to R_a, so it is underestimated by 15.7 %. If the droop is 10 % of no-load speed, the speed error is 1.6 %: acceptable. If the motor runs at stall-like loads where droop is 50 %, the error is 7.9 %: not acceptable, and R_a must become temperature-dependent — making temperature a *state* coupled to an electrical model (Section 25.2).

Moral. Whether an assumption is valid depends on how sensitive the *output of interest* is to it, which is a question about the model's sensitivity, not only about the size of the neglected effect.

Engineering Note — write the assumptions down

Professional models (a thermal design report, a link budget, a SPICE netlist submitted for review) should begin with a numbered list of assumptions, each with its validity criterion and, ideally, the computed margin ("lumped: $\ell/\lambda = 0.03$ at the highest frequency of interest"). When the design changes — a faster edge, a hotter enclosure — the list tells you immediately which parts of the model must be revisited.

Common Pitfall — validity by habit

Assumptions inherited from a textbook or a previous project ("op-amps are ideal", "wires are short", "noise is white", "the load is resistive") are the most dangerous, because they are never questioned. The circuit that worked at 1 MHz does not work at 100 MHz for precisely this reason. Each assumption should be re-justified for every new operating range.

Conservative and non-conservative assumptions

Some assumptions err in a known direction. Neglecting a heat path *over*-predicts temperature (conservative for reliability); neglecting a parasitic capacitance may *under*-predict oscillation risk (non-conservative). When an assumption cannot be justified precisely, choosing the conservative direction lets the model still give a safe answer — a bound rather than an estimate. Worst-case and corner analysis (setting each uncertain parameter at the extreme that hurts most) is the systematic version of this idea; Monte Carlo analysis (Ch. 24) is the statistical version.

25.7 Model validation

Verification, calibration, validation

Three activities are often confused:

Verification, calibration and validation

- **Verification** asks *"Are we solving the equations right?"* — is the code or derivation a correct solution of the stated mathematical model? (Checked against analytical solutions, convergence tests, conservation checks.)
- **Calibration** (parameter identification, Section 25.8) asks *"What parameter values make the model match these data?"*
- **Validation** asks *"Are we solving the right equations?"* — does the calibrated model reproduce the behaviour of the real system, to the accuracy required, on data that were **not** used for calibration?

A model can be perfectly verified and perfectly calibrated and still be invalid: a first-order model fitted by least squares to a second-order system will be solved exactly and fitted optimally, and still be wrong. Validation is the step that catches structural error, and it requires data the model has not seen.

Residuals

Residual

Given measurements y_k ($k = 1, \dots, N$) and model predictions $\hat{y}_k$ at the same conditions, the **residuals** are

$$e_k = y_k - \hat{y}_k.$$

If the model is structurally correct and the measurements contain independent zero-mean noise of standard deviation σ, the residuals should look like that noise: zero mean, standard deviation $\approx \sigma$, no trend against time, input or predicted value, and no correlation between neighbours.

Residual analysis is the single most informative validation tool, because *structure in the residuals points to the missing physics*. A bowed residual plot means a missing curvature (a quadratic term, a saturation); residuals growing with $\hat{y}$ mean multiplicative rather than additive error; residuals that oscillate in time mean an unmodelled mode; a step in the residuals means an unmodelled event.

Goodness-of-fit measures

For a model with p fitted parameters and N data points, with $\bar{y} = \frac{1}{N}\sum y_k$:

Measure	Definition	Interpretation
Sum of squared errors	$\mathrm{SSE} = \sum e_k^2$	raw misfit; depends on units and N
Root-mean-square error	$\mathrm{RMSE} = \sqrt{\mathrm{SSE}/N}$	typical error, in units of y
Residual standard error	$s = \sqrt{\mathrm{SSE}/(N-p)}$	unbiased estimate of σ (Ch. 20)
Coefficient of determination	$R^2 = 1 - \mathrm{SSE}/\mathrm{SST},\ \mathrm{SST} = \sum (y_k - \bar{y})^2$	fraction of variance "explained"
Adjusted R^2	$1 - \dfrac{\mathrm{SSE}/(N-p)}{\mathrm{SST}/(N-1)}$	penalises extra parameters
Chi-square	$\chi^2 = \sum (e_k/\sigma_k)^2$	with known noise σ_k
Reduced chi-square	$\chi^2_\nu = \chi^2/\nu,\ \nu = N - p$	≈ 1 for an adequate model
Normalized fit	$100\left(1 - \dfrac{\lVert \mathbf{y} - \hat{\mathbf{y}} \rVert}{\lVert \mathbf{y} - \bar{y}\mathbf{1} \rVert}\right)\%$	used in system identification

Reduced chi-square test

If the model is correct, the noise is Gaussian with known standard deviations σ_k, and p linear parameters are fitted, then χ^2 follows a chi-square distribution with $\nu = N - p$ degrees of freedom (Ch. 20). Hence $E[\chi^2_\nu] = 1$ and $\mathrm{Var}(\chi^2_\nu) = 2/\nu$. A value of χ^2_ν far above $1 + 2\sqrt{2/\nu}$ indicates model inadequacy (or underestimated noise); a value far below 1 indicates overestimated noise or overfitting.

Common Pitfall — a high R^2 does not validate a model

R^2 measures how much of the *variation in the data* the model reproduces. When the data span a wide range (a sensor calibrated from 0 to 400 °C), almost any monotonic model achieves $R^2 > 0.999$, while its errors can still be fifty times the measurement noise. R^2 cannot detect structural error; residual plots and χ^2_ν can.

Worked Example 25.22 — Validating a linear RTD model

Problem. A platinum resistance thermometer is calibrated at nine temperatures; the resistance meter has standard uncertainty $\sigma = 0.02\ \Omega$.

T (°C)	0	50	100	150	200	250	300	350	400
R (Ω)	100.04	119.41	138.51	157.29	175.85	194.09	212.05	229.70	247.09

Fit (a) a linear model $R = c_0 + c_1 T$ and (b) a quadratic model $R = c_0 + c_1 T + c_2 T^2$. Validate each.

(a) Linear. Least squares (Section 25.8) gives $c_0 = 101.362\ \Omega$, $c_1 = 0.367\,65\ \Omega/^\circ\mathrm{C}$. Then

$$\mathrm{SSE} = 6.242\ \Omega^2, \quad R^2 = 0.999\,69, \quad \mathrm{RMSE} = 0.833\ \Omega, \quad \chi^2_\nu = \frac{6.242/0.02^2}{7} = 2229.$$

R^2 looks superb. But the residuals are

$$-1.32,\ -0.34,\ +0.38,\ +0.78,\ +0.96,\ +0.82,\ +0.39,\ -0.34,\ -1.33\ \ \Omega,$$

a symmetric bow, up to sixty-five times the noise level, and $\chi^2_\nu \approx 2229$ is absurdly larger than 1. The linear model is **invalid** at this accuracy: it is missing curvature. As a temperature sensor it would err by up to $1.33/0.368 \approx 3.6\ ^\circ\mathrm{C}$.

(b) Quadratic. $c_0 = 100.034\ \Omega$, $c_1 = 0.390\,43\ \Omega/^\circ\mathrm{C}$, $c_2 = -5.694 \times 10^{-5}\ \Omega/^\circ\mathrm{C}^2$, with

$$\mathrm{SSE} = 1.15 \times 10^{-3}\ \Omega^2, \quad \mathrm{RMSE} = 0.011\ \Omega, \quad \chi^2_\nu = \frac{2.87}{6} = 0.48.$$

Residuals $(+0.006, -0.003, +0.003, -0.026, +0.009, +0.009, +0.013, -0.008, -0.004\ \Omega)$ show no pattern and are at the noise level. With $\nu = 6$, the 95 % range of χ^2_ν is roughly 0.21 to 2.41, so 0.48 is consistent with a correct model (the data were also rounded to 0.01 Ω, which slightly reduces the apparent noise).

Physics check. The fitted $c_1/c_0 = 3.903 \times 10^{-3}$ and $c_2/c_0 = -5.69 \times 10^{-7}$ per °C² are close to the Callendar–Van Dusen standard coefficients $A = 3.9083 \times 10^{-3}$, $B = -5.775 \times 10^{-7}$ — independent confirmation that the quadratic structure is physical, not just a better curve.

Residual tests for dynamic models

For time-series data, residuals must also be **uncorrelated in time**. The sample autocorrelation of the residuals,

$$\hat{r}(k) = \frac{\sum_{n=1}^{N-k} (e_n - \bar{e})(e_{n+k} - \bar{e})}{\sum_{n=1}^{N} (e_n - \bar{e})^2},$$

is approximately $\mathcal{N}(0, 1/N)$ for each $k \geq 1$ if the residuals are white (Ch. 21). Values outside $\pm 1.96/\sqrt{N}$ at more than about 5 % of lags indicate unmodelled dynamics. A complementary test is the cross-correlation between residuals and past inputs, which should also vanish if the model has captured the input–output dynamics.

Worked Example 25.23 — Detecting a missing time constant

Problem. A sensor's step response is sampled at 251 points over 5 s, with noise of standard deviation 0.01. Unknown to the modeller, the true response is second order with time constants 1.0 s and 0.2 s. Fit a first-order model $K(1 - e^{-t/\tau})$ and a second-order model, and compare residual autocorrelations.

First-order fit. Nonlinear least squares gives $K = 1.037$, $\tau = 1.334$ s, RMSE $= 0.030$ — only three times the noise, and a plot of model against data "looks good". But the residual autocorrelation is

$$\hat{r}(1) = 0.88, \quad \hat{r}(2) = 0.88, \quad \hat{r}(5) = 0.84, \quad \hat{r}(10) = 0.75,$$

against a whiteness bound $1.96/\sqrt{251} = 0.124$. The residuals are a slow, smooth curve — the signature of a missing mode. Note also that the fitted τ (1.33 s) is not either true time constant: an incorrect structure biases the parameters.

Second-order fit. $K = 0.999$, $\tau_1 = 0.991$ s, $\tau_2 = 0.205$ s, RMSE $= 0.0096$ (matching the noise), $\hat{r}(1) = -0.06$, $\hat{r}(2) = -0.04$, $\hat{r}(5) = -0.08$, $\hat{r}(10) = 0.02$: all within the bound. The model is accepted, and its parameters are now close to the true ones.

Overfitting and the need for independent data

Adding parameters always reduces SSE on the data used for fitting: a polynomial of degree $N - 1$ passes through all N points exactly. A model that fits the noise rather than the system is **overfitted**: it reproduces the calibration data beautifully and predicts new data badly. The expected prediction error of a model decomposes (for squared error) as

$$E\left[(y_{\text{new}} - \hat{y})^2\right] = \underbrace{\sigma^2}_{\text{irreducible noise}} + \underbrace{\left(\text{bias}\right)^2}_{\text{structural error}} + \underbrace{\text{variance}}_{\text{parameter uncertainty}},$$

the **bias–variance trade-off**. Too simple a model has large bias; too complex a model has large variance because its many parameters are poorly determined by finite data. The goal is the minimum of the sum, and it can only be found by testing on data that were not used for fitting.

Cross-validation

- **Hold-out validation:** split the data into a *training* set (for fitting) and a *validation* set (for evaluating prediction error).
- **k-fold cross-validation:** split the data into k parts; fit k times, each time leaving one part out and computing the prediction error on it; average the k errors.
- **Leave-one-out cross-validation (LOOCV):** $k = N$. For linear least squares it needs no refitting: with hat matrix $\mathbf{H} = \mathbf{X}(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}$ and leverages h_{kk}, the leave-one-out residual is $e_k/(1 - h_{kk})$, and the **PRESS** statistic is

$$\mathrm{PRESS} = \sum_{k=1}^{N} \left(\frac{e_k}{1 - h_{kk}} \right)^2 .$$

Why the shortcut holds (sketch). Removing observation k changes the normal-equation matrix by a rank-one term $-\mathbf{x}_k\mathbf{x}_k^{\mathsf{T}}$; the Sherman–Morrison formula for the inverse of a rank-one update gives the new prediction at $\mathbf{x}_k$ in closed form, and simplifying yields $y_k - \hat{y}_{k,(-k)} = e_k/(1 - h_{kk})$. Points with high leverage (h_{kk} near 1, typically at the ends of the range) have their leave-one-out errors amplified the most, which is exactly where overfitted polynomials misbehave.

Worked Example 25.24 — Choosing the polynomial order by cross-validation

Problem. For the RTD data of Example 25.22, compare degrees 1, 2 and 3 by LOOCV.

Computation (PRESS via leverages):

Degree	p	Training RMSE (Ω)	LOOCV RMSE $\sqrt{\mathrm{PRESS}/N}$ (Ω)	AICc
1	2	0.833	1.192	— (structurally inadequate)
2	3	0.0113	**0.0161**	−69.9
3	4	0.0097	0.0175	−65.5

The training RMSE keeps falling as parameters are added, as it always must. The leave-one-out error is smallest for the quadratic: the cubic term reduces the training error by fitting noise, and that "improvement" does not survive prediction of withheld points. The small-sample Akaike criterion, $\mathrm{AICc} = N\ln(\mathrm{SSE}/N) + 2p + 2p(p+1)/(N-p-1)$, agrees. Both select the physically motivated quadratic model.

Common Pitfall — cross-validating time series by random shuffling

For dynamic data, neighbouring samples are correlated. Randomly assigning samples to folds lets the model "see" the neighbours of every validation point, and the cross-validation error is optimistically biased. Use **blocked** folds (contiguous segments of time), or better, validate on an entirely separate experiment with a different input signal.

Engineering Note — validate against the purpose

A model is validated *for a purpose*. A thermal model intended to predict peak junction temperature should be validated on the peak, under the worst-case load profile, not on the average temperature under a gentle one. Choose validation experiments that stress the conditions where the model will be used, and especially those where the assumptions of Section 25.6 are closest to failing.

25.8 Parameter identification

The identification problem

A grey-box model has a structure from physics and parameters from data. **Parameter identification** (estimation, calibration, fitting) is the inverse problem: given input–output measurements, find the parameter vector $\mathbf{p}$ that makes the model reproduce them.

Output-error parameter estimation

Given data $\{(u_k, y_k)\}_{k=1}^{N}$ and a model that predicts $\hat{y}_k(\mathbf{p})$, the **least-squares estimate** is

$$\hat{\mathbf{p}} = \arg\min_{\mathbf{p}} J(\mathbf{p}), \qquad J(\mathbf{p}) = \sum_{k=1}^{N} w_k \big(y_k - \hat{y}_k(\mathbf{p})\big)^2,$$

with weights $w_k = 1/\sigma_k^2$ when measurement uncertainties differ. If the errors are independent Gaussian, this is also the maximum-likelihood estimate (Ch. 20).

Three families of method are used in practice, in increasing generality: graphical/characteristic-point methods (read parameters off a step response), linear least squares (when the model is linear in the parameters) and nonlinear least squares (everything else). All of them must be followed by an identifiability check: are the data actually capable of determining the parameters?

Identification from a step response

The step response is the most common identification experiment in EE: switch on a heater, a motor voltage, a reference input, and record the output. Standard model structures have parameters that can be read from characteristic features.

First-order step response

For $\tau\dot{y} + y = Ku$ with a step of size Δu at $t = 0$ from equilibrium, $y(t) - y(0) = K\Delta u\left(1 - e^{-t/\tau}\right)$. Hence

- **gain:** $K = \Delta y_\infty / \Delta u$;
- **time constant:** τ is the time to reach $1 - e^{-1} = 63.2\,\%$ of the final change; equivalently, the initial slope is $K\Delta u/\tau$;
- **log-linear form:** $\ln\left(1 - \dfrac{y(t) - y(0)}{\Delta y_\infty}\right) = -\dfrac{t}{\tau}$, a straight line through the origin with slope $-1/\tau$.

The log-linear form is preferable to reading a single point, because it uses all the data and its straightness is itself a validation test: curvature at early times reveals a second, faster time constant or a dead time. For a first-order-plus-dead-time (FOPDT) model $Ke^{-\theta s}/(\tau s + 1)$, a classic two-point method uses the times t_{28} and t_{63} at which the response reaches 28.3 % and 63.2 %: $\tau = 1.5\,(t_{63} - t_{28})$, $\theta = t_{63} - \tau$ (these follow from $1 - e^{-1/3} = 0.283$ and $1 - e^{-1} = 0.632$).

Worked Example 25.25 — Identifying a first-order system from step data

Problem. The supply node of Example 25.1 is tested: after switch-on, its voltage settles at $v_\infty = 4.00$ V, and samples are

t (s)	0.02	0.05	0.10	0.15	0.20	0.30
v (V)	0.743	1.571	2.524	3.081	3.459	3.798

Estimate τ.

Single point. $0.632 \times 4.00 = 2.528$ V is reached at about $t = 0.10$ s, so $\tau \approx 0.10$ s.

Log-linear fit. Compute $z = \ln(1 - v/4.00)$: $-0.2055, -0.4988, -0.9970, -1.4708, -2.0006, -2.9858$. The model $z = -t/\tau$ is a line through the origin, so the least-squares slope is

$$\hat{m} = \frac{\sum t_k z_k}{\sum t_k^2} = -9.947\ \text{s}^{-1}, \qquad \hat{\tau} = -1/\hat{m} = 0.1005\ \text{s}.$$

The points lie on the line without systematic curvature (e.g. $z/t = -10.3, -9.98, -9.97, -9.81, -10.0, -9.95$), supporting the first-order structure. Combined with $R = 1\ \text{k}\Omega$ known, $C = \tau/R = 100.5\ \mu\text{F}$.

Caution. The log transform amplifies noise near the end of the transient, where $1 - v/v_\infty$ is small; points beyond about 3τ should be down-weighted or omitted, and an error in v_∞ bends the whole line. Nonlinear least squares on the untransformed data avoids both problems.

Underdamped second-order step response

For $y'' + 2\zeta\omega_n y' + \omega_n^2 y = \omega_n^2 K u$ with $0 < \zeta < 1$, the fractional overshoot M_p and the peak time t_p satisfy

$$M_p = e^{-\pi\zeta/\sqrt{1-\zeta^2}}, \qquad t_p = \frac{\pi}{\omega_d} = \frac{\pi}{\omega_n\sqrt{1-\zeta^2}}.$$

Inverting,

$$\zeta = \frac{-\ln M_p}{\sqrt{\pi^2 + \ln^2 M_p}}, \qquad \omega_n = \frac{\pi}{t_p\sqrt{1-\zeta^2}}.$$

For a free (or impulse) response with successive peaks x_k, x_{k+1} one period apart, the **logarithmic decrement** $\delta = \ln(x_k/x_{k+1}) = 2\pi\zeta/\sqrt{1-\zeta^2}$ gives $\zeta = \delta/\sqrt{4\pi^2 + \delta^2}$; using peaks m periods apart, $\delta = \frac{1}{m}\ln(x_k/x_{k+m})$, is more accurate.

Worked Example 25.26 — Identifying an RLC network from overshoot and peak time

Problem. A filter section modelled as a series RLC circuit with known $C = 1\ \mu\text{F}$ shows, in its capacitor-voltage step response, 25 % overshoot at $t_p = 1.2$ ms. Identify ζ, ω_n, L and R.

Damping. $\ln 0.25 = -1.3863$:

$$\zeta = \frac{1.3863}{\sqrt{9.8696 + 1.9218}} = \frac{1.3863}{3.4339} = 0.404.$$

Natural frequency. $\omega_d = \pi/t_p = 2618$ rad/s; $\sqrt{1-\zeta^2} = 0.9149$, so $\omega_n = 2862$ rad/s ($f_n = 455$ Hz).

Element values. From $\omega_n = 1/\sqrt{LC}$: $L = 1/(\omega_n^2 C) = 1/(8.19 \times 10^6 \times 10^{-6}) = 0.122$ H. From $\zeta = \frac{R}{2}\sqrt{C/L}$: $R = 2\zeta\sqrt{L/C} = 2(0.404)(349.5) = 282\ \Omega$.

Identifiability note. Without knowing C, the step response determines only ω_n and ζ — two numbers — and not the three element values. We return to this below.

Linear least squares

If the model output is linear in the parameters, $\hat{y}_k = \boldsymbol{\varphi}_k^{\mathsf{T}}\mathbf{p}$ (the **regressors** $\boldsymbol{\varphi}_k$ may be nonlinear functions of the inputs), stacking gives $\hat{\mathbf{y}} = \mathbf{X}\mathbf{p}$ with $\mathbf{X}$ the $N \times p$ regression matrix.

Least-squares estimate and its covariance

The minimizer of $\|\mathbf{y} - \mathbf{X}\mathbf{p}\|^2$ satisfies the **normal equations** $\mathbf{X}^{\mathsf{T}}\mathbf{X}\hat{\mathbf{p}} = \mathbf{X}^{\mathsf{T}}\mathbf{y}$; if $\mathbf{X}$ has full column rank,

$$\hat{\mathbf{p}} = (\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{y}.$$

If $\mathbf{y} = \mathbf{X}\mathbf{p}_0 + \boldsymbol{\epsilon}$ with $E[\boldsymbol{\epsilon}] = \mathbf{0}$ and $\mathrm{Cov}(\boldsymbol{\epsilon}) = \sigma^2\mathbf{I}$, then $\hat{\mathbf{p}}$ is unbiased and

$$\mathrm{Cov}(\hat{\mathbf{p}}) = \sigma^2(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1},$$

with σ^2 estimated by $s^2 = \mathrm{SSE}/(N-p)$. (Gauss–Markov: no other linear unbiased estimator has smaller variance.)

Derivation. $J = (\mathbf{y}-\mathbf{X}\mathbf{p})^{\mathsf{T}}(\mathbf{y}-\mathbf{X}\mathbf{p})$ has gradient $-2\mathbf{X}^{\mathsf{T}}(\mathbf{y}-\mathbf{X}\mathbf{p})$ (Ch. 6); setting it to zero gives the normal equations, and the Hessian $2\mathbf{X}^{\mathsf{T}}\mathbf{X}$ is positive definite under full rank, so the stationary point is the global minimum (Ch. 23). Substituting $\mathbf{y}$: $\hat{\mathbf{p}} - \mathbf{p}_0 = (\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\boldsymbol{\epsilon}$, whose mean is zero and whose covariance is $(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}(\sigma^2\mathbf{I})\mathbf{X}(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1} = \sigma^2(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}$. $\square$

Numerically, the normal equations square the condition number of $\mathbf{X}$; QR factorization or the SVD (Ch. 22, Ch. 24) should be used for anything but small, well-conditioned problems.

Many nonlinear models become linear in transformed parameters. The diode equation, the Arrhenius law, power laws $y = ax^b$ and exponential decays all linearize under a logarithm. The transformation also transforms the noise: additive noise of constant variance on y becomes noise of variance σ^2/y^2 on $\ln y$, so an unweighted log-domain fit over-weights small values. Conversely, *multiplicative* (percentage) noise becomes additive with constant variance in the log domain — then the log fit is exactly right.

Worked Example 25.27 — Extracting diode parameters by linear least squares

Problem. A small-signal diode is measured at 300 K ($V_T = 25.85$ mV); the ammeter error is about 2 % of reading.

V (V)	0.40	0.45	0.50	0.55	0.60	0.65
I (A)	1.744×10^{-5}	5.186×10^{-5}	1.653×10^{-4}	4.737×10^{-4}	1.441×10^{-3}	4.479×10^{-3}

Estimate I_S and n with standard errors.

Linearize the model. For $I \gg I_S$, $\ln I = \ln I_S + V/(nV_T)$: linear in $p_1 = \ln I_S$ and $p_2 = 1/(nV_T)$, with regressors $\boldsymbol{\varphi}_k = [1,\ V_k]^{\mathsf{T}}$. Because the noise is a percentage of reading, it is additive with constant variance on $\ln I$, so an unweighted fit is appropriate.

Normal equations. $\sum 1 = 6$, $\sum V = 3.15$, $\sum V^2 = 1.6975$, giving $\mathbf{X}^{\mathsf{T}}\mathbf{X} = \begin{bmatrix} 6 & 3.15 \\ 3.15 & 1.6975 \end{bmatrix}$. Solving with $\mathbf{X}^{\mathsf{T}}\mathbf{y}$ from $y_k = \ln I_k$:

$$\hat{p}_1 = -19.820, \qquad \hat{p}_2 = 22.153\ \mathrm{V}^{-1}.$$

Parameters. $\hat{n} = 1/(\hat{p}_2 V_T) = 1/(22.153 \times 0.025\,85) = 1.746$; $\hat{I}_S = e^{-19.820} = 2.47\times10^{-9}$ A.

Uncertainty. Residual standard error $s = 0.0237$ (i.e. 2.4 % — consistent with the stated 2 % meter error). $\mathrm{Cov}(\hat{\mathbf{p}}) = s^2(\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}$ gives standard errors 0.060 for $\hat{p}_1$ and 0.113 V^{-1} for $\hat{p}_2$. Propagating (Ch. 20): $\sigma_n = \sigma_{p_2}/(p_2^2 V_T) = 0.009$, and since $\sigma_{\ln I_S} = 0.060$, I_S is known to about 6 %. Result: $n = 1.746 \pm 0.009$, $I_S = (2.47 \pm 0.15)$ nA.

Correlation. The correlation coefficient between $\hat{p}_1$ and $\hat{p}_2$ is -0.987. The intercept $\ln I_S$ is an extrapolation to $V = 0$, far outside the data (0.40–0.65 V); any tilt of the line moves the intercept. This strong correlation is a mild form of the identifiability problem discussed next. Re-parameterizing around the data centre, $\ln I = \ln I(V_0) + (V - V_0)/(nV_T)$ with $V_0 = 0.525$ V, makes the two estimates uncorrelated.

Validation. At higher currents the series resistance R_s makes the curve bend below the straight line; residuals trending negative at the top of the range would be the signal to add R_s to the model ($V = nV_T\ln(I/I_S) + IR_s$, no longer linear in the parameters).

Nonlinear least squares

When the model is not linear in its parameters — a step response in τ, a resonance in ω_n and ζ, a diode with series resistance — $J(\mathbf{p})$ is minimized iteratively by the **Gauss–Newton** or **Levenberg–Marquardt** methods of Ch. 23. Linearizing the model about the current estimate $\mathbf{p}^{(m)}$,

$$\hat{\mathbf{y}}(\mathbf{p}) \approx \hat{\mathbf{y}}(\mathbf{p}^{(m)}) + \mathbf{S}\,\Delta\mathbf{p}, \qquad S_{ki} = \left.\frac{\partial \hat{y}_k}{\partial p_i}\right|_{\mathbf{p}^{(m)}},$$

turns each step into a linear least-squares problem for $\Delta\mathbf{p}$:

$$(\mathbf{S}^{\mathsf{T}}\mathbf{S} + \lambda\mathbf{I})\,\Delta\mathbf{p} = \mathbf{S}^{\mathsf{T}}\big(\mathbf{y} - \hat{\mathbf{y}}(\mathbf{p}^{(m)})\big),$$

with $\lambda = 0$ for Gauss–Newton and $\lambda > 0$ adapted for robustness in Levenberg–Marquardt. The **sensitivity matrix** $\mathbf{S}$ plays the role of $\mathbf{X}$; at convergence, $\mathrm{Cov}(\hat{\mathbf{p}}) \approx \sigma^2(\mathbf{S}^{\mathsf{T}}\mathbf{S})^{-1}$. Good starting values — often from the graphical methods above — are essential, because J may have several local minima.

Identifiability

Structural and practical identifiability

A parameter is **structurally identifiable** if, with perfect noise-free data from the chosen experiment, it can be determined uniquely (globally) or up to a finite set of values (locally). It is **practically identifiable** if it can be determined with acceptable precision from the finite, noisy data actually available.

Structural identifiability is a property of the *model and experiment*, independent of the data quality. The test for a linear model: compute the transfer function from the measured input to the measured output; its coefficients are all the data can ever reveal. Each parameter is identifiable only if it can be recovered from those coefficients.

Worked Example 25.28 — Which RC parameters can a step test identify?

Problem. In the circuit of Example 25.1, a voltage step drives R and C, and only the capacitor voltage is measured. Can R and C both be identified? What if the source current is measured too?

Voltage only. The transfer function is $V_C(s)/V_s(s) = 1/(RCs+1)$. Its single coefficient is RC. Every pair (R, C) with the same product gives *identical* data: R and C are individually **not structurally identifiable**; only $\tau = RC$ is. No amount of data or cleverness changes this.

Current as well. $I(s)/V_s(s) = Cs/(RCs+1)$. The initial current after the step is V_s/R, giving R; combined with τ, $C = \tau/R$. Both are now identifiable. The remedy for structural non-identifiability is a *different experiment* — another sensor, another input — not a better optimizer.

The same reasoning explains Example 25.26: the capacitor-voltage step response of a series RLC circuit has transfer function $1/(LCs^2 + RCs + 1)$, i.e. two coefficients for three unknowns, so one element value must be known independently.

Practical identifiability is diagnosed from the **Fisher information matrix** $\mathbf{F} = \mathbf{S}^{\mathsf{T}}\mathbf{S}/\sigma^2$, whose inverse approximates the covariance of the estimates (the Cramér–Rao bound). Warning signs are a large condition number of $\mathbf{F}$, correlation coefficients between parameter estimates near ± 1, and standard errors comparable to the parameters themselves.

Worked Example 25.29 — Practical identifiability depends on the experiment duration

Problem. A first-order step response $y = K(1 - e^{-t/\tau})$ with true $K = 1$, $\tau = 1$ s is sampled at 50 equally spaced points over a window $[0, W]$, with noise $\sigma = 0.01$. Compute the standard errors of $\hat{K}$ and $\hat{\tau}$ and their correlation for $W = 0.2$ s, 1 s and 5 s.

Sensitivities. $\partial y/\partial K = 1 - e^{-t/\tau}$, $\partial y/\partial \tau = -(Kt/\tau^2)e^{-t/\tau}$. Form $\mathbf{S}$ (50 × 2), $\mathbf{F} = \mathbf{S}^{\mathsf{T}}\mathbf{S}/\sigma^2$, and invert:

Window W	$\sigma_{\hat{K}}$	$\sigma_{\hat{\tau}}$ (s)	corr$(\hat{K}, \hat{\tau})$	cond$(\mathbf{F})$
0.2τ	0.63	0.68	0.9998	9 600
1τ	0.028	0.041	0.993	320
5τ	0.0026	0.0097	0.75	36

Interpretation. For $t \ll \tau$, $y \approx Kt/\tau$: the early response depends only on the *ratio* K/τ, so the two parameters are almost perfectly correlated and individually undetermined (63 % and 68 % uncertainty despite 1 % noise!). Recording until the response has settled separates them, since the final value fixes K alone. The model is structurally identifiable in all three cases; practically, only the long experiment identifies it.

Design rule. Plan identification experiments so that each parameter has a distinct, strong effect on the measured output somewhere in the record: run step tests to at least 4–5τ, excite all frequencies of interest (Ch. 21: a persistently exciting input, e.g. a pseudo-random binary sequence), and measure the variables that break structural ambiguities.

Discrete-time (ARX) identification

For sampled data, a powerful shortcut is to fit a difference equation directly. The first-order ARX model

$$y[n] = a\,y[n-1] + b\,u[n-1] + \epsilon[n]$$

is *linear* in (a, b), so linear least squares applies with regressors $\boldsymbol{\varphi}_n = [y[n-1],\ u[n-1]]^{\mathsf{T}}$. The continuous parameters follow from the ZOH relations $a = e^{-T/\tau}$, $b = K(1-a)$: $\hat{\tau} = -T/\ln \hat{a}$, $\hat{K} = \hat{b}/(1-\hat{a})$. Because past noisy outputs appear as regressors, the estimate is biased when the measurement noise is not white in the equation-error sense; instrumental-variable or output-error methods remove the bias. Higher-order ARX, ARMAX and subspace methods generalize the idea and are the workhorses of black- and grey-box system identification.

Common Pitfall — fitting parameters that the model cannot carry

If the residuals of Section 25.7 show structure, fitted parameters are biased in ways that cannot be fixed by more data (Example 25.23: the first-order fit gave $\tau = 1.33$ s, matching neither true time constant). Parameters are only meaningful once the structure has been validated; identification and validation must iterate together.

25.9 Analytical versus numerical solutions

Two ways to answer the same question

Once a model is formulated, scaled, simplified and calibrated, it must be solved. There are two broad routes. An **analytical** (closed-form) solution expresses the answer as a formula in the parameters — $v(t) = v_\infty(1 - e^{-t/RC})$, $\delta = \sqrt{2/(\omega\mu\sigma)}$, $r_d = nV_T/I_D$. A **numerical** solution computes the answer for specific parameter values by an algorithm — an ODE integrator, a finite-element solver, Newton iteration, a Monte Carlo simulation (Ch. 22, Ch. 24). Neither is universally better. The choice is a modeling decision, made with the purpose in mind.

Criterion	Analytical	Numerical
Scope	linear, low-order, simple geometry, special nonlinearities	essentially unrestricted: nonlinear, high-order, complex geometry

Criterion	Analytical	Numerical
Parameter dependence	explicit — sensitivities, scaling laws and design rules read off directly	one parameter set per run; trends need sweeps
Insight	high: shows *why* and which groups matter	low unless combined with scaling and visualization
Accuracy	exact for the model (but the model may be oversimplified to permit it)	approximate: discretization, round-off, convergence tolerances
Cost	cheap to evaluate once found; finding it may be impossible	cheap to set up; can be expensive to run (stiff, 3-D, many runs)
Failure modes	algebra errors; hidden assumptions made "to get a formula"	instability, non-convergence, under-resolved meshes, silently wrong answers
Verification	check limits, dimensions, special cases	compare with analytical cases, refine steps, check conservation

The most effective practice combines both: use analysis to understand structure, find scales, derive limiting cases and check codes; use computation to handle the full model.

When a closed form exists — and when it does not

Closed forms are available for linear constant-coefficient ODEs and PDEs on simple domains (Chs. 11–16), for some nonlinear first-order equations (separable, Bernoulli, Riccati with a known solution), and for special nonlinear problems whose solutions are **special functions** (elliptic integrals for the pendulum, Bessel functions for cylindrical problems, the Lambert W function for diode circuits). Outside these islands — nonlinear circuits of order two or more, coupled multi-physics, irregular geometry — numerical methods are the only route.

Between the two lie **semi-analytical** methods: perturbation expansions in a small parameter (Section 25.4), averaging, describing functions (Section 25.5), and series or transform solutions evaluated numerically. They often give the best of both worlds — formulas that are accurate in a stated regime.

Worked Example 25.30 — A diode circuit: special function versus root-finding

Problem. A source $V_s = 5$ V drives the diode of Example 25.27 ($I_S = 2.47$ nA, $n = 1.746$) through $R = 1$ kΩ. Find the operating point (a) numerically, (b) in closed form.

Equation. KCL: $\dfrac{V_s - v}{R} = I_S\left(e^{v/(nV_T)} - 1\right)$, a transcendental equation with no solution in elementary functions.

(a) Numerical. Bracketing on $[0, 1]$ V and applying Brent's method (or Newton's method, Ch. 22) gives $v = 0.6492$ V, $I = 4.351$ mA in a few iterations.

(b) Closed form. Rearranging to the form $we^{w} = z$ gives, with $a = V_s + RI_S$,

$$v = a - nV_T\, W\!\left(\frac{RI_S}{nV_T}\, e^{a/(nV_T)}\right),$$

where W is the Lambert W function (the inverse of we^{w}). Evaluating gives $v = 0.6492$ V, identical.

Which is better? For one operating point, either. The closed form, however, shows the structure at a glance — v depends on $RI_S/(nV_T)$ and $V_s/(nV_T)$ only, two dimensionless groups — and can be differentiated to obtain sensitivities in closed form. In practice W is itself evaluated by a Newton iteration inside a library, so the "analytical" answer is numerical one level down. The real distinction is not formula versus algorithm, but whether the parameter dependence is *explicit*.

Numerical solutions must be verified

A numerical solution is an approximation whose error must be controlled. Analytical solutions of simplified cases are the main verification tool, and analytical insight (eigenvalues, time scales) predicts the step sizes a numerical method needs.

Stability of forward Euler for a linear system

Applied to $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ with step h, forward Euler gives $\mathbf{x}_{k+1} = (\mathbf{I} + h\mathbf{A})\mathbf{x}_k$, which is stable if and only if $|1 + h\lambda_i| < 1$ for every eigenvalue λ_i of $\mathbf{A}$ (for diagonalizable $\mathbf{A}$; Ch. 22). For $\lambda = -\sigma \pm j\omega_d$, this requires

$$h < \frac{2\sigma}{\sigma^2 + \omega_d^2} = \frac{2\zeta}{\omega_n}.$$

Worked Example 25.31 — Verifying an integrator on the RLC circuit

Problem. Simulate the step response of the RLC circuit of Example 25.4 ($\omega_n = 31\,623$ rad/s, $\zeta = 0.158$) to $t = 1$ ms by forward Euler and by fourth-order Runge–Kutta, and compare with the exact solution $v_C(1\text{ ms}) = 0.993\,59$ V for a 1 V step.

Predicted stability limit. $h_{\max} = 2\zeta/\omega_n = 2(0.158)/31\,623 = 10.0\ \mu$s — even though the ringing period is 201 μs.

Results.

Method	h (μs)	$v_C(1\text{ ms})$ (V)	error (V)
Forward Euler	1	0.9892	4.4×10^{-3}
Forward Euler	2	0.9821	1.1×10^{-2}
Forward Euler	5	0.9208	7.3×10^{-2}
Forward Euler	10	0.0039	≈ 1 (no decay: at the stability limit)
Forward Euler	12	−1.698	diverging
RK4	10	0.993 59	3.4×10^{-6}

Interpretation. The Euler error roughly doubles when h doubles (first-order convergence) until the stability limit predicted analytically is reached, where the answer becomes meaningless. RK4 at $h = 10\ \mu$s is a thousand times more accurate than Euler at 1 μs. Without the exact solution to compare against, the $h = 5\ \mu$s Euler answer (7 % low) might well have been accepted. The habit to cultivate: *before trusting a simulation of the full model, run it on a special case with a known answer*, and *refine the step until the answer stops changing*.

Stiffness: when analysis tells you which solver to use

Stiff system

A system is **stiff** when its eigenvalues (time constants) span many orders of magnitude and the behaviour of interest is governed by the slow ones. Explicit methods are then forced, by stability rather than accuracy, to use steps comparable to the *fastest* time constant over a horizon set by the *slowest*.

Worked Example 25.32 — A stiff RLC circuit

Problem. A series circuit has $R = 1$ kΩ, a parasitic inductance $L = 1\ \mu$H, and $C = 1\ \mu$F. Characterise its time scales and choose a solver for a 5 ms simulation.

Scaling (Section 25.4). $\zeta = \frac{R}{2}\sqrt{C/L} = 500$, so $\varepsilon = 1/(4\zeta^2) = 10^{-6}$. The eigenvalues are the roots of $\lambda^2 + 10^9\lambda + 10^{12} = 0$: $\lambda_1 \approx -10^3$ s^{-1} ($RC = 1$ ms) and $\lambda_2 \approx -10^9$ s^{-1} ($L/R = 1$ ns). The stiffness ratio is 10^6.

Explicit solver. Forward Euler needs $h < 2/10^9 = 2$ ns for stability, i.e. at least 2.5×10^6 steps for 5 ms — all spent resolving a nanosecond transient that ended long ago.

Implicit solver. Backward Euler, the trapezoidal rule or BDF methods (Ch. 22) are stable for any step on this problem; accuracy on the slow mode requires only $h \sim 10$–$50\ \mu$s, about 100–500 steps. Circuit simulators use implicit methods for precisely this reason.

Or remove the stiffness analytically. Since $\varepsilon \ll 1$ and the purpose concerns the millisecond behaviour, the reduced model $RC\dot{v} + v = v_s$ (Section 25.4) is accurate to about ε after the first few nanoseconds, and has a closed-form solution. Analysis has not only chosen the solver; it has made the solver unnecessary.

Common Pitfall — believing the simulation because it is detailed

A detailed numerical model inspires confidence it may not deserve. Mesh too coarse, step too long, tolerance too loose, a unit typed as mV instead of V, a boundary condition on the wrong face — all produce smooth, plausible, wrong results. The analytical checks of this chapter (dimensions, limiting cases, scaling laws, conservation, special-case solutions) are the defence. A simulation that has never been compared with anything is a hypothesis, not a result.

Engineering Note — a practical decision rule

1. Always derive what can be derived cheaply: equilibria, scales, dimensionless groups, linearized eigenvalues, limiting cases.
2. If the question can be answered from those, stop — the formula is the best deliverable.
3. Otherwise, solve numerically, using the analytical results to choose the method and step, to verify the code, and to interpret the output in terms of the dimensionless groups.
4. Present numerical results in scaled form wherever possible, so that one set of curves covers a family of designs.

Synthesis: the book as a modeling toolkit

This chapter has been, in effect, a map of how the rest of the book is used. Every method in the earlier chapters enters the modeling cycle at a particular stage:

Stage of modeling	Methods from this book
Formulating relations	algebra, functions and dimensional consistency (Ch. 1); complex numbers and phasors (Ch. 2–3); derivatives as rates (Ch. 4); integrals as accumulation (Ch. 5); vector calculus for fields and balance laws (Ch. 7)

Stage of modeling	Methods from this book
Organizing the equations	matrices and linear systems (Ch. 8); vector spaces, null spaces and rank — the heart of the Pi theorem (Ch. 9); ODEs and PDEs as the language of dynamics and distributed systems (Ch. 11–13)
Simplifying	Taylor expansion and Jacobians for linearization (Ch. 4, 6); eigenvalues for modes, stability and time-scale separation (Ch. 10); scaling and dimensional analysis (Ch. 1, 25)
Solving	Laplace, Fourier and Z-transforms for linear time-invariant models (Ch. 14–17); complex analysis for inversion and stability (Ch. 18); numerical methods, optimization and computational mathematics when closed forms run out (Ch. 22–24)
Confronting data	probability, statistics and random processes for noise, residuals, estimation, identification and uncertainty (Ch. 19–21); least squares and optimization for calibration (Ch. 20, 23)

Three ideas recur throughout. **Linearity** — superposition, transforms, eigen-decomposition — is the great simplifier, and linearization is how nonlinear reality is brought within its reach. **Dimensionless thinking** — scales, groups, regimes of validity — tells us which effects matter and when a simplification is legitimate. **Comparison with data**, through residuals, likelihoods and cross-validation, is what turns a mathematical exercise into an engineering model. The mathematics of this book is not a collection of separate techniques but a single toolkit, and modeling is the craft of choosing the right tool for each stage of the question.

Summary

Topic	Key formula or rule
Modeling cycle	purpose → concept → equations → solution → validation → use, iterated
Balance law	$\frac{d}{dt}(\text{stored}) = \text{in} - \text{out} + \text{generated}$; constitutive relations close the system
State-space model	$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}; \mathbf{p}),\ \mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u}; \mathbf{p})$
LTI transfer function	$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}$; invariant under $\mathbf{z} = \mathbf{T}\mathbf{x}$
Circuit order	$n = n_C + n_L - n_{\text{C-loops}} - n_{\text{L-cutsets}}$
Buckingham Pi	n quantities, dimension matrix rank $r \Rightarrow n - r$ groups; exponents span null$(\mathbf{D})$
Skin depth	$\delta = \sqrt{2/(\omega\mu\sigma)}$ (form from dimensions alone)
Short dipole	$P = \eta_0 I_0^2\, \Phi(k\ell),\ \Phi = (k\ell)^2/(12\pi)$ for $k\ell \ll 1$
Convection	$\mathrm{Nu} = h\ell/k = \Phi(\mathrm{Re}, \mathrm{Pr}),\ \mathrm{Re} = \rho V \ell/\mu,\ \mathrm{Pr} = \mu c_p/k$
Second-order standard form	$y'' + 2\zeta y' + y = u,\ \tau = \omega_n t,\ \omega_n = 1/\sqrt{LC},\ \zeta = \frac{R}{2}\sqrt{C/L} = 1/(2Q)$
Step-response metrics	$M_p = e^{-\pi\zeta/\sqrt{1-\zeta^2}},\ t_p = \pi/(\omega_n\sqrt{1-\zeta^2}),\ t_s \approx 4/(\zeta\omega_n)$
Biot and Fourier numbers	$\mathrm{Bi} = h\ell/k$ (lumped if < 0.1), $\mathrm{Fo} = \alpha t/\ell^2$
Singular perturbation (RLC)	$\varepsilon y'' + y' + y = u,\ \varepsilon = L/(R^2C) = 1/(4\zeta^2)$
Van der Pol scaling	$x'' - \mu(1 - x^2)x' + x = 0,\ \mu = a\sqrt{L/C},\ v = x\sqrt{a/(3b)}$
Linearization	$\mathbf{A} = \partial\mathbf{f}/\partial\mathbf{x},\ \mathbf{B} = \partial\mathbf{f}/\partial\mathbf{u}$ at $(\bar{\mathbf{x}}, \bar{\mathbf{u}})$; stability from eigenvalues unless on the $j\omega$-axis
Diode small signal	$r_d = nV_T/I_D$; relative error $\approx \lvert\delta v\rvert/(2nV_T)$; $\mathrm{HD}_2 \approx \hat{V}/(4nV_T)$
Pendulum	$T/T_0 = \frac{2}{\pi}K(\sin\frac{\theta_0}{2}) \approx 1 + \theta_0^2/16$
Lumped-circuit validity	$\ell < \lambda/10$, or $t_r \gtrsim 6\, t_{pd}$
Ideal op-amp validity	$\lvert A\beta\rvert \gg 1$; closed-loop bandwidth $\approx f_{\mathrm{GBW}}\beta$
Capacitor self-resonance	$f_{\mathrm{SRF}} = 1/(2\pi\sqrt{L_{\mathrm{ESL}}C})$
Goodness of fit	$R^2 = 1 - \mathrm{SSE}/\mathrm{SST},\ s = \sqrt{\mathrm{SSE}/(N-p)},\ \chi^2_\nu = \sum(e_k/\sigma_k)^2/(N-p) \approx 1$
Residual whiteness	$\lvert\hat{r}(k)\rvert < 1.96/\sqrt{N}$ for most lags
LOOCV (linear LS)	$\mathrm{PRESS} = \sum\big(e_k/(1-h_{kk})\big)^2,\ \mathbf{H} = \mathbf{X}(\mathbf{X}^\mathsf{T}\mathbf{X})^{-1}\mathbf{X}^\mathsf{T}$
First-order identification	$K = \Delta y_\infty/\Delta u$; τ at 63.2 %; $\ln(1 - \Delta y/\Delta y_\infty) = -t/\tau$
Second-order identification	$\zeta = -\ln M_p/\sqrt{\pi^2 + \ln^2 M_p};\ \omega_n = \pi/(t_p\sqrt{1-\zeta^2});\ \zeta = \delta/\sqrt{4\pi^2 + \delta^2}$
Linear least squares	$\hat{\mathbf{p}} = (\mathbf{X}^\mathsf{T}\mathbf{X})^{-1}\mathbf{X}^\mathsf{T}\mathbf{y},\ \mathrm{Cov}(\hat{\mathbf{p}}) = \sigma^2(\mathbf{X}^\mathsf{T}\mathbf{X})^{-1}$
Nonlinear LS step	$(\mathbf{S}^\mathsf{T}\mathbf{S} + \lambda\mathbf{I})\Delta\mathbf{p} = \mathbf{S}^\mathsf{T}(\mathbf{y} - \hat{\mathbf{y}})$
Identifiability	structural: recoverable from transfer-function coefficients; practical: $\mathbf{F} = \mathbf{S}^\mathsf{T}\mathbf{S}/\sigma^2$ well conditioned
ARX first order	$y[n] = ay[n-1] + bu[n-1];\ \tau = -T/\ln a,\ K = b/(1-a)$
Forward Euler stability	$\lvert 1 + h\lambda\rvert < 1$; for $\lambda = -\zeta\omega_n \pm j\omega_d$: $h < 2\zeta/\omega_n$
Stiffness ratio	$\lvert\lambda_{\max}\rvert/\lvert\lambda_{\min}\rvert \gg 1 \Rightarrow$ implicit solver or reduced model

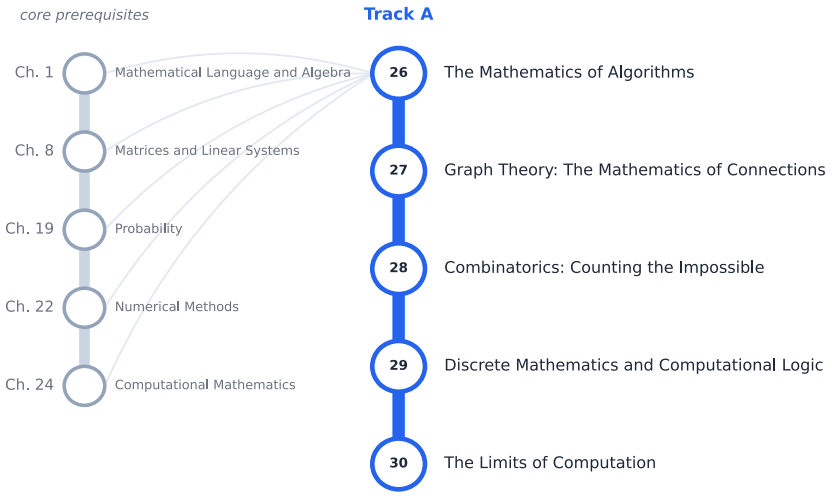
Level 2 — Specializations

Tracks A–I. Each track has its own prerequisite graph; read the ones you need, in any order.

Track A — The Mathematics Behind Algorithms

> **Level 2 — Specializations.** How to make programs faster, prove they work, and understand the limits of computation.



Suggested reading order for Track A. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 1 — Mathematical Language and Algebra
- Ch. 8 — Matrices and Linear Systems
- Ch. 19 — Probability
- Ch. 22 — Numerical Methods
- Ch. 24 — Computational Mathematics

Chapters

Ch.	Chapter	What it explores
26	The Mathematics of Algorithms	Asymptotic analysis, Big-O/Theta/Omega, recurrences, amortized analysis, algorithmic lower bounds, and complexity trade-offs.
27	Graph Theory: The Mathematics of Connections	Paths, trees, flows, matchings, connectivity, graph coloring, planar graphs, network centrality, spectral graph theory.
28	Combinatorics: Counting the Impossible	Permutations, combinations, inclusion–exclusion, recurrence relations, generating functions, pigeonhole principle, Ramsey theory, extremal combinatorics.
29	Discrete Mathematics and Computational Logic	Propositional and predicate logic, induction, relations, sets, discrete structures, Boolean algebra, invariants, proof techniques.
30	The Limits of Computation	Automata, formal languages, Turing machines, decidability, computability, reductions, P versus NP, and undecidable problems.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 26 — The Mathematics of Algorithms

> **Level 2 · Track A — The Mathematics Behind Algorithms Builds on:** Ch. 1, Ch. 17, Ch. 24 · **Leads to:** Ch. 27, Ch. 28, Ch. 30 · **Related:** Ch. 52, Ch. 32 **Reading time:** ~25 min

26.1 The hook

Two engineers are asked to write the same routine. It takes a list of n items (sensors to switch on, jobs to schedule, wires to route) and picks the best combination.

Engineer X writes the obvious thing: try every subset of the n items, score each one, keep the best. There are 2^n subsets, and each one is scored in about one elementary step. Engineer Y writes something cleverer, full of tables and bookkeeping, that needs about $50\,n^2$ elementary steps.

They race the two programs on the test suite, where n runs from 5 to 12. X wins every single test. At $n = 10$, X takes $2^{10} = 1024$ steps and Y takes $50 \times 100 = 5000$: the "naive" code is almost five times faster. Y's code is longer, harder to read, and slower. The team ships X.

Six months later a customer runs it with $n = 40$. On a machine doing 10^9 steps per second, X needs $2^{40} \approx 1.1 \times 10^{12}$ steps, about **18 minutes**. Y would have needed $50 \times 1600 = 80{,}000$ steps: 80 microseconds. A second customer tries $n = 60$. X now needs $2^{60} \approx 1.15 \times 10^{18}$ steps, about **36 years**. Y: 180,000 steps, under a fifth of a millisecond.

Nothing was wrong with the test suite. Every measurement was correct. The machine did not get slower. And yet a program that was five times *faster* became trillions of times *slower*, just because the input grew from 10 to 60.

> **The challenge of this chapter:** Why can an algorithm that is faster on small inputs become terrible on large ones? And can you tell, *before* the customer does, which one it will be?

The answer is not "computers are mysterious". It is a theorem, and a short one. By the end of this chapter you will be able to prove it, predict exactly where the crossover happens, and show that no amount of hardware or clever coding can rescue the exponential.

26.2 The big idea

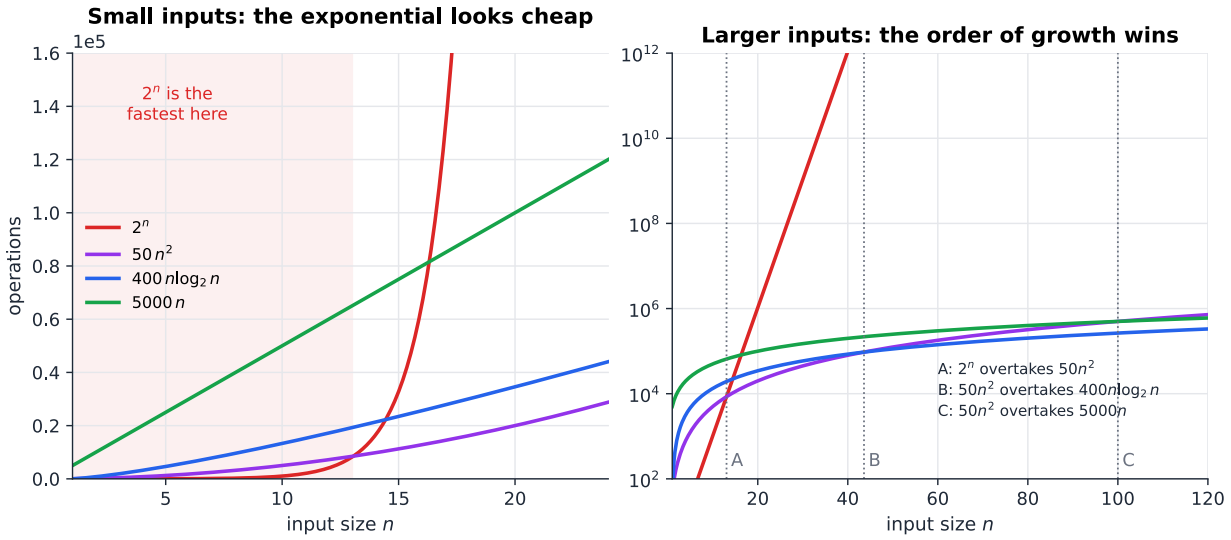
Forget seconds. An algorithm's running time is a **function of the input size**, $T(n)$, and what matters for large inputs is the *shape* of that function, not its value at any particular n.

Here is the most useful single experiment in algorithm analysis: **double the input and see what happens to the cost.**

Cost $T(n)$	$T(2n)$	Doubling the input…
n	$2n$	doubles the cost
$n \log_2 n$	$2n \log_2 n + 2n$	slightly more than doubles it
n^2	$4n^2$	quadruples it
n^3	$8n^3$	multiplies it by 8
2^n	$2^{2n} = (2^n)^2$	**squares** it

That last row is the whole story of the hook. For a polynomial cost, doubling n multiplies the cost by a *fixed* factor (2^k for n^k). For an exponential cost, doubling n *squares* the cost. A thousand steps becomes a million; a million becomes a trillion. No fixed factor can keep up with squaring.

An analogy: a polynomial algorithm is a salary with a raise; an exponential algorithm is compound interest. Over the first few years the big salary looks better. Over a lifetime compound interest wins, and the only question is *when*.



Costs with very different constants. On small inputs (left) the exponential is the cheapest of all four; on a logarithmic scale (right) it is a straight line climbing away from every polynomial. The polynomials reorder too: crossovers A, B, C are where a slower-growing cost finally pays off its larger constant.

Look at the right panel carefully, because it hides a second lesson. The polynomial curves cross each other too. $5000\,n$ has a large constant and is the *worst* of the three polynomials until $n = 100$, after which it beats $50\,n^2$ forever. Every pair of growth rates has a crossover point. Below it the constants decide; above it the **order of growth** decides, and it decides permanently.

So the answer to the challenge question is already visible: small inputs measure constants, large inputs measure growth rates, and the two can disagree. The mathematics will tell us *how far* the crossover can be pushed, and the answer is shockingly small.

26.3 The mathematics

Asymptotic notation, in one paragraph

The definitions of O, Ω and Θ are in Ch. 24, §24.1: $f = O(g)$ means $f(n) \le c\,g(n)$ for all large n; Ω is the reverse inequality; Θ is both. We add one tool and one symbol.

Little-o and the limit test

$f = o(g)$ ("f grows strictly slower than g") means $f(n)/g(n) \to 0$ as $n \to \infty$. If $\lim_{n\to\infty} f(n)/g(n) = L$ exists, then

- $L = 0$ gives $f = o(g)$, hence $f = O(g)$ but not $\Theta(g)$;
- $0 < L < \infty$ gives $f = \Theta(g)$;
- $L = \infty$ gives $g = o(f)$.

The limit test turns "which algorithm scales better?" into a calculus question, and L'Hôpital's rule (Ch. 4) often answers it in one line. For example, $\ln n / n^{0.01} \to 0$: even the feeblest power of n eventually beats a logarithm.

Result 1: every exponential beats every polynomial

Polynomials lose to exponentials

For every fixed $k \ge 0$ and every base $b > 1$,

$$\lim_{n\to\infty} \frac{n^k}{b^n} = 0.$$

Consequently, for any constants $c_1, c_2 > 0$ there is an N such that $c_1\,n^k < c_2\,b^n$ for all $n > N$.

Proof. Let $a_n = n^k / b^n$. The ratio of consecutive terms is

$$\frac{a_{n+1}}{a_n} = \left(1 + \frac{1}{n}\right)^k \frac{1}{b} \;\longrightarrow\; \frac{1}{b} < 1.$$

Pick any q with $1/b < q < 1$. Because the ratio converges to $1/b$, there is an M with $a_{n+1} \le q\,a_n$ for all $n \ge M$. Then $a_n \le a_M\,q^{n-M}$ for $n \ge M$, and $q^{n-M} \to 0$ because $0 < q < 1$. So $a_n \to 0$.

For the second claim, $c_1 n^k / (c_2 b^n) = (c_1/c_2)\,a_n \to 0$, so it is eventually below 1. ∎

That proves the hook's disaster was inevitable. But it does not yet say *when*, and that is where the real surprise is.

How far can a constant push the crossover?

Suppose the exponential algorithm is made c times cheaper than a quadratic one: compare 2^n against $c\,n^2$. Take $\log_2$ of both sides. The exponential is still the cheaper one exactly when

$$n \;<\; \log_2 c + 2\log_2 n.$$

The constant enters only through $\log_2 c$. Every factor of two you squeeze out of the exponential algorithm (a faster chip, better code, a parallel cluster of two machines) buys you **one** more input item before the crossover. A factor of a million buys about $\log_2 10^6 \approx 20$.

With the hook's numbers, $c = 50$ gives a crossover at $n \approx 13.1$. Make the exponential code a million times faster ($c = 5 \times 10^7$) and the crossover moves to $n \approx 35.9$. Twenty-three more items, bought with a millionfold speed-up. Go to $c = 5 \times 10^9$ and you reach $n \approx 43$. The customer with $n = 60$ is out of reach of every computer that will ever be built.

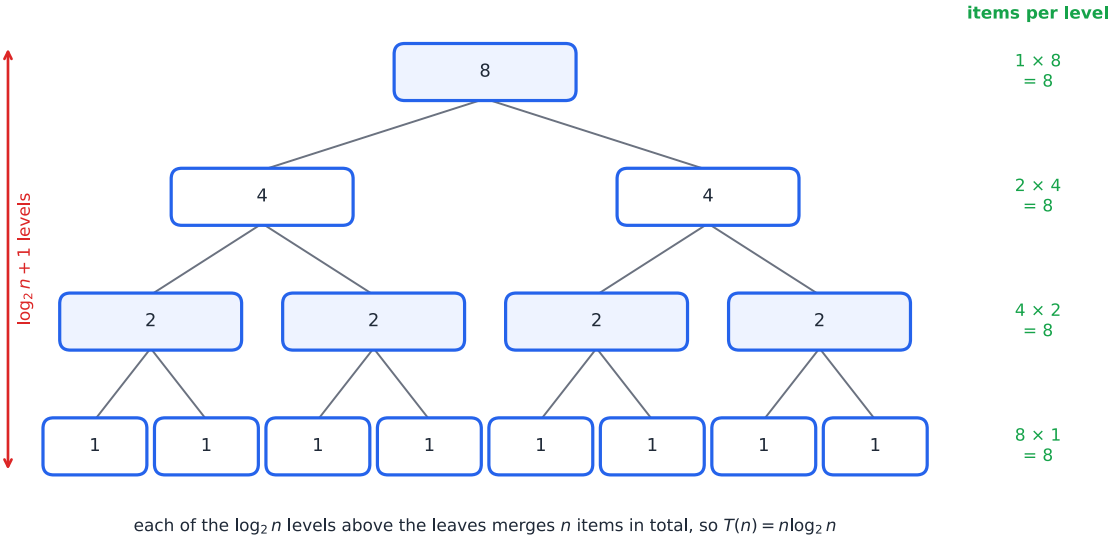
> **The engineering rule**
>
> Hardware improvements multiply your speed, which **adds** to the feasible n of an exponential algorithm and **multiplies** the feasible n of a polynomial one. Moore's law makes an $O(n^2)$ code handle $\sqrt{2}$ times larger inputs every doubling; it makes an $O(2^n)$ code handle exactly one more item.

Result 2: solving a recurrence with a recursion tree

Divide-and-conquer algorithms are analysed by **recurrences**. Merge sort splits a list in half, sorts each half recursively, and merges the two sorted halves in at most n comparisons:

$$T(n) = 2\,T(n/2) + n, \qquad T(1) = 0.$$

A recurrence is a difference equation in disguise. Ch. 17 solves linear difference equations with the Z-transform; here the index *halves* instead of decreasing by one, so we draw the recursion instead.



The recursion tree of merge sort for $n = 8$. Each level splits the work into more, smaller pieces, but the total per level stays n. The height is the number of halvings, $\log_2 n$.

> **Merge-sort recurrence**
>
> For $n = 2^m$, the recurrence $T(n) = 2T(n/2) + n$, $T(1) = 0$, has the exact solution $T(n) = n\log_2 n$.

Proof by induction on m. For $m = 0$: $T(1) = 0 = 1 \cdot \log_2 1$. Assume $T(2^m) = 2^m m$. Then

$$T(2^{m+1}) = 2\,T(2^m) + 2^{m+1} = 2 \cdot 2^m m + 2^{m+1} = 2^{m+1}(m+1),$$

which is $n\log_2 n$ for $n = 2^{m+1}$. ■

The tree shows *why*: at depth i there are 2^i subproblems of size $n/2^i$, so each level costs $2^i \cdot n/2^i = n$, and there are $\log_2 n$ levels that do merging. The general version, $T(n) = a\,T(n/b) + \Theta(n^d)$, is the master theorem stated in Ch. 24, §24.1. The recursion tree explains its three cases in one sentence: the work per level forms a geometric series with ratio a/b^d. If the ratio is below 1 the root dominates, $\Theta(n^d)$; if it equals 1 every level counts equally and you pay a $\log n$ factor; if it is above 1 the leaves dominate, $\Theta(n^{\log_b a})$.

> **Why the exponent of matrix multiplication is not 3**
>
> Multiplying two $n \times n$ matrices by splitting into 2×2 blocks needs 8 block products: $T(n) = 8T(n/2) + \Theta(n^2)$, so $\Theta(n^{\log_2 8}) = \Theta(n^3)$. Strassen found a way with 7 block products. The ratio $7/2^2 > 1$ puts us in the leaf-dominated case: $\Theta(n^{\log_2 7}) = \Theta(n^{2.807})$. Saving one multiplication out of eight at the top changes the exponent, because the saving compounds at every level.

? The exponent nobody knows

Strassen's trick was improved again and again, and as of 2024 the best known exponent for matrix multiplication is about 2.371. The obvious lower bound is 2 (you have to read n^2 entries). Is the true exponent ω equal to 2? Nobody knows. It is one of the great open problems of algorithm theory, and how mathematicians attack problems like it is the subject of Ch. 98.

Result 3: amortized analysis — the cheap average of an expensive worst case

A dynamic array (Python's `list`, C++'s `vector`) stores items in a fixed block of memory. When the block is full, the next append allocates a block **twice as large** and copies everything over. A single append can therefore cost n copies. Is appending $O(n)$?

Doubling makes appends $O(1)$ amortized

Starting from capacity 1 and doubling when full, any sequence of n appends performs fewer than $3n$ elementary writes in total. The **amortized** cost per append is therefore $O(1)$, even though a single append can cost $\Theta(n)$.

Proof. Each append writes its own item once: n writes. Copies happen when the size reaches $1, 2, 4, \dots, 2^k$ where $2^k < n$, costing $1 + 2 + 4 + \cdots + 2^k = 2^{k+1} - 1 < 2n$ copies. Total: fewer than $n + 2n = 3n$. ∎

Amortization is a statement about *sequences* of operations, not single ones. Here is the trap in the other direction: grow the block by a fixed $+100$ slots instead of doubling, and the copies cost $100 + 200 + \cdots \approx n^2/200$, which is $\Theta(n^2)$ in total. Both versions are instant in a unit test with 1000 items. Only one survives ten million.

The proof above simply added the costs (the **aggregate method**). The more powerful **potential method** stores "prepaid credit" Φ in the data structure: each cheap append pays 3 units, uses 1, and banks 2 against the next expensive copy. It is the same accounting idea an engineer uses for energy in a capacitor: cheap steps charge it, the expensive step discharges it, and the books balance over any window.

Result 4: a lower bound — no sorting algorithm can beat $n \log n$

Big-O answers "how fast is *this* algorithm?". A **lower bound** answers a far bolder question: "how fast can *any* algorithm possibly be?". Lower bounds are rare and precious, because they speak about programs nobody has written yet.

The comparison-sorting lower bound

Any algorithm that sorts n distinct items using only pairwise comparisons ("is $x_i < x_j$?") needs at least $\lceil \log_2 n! \rceil$ comparisons in the worst case, and $\log_2 n! = \Theta(n \log n)$.

Proof. Model any such algorithm as a **decision tree**: each internal node is a comparison, each branch is its outcome, and each leaf is a final answer ("the sorted order is $x_3 < x_1 < x_2$"). Different input orderings must reach different leaves, otherwise the algorithm gives the same answer to two inputs that need different answers. There are $n!$ orderings, so the tree has at least $n!$ leaves. A binary tree of height h has at most 2^h leaves, so $2^h \geq n!$, that is $h \geq \log_2 n!$. The height is the worst-case number of comparisons.

For the growth rate: the largest $n/2$ factors of $n!$ are each at least $n/2$, so $n! \geq (n/2)^{n/2}$ and $\log_2 n! \geq \frac{n}{2} \log_2 \frac{n}{2} = \Omega(n \log n)$. Also $n! \leq n^n$ gives $\log_2 n! \leq n \log_2 n$. ∎

For $n = 10$ the bound is $\lceil \log_2 3{,}628{,}800 \rceil = \lceil 21.79 \rceil = 22$ comparisons. For $n = 10^6$ it is about 1.85×10^7, while merge sort uses at most $n \log_2 n \approx 1.99 \times 10^7$. Merge sort is within 8% of the best that is *logically possible*. That is the power of a lower bound: it tells you when to stop optimizing.

Lower bounds have fine print

The theorem is about the *comparison model*. Sort n integers that fit in a machine word and radix sort runs in $O(n)$, because it looks at digits instead of comparing. A lower bound is only as strong as the model it is proved in, and many famous "impossibility" results are really statements about one model of computation.

Trade-offs: what big-O does not tell you

Big-O picks the winner as $n \to \infty$. Engineers live at finite n, and three trade-offs decide real choices:

- **Time against memory.** A lookup table turns a computation into $O(1)$ time at the cost of memory; memoization (Ch. 52) turns some exponential recursions into polynomial ones by storing every sub-answer.
- **Worst case against typical case.** Quicksort is $\Theta(n^2)$ in the worst case and roughly $1.39\, n \log_2 n$ comparisons on average; it is usually faster than merge sort anyway.
- **Constants against growth.** Library sorts switch to insertion sort ($\Theta(n^2)$) for sub-lists below about 16–32 items, exactly because of the left panel of the first figure.

? Where does the 1.39 come from?

Quicksort with a random pivot makes about $2n \ln n \approx 1.39\, n \log_2 n$ comparisons on average. The worst case is quadratic, so the average needs a probability argument over all $n!$ orderings, and the constant $2 \ln 2 \approx 1.39$ comes out of a harmonic sum. That argument, counting random arrangements, is developed in Ch. 32.

26.4 The algorithm

Analysis becomes real when you can *count*. Here is merge sort instrumented to return the number of comparisons it makes, the quantity the lower bound talks about:

```
def merge_sort(a):
    """Return (sorted copy of a, number of comparisons)."""
    if len(a) <= 1:
        return list(a), 0
    mid = len(a) // 2
    left, cl = merge_sort(a[:mid])
    right, cr = merge_sort(a[mid:])
    out, i, j, comps = [], 0, 0, cl + cr
    while i < len(left) and j < len(right):
        comps += 1
        if left[i] <= right[j]:
            out.append(left[i]); i += 1
        else:
            out.append(right[j]); j += 1
    out += left[i:] + right[j:]          # one side is exhausted: no comparisons needed
    return out, comps
```

On a random permutation of 1000 items this makes about 8700 comparisons, below the worst-case $n \log_2 n \approx 9966$ and above the information-theoretic floor $\log_2 1000! \approx 8530$.

Complexity. Time $\Theta(n \log n)$ in every case (best, average, worst), by the recursion tree. Extra memory $\Theta(n)$ for the merged lists. Recursion depth $\lceil \log_2 n \rceil$, so about 20 for a million items: no risk of stack overflow.

How to analyse any algorithm in four moves.

1. *Choose the cost unit.* Comparisons, arithmetic operations, memory reads, disk seeks, messages over a network. The right unit is the one that dominates the wall-clock time.
2. *Write the cost as a function of n.* Loops become sums ($\sum_{i=1}^{n} i = n(n+1)/2$ for a triangular double loop); recursion becomes a recurrence.
3. *Solve or bound it.* Sums by closed forms or integrals (Ch. 5); recurrences by recursion trees, the master theorem, or generating functions (Ch. 28).
4. *Check the constant at realistic sizes.* Measure. Big-O says who wins eventually, not who wins at *your* n.

Failure cases worth knowing.

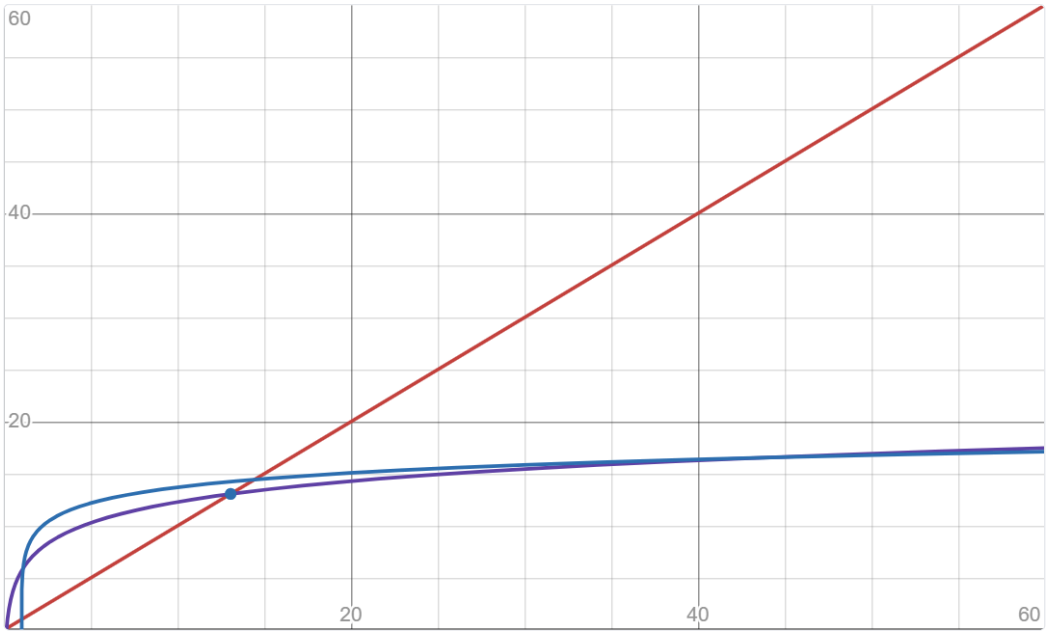
- *Quicksort on sorted input.* With "first element as pivot", an already-sorted list splits into sizes 0 and $n-1$ every time: $T(n) = T(n-1) + n = \Theta(n^2)$, and recursion depth n. Random pivots fix the expected cost, not the worst case.
- *Hash tables under attack.* A hash table is $O(1)$ per lookup *on average*. An adversary who knows the hash function can make every key collide, turning a web server's $O(n)$ request parsing into $O(n^2)$. This is a real denial-of-service attack, and the reason many languages randomize their hash seeds.
- *The hidden factor in "linear".* String concatenation in a loop (`s = s + piece`) copies the whole string every time: $\Theta(n^2)$ characters copied, the same trap as growing an array by $+100$.

> **Measuring is not analysing**
>
> Timing a program at $n = 10, 20, 40$ and fitting a curve can tell you the exponent of a polynomial (log–log slope), but it cannot distinguish n^{10} from 2^n over a short range, and it cannot see a worst case that your test data never triggers. Measurement estimates constants; analysis guarantees growth.

26.5 The experiment

Where is the crossover? (drag the constant)

Plotting $\log_2$ of the cost turns the exponential 2^n into the straight line $y = n$ and turns $c\,n^2$ into $\log_2 c + 2\log_2 n$, a curve that bends over and flattens:



Vertical axis: $\log_2(\text{cost})$. *Red is* 2^n, *purple is* $50\,n^2$, *blue is* $400\,n\log_2 n$. *The red line crosses each curve once and never comes back.*

Change the **50** in the purple curve to **50000000** (a millionfold handicap for the exponential algorithm). The purple curve rises by about 20 units, and the crossover slides only from $n \approx 13$ to $n \approx 36$. Then change the **2** in front of the second term to **3** (a cubic algorithm) and see how little that changes the picture: the logarithm of any polynomial is a gently bending curve, and the logarithm of an exponential is a straight line that always gets out from under it.

Insertion sort against merge sort (run it)

Insertion sort is $\Theta(n^2)$ but each step is tiny; merge sort is $\Theta(n \log n)$ but each comparison carries the overhead of recursion and list copying. The script counts comparisons for both and charges merge sort a configurable overhead per comparison.

```
import numpy as np
import matplotlib.pyplot as plt

def insertion_cost(a):              # comparisons made by insertion sort
    a, c = list(a), 0
    for i in range(1, len(a)):
        j = i
        while j > 0:
            c += 1
            if a[j - 1] <= a[j]:
                break
            a[j - 1], a[j] = a[j], a[j - 1]
            j -= 1
    return c

def merge_cost(a):                  # comparisons made by merge sort
    if len(a) <= 1:
        return list(a), 0
    m = len(a) // 2
    (L, cl), (R, cr) = merge_cost(a[:m]), merge_cost(a[m:])
    out, i, j, c = [], 0, 0, cl + cr
    while i < len(L) and j < len(R):
        c += 1
        if L[i] <= R[j]: out.append(L[i]); i += 1
        else:            out.append(R[j]); j += 1
    return out + L[i:] + R[j:], c

OVERHEAD = 4.0                      # KNOB: extra cost per merge-sort comparison
rng = np.random.default_rng(0)
ns = np.arange(2, 201, 2)           # KNOB: range of input sizes
ins = [np.mean([insertion_cost(rng.permutation(n)) for _ in range(20)]) for n in ns]
mer = [OVERHEAD * np.mean([merge_cost(list(rng.permutation(n)))[1] for _ in range(20)]) for n in ns]
cross = ns[np.argmax(np.array(ins) > np.array(mer))]
print("insertion sort stops winning at n =", cross)
plt.plot(ns, ins, label="insertion sort"); plt.plot(ns, mer, label=f"merge sort x {OVERHEAD}")
plt.axvline(cross, ls=":"); plt.xlabel("n"); plt.ylabel("cost"); plt.legend(); plt.show()
```

With `OVERHEAD = 4.0` the crossover lands at about $n = 78$; with `1.0` it is about 4, with `2.0` about 28. Try `8.0` and widen `ns` to 600: the crossover keeps moving right, but it always exists. Then replace `rng.permutation(n)` with `np.arange(n)` (already sorted input) and watch insertion sort become *linear*: the "worst" algorithm is the best one on nearly-sorted data, which is why it survives inside every production sort.

26.6 The challenge

1. **Intuition.** Algorithm P costs n^{100} steps and algorithm E costs 1.01^n steps. Theorem 1 says E eventually loses. Without computing anything exactly, explain why "eventually" here means an astronomically large n, and argue which one you would actually deploy for $n \le 10^6$.
2. **Derivation.** Solve the recurrence $T(n) = 3\,T(n/2) + n$, $T(1) = 1$, for $n = 2^m$ exactly, by summing the recursion tree level by level. Show that the answer is $\Theta(n^{\log_2 3})$ and identify which level of the tree carries most of the work. (This recurrence is Karatsuba's fast multiplication of n-digit numbers.)
3. **Implementation.** Write a dynamic array class with a `growth` parameter: capacity is multiplied by `growth` when full. Count total element copies for 10^6 appends with growth factors 1.1, 1.5, 2 and 4, and also record the peak wasted memory (capacity minus size). Plot copies against waste. Which factor would you choose, and why do real libraries use something between 1.5 and 2?
4. **Open investigation.** The comparison lower bound $\lceil \log_2 n! \rceil$ is not always achievable. For $n = 12$ it equals 29, yet the minimum worst-case number of comparisons needed to sort 12 items is known to be 30. Write a program that searches for optimal comparison strategies for small n ($n \le 6$ is feasible) and compare with $\lceil \log_2 n! \rceil$. The exact optimum is still unknown for many n above 15: what patterns can you find?

26.7 Loose threads

This chapter answered its challenge: an algorithm that is fast on small inputs becomes terrible on large ones when its *order of growth* is worse, because constants only shift the crossover by a logarithmic amount, while growth rates compound. We proved that every exponential beats every polynomial, solved a recurrence exactly, showed that amortization tames occasional expensive steps, and proved that no comparison sort can beat $n \log n$.

But we only ever counted *steps*. Several questions were raised and left on the table.

> **? Is the exponential ever necessary?**
>
> Engineer X used 2^n steps because they tried every subset. For many subset problems (the knapsack problem, scheduling, circuit satisfiability) nobody knows any algorithm that is polynomial in the worst case, and nobody can prove one does not exist. Our sorting lower bound worked because the comparison model is simple; for general programs, proving that a problem *needs* exponential time is the P versus NP question, the subject of Ch. 30.

The other threads run through the rest of this track and beyond:

- **Recurrences that don't halve.** Fibonacci-style recurrences $T(n) = T(n-1) + T(n-2)$ grow like φ^n with $\varphi \approx 1.618$. Where that golden ratio comes from, and how generating functions solve such recurrences mechanically, is in Ch. 28.
- **From exponential to polynomial by remembering.** Many exponential recursions collapse to polynomial time when you store sub-answers: Ch. 52.
- **Algorithms on networks.** The most-used algorithms on Earth (route planning, matching, page ranking) run on graphs, and their analysis needs the language of Ch. 27.
- **Proving the code is right, not just fast.** A fast wrong answer is worthless. Loop invariants and induction, the tools that turn "it passed the tests" into "it works for every input", are in Ch. 29.

Chapter 27 — Graph Theory: The Mathematics of Connections

> **Level 2 · Track A — The Mathematics Behind Algorithms Builds on:** Ch. 8, Ch. 10, Ch. 26 · **Leads to:** Ch. 28, Ch. 87, Ch. 90 · **Related:** Ch. 34, Ch. 48, Ch. 52 **Reading time:** ~25 min

27.1 The hook

It is 6 p.m. on a Friday at a ride-hailing company. Three engineers have three problems.

The router must send a car from the depot to a pickup across a city of 200,000 intersections. The number of distinct routes is astronomically large: on a modest 20×20 grid of streets there are already $\binom{40}{20} \approx 1.4 \times 10^{11}$ shortest-looking staircase routes alone, and the real city is not a grid. Yet the app must answer in milliseconds, for millions of requests an hour.

The matcher has 1000 free drivers and 1000 waiting riders. Each driver can reach only some riders in time. She wants as many riders served as possible. The number of ways to pair 1000 drivers with 1000 riders is $1000! \approx 10^{2567}$, a number with 2568 digits. Trying them all is not slow; it is meaningless.

The analyst has a year of trip data: who rides from where to where. Management suspects the city has "hidden neighbourhoods", clusters of places that trade riders mostly among themselves, which do not match any map. Nobody has told her how many clusters there are, or where.

> **The challenge of this chapter:** How would you find the best route, match thousands of people, or detect hidden communities?

All three problems have the same shape: things, and connections between things. Strip away the cars, the people and the streets, and what is left is a drawing of dots and lines. That drawing is a **graph**, and the surprise of this chapter is that one drawing supports three completely different kinds of mathematics. The router will be saved by a greedy argument, the matcher by an alternating path, and the analyst by an eigenvector.

27.2 The big idea

A graph forgets everything except **who is connected to whom** (and sometimes, how strongly). A street map becomes intersections (vertices) and road segments (edges) with travel times as weights. A dating app becomes two columns of people with lines for "would accept". A friendship network becomes dots with lines for "talks to".

Once the problem is a graph, three big ideas do most of the work.

Grow outward, never look back. To find shortest routes from the depot, don't enumerate routes. Instead, spread out from the depot like a ripple in a pond, settling each intersection at the moment the ripple reaches it. A place reached first by the ripple can never be reached sooner by a longer detour. That is Dijkstra's algorithm, and it touches each road only once.

Improve by flipping. To enlarge a matching, look for a path that zig-zags between unmatched and matched edges, starting and ending at people nobody has served yet. Flip every edge along it, matched to unmatched and back, and the matching grows by one. When no such path exists, the matching is provably the largest possible.

Let the network vibrate. Encode the graph as a matrix and compute its eigenvectors. A graph with two loosely tied communities "vibrates" like two masses joined by a weak spring: the slowest non-trivial mode moves one community up while the other moves down. The sign of that eigenvector reveals the communities, with no labels and no guesswork about where they are.

The analogy that ties these together: a graph is a mechanical structure. Shortest paths are the strings that go taut when you pull two knots apart; matchings are how you pair up the bolts; communities are the parts that wobble together.

27.3 The mathematics

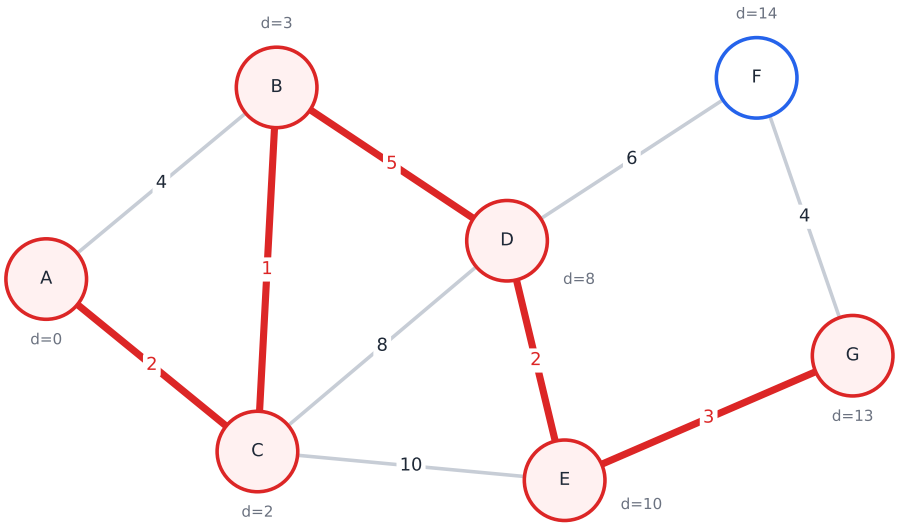
Vocabulary in five lines

> **Graphs**
>
> A **graph** $G = (V, E)$ is a set V of vertices and a set E of edges, each edge joining two vertices. The **degree** $\deg v$ is the number of edges at v. A **path** is a sequence of distinct vertices with consecutive ones adjacent; a **cycle** is a path that returns to its start. G is **connected** if every pair of vertices is joined by a path. A **tree** is a connected graph with no cycles. In a **weighted** graph each edge e carries a length $w(e) \geq 0$, and the length of a path is the sum of its edge lengths.

Two facts come up constantly. First, the **handshake lemma**: $\sum_v \deg v = 2|E|$, because every edge has two ends and is counted once at each. (So the number of odd-degree vertices is always even.) Second, every tree on n vertices has exactly $n - 1$ edges: remove a leaf and its edge, and induct.

Graphs are also matrices. The **adjacency matrix** $\mathbf{A}$ has $A_{ij} = 1$ if i and j are adjacent, else 0; the **degree matrix** $\mathbf{D}$ is diagonal with $D_{ii} = \deg i$. Both are symmetric, which will matter at the end.

Result 1: shortest paths — why the greedy ripple is correct



shortest A to G: A - C - B - D - E - G (length 13)

A small road network. The direct road A–B (length 4) loses to the detour A–C–B (length 3), and the shortest route to G (length 13) passes through four intermediate intersections. Each label d is the distance Dijkstra's algorithm assigns.

Dijkstra's algorithm keeps a tentative distance $d(v)$ for every vertex, starting at $d(s) = 0$ for the source and ∞ elsewhere, and a set S of **settled** vertices, initially empty. Repeatedly:

1. pick the unsettled vertex u with the smallest $d(u)$ and settle it;
2. for every edge (u, v), **relax** it: $d(v) \leftarrow \min\{d(v),\ d(u) + w(u, v)\}$.

On the network above the vertices settle in the order A (0), C (2), B (3), D (8), E (10), G (13), F (14). Notice that B is first given tentative distance 4 by the direct road, then lowered to 3 when C is settled. Once settled, a distance never changes again. That is the claim we must prove.

> **Correctness of Dijkstra's algorithm**
>
> If all edge weights are non-negative, then when a vertex u is settled, $d(u)$ equals the true shortest-path distance $\delta(s, u)$.

Proof. Every tentative value $d(v)$ is the length of some actual path (relaxation only ever writes path lengths), so $d(v) \geq \delta(s, v)$ always. Suppose, for contradiction, that u is the **first** vertex settled with $d(u) > \delta(s, u)$. Take a true shortest path P from s to u. It starts inside S (at s) and ends outside, so it has a first edge (x, y) with $x \in S$ and $y \notin S$.

- x was settled before u, so (by the choice of u) $d(x) = \delta(s, x)$, and when x was settled the edge (x, y) was relaxed. Hence $d(y) \leq \delta(s, x) + w(x, y) = \delta(s, y)$, the last step because P's prefix up to y is a shortest path. So $d(y) = \delta(s, y)$.
- Weights are non-negative, so the rest of P from y to u has length ≥ 0: $\delta(s, y) \leq \delta(s, u)$.

Putting it together, $d(y) = \delta(s, y) \leq \delta(s, u) < d(u)$. But the algorithm chose u because it had the *smallest* tentative distance among unsettled vertices, and y is unsettled with a smaller one. Contradiction. ■

Look at where the proof used "non-negative": the remainder of the path cannot be negative, so a detour can never come back cheaper. That single word is load-bearing.

> **? The clue we're holding back**
>
> Put a single negative weight on one road (a toll refund, a downhill battery recharge for an electric car) and Dijkstra can return a wrong answer with full confidence. The fix, the Bellman–Ford algorithm, relaxes every edge $|V| - 1$ times and costs $O(|V|\,|E|)$ instead of roughly $O(|E| \log |V|)$. Why $|V| - 1$ rounds are exactly enough is a dynamic-programming argument about the number of edges in a path: Ch. 52.

Flows and matchings

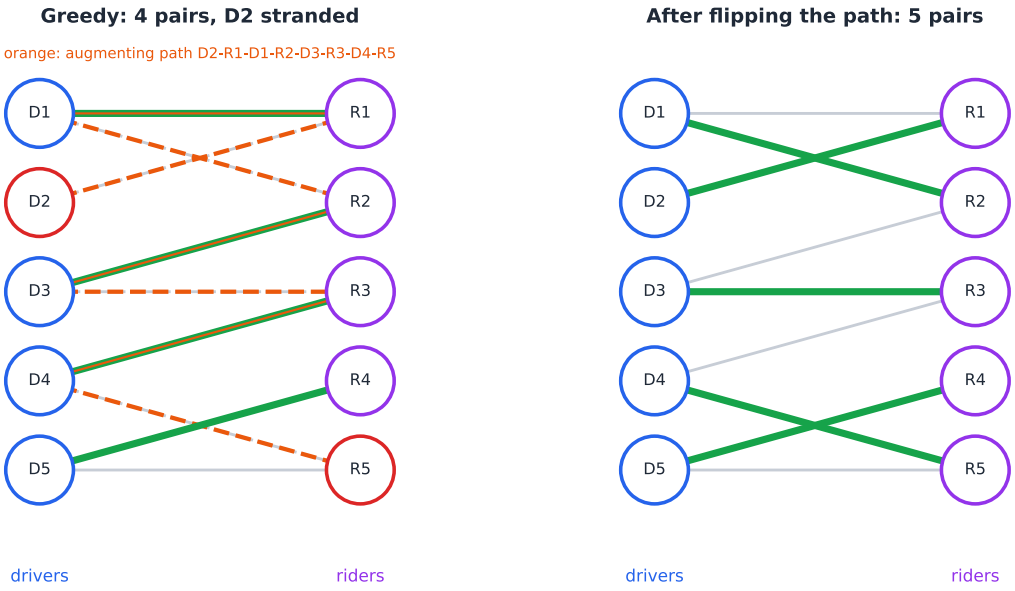
A **flow network** has a source s, a sink t, and a capacity $c(e) \geq 0$ on each directed edge. A flow assigns $f(e)$ with $0 \leq f(e) \leq c(e)$, conserved at every vertex except s and t (in equals out, Kirchhoff's current law from circuit theory). A **cut** splits the vertices into a side containing s and a side containing t; its capacity is the total capacity of edges crossing from the s-side to the t-side.

Any flow must cross every cut, so the value of any flow is at most the capacity of any cut. The astonishing theorem is that the bound is tight.

> **Max-flow min-cut (stated)**
>
> In any flow network, the maximum value of an s–t flow equals the minimum capacity of an s–t cut.

The algorithmic idea is the same "improve by flipping" from §27.2: while some path from s to t has spare capacity (counting the option of *cancelling* existing flow on reverse edges), push more flow along it. When no such path exists, the vertices still reachable from s form a cut whose capacity equals the current flow, and both are optimal at once. Max-flow min-cut is a linear program and its dual, two problems with the same optimum; why that always happens is the theme of Ch. 48.

Matching is flow in disguise. Put drivers on the left and riders on the right, an edge for every feasible pairing, a source joined to every driver and every rider joined to a sink, all with capacity 1. A maximum flow is a maximum matching.



*Greedy matching gets stuck at four pairs: D2's only rider R1 is taken. The orange **augmenting path** alternates unmatched and matched edges between two free vertices; flipping it swaps three matched edges for four and serves everyone.*

When can *every* driver be matched? An obvious obstacle: if some group of k drivers can, between them, reach fewer than k riders, someone is left out. Write $N(W)$ for the set of riders adjacent to at least one driver in W.

Hall's marriage theorem

A bipartite graph with left side L has a matching that covers every vertex of L if and only if $|N(W)| \geq |W|$ for every subset $W \subseteq L$.

Proof of necessity. If a matching covers L, then the drivers in W are matched to $|W|$ *distinct* riders, all of them in $N(W)$. So $|N(W)| \geq |W|$. ■

Sufficiency, the deep direction, says the obvious obstacle is the *only* obstacle: if no small group is starved, the augmenting-path algorithm never gets stuck. It follows from max-flow min-cut (a minimum cut that is smaller than $|L|$ can be read off as a starved group W). The matcher's problem with 1000 drivers is solved not by trying 10^{2567} pairings but by at most 1000 augmenting-path searches, each $O(|E|)$.

Colouring and planarity

Assign each vertex a colour so that adjacent vertices differ. The minimum number of colours is the **chromatic number** $\chi(G)$. Colouring is scheduling in disguise: exams are vertices, an edge joins two exams sharing a student, colours are time slots. Radio transmitters that interfere need different frequencies; registers in a compiler that are live at the same time need different physical registers.

A graph is **planar** if it can be drawn in the plane with no crossing edges, like a circuit on a single-layer board. A drawing divides the plane into F regions (faces, counting the outside).

Euler's formula and its consequence

For a connected planar drawing, $V - E + F = 2$. If moreover $V \geq 3$, then $E \leq 3V - 6$.

Proof sketch of Euler's formula. A tree has $E = V - 1$ and one face: $V - (V - 1) + 1 = 2$. Every other connected planar graph is a tree plus extra edges, and each extra edge closes a cycle, splitting one face into two: E and F both rise by 1 and $V - E + F$ is unchanged.

Proof of the inequality. Every face is bounded by at least 3 edges (no loops or double edges, and $V \geq 3$), and every edge borders at most 2 faces. Counting edge–face incidences two ways gives $3F \leq 2E$. Substitute $F = 2 - V + E$ from Euler's formula: $3(2 - V + E) \leq 2E$, that is $E \leq 3V - 6$. ■

The inequality instantly proves an impossibility. The complete graph K_5 (five vertices, all joined) has $V = 5$ and $E = 10$, but $3V - 6 = 9$. So K_5 **cannot be drawn without a crossing**, however clever you are. No search, no trial and error: one line of counting rules out infinitely many drawings at once. (The same argument with faces of length at least 4 shows the "three houses, three utilities" graph $K_{3,3}$ is not planar either.)

? Four colours, and a proof no human has checked

Every planar map can be coloured with at most **four** colours so that neighbouring regions differ. The inequality $E \le 3V - 6$ quickly shows that five colours always suffice. The step from five to four resisted mathematicians for 124 years, and when it was finally proved in 1976 the proof required a computer to check nearly two thousand configurations. What it means to trust such a proof, and how modern proof assistants have since verified it, is part of Ch. 98 and Ch. 67.

Planar graphs are the gentle case. For a general graph, deciding whether three colours suffice is NP-complete: no known algorithm beats exponential time in the worst case. Why that classification is so damning is Ch. 30's story.

Centrality: who matters in a network?

There is no single answer, which is why there are several centrality measures.

- **Degree centrality**: how many connections. Simple, local, easy to fool.
- **Betweenness centrality**: the fraction of shortest paths between other pairs that pass through v. A bridge between two communities has low degree but huge betweenness, and it is the vertex whose failure splits the network.
- **Eigenvector centrality and PageRank**: you are important if important vertices point to you. That circular definition is an eigenvector equation, $\mathbf{A}^{\mathsf{T}}\mathbf{x} = \lambda \mathbf{x}$, and PageRank adds a small chance of jumping to a random page so the eigenvector is unique.

Engineering note

In a power grid, betweenness identifies transmission lines whose loss reroutes the most power flow; in a chip's interconnect, it flags wires that are on many critical paths. Degree alone would miss both.

Result 2: the Laplacian sees connectivity

Define the **graph Laplacian** $\mathbf{L} = \mathbf{D} - \mathbf{A}$. It is the discrete cousin of ∇^2 (Ch. 13) and the nodal admittance matrix of a resistor network in which every edge is a 1 S conductance (Ch. 8). Its key property is a quadratic form.

The Laplacian quadratic form

For every vector $\mathbf{x} \in \mathbb{R}^V$,

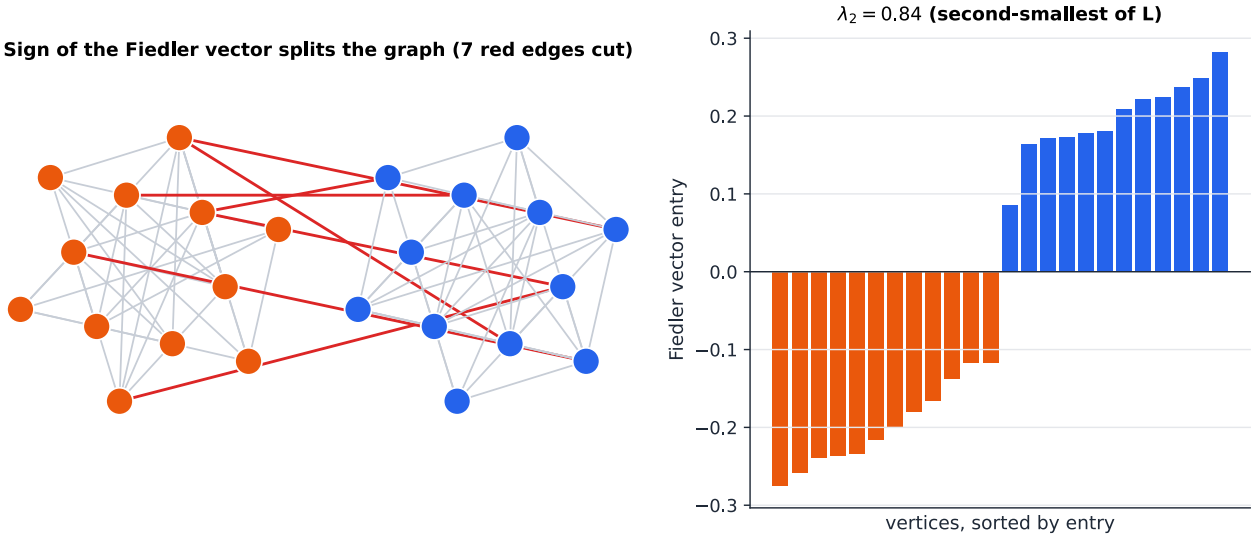
$$\mathbf{x}^{\mathsf{T}} \mathbf{L}\, \mathbf{x} = \sum_{\{i,j\} \in E} (x_i - x_j)^2 .$$

Hence $\mathbf{L}$ is positive semidefinite, and **the number of zero eigenvalues of $\mathbf{L}$ equals the number of connected components of G.**

Proof. $\mathbf{x}^{\mathsf{T}}\mathbf{D}\mathbf{x} = \sum_i \deg(i)\, x_i^2$, and by the handshake idea this equals $\sum_{\{i,j\}\in E}(x_i^2 + x_j^2)$: each edge contributes the squares of its two ends. Also $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \sum_{i,j} A_{ij} x_i x_j = \sum_{\{i,j\}\in E} 2 x_i x_j$. Subtracting, each edge gives $x_i^2 - 2x_i x_j + x_j^2 = (x_i - x_j)^2$.

A sum of squares is ≥ 0, so $\mathbf{L}$ is positive semidefinite and its eigenvalues are real and non-negative (Ch. 10, §10.5). Now $\mathbf{L}\mathbf{x} = \mathbf{0}$ implies $\mathbf{x}^{\mathsf{T}}\mathbf{L}\mathbf{x} = 0$, so $x_i = x_j$ across every edge, so $\mathbf{x}$ is constant on each connected component. Conversely, any vector constant on each component satisfies $\mathbf{L}\mathbf{x} = \mathbf{0}$ (each row of $\mathbf{L}$ sums to zero). The null space is therefore spanned by the indicator vectors of the k components, which are linearly independent: its dimension is k. Since $\mathbf{L}$ is symmetric, the multiplicity of eigenvalue 0 equals the dimension of the null space. ∎

So a matrix computation can *count the pieces* of a network. Now push the idea one step. If the graph is connected, the smallest eigenvalue $\lambda_1 = 0$ belongs to the constant vector, and the second-smallest, $\lambda_2 > 0$, is small exactly when the graph is *almost* disconnected. Its eigenvector, the **Fiedler vector**, minimizes $\sum_E (x_i - x_j)^2$ among unit vectors orthogonal to the constants: it tries to give neighbours equal values while being forced to take both signs. The cheapest way to do that is to be positive on one tightly-knit community, negative on the other, and pay the penalty only on the few edges between them.



The analyst's trick on a small example. Colouring each vertex by the sign of the second eigenvector of $\mathbf{L}$ recovers the two planted communities exactly; only the 7 red edges run between them. The algorithm was never told that there were communities.

> **? Why does one eigenvalue measure a bottleneck?**
>
> We showed that $\lambda_2 = 0$ exactly when the graph falls apart. The quantitative version, **Cheeger's inequality**, says λ_2 is small *if and only if* the graph has a cut that removes few edges relative to the sizes of the pieces, and it gives explicit bounds in both directions. The proof needs the variational theory of eigenvalues and the analogy with vibrating membranes, which is developed in Ch. 90.

27.4 The algorithm

Dijkstra with a priority queue

```
import heapq

def dijkstra(adj, source):
    """adj[u] = list of (v, weight) with weight >= 0. Returns (dist, prev)."""
    dist, prev = {source: 0}, {}
    heap = [(0, source)]                 # (tentative distance, vertex)
    while heap:
        d, u = heapq.heappop(heap)
        if d > dist[u]:                  # stale entry: u was already settled cheaper
            continue
        for v, w in adj[u]:
            nd = d + w
            if nd < dist.get(v, float("inf")):
                dist[v], prev[v] = nd, u   # relax edge (u, v)
                heapq.heappush(heap, (nd, v))
    return dist, prev
```

Follow `prev` backwards from the target to read off the route. Each edge is relaxed at most once per settled endpoint and each heap operation costs $O(\log |V|)$, so the running time is $O((|V| + |E|)\log |V|)$. Road networks have $|E| \approx 2.5|V|$, so 200,000 intersections cost a few million elementary steps: milliseconds.

Failure cases. A negative edge weight breaks the proof (and the answer). Floating-point weights that are "almost equal" can make two routes tie and flip between runs, so production routers break ties deterministically. And for a whole continent, even milliseconds per query is too slow: real map services *preprocess* the graph (contraction hierarchies, landmark heuristics such as A*) so that each query explores only a thin corridor instead of a disc around the source.

Maximum bipartite matching by augmenting paths

```
def max_matching(adj, left):
    """adj[d] = riders driver d can reach. Returns dict rider -> driver."""
    match = {}                           # rider -> driver

    def try_augment(d, seen):
        for r in adj[d]:
            if r in seen:
                continue
            seen.add(r)
            # r is free, or r's current driver can be re-routed elsewhere
            if r not in match or try_augment(match[r], seen):
                match[r] = d             # flip the edges along the path
                return True
        return False

    for d in left:
        try_augment(d, set())
    return match
```

Each call to `try_augment` searches for one augmenting path by depth-first search, in $O(|E|)$; there are $|L|$ calls, so the total is $O(|L|\,|E|)$. The Hopcroft–Karp algorithm finds many shortest augmenting paths at once and improves this to $O(\sqrt{|V|}\,|E|)$. On 1000 drivers each reaching 50 riders that is about 50,000 edges, solved in well under a second, compared with the 10^{2567} pairings of brute force.

Failure cases. The recursion depth can reach $|L|$; for very large graphs, write the search iteratively. And this finds *a* largest matching, not the *cheapest* one. If each pairing has a cost (pickup time), you need the weighted version, the assignment problem, solved by the Hungarian algorithm in $O(n^3)$ or as a linear program (Ch. 23, §23.3).

Spectral community detection

1. Build $\mathbf{L} = \mathbf{D} - \mathbf{A}$ (sparse, if the graph is large).
2. Compute the eigenvector $\mathbf{v}_2$ of the second-smallest eigenvalue.
3. Split the vertices by the sign of $\mathbf{v}_2$ (or, better, try every threshold along the sorted entries and keep the cut with the best ratio of cut edges to community sizes).

A dense eigen-solve costs $O(|V|^3)$, fine for a few thousand vertices. For a million, use a sparse iterative method such as Lanczos (Ch. 24, §24.4), which needs only matrix–vector products. For k communities, take the k smallest eigenvectors as coordinates and cluster the points.

Failure cases. One isolated vertex creates an extra zero eigenvalue and the Fiedler vector happily "discovers" a community of size 1. Very unequal degrees distort the split, which is why practitioners often use the *normalized* Laplacian $\mathbf{I} - \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$ instead.

27.5 The experiment

The script plants two communities of 100 people, links people in the same community with probability `P_IN` and across communities with probability `P_OUT`, shuffles the vertices to hide the structure, and asks the Fiedler vector to find it.

```
import numpy as np
import matplotlib.pyplot as plt

N_PER = 100          # KNOB: people per community
P_IN = 0.10          # KNOB: chance two people in the SAME community are linked
P_OUT = 0.02         # KNOB: chance two people in DIFFERENT communities are linked
SEED = 1

rng = np.random.default_rng(SEED)
truth = np.repeat([0, 1], N_PER)
N = truth.size
P = np.where(truth[:, None] == truth[None, :], P_IN, P_OUT)
A = np.triu(rng.random((N, N)) < P, 1).astype(float)
A = A + A.T                                  # undirected adjacency matrix
L = np.diag(A.sum(axis=1)) - A               # graph Laplacian L = D - A
vals, vecs = np.linalg.eigh(L)               # symmetric: real eigenvalues, ascending
fiedler = vecs[:, 1]
guess = (fiedler > 0).astype(int)
acc = max(np.mean(guess == truth), np.mean(guess != truth))
print(f"lambda_2 = {vals[1]:.3f}, communities recovered: {100 * acc:.1f}%")

perm = rng.permutation(N)                    # hide the structure, then reveal it
fig, ax = plt.subplots(1, 3, figsize=(12, 4))
ax[0].imshow(A[np.ix_(perm, perm)], cmap="Greys"); ax[0].set_title("adjacency, shuffled")
order = np.argsort(fiedler[perm])
ax[1].imshow(A[np.ix_(perm[order], perm[order])], cmap="Greys"); ax[1].set_title("sorted by Fiedler vector")
ax[2].plot(vals[:10], "o-"); ax[2].set_title("smallest eigenvalues of L")
plt.tight_layout(); plt.show()
```

With the default knobs the Fiedler vector recovers about 95% of the labels, and the middle panel turns a shapeless grey square into two dark blocks. Now turn the knobs:

- Lower `P_IN` to 0.08, 0.07, 0.06 and run several seeds. Recovery becomes erratic, sometimes above 90%, sometimes near 55%, even though each person still has more than twice as many friends inside their community as outside.
- Lower `P_IN` to 0.03. Now some people have no links at all, λ_2 drops to 0, and the method collapses to a coin toss (about 50%): it has found an isolated vertex, not a community. Count the zero eigenvalues in the right panel and compare with the theorem of §27.3.
- Set `P_OUT = 0` to make the communities disconnected. Two eigenvalues are exactly 0, and the split is perfect.

Somewhere between "easy" and "impossible" there is a boundary, and it is sharper than you might expect.

27.6 The challenge

1. **Intuition.** In the road network figure, which single road could you remove to increase the distance from A to G the most, and by how much? Answer by inspection first, then explain why the roads *not* on the shortest path can be removed for free. What does that say about the union of all shortest paths from A (it is a famous kind of graph)?
2. **Derivation.** A **star** on n vertices has one centre joined to $n-1$ leaves. Write down its Laplacian and find all its eigenvalues by hand (hint: try vectors that are zero at the centre and sum to zero on the leaves). Show that $\lambda_2 = 1$ for every n, and explain why a star, despite being connected, is "fragile".
3. **Implementation.** Extend the matching code to the **stable marriage** problem: each driver ranks riders and each rider ranks drivers. Implement the Gale–Shapley proposal algorithm, prove (on paper) that it always terminates after at most n^2 proposals, and test on random preferences how often the driver-proposing and rider-proposing versions give different answers as n grows.
4. **Open investigation.** In the experiment, fix `N_PER = 500` and `P_OUT = 0.01` and scan `P_IN` finely. Plot recovery (averaged over 10 seeds) against `P_IN`. Is there a threshold where recovery jumps from near 50% to well above it? How does the threshold move with `N_PER`? Try replacing $\mathbf{L}$ by the normalized Laplacian, or by $\mathbf{A}$ itself, and see whether the threshold moves.

27.7 Loose threads

The three engineers have their answers. The router uses a greedy ripple, proved correct by a first-failure argument that leans entirely on non-negative weights. The matcher uses augmenting paths, and Hall's theorem tells her exactly when a perfect match is impossible. The analyst uses the Laplacian, whose zero eigenvalues count the pieces of the network and whose second eigenvector cuts it along its weakest seam.

What we did not tell you:

- **Negative weights** need a different algorithm and a different cost, and the reason lives in dynamic programming (Ch. 52).
- **The four-colour theorem** is true, but its proof is a story about computers and trust (Ch. 98).
- **Cheeger's inequality**, the exact link between λ_2 and bottlenecks, needs spectral theory (Ch. 90).

- **Detectability.** The threshold you met in the experiment is real. For large random networks with planted communities, there is a sharp limit below which *no* algorithm can beat random guessing, and it was located only in the 2010s, with ideas borrowed from statistical physics. Real networks, with hubs, small worlds and power-law degrees, are the subject of Ch. 87.
- **PageRank** is the stationary distribution of a random walk on the web graph; why that walk settles down at all is Ch. 34.
- **Hard graph problems.** Shortest paths and matchings are easy; colouring with three colours, the travelling-salesman tour and the longest path are not known to be. Where that line falls is Ch. 30, and how to attack the hard side anyway is Ch. 49. And counting the graphs themselves (how many trees, how many colourings) is Ch. 28.

Chapter 28 — Combinatorics: Counting the Impossible

> **Level 2 · Track A — The Mathematics Behind Algorithms Builds on:** Ch. 1, Ch. 17, Ch. 19, Ch. 26 · **Leads to:** Ch. 29, Ch. 32, Ch. 57 · **Related:** Ch. 27, Ch. 33, Ch. 18 **Reading time:** ~25 min

28.1 The hook

Pick up an ordinary deck of 52 cards and shuffle it well. The order you are holding has, almost certainly, **never existed before in the history of the universe**, and will never exist again.

That sounds like mysticism. It is arithmetic. The number of orderings of 52 cards is

$$52! = 52 \times 51 \times 50 \times \cdots \times 2 \times 1 \approx 8.07 \times 10^{67}.$$

If every one of the roughly eight billion people alive had shuffled a deck once per second since the Big Bang, about 4×10^{17} seconds ago, they would have produced around 3×10^{27} orderings: a fraction 4×10^{-41} of the possibilities.

The deck is small change. The number of atoms in the observable universe is usually estimated at about 10^{80}. A Go board has 361 points, each empty, black or white, so at most $3^{361} \approx 1.7 \times 10^{172}$ configurations; the number of *legal* positions was computed exactly in 2016 and is about 2.08×10^{170}. That is more than 10^{90} positions **for every atom in the universe**. And the simplest example of all: a memory of just 266 bits (34 bytes, shorter than this sentence) has $2^{266} \approx 1.2 \times 10^{80}$ possible contents, already more than there are atoms.

> **The challenge of this chapter:** How can a problem have more possible configurations than atoms in the observable universe?

And if the space is that large, how can we say *anything* about it, how many configurations have a property, whether some pattern must appear, without ever looking at them? That is what combinatorics is: the mathematics of counting things you could never list.

28.2 The big idea

The answer to the challenge is one rule, applied over and over:

> **If a choice is made in stages, the counts multiply.**

A configuration of a big system is a sequence of small choices. 266 bits are 266 two-way choices: $2 \times 2 \times \cdots \times 2 = 2^{266}$. A deck is 52 choices of "which card next" with one fewer option each time. Physical systems add their parts, $1 + 1 + \ldots$; configuration spaces multiply them, $2 \times 2 \times \ldots$. Adding builds sizes like the number of atoms. Multiplying builds sizes like the number of states of those atoms. That is why a modest number of parts outruns the universe: Ch. 26 showed that every exponential eventually beats every polynomial, and here the exponential is not a running time but a count.

So listing is hopeless. Combinatorics replaces listing with four tricks of reasoning:

1. **Multiply** stages (the product rule), and **divide** out orderings you don't care about.
2. **Biject:** count a set by matching it one-to-one with a set that is easier to count.
3. **Correct overcounts** systematically: inclusion–exclusion.
4. **Guarantee without searching:** the pigeonhole principle and Ramsey theory prove that a pattern *must* exist in every configuration, even in spaces too large to search.

The analogy: you cannot count the grains of sand on a beach one by one, but you can measure the beach's volume and one grain's volume and divide. Combinatorics is the art of finding the right "volume" to measure.

28.3 The mathematics

Permutations and combinations

Counting arrangements and selections

The number of **permutations** (orderings) of n distinct objects is $n! = n(n-1)\cdots 1$, with $0! = 1$. The number of ordered selections of k out of n is $n(n-1)\cdots(n-k+1) = \dfrac{n!}{(n-k)!}$. The number of **combinations**, unordered selections of k out of n, is the binomial coefficient

$$\binom{n}{k} = \frac{n!}{k!\,(n-k)!}.$$

The combination count comes from the "divide out" trick: each unordered k-set appears $k!$ times among the ordered selections. A lottery that draws 6 numbers from 49 has $\binom{49}{6} = 13{,}983{,}816$ outcomes; a 20×20 street grid has $\binom{40}{20} \approx 1.38 \times 10^{11}$ shortest staircase routes from one corner to the other (choose which 20 of the 40 steps go east).

How big is $n!$? **Stirling's approximation** answers it:

$$n! \approx \sqrt{2\pi n}\left(\frac{n}{e}\right)^n,$$

with relative error about $1/(12n)$. For $n = 52$ it gives 8.05×10^{67}, within 0.2% of the truth. So $\log n! \approx n \log n$: factorials grow faster than any exponential b^n, because the "base" n/e keeps increasing.

Result 1: Pascal's rule, by a story rather than algebra

Pascal's rule

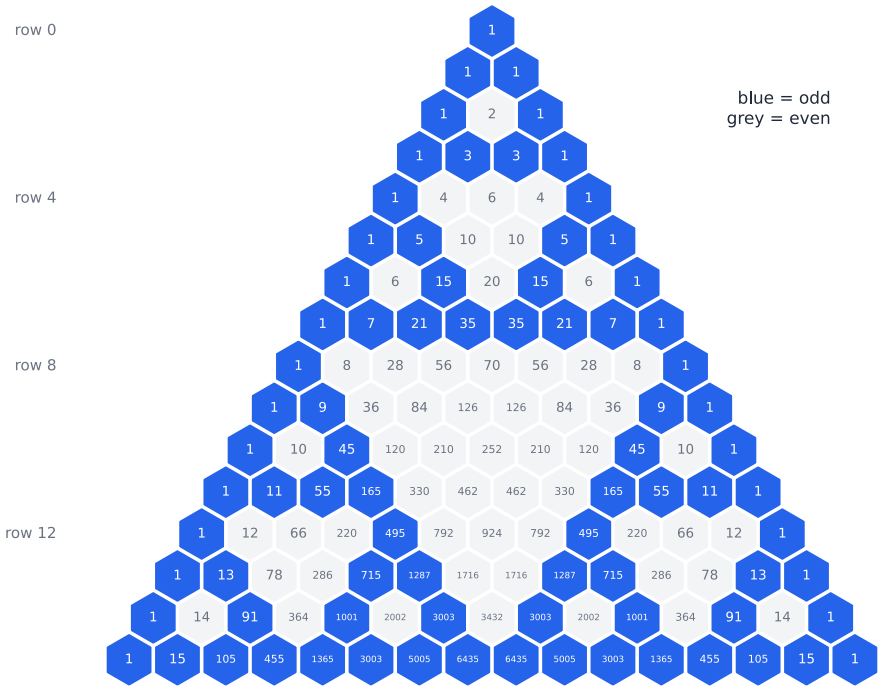
For $1 \le k \le n-1$,

$$\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}.$$

Proof (by double counting). Count the k-member committees chosen from n people, one of whom is Ada. Every committee either includes Ada or not. Those that include her are completed by choosing $k-1$ of the other $n-1$ people: $\binom{n-1}{k-1}$ ways. Those that exclude her choose all k from the other $n-1$: $\binom{n-1}{k}$ ways. The two cases do not overlap and cover everything, so the counts add. ■

No factorials were harmed. This is the combinatorial style of proof: find two honest ways to count the same set, and equate them. Applied to $(1+x)^n = (1+x)(1+x)\cdots(1+x)$, where the coefficient of x^k counts ways to pick the x from k of the n factors, the same idea gives the **binomial theorem** $(1+x)^n = \sum_k \binom{n}{k} x^k$.

Pascal's rule builds the famous triangle: each entry is the sum of the two above it. Now do something strange with it: colour each entry by whether it is odd or even.



Pascal's triangle with odd entries in blue. A fractal appears: three copies of the top half of the triangle, with a grey hole in the middle, each copy made of three smaller copies, and so on. Rows 1, 3, 7 and 15 are entirely odd.

Why should a rule about adding numbers produce a fractal? Taking parity turns Pascal's rule into $a \oplus b$ (addition mod 2, the XOR gate), and the triangle becomes a cellular automaton: each cell is the XOR of its two parents. That much explains *that* there is a self-similar pattern. It does not explain *which* entries are odd.

? The odd ones

$\binom{n}{k}$ is odd exactly when every binary digit of k is at most the corresponding binary digit of n, so row n contains exactly 2^s odd entries, where s is the number of 1s in n written in binary. (Row 12 = 1100_2 has 4 odd entries; check the picture.) The reason is Lucas's theorem on binomial coefficients modulo a prime, and it lives in Ch. 57.

Result 2: inclusion–exclusion and the hat-check problem

Adding the sizes of overlapping sets overcounts the overlaps. For two sets, $|A \cup B| = |A| + |B| - |A \cap B|$, which is the same formula as $P(A \cup B)$ in Ch. 19, §19.1. For many sets the corrections alternate.

Inclusion–exclusion

For finite sets $A_1, \dots, A_n$,

$$\left|\bigcup_{i=1}^{n} A_i\right| = \sum_i |A_i| - \sum_{i<j} |A_i \cap A_j| + \sum_{i<j<k} |A_i \cap A_j \cap A_k| - \cdots + (-1)^{n+1} |A_1 \cap \cdots \cap A_n|.$$

Proof. Take any element x that lies in exactly $m \geq 1$ of the sets. It is counted $\binom{m}{1}$ times in the first sum, $\binom{m}{2}$ times in the second, and so on, so its net count on the right is

$$\binom{m}{1} - \binom{m}{2} + \binom{m}{3} - \cdots = 1 - \sum_{j=0}^{m} (-1)^j \binom{m}{j} = 1 - (1-1)^m = 1,$$

by the binomial theorem. An element in none of the sets is counted 0 times on both sides. So both sides count every element exactly once. ∎

The hat-check problem. n people check their hats, and the hats are handed back in random order. What is the chance that *nobody* gets their own hat? A permutation with no fixed point is a **derangement**. Let A_i be the permutations that fix person i. Any k specified people can be fixed in $(n-k)!$ ways, and there are $\binom{n}{k}$ ways to specify them, so inclusion–exclusion gives the number of permutations fixing *somebody*, and subtracting from $n!$:

$$D_n = \sum_{k=0}^{n} (-1)^k \binom{n}{k} (n-k)! = n! \sum_{k=0}^{n} \frac{(-1)^k}{k!}.$$

The probability is $D_n/n! = \sum_{k=0}^{n} (-1)^k/k!$, the partial sum of the series for e^{-1}. So the answer converges to $1/e \approx 0.3679$, and it does so astonishingly fast: for $n = 10$ it is $0.367879\ldots$, already correct to six decimal places, and $D_{10} = 1{,}334{,}961$. Remarkably, the answer barely depends on whether there are 10 guests or 10 million.

Result 3: recurrences and generating functions

Many counts are easier to describe by a rule than by a formula. How many ways t_n are there to tile a $1 \times n$ strip with squares (1×1) and dominoes (1×2)? Look at the last tile: it is a square (leaving a strip of length $n-1$) or a domino (leaving $n-2$). So

$$t_n = t_{n-1} + t_{n-2}, \qquad t_0 = 1,\ t_1 = 1,$$

the Fibonacci recurrence: $1, 1, 2, 3, 5, 8, 13, \ldots$. Recurrences like this are exactly the difference equations of Ch. 17, §17.5, and combinatorics has its own name for the Z-transform: the **generating function**, the power series whose coefficients are the counts.

Closed form by generating function

The tiling numbers have generating function $T(x) = \sum_{n \geq 0} t_n x^n = \dfrac{1}{1 - x - x^2}$, and

$$t_n = \frac{\varphi^{n+1} - \psi^{n+1}}{\sqrt{5}}, \qquad \varphi = \frac{1+\sqrt{5}}{2} \approx 1.618, \quad \psi = \frac{1-\sqrt{5}}{2} \approx -0.618.$$

Proof. Multiply the recurrence by x^n and sum over $n \geq 2$: $T(x) - 1 - x = x\,(T(x) - 1) + x^2 T(x)$. Solving, $T(x)(1 - x - x^2) = 1$. The denominator factors as $(1 - \varphi x)(1 - \psi x)$, because $\varphi + \psi = 1$ and $\varphi\psi = -1$. Partial fractions give

$$\frac{1}{(1-\varphi x)(1-\psi x)} = \frac{1}{\varphi - \psi}\left(\frac{\varphi}{1-\varphi x} - \frac{\psi}{1-\psi x}\right),$$

and expanding each term as a geometric series, the coefficient of x^n is $(\varphi^{n+1} - \psi^{n+1})/(\varphi - \psi)$, with $\varphi - \psi = \sqrt{5}$. ∎

Since $|\psi| < 1$, the second term dies out and t_n is the nearest integer to $\varphi^{n+1}/\sqrt{5}$: tilings grow like 1.618^n, an exponential, which is the configuration explosion of the hook in miniature. The growth rate is set by the root of the denominator closest to the origin, $x = 1/\varphi$, exactly like the dominant pole of a discrete-time system.

Generating functions do far more than solve recurrences. A product of generating functions counts combined choices; that is how one counts **partitions** of an integer (ways to write n as a sum of positive integers, ignoring order). The generating function is $\prod_{k \geq 1} \frac{1}{1 - x^k}$, and $p(100) = 190{,}569{,}292$.

? A formula with π in it, for a problem with no circles

The number of partitions grows like $p(n) \sim \dfrac{1}{4n\sqrt{3}} \exp\!\left(\pi\sqrt{2n/3}\right)$. A question about adding whole numbers has an answer involving π, e and $\sqrt{3}$. Hardy and Ramanujan found it by treating the generating function as a function of a *complex* variable and studying how it blows up near the unit circle. That method of reading growth from singularities is built on the tools of Ch. 18, and it is the gateway to analytic combinatorics.

Result 4: the pigeonhole principle and the party problem

The pigeonhole principle

If more than k objects are placed into k boxes, some box contains at least two objects. More generally, if N objects go into k boxes, some box contains at least $\lceil N/k \rceil$.

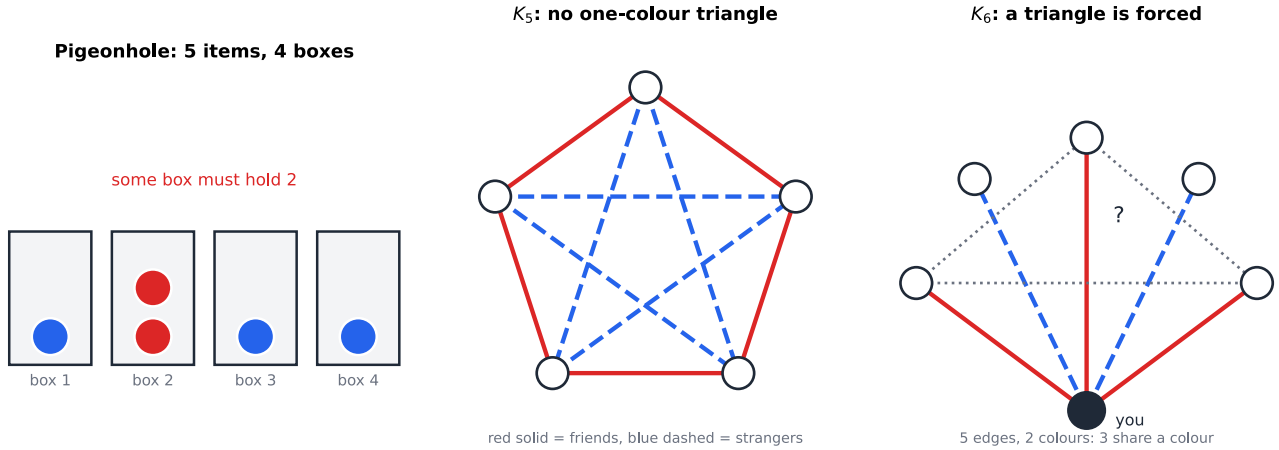
Proof. If every box had at most $\lceil N/k \rceil - 1 < N/k$ objects, the total would be less than $k \cdot N/k = N$. ∎

It is the most obvious statement in this book and one of the most powerful, because it proves existence without construction.

Why no compressor can shrink every file

There are 2^n files of exactly n bits, but only $2^0 + 2^1 + \cdots + 2^{n-1} = 2^n - 1$ files shorter than n bits. A lossless compressor must map different files to different outputs, so by pigeonhole at least one n-bit file cannot get shorter. Every compressor that shrinks some files must enlarge others. How much compression is possible *on average* is the entropy bound of Ch. 33.

Now the party problem. At any party of six people, either some three all know each other, or some three are mutual strangers. Model people as vertices of the complete graph K_6, colour each edge red (acquainted) or blue (strangers). The claim is that every red/blue colouring of K_6 contains a **monochromatic triangle**.



Pigeonhole (left) powers Ramsey's theorem. Five guests are not enough: the pentagon/pentagram colouring of K_5 (middle) has no single-colour triangle. With six, any vertex has five edges, so three share a colour; whatever colour the dotted edges get, a one-colour triangle appears (right).

The party theorem: $R(3,3) = 6$

Every 2-colouring of the edges of K_6 contains a monochromatic triangle, and K_5 has a 2-colouring with none.

Proof. Fix a vertex v of K_6. It has 5 edges and there are 2 colours, so by pigeonhole at least $\lceil 5/2 \rceil = 3$ of them share a colour, say red, going to a, b, c. If any of the edges ab, bc, ca is red, it forms a red triangle with v. If none is red, then a, b, c form a blue triangle. Either way a monochromatic triangle exists. For K_5, colour the five outer edges of a pentagon red and the five diagonals blue: the red edges form a 5-cycle and the blue edges form another 5-cycle (the pentagram), and a 5-cycle contains no triangle. ■

The **Ramsey number** $R(s,t)$ is the smallest N such that every red/blue colouring of K_N contains a red K_s or a blue K_t. Ramsey's theorem says it always exists: complete disorder is impossible, and any large enough structure contains an orderly piece. The slogan of the field: in a big enough system, patterns are not a coincidence but a certainty.

But the numbers are brutal. $R(3,3) = 6$; $R(4,4) = 18$. For $R(5,5)$, the best we know is $43 \le R(5,5) \le 46$ (the upper bound was lowered to 46 only in 2024). Why can't we just check? Settling whether 43 suffices means examining 2-colourings of K_{43}, and there are $2^{\binom{43}{2}} = 2^{903} \approx 10^{272}$ of them. The configuration explosion of the hook is the very thing that keeps a five-person party question unsolved.

? Five friends, and a problem that defeats every computer

What is $R(5,5)$? Symmetry and clever pruning got the bounds to $43 \le R(5,5) \le 46$, but no known method closes the gap. For $R(6,6)$ the gap is far wider: at least 102, and an upper bound still in the 160s. It is a genuine open problem; how mathematicians chip away at problems like this (and why a famous quip says we would be wiser to fight an alien army than to compute $R(6,6)$) is in Ch. 98.

Extremal combinatorics: how much can you have without a pattern?

Ramsey asks when a pattern is forced. **Extremal combinatorics** asks the quantitative version: how large can a structure be while still avoiding the pattern? The first result of the subject is a gem.

Mantel's theorem

A graph on n vertices with no triangle has at most $n^2/4$ edges, and the complete bipartite graph with two halves of size $n/2$ achieves this.

Proof. If uv is an edge, u and v have no common neighbour (that would make a triangle), so $\deg u + \deg v \le n$. Summing over all edges, each vertex w appears in $\deg w$ edges, so $\sum_w (\deg w)^2 \le n|E|$. By the Cauchy–Schwarz inequality, $\sum_w (\deg w)^2 \ge \frac{1}{n}\left(\sum_w \deg w\right)^2 = \frac{4|E|^2}{n}$ (handshake lemma, Ch. 27). Combining, $4|E|^2/n \le n|E|$, so $|E| \le n^2/4$. ■

So a network of 100 nodes with more than 2500 links *must* contain a triangle, whatever its wiring. The extremal example, two halves with every link between them, is exactly the "two communities that only talk across" picture: the extremal answer has structure.

28.4 The algorithm

Combinatorics changes how you compute in two opposite ways: it tells you how to compute huge counts *exactly* without listing anything, and it tells you when a search is hopeless.

Counting without listing: dynamic programming over a recurrence

The partition numbers satisfy no simple formula, but the generating function $\prod_k 1/(1-x^k)$ translates directly into a loop: multiply in one factor $1/(1-x^k) = 1 + x^k + x^{2k} + \cdots$ at a time.

```
def partitions(N):
    """p[n] = number of partitions of n, for n = 0..N."""
    p = [1] + [0] * N                # the series for the empty product: 1
    for k in range(1, N + 1):        # multiply by 1/(1 - x^k)
        for n in range(k, N + 1):
            p[n] += p[n - k]         # allow any number of parts equal to k
    return p

print(partitions(100)[100])         # 190569292
```

That is $O(N^2)$ additions to compute a number that counts 190 million objects, none of which is ever constructed. The same pattern (a recurrence evaluated bottom-up, from small cases to large) counts lattice paths, tilings, binary trees and coin-change combinations; it is the counting cousin of dynamic programming (Ch. 52).

Binomial coefficients without overflow

Computing $\binom{n}{k}$ as `factorial(n) // (factorial(k) * factorial(n - k))` builds enormous intermediate numbers. In fixed-width arithmetic it overflows long before the answer does: $\binom{67}{33}$ fits in 64 bits but $67!$ needs more than 300 bits. The fix multiplies and divides alternately,

$$\binom{n}{k} = \prod_{i=1}^{k} \frac{n-k+i}{i},$$

where after step i the running product is itself the integer $\binom{n-k+i}{i}$, so every division is exact. Use $k \leftarrow \min(k, n-k)$ to halve the work. In floating point, work with logarithms instead: `math.lgamma(n + 1)` gives $\ln n!$ without ever forming $n!$, which is how probabilities like $\binom{1000}{500}2^{-1000}$ are computed safely.

Exhaustive search, and how to survive it

Sometimes you must actually enumerate (to find a colouring of K_5 with no monochromatic triangle, or to test a conjecture on small cases). Three techniques push the frontier of what is feasible:

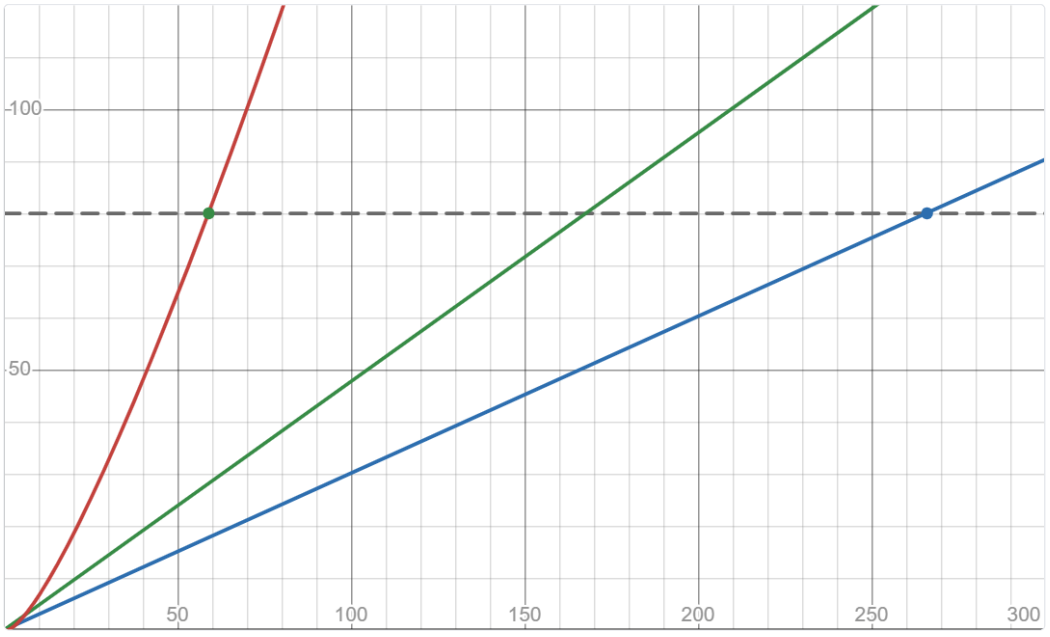
- **Backtracking**: build a configuration choice by choice and abandon a partial one the moment it is doomed. Colouring edges of K_N one at a time and stopping at the first one-colour triangle prunes almost all of the $2^{\binom{N}{2}}$ colourings.
- **Symmetry breaking**: relabelling the vertices or swapping colours gives an equivalent colouring, so search only one representative per class, saving up to a factor $2 \cdot N!$.
- **Reduction to SAT**: encode "no monochromatic K_s" as a Boolean formula and hand it to an industrial satisfiability solver. Several Ramsey-type results were settled this way, with machine-checkable certificates.

Even so, the counts in this chapter are a warning: every exponential search hits a wall, and the wall's position moves only logarithmically with your hardware (Ch. 26). Whether some cleverer method could always avoid the search is the question of Ch. 30.

28.5 The experiment

Where does a configuration space pass the universe?

Plot $\log_{10}$ of each count against the number of parts n. The horizontal line at 80 is the number of atoms in the observable universe.



Blue: 2^n (bits). Green: 3^n (Go points). Red: $n!$ via Stirling (orderings of a deck). The grey line is 10^{80}.

The blue line crosses the universe at $n \approx 266$, the green at $n \approx 168$, and the red at only $n \approx 59$: a deck of 59 cards has more orderings than the universe has atoms. Change the **3** in the green curve to **10** (decimal digits) and then to **26** (letters): how long a password beats the universe? Then add the line `y=x^{2}\frac{\ln(2)}{\ln(10)}` : that is the number of black-and-white images of $n \times n$ pixels, and it leaves the screen almost immediately.

The party and the hats (run it)

The script does two things. It checks the party theorem by brute force over every colouring of K_N, and it simulates the hat-check problem against the inclusion–exclusion formula.

```
import itertools
import numpy as np
import matplotlib.pyplot as plt

# Part 1: party problem by brute force. Is there a 2-colouring of K_N with no one-colour triangle?
N = 5                                  # KNOB: try 5, then 6 (7 takes a few minutes)
edges = list(itertools.combinations(range(N), 2))
index = {e: i for i, e in enumerate(edges)}
tris = [(index[(a, b)], index[(a, c)], index[(b, c)]) for a, b, c in itertools.combinations(range(N), 3)]
good = 0
for colours in itertools.product((0, 1), repeat=len(edges)):
    if all(not (colours[x] == colours[y] == colours[z]) for x, y, z in tris):
        good += 1
print(f"K_{N}: {2 ** len(edges)} colourings, {good} with no one-colour triangle")

# Part 2: the hat-check problem. Return n hats at random; chance nobody gets their own?
rng = np.random.default_rng(0)
TRIALS = 20000                         # KNOB: more trials, less noise
ns = np.arange(1, 13)
sim = [np.mean([not np.any(rng.permutation(n) == np.arange(n)) for _ in range(TRIALS)]) for n in ns]
exact = [sum((-1) ** k / np.prod(np.arange(1, k + 1)) for k in range(n + 1)) for n in ns]
plt.plot(ns, sim, "o", label="simulation")
plt.plot(ns, exact, "-", label="inclusion-exclusion")
plt.axhline(np.exp(-1), ls=":", label="1/e")
plt.xlabel("number of hats n"); plt.ylabel("P(no one gets own hat)"); plt.legend(); plt.show()
```

With `N = 5` it reports 1024 colourings, of which exactly 12 avoid a one-colour triangle. Each of them is a pentagon/pentagram picture like the figure, with the vertices relabelled. With `N = 6` it reports 32,768 colourings and **zero** good ones: the party theorem, verified by exhaustion. Try `N = 7` and notice that the run time grows by a factor of more than 64 for one extra guest: you are watching the configuration explosion from the inside. Can you make it faster by stopping each colouring at its first bad triangle?

In the second part, the probability settles onto $1/e$ by about $n = 5$. Change `TRIALS` to 200 and see how much of the wiggle in the dots is just sampling noise.

28.6 The challenge

1. **Intuition.** In a room of 23 people the chance that two share a birthday is just over one half, yet the chance that someone shares *your* birthday is only about 6%. Explain, by counting *pairs* rather than people, why these two numbers are so different, without computing either one exactly.
2. **Derivation.** Count the number of surjections (onto functions) from a set of n elements to a set of k elements using inclusion–exclusion, with A_i the functions that miss element i. Check your formula for $n = 4$, $k = 2$ by listing, and use it to show that $\sum_{j=0}^{k} (-1)^j \binom{k}{j} (k-j)^n = 0$ whenever $n < k$.

3. **Implementation.** Write a backtracking search that 2-colours the edges of K_N one at a time and backtracks as soon as a red K_3 or a blue K_4 appears. Use it to find a colouring of K_8 with neither, and estimate how many partial colourings your search visits compared with the full 2^{28}. (The fact $R(3,4)=9$ says K_9 has no such colouring; can your code confirm it in reasonable time?)
4. **Open investigation.** Colour each edge of K_N red or blue **at random**. Estimate by simulation the probability that there is no monochromatic K_4, for N from 6 to 17. How does it fall off as N approaches $R(4,4)=18$? Then compute the *expected number* of monochromatic K_4s exactly by counting. What does the comparison suggest about how good random colourings are at avoiding patterns, and how far could the idea be pushed for larger k?

28.7 Loose threads

The challenge is answered. A problem has more configurations than the universe has atoms because configurations **multiply** while matter **adds**: 266 binary choices, 168 three-way choices or 59 cards in order are enough. And combinatorics lets us reason about such spaces without listing them: counting by multiplication and bijection, correcting overcounts by inclusion–exclusion, solving recurrences with generating functions, and forcing patterns to exist with the pigeonhole principle and Ramsey's theorem.

What we left on the table:

- **Lucas's theorem**, the arithmetic behind the fractal in Pascal's triangle, waits in Ch. 57.
- **Analytic combinatorics**: the π in the partition asymptotics comes from complex analysis (Ch. 18), and the same method turns any generating function into its growth rate.
- **Ramsey numbers**: $R(5,5)$ is unknown, and the frontier of such problems is in Ch. 98. The challenge's fourth problem hints at the most surprising tool for it.
- **The probabilistic method.** In 1947 Erdős proved that $R(k,k)>2^{k/2}$ without exhibiting a single good colouring: he showed that a *random* colouring works with positive probability. It is a proof of existence by counting random worlds, the subject of Ch. 32. Nobody knows how to *construct* colourings nearly as good.
- **Counting as logic.** Every proof in this chapter quietly used induction or double counting. What makes such arguments airtight, and how to prove a statement for *all* n at once, is Ch. 29.

29.1 The hook

Binary search is the first "clever" algorithm most programmers meet. You have a sorted array, you look at the middle element, and you throw away the half that cannot contain your target. Ten lines of code. Everyone has written it.

Almost everyone has written it wrong. In his book *Programming Pearls*, Jon Bentley reports giving the problem to professional programmers in courses. Given a couple of hours, about ninety percent of them handed in code with a bug. Knuth notes that binary search was first published in 1946, but the first version that worked for every array size did not appear until 1962.

Then there is the bug nobody saw. In 2006 Joshua Bloch, who had written the binary search in Java's standard library, reported that it had been broken for about nine years. The bug was in this line, which also appears in Bentley's own carefully argued version:

```
mid = (low + high) // 2
```

With 32-bit integers, `low + high` overflows once the array has more than about $2^{30} \approx 1.07 \times 10^9$ elements. The sum wraps round to a negative number, `mid` becomes negative, and the program crashes or reads garbage. When the code was written, arrays that large were rare. By 2006 they were routine.

So the code had been read by experts, published in a classic book, shipped to millions of machines and tested, and it was still wrong. Testing could not have saved it. Two 32-bit indices give $2^{64} \approx 1.8 \times 10^{19}$ input pairs; at a billion tests per second, trying them all takes about 585 years. Edsger Dijkstra's remark is the one to keep in mind: testing can show that bugs are present, but never that they are absent.

That leaves the challenge of this chapter:

> **How do you prove that a program must work for every valid input?**

You cannot run infinitely many cases. But you can write a *finite* argument that covers them all. That idea, a finite proof standing in for an infinite set of tests, is the core of discrete mathematics, and it is what this chapter builds.

29.2 The big idea

An electrical engineer analysing a circuit never simulates every possible voltage waveform. She writes Kirchhoff's current law at each node: *the current in equals the current out, at every instant*. That one statement holds whatever the inputs do, and every later step of the analysis leans on it. It is a **conserved quantity**.

Programs have conserved quantities too. They are called **invariants**. Look at binary search again. At every moment the array splits into three zones (Figure 29.3, in §29.3):

- everything to the left of `lo` is known to be smaller than the target,
- everything from `hi` onwards is known to be larger,
- the target, if it is anywhere, is in the window between them.

Each step of the loop shrinks the window, *and the three statements stay true*. When the window is empty the invariant tells you the answer: the target is not there. You never had to try a single input. You proved one statement about one step, and an induction argument carried it through every step of every run.

To make that rigorous you need a small toolkit:

1. a language precise enough to state what "correct" means (**logic**),
2. objects to state it about (**sets, relations, functions**),
3. a way to push a claim from one step to the next, forever (**induction**),
4. a guarantee that the loop actually stops (**well-founded orders**).

Underneath all of it sits a very small algebra of two values, true and false, which turns out to be the same algebra your laptop's transistors compute. We start there.

29.3 The mathematics

Propositional logic and Boolean algebra

A **proposition** is a statement that is either true or false. We combine propositions p, q with connectives: $\neg p$ (not), $p \wedge q$ (and), $p \vee q$ (or), $p \oplus q$ (exclusive or), $p \Rightarrow q$ (implies). Ch. 1 introduces the symbols and the contrapositive in §1.10; here we treat them as *functions*. Write 1 for true and 0 for false. Then each connective is a function from $\{0,1\}^k$ to $\{0,1\}$, and a truth table is just its table of values (Figure 29.1).

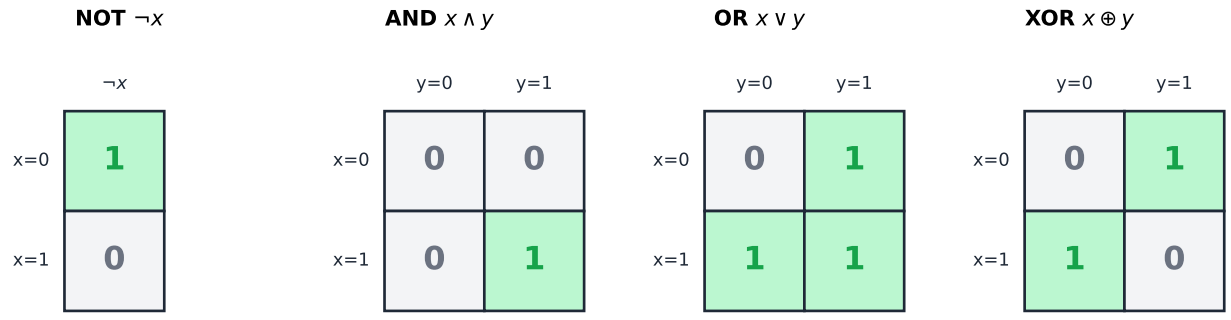

Figure 29.1 — The four basic connectives as grids. Green cells are 1 (true). AND has a single green cell, OR a single grey one, and XOR is green exactly where the inputs differ.

Boolean function, formula, equivalence

A **Boolean function** of n variables is any map $f : \{0,1\}^n \to \{0,1\}$. A **formula** is an expression built from variables with $\neg, \wedge, \vee$. Two formulas are **equivalent**, $\varphi \equiv \psi$, if they have the same truth table. A formula is a **tautology** if it is 1 under every assignment, and **satisfiable** if it is 1 under at least one.

There are 2^n rows in a truth table on n variables, and each row can be 0 or 1, so there are 2^{2^n} Boolean functions: 16 for $n = 2$, 256 for $n = 3$, and 2^{64} for $n = 6$. The algebra obeys a short list of laws, each checkable from the grids:

$$\begin{aligned} &p \wedge q \equiv q \wedge p, && p \wedge (q \vee r) \equiv (p \wedge q) \vee (p \wedge r),\\ &p \vee q \equiv q \vee p, && p \vee (q \wedge r) \equiv (p \vee q) \wedge (p \vee r),\\ &\neg(p \wedge q) \equiv \neg p \vee \neg q, && \neg(p \vee q) \equiv \neg p \wedge \neg q,\\ &p \vee \neg p \equiv 1, && p \wedge \neg p \equiv 0. \end{aligned}$$

The third line is **De Morgan's laws**. Notice the second distributive law, $p \vee (q \wedge r) \equiv (p \vee q) \wedge (p \vee r)$: it fails for ordinary numbers ($2 + 3 \cdot 4 \neq 5 \cdot 6$) but holds here. Boolean algebra is not arithmetic in disguise. Its closest arithmetic relative is XOR, which is addition modulo 2: $p \oplus q = p + q \bmod 2$. Pair XOR with AND as multiplication and you have the two-element field $\mathbb{F}_2$, the arithmetic behind error-correcting codes in Ch. 79.

How many connectives do we actually need? Here is the first result worth proving.

Theorem 29.1 — Every Boolean function has a formula

Every Boolean function $f : \{0,1\}^n \to \{0,1\}$ is equivalent to a formula using only $\neg, \wedge, \vee$. Consequently the single connective NAND, $p \uparrow q := \neg(p \wedge q)$, can express every Boolean function.

Proof. If f is never 1, take the formula $x_1 \wedge \neg x_1$. Otherwise, for each input $\mathbf{a} = (a_1, \dots, a_n)$ with $f(\mathbf{a}) = 1$ build the **minterm**

$$m_{\mathbf{a}} = \ell_1 \wedge \ell_2 \wedge \cdots \wedge \ell_n, \qquad \ell_i = \begin{cases} x_i & a_i = 1,\\ \neg x_i & a_i = 0. \end{cases}$$

By construction $m_{\mathbf{a}}$ is 1 on input $\mathbf{a}$ and on no other input: on any $\mathbf{b} \neq \mathbf{a}$ some coordinate differs, and the matching literal is 0. Now take the OR of all these minterms,

$$\varphi = \bigvee_{\mathbf{a}\,:\, f(\mathbf{a})=1} m_{\mathbf{a}}.$$

On an input where $f = 1$, its own minterm is 1, so $\varphi = 1$. On an input where $f = 0$, every minterm is 0, so $\varphi = 0$. Hence $\varphi \equiv f$. This is the **disjunctive normal form**.

For NAND it is enough to build $\neg$, $\wedge$ and $\vee$ from it:

$$\neg p \equiv p \uparrow p, \qquad p \wedge q \equiv (p \uparrow q) \uparrow (p \uparrow q), \qquad p \vee q \equiv (p \uparrow p) \uparrow (q \uparrow q).$$

The first holds because $p \wedge p = p$. The second negates a NAND. The third is De Morgan: $\neg(\neg p \wedge \neg q) \equiv p \vee q$. Substitute these into the DNF and only NAND remains. $\square$

This is why a chip factory can build an entire processor from one kind of gate. It also hides a trap. The DNF of f can have up to 2^n minterms; the parity function $x_1 \oplus \cdots \oplus x_n$ needs all 2^{n-1} of its minterms in DNF. "Expressible" and "expressible *cheaply*" are very different statements.

Satisfiable is not the same as easy to check

Deciding whether a formula is a tautology is the same as deciding whether its negation is unsatisfiable. The obvious method fills in all 2^n rows of the truth table. For $n = 300$ variables, a typical size for a small hardware-verification problem, that is more rows than there are atoms in the observable universe.

Predicate logic: saying "for every input"

Propositional logic cannot say "for every input". For that we need variables that range over a domain, **predicates** about them, and the quantifiers $\forall$ and $\exists$ (their order and negation rules are in §1.10). With them, a specification becomes a precise sentence. "The array $a[0..n)$ is sorted" is

$$\forall i \, \forall j \, \big(0 \le i < j < n \Rightarrow a[i] \le a[j]\big),$$

and "search returns r correctly" is

$$\big(r \geq 0 \wedge a[r] = t\big) \;\vee\; \big(r = -1 \wedge \forall i\,(0 \leq i < n \Rightarrow a[i] \neq t)\big).$$

Many real bugs are wrong specifications, not wrong code. If t appears three times, the predicate above accepts any of its indices; a caller who assumed "the first one" has a bug no proof will catch.

Sets, relations and orders

A **relation** R on a set S is a subset of $S \times S$; we write $x\,R\,y$ for $(x, y) \in R$. Three families matter constantly in computing.

An **equivalence relation** is reflexive ($x\,R\,x$), symmetric ($x\,R\,y \Rightarrow y\,R\,x$) and transitive ($x\,R\,y \wedge y\,R\,z \Rightarrow x\,R\,z$). Every equivalence relation chops S into disjoint **classes**, and every partition comes from one. "Same remainder mod 3" splits the integers into three classes; Ch. 30 builds a machine whose states *are* those classes.

A **partial order** $\preceq$ is reflexive, transitive and antisymmetric ($x \preceq y \wedge y \preceq x \Rightarrow x = y$). Not every pair need be comparable: neither of 6 and 10 divides the other. We draw a partial order as a **Hasse diagram**, with an edge from x up to y when y covers x (Figure 29.2).

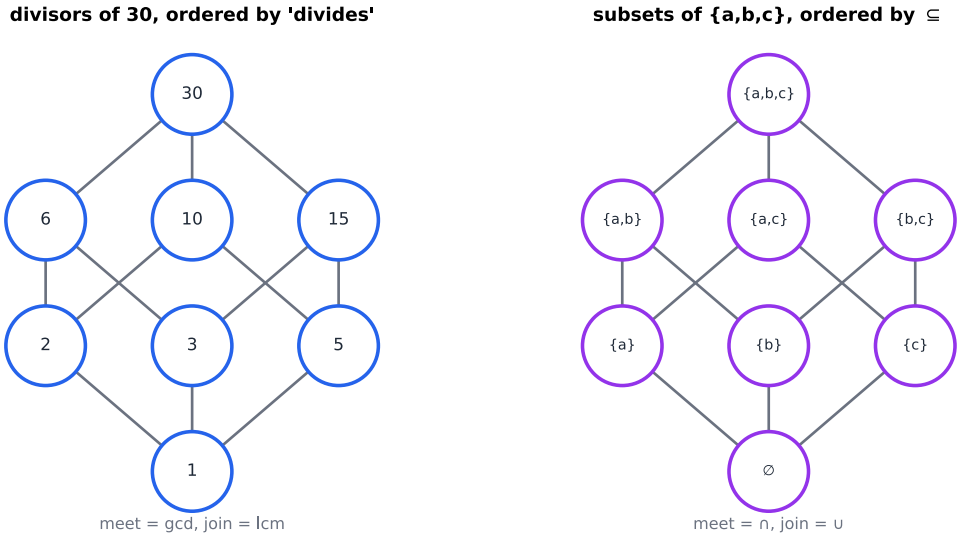

Figure 29.2 — Two partial orders with the same shape: the divisors of 30 under "divides" and the subsets of $\{a, b, c\}$ under $\subseteq$. Both are cubes, because $30 = 2 \cdot 3 \cdot 5$ and each divisor picks a subset of the three primes.

In both orders every pair has a greatest lower bound (gcd, or intersection) and a least upper bound (lcm, or union). Such an order is a **lattice**. In the cube on the right, the meet is $\wedge$, the join is $\vee$, and complement is $\neg$: the subsets of an n-element set form a Boolean algebra, the same algebra as the truth tables. Hardware, set theory and number theory meet in one picture.

A partial order is **well-founded** if it has no infinite descending chain $x_0 \succ x_1 \succ x_2 \succ \cdots$. The natural numbers under $\leq$ are the standard example, and they are the reason loops stop.

Induction, three ways

The **principle of induction** says: if $P(0)$ holds and $P(k) \Rightarrow P(k+1)$ for every k, then $P(n)$ holds for every $n \in \mathbb{N}$. Ch. 1 gives the standard worked example in §1.10. Three variants do most of the work in computer science.

- **Strong induction:** assume $P(0), \ldots, P(k)$ all hold and deduce $P(k+1)$. This is the natural form for divide-and-conquer, where a problem of size $k+1$ calls itself on sizes like $\lfloor (k+1)/2 \rfloor$.
- **Well-ordering:** every non-empty subset of $\mathbb{N}$ has a least element. To prove $P(n)$ for all n, suppose not, take the *smallest* counterexample, and derive a contradiction by finding a smaller one. This is equivalent to induction, and it is often the easier way to think.
- **Structural induction:** to prove something about every formula, tree or list, prove it for the atoms and show that each constructor preserves it. The proof of Theorem 29.1 is essentially a structural induction in disguise: we built the formula from literals up.

Loop invariants: induction over time

Now the central tool. Consider a loop

```
INIT
while GUARD:
    BODY
```

Theorem 29.2 — The loop-invariant principle

Let I be a predicate on the program state and V an integer-valued function of the state. Suppose

1. **Initialisation:** I holds after INIT.
2. **Maintenance:** if I and GUARD hold before BODY, then I holds after it.
3. **Variant:** whenever I and GUARD hold, $V \geq 0$, and each execution of BODY strictly decreases V.

Then the loop terminates, and on exit $I \wedge \neg$GUARD holds.

Proof. Let s_k be the state after k executions of BODY (if the loop runs that long). We show by induction on k that $I(s_k)$ holds. The base case $k = 0$ is initialisation. If $I(s_k)$ holds and the loop runs again, GUARD held in s_k, so maintenance gives $I(s_{k+1})$. That proves the claim for every k the loop reaches.

For termination, suppose the loop ran forever. Then GUARD and I hold in every s_k, so the variant gives $V(s_0) > V(s_1) > V(s_2) > \cdots$, an infinite strictly decreasing sequence of non-negative integers. By well-ordering the set $\{V(s_k)\}$ has a least element $V(s_m)$, yet $V(s_{m+1}) < V(s_m)$ is in the set: contradiction. So the loop stops after some K iterations. It stopped because GUARD failed, and $I(s_K)$ holds by the induction. □

The theorem converts one infinite question (does this work on all inputs?) into three finite ones, each about a *single* step. Let us cash it in.

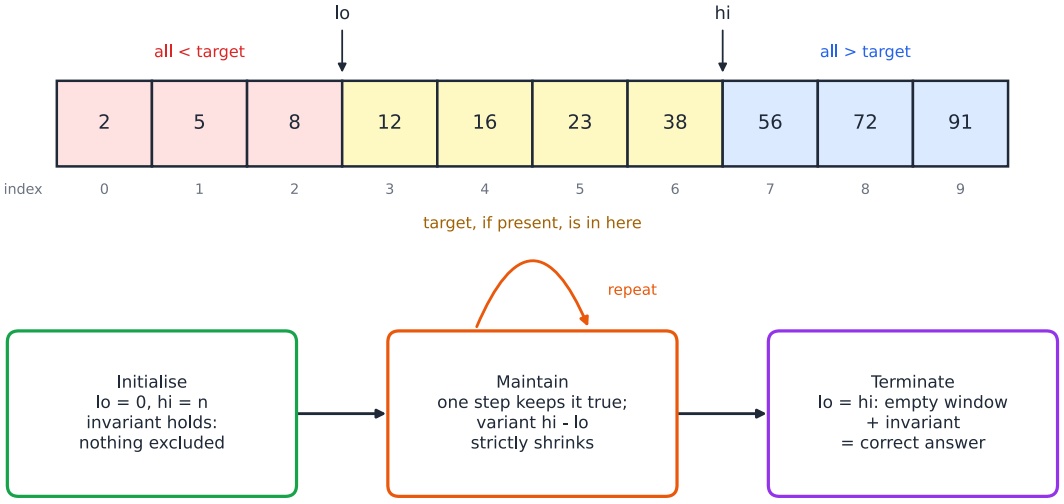

Figure 29.3 — Binary search mid-run, searching for 38 or anything else. Red cells are proved smaller than the target, blue cells proved larger; the yellow window is all that is left. The three boxes are the three hypotheses of Theorem 29.2.

Theorem 29.3 — Binary search is correct

Let $a[0..n)$ be sorted. The loop `lo, hi = 0, n; while lo < hi: mid = lo + (hi-lo)//2; if a[mid] < t: lo = mid+1 elif a[mid] > t: hi = mid else: return mid`, followed by `return -1`, always terminates and meets the specification of the previous subsection. With exact integers, every index it touches lies in $[0, n)$.

Proof. Take the invariant

$$I: \quad 0 \leq lo \leq hi \leq n \ \wedge\ \forall i < lo:\ a[i] < t \ \wedge\ \forall i \geq hi\,(i < n):\ a[i] > t,$$

and the variant $V = hi - lo$.

Initialisation. With $lo = 0$, $hi = n$ both quantified parts are about empty ranges, so they hold vacuously.

Maintenance. Suppose I holds and $lo < hi$. Then $mid = lo + \lfloor (hi - lo)/2 \rfloor$ satisfies $lo \leq mid < hi \leq n$, so $a[mid]$ is a valid read. If $a[mid] < t$, sortedness gives $a[i] \leq a[mid] < t$ for every $i \leq mid$, so setting $lo = mid + 1$ keeps the left clause, and $lo \leq hi$ still holds since $mid < hi$. If $a[mid] > t$, then $a[i] \geq a[mid] > t$ for every $i \geq mid$, so $hi = mid$ keeps the right clause. If $a[mid] = t$ we return a correct index.

Variant. $V \geq 1$ while the guard holds. The new window is $[mid + 1, hi)$ or $[lo, mid)$, both strictly shorter than $[lo, hi)$ because $lo \leq mid < hi$.

Exit. By Theorem 29.2 the loop stops. If it stops without returning, $lo = hi$, and the invariant says every element is either $< t$ (index below lo) or $> t$ (index at or above hi). So t is absent and -1 is correct. □

Where was the 2006 bug? Look at the phrase "with exact integers". The proof uses $lo \leq mid < hi$, which is true in $\mathbb{Z}$. In 32-bit arithmetic, $(lo + hi)/2$ can be negative, so the step "$a[mid]$ is a valid read" is false. The proof was never wrong. The *model* was: it assumed integers that machines do not have. Writing $lo + (hi - lo)/2$ keeps every intermediate value between lo and hi, so the proof goes through for machine integers too. A careful proof would have demanded exactly that check; a test suite of arrays under a billion elements never could.

? The invariant nobody gave you

Every proof in this section started with someone *handing* us the invariant. Finding it was the creative step. Could a program read any loop and produce its invariant, or decide whether a given program meets its specification at all? Ch. 30 proves that no algorithm can do this in general, and Ch. 67 shows what verification tools do instead.

A toolbox of proof techniques

Ch. 1 lists direct proof, contrapositive, contradiction and induction (§1.10). Computing adds a few more habits:

Technique	Pattern	Where it shows up
Invariant	a property preserved by every step	loops, protocols, puzzles (the 15-puzzle's parity)
Variant / potential	a quantity in a well-founded order that must drop	termination, amortised analysis (Ch. 26)
Construction	prove $\exists x$ by building x	DNF in Theorem 29.1, Euclid's coefficients
Counterexample	refute $\forall x\, P(x)$ with one x	the 2006 overflow input
Pigeonhole	$n+1$ objects in n boxes	hashing collisions (Ch. 28)
Diagonalisation	build an object that differs from every item in a list	the halting problem (Ch. 30)

Each of these is a finite argument about infinitely many cases. That is the whole trick.

? Is every true statement provable?

Our proofs worked inside predicate logic. Is there a fixed set of rules that proves *every* true sentence of predicate logic? For pure logic, yes, and that is Gödel's completeness theorem. For arithmetic on $\mathbb{N}$, the very structure induction lives in, the answer flips to no. Why the same logician got opposite answers is the story of Ch. 65 and Ch. 68.

29.4 The algorithm

Writing the invariant into the code

A proof is most useful when it lives next to the code. Here is binary search with its invariant and variant written as runtime checks. The checks are expensive (the invariant check is $O(n)$ per step, which ruins the $O(\log n)$ running time), so you switch them off in production, but they turn the proof into something a test can falsify.

```
def binary_search(a, t):
    lo, hi = 0, len(a)
    while lo < hi:
        assert all(x < t for x in a[:lo]) and all(x > t for x in a[hi:])  # invariant I
        v = hi - lo                                                       # variant V
        mid = lo + (hi - lo) // 2          # never leaves [lo, hi), even in 32-bit
        if a[mid] < t:
            lo = mid + 1
        elif a[mid] > t:
            hi = mid
        else:
            return mid
        assert hi - lo < v                                                # V decreased
    return -1
```

The window halves (or better) each step, so after k steps $V \le n/2^k$, and the loop runs at most $\lfloor \log_2 n \rfloor + 1$ times: 30 iterations for a billion elements.

A second example: Euclid's algorithm

The oldest non-trivial algorithm has the cleanest invariant.

```
def gcd(a, b):            # a, b >= 0, not both zero
    while b != 0:
        a, b = b, a % b   # invariant: gcd(a, b) never changes; variant: b
    return a
```

Invariant. Any common divisor of a and b divides $a \bmod b = a - qb$, and any common divisor of b and $a \bmod b$ divides $a = qb + (a \bmod b)$. So the pairs (a, b) and $(b, a \bmod b)$ have exactly the same common divisors and the same gcd. *Variant.* $0 \le a \bmod b < b$, so b strictly decreases in $\mathbb{N}$. *Exit.* When $b = 0$, $\gcd(a, 0) = a$. By Theorem 29.2, the function returns gcd of the original inputs. For $\gcd(1071, 462)$ the states are $(1071, 462) \to (462, 147) \to (147, 21) \to (21, 0)$, and the answer is 21.

The variant gives termination but a weak bound (b steps). A sharper look shows that b at least halves every two steps, so the loop runs $O(\log b)$ times; the worst case is consecutive Fibonacci numbers, which ties this chapter back to recurrences in Ch. 28.

Brute-force logic, and why it does not scale

Theorem 29.1 suggests an algorithm for checking any propositional claim: enumerate the truth table, `all(f(*bits) for bits in itertools.product([False, True], repeat=n))`. This is correct and costs 2^n evaluations. Doubling the variable count squares the work. For the specifications of real programs, which talk about 32- or 64-bit integers, it is hopeless: a single 64-bit variable is already 64 Boolean variables. Industrial tools (SAT solvers) do something far cleverer and routinely handle millions of variables in practice, yet nobody knows an algorithm that is guaranteed to be fast on *every* formula.

> **? The price of a truth table**
>
> Checking that one given assignment satisfies a formula takes time linear in the formula's length. *Finding* one seems to need exponential time. Is that gap real, or have we just not been clever enough? This is the P versus NP question, and the satisfiability problem sits at its very centre: see Ch. 30.

Failure cases

- **Wrong model.** The proof assumes mathematical integers, exact reals, or memory that never runs out; the machine has none of these. Overflow, rounding (Ch. 22) and aliasing break proofs that were valid on paper.
- **Wrong specification.** The proof shows the code meets the predicate you wrote, not the one you meant.
- **Too-weak invariant.** "$0 \le lo \le hi \le n$" is preserved by binary search, but it says nothing about where t is, so it proves nothing useful. A good invariant is strong enough to imply the goal at exit and weak enough to be true at the start.

29.5 The experiment

Proof and exhaustive testing are not enemies. On *small* inputs you can test everything, and a planted bug almost always shows up on a tiny case. The script below checks binary search, with its invariant asserted, on every sorted array of length up to `N_MAX` with entries from `0..VALUES-1`, for every target. Then it reproduces the 2006 overflow with 32-bit numbers.

```
import itertools
import numpy as np

N_MAX = 6        # knob: longest array tested
VALUES = 4       # knob: entries drawn from 0..VALUES-1
BUGGY = False    # knob: True plants an off-by-one bug

def search(a, t):
    lo, hi = 0, len(a)
    while lo < hi:
        # invariant: a[:lo] < t  and  a[hi:] > t
        assert all(x < t for x in a[:lo]) and all(x > t for x in a[hi:])
        mid = lo + (hi - lo) // 2
        if a[mid] < t:
            lo = mid + 1
        elif a[mid] > t:
            hi = mid if not BUGGY else mid - 1
        else:
            return mid
    return -1

cases = 0
for n in range(N_MAX + 1):
    for a in itertools.combinations_with_replacement(range(VALUES), n):
        for t in range(-1, VALUES + 1):
            r = search(list(a), t)
            ok = (r == -1 and t not in a) or (r >= 0 and a[r] == t)
            assert ok, f"wrong answer on a={a}, t={t}"
            cases += 1
print("all", cases, "cases correct")

# the 2006 bug: (lo + hi) // 2 in 32-bit arithmetic
lo, hi = np.int32(1_500_000_000), np.int32(2_000_000_000)
with np.errstate(over="ignore"):
    print("(lo+hi)//2   =", (lo + hi) // np.int32(2))
print("lo+(hi-lo)//2 =", lo + (hi - lo) // np.int32(2))
```

With the default knobs it reports `all 1260 cases correct`, then prints a midpoint of $-397{,}483{,}648$ for the naive formula and $1{,}750{,}000{,}000$ for the safe one.

Things to try:

1. Set `BUGGY = True`. The very first failure is on the array `(0, 1)` with target `0`, an input of length two. Notice *which* assertion fires: not the invariant check but the final answer check, because the loop exits right after the bad step, before the invariant is checked again. Where should a second invariant check go so that it catches the bug itself?
2. Change `mid = lo + (hi - lo) // 2` to `mid = lo + (hi - lo + 1) // 2` (round up instead of down). Does it still pass? Now also change `lo = mid + 1` to `lo = mid`. What goes wrong, and which hypothesis of Theorem 29.2 failed? The **small-scope hypothesis** behind this experiment says that most bugs have a small counterexample. It is a heuristic, not a theorem: the overflow bug has no small counterexample at all, because it needs over a billion elements. That is exactly the case where only a proof helps.

29.6 The challenge

No answers are given. Work them out, then compare with a friend.

1. **Intuition.** A loop starts with $x = 0$, $y = 1$ and repeats `x, y = y, x + y`. Without running it, find a quantity built from x and y that stays the same up to sign on every step (hint: try $y^2 - xy - x^2$). What does your invariant tell you about consecutive Fibonacci numbers, and why does it imply that they are coprime?
2. **Derivation.** Prove that $\{\neg, \vee\}$ is functionally complete but $\{\wedge, \vee\}$ is not. For the second part, find a property that every $\{\wedge, \vee\}$ formula has (structural induction) and that $\neg x$ lacks.
3. **Implementation.** Write insertion sort with an explicit invariant ("the prefix `a[:i]` is sorted and is a permutation of the original prefix") and an explicit variant, both as `assert` statements. Test it exhaustively on every list of length at most 7 over three values, then plant three different bugs and see how small the smallest counterexample is for each.
4. **Open investigation.** The *Collatz loop* `while n != 1: n = n // 2 if n % 2 == 0 else 3 * n + 1` has been checked to terminate for every start below $2^{68} \approx 3 \times 10^{20}$, and nobody can prove it terminates for all n. Starting from 27 it takes 111 steps and climbs to 9232. Try to build a variant function: a quantity that decreases on every step, or on every *block* of steps. Experiment with candidates such as $\log n$ averaged over many steps. Where does each attempt break?

29.7 Loose threads

This chapter answered its challenge. You prove a program works for every valid input by writing a precise specification in predicate logic, finding an invariant, and using induction over the steps of the computation, with a variant in a well-founded order to show that the steps run out. Binary search, the program that fooled experts for decades, fell to a one-page argument, and the argument even pointed at the line where machine integers break the mathematics.

But we cheated in three places, and each one opens a door.

- **We were handed the invariants.** Is finding them a matter of skill, or is there a mechanical method? The first mystery above points to Ch. 30, which proves a startling negative answer for the general question "does this program meet its specification?", and to Ch. 67, where tools such as Hoare logic and proof assistants make the best of it.
- **We checked logic by brute force.** Truth tables grow like 2^n. Whether satisfiability can be decided in polynomial time is a million-dollar open problem, and Ch. 30 explains why so many other problems rise or fall with it.
- **We trusted our proof rules.** Induction, the quantifier rules and the Boolean laws were taken on faith. Are they consistent? Are they enough? Ch. 65 formalises them, and Ch. 68 shows that for arithmetic they can never be enough.

There is one further crack. Theorem 29.2 needed a variant, and the Collatz loop has none that anyone can find. Some loops may stop for every input with no proof that they do. Whether that is a temporary embarrassment or a permanent feature of mathematics is the question the next chapter takes head-on.

Chapter 30 — The Limits of Computation

> **Level 2 · Track A — The Mathematics Behind Algorithms Builds on:** Ch. 26, Ch. 28, Ch. 29, Ch. 24 · **Leads to:** Ch. 65, Ch. 68, Ch. 77 · **Related:** Ch. 49, Ch. 64, Ch. 86 **Reading time:** ~25 min

30.1 The hook

Here is a five-line program.

```
def collatz(n):
    while n != 1:
        n = n // 2 if n % 2 == 0 else 3 * n + 1
    return "done"
```

Does it return for every positive integer n? Start at 27 and it wanders for 111 steps, climbing as high as 9232 before falling to 1. Computers have checked every starting value below $2^{68} \approx 3 \times 10^{20}$, and every one of them reaches 1. Yet nobody can prove that all of them do. The question has been open since 1937. The mathematician Paul Erdős said that mathematics was not yet ready for problems like it.

Now imagine you are the engineer in charge of a code-review tool. Your manager wants a feature: *flag every function that can loop forever*. You would not need to understand Collatz yourself. Your tool would just say "halts" or "loops", and Collatz would be settled. So would a frightening number of other open problems, because many famous conjectures can be written as "this search program never finds a counterexample". Goldbach's conjecture is one: write a loop that tests $4, 6, 8, \ldots$ for being a sum of two primes and stops at the first failure.

In 1928 David Hilbert asked for something even bigger, the **Entscheidungsproblem**: a mechanical procedure that decides, for any mathematical statement, whether it is provable. If it existed, mathematics would become computation.

In 1936 Alan Turing, aged 23, answered: no such procedure exists. Not "we haven't found one yet". It *cannot* exist. To prove that, he first had to say exactly what a "mechanical procedure" is, and in doing so he invented the modern computer on paper.

> **Are there problems that no computer program can ever solve?**

By the end of this chapter you will have a proof that the answer is yes, a sense of how *many* such problems there are, and a map of a second, subtler frontier: problems that can be solved, but perhaps never quickly.

30.2 The big idea

There are two ideas, and both fit in a paragraph.

Idea 1: programs are data. Every program is a finite string of characters. Strings can be listed: first all strings of length 1, then length 2, and so on. So the programs can be numbered $P_1, P_2, P_3, \ldots$. A *problem*, on the other hand, is any yes/no question about inputs, which amounts to any subset of the set of all strings. There are as many such subsets as there are real numbers, which is strictly more than there are whole numbers (Ch. 64 proves Cantor's theorem behind this). There are not enough programs to go round. Almost every problem has no program at all.

Idea 2: a program that feeds on itself. The counting argument says that unsolvable problems exist but does not name one. To name one, Turing used the oldest trick in logic, the liar's paradox ("this sentence is false"). Because programs are data, a program can be given *its own text* as input. Suppose some program claims to predict the behaviour of every program. Build a contrarian that asks the predictor about itself and then does the opposite. The predictor must be wrong about the contrarian. That is the halting problem, and §30.3 makes it rigorous.

The second half of the chapter asks a finer question. Among problems that *can* be solved, some seem to need exponential time. Ch. 29 left one hanging: checking a proposed satisfying assignment of a formula is fast, but finding one appears hard. Is "easy to check" really different from "easy to solve"? That is the P versus NP question, the most famous open problem in computer science.

A useful picture is a ladder of machines. Each rung adds memory and can recognise more:

Machine	Memory	Recognises	Example it can't handle
finite automaton	a fixed number of states	regular languages	$\{0^n 1^n\}$
pushdown automaton	one stack	context-free languages	$\{a^n b^n c^n\}$
Turing machine	unbounded tape	recursively enumerable languages	the complement of HALT

The top rung is as high as the ladder goes. Every computer ever built, and every programming language, sits at exactly that rung or below.

30.3 The mathematics

Strings, languages and finite automata

An **alphabet** Σ is a finite set of symbols, such as $\{0, 1\}$. A **string** is a finite sequence of symbols, Σ^* is the set of all strings (including the empty string ε), and a **language** is any subset $L \subseteq \Sigma^*$. Every yes/no problem is a language: the language of binary numerals divisible by 3, of satisfiable formulas, of programs that halt.

Deterministic finite automaton (DFA)

A DFA is $M = (Q, \Sigma, \delta, q_0, F)$: a finite set of states Q, an alphabet Σ, a transition function $\delta : Q \times \Sigma \to Q$, a start state q_0 and a set of accepting states $F \subseteq Q$. It reads a string one symbol at a time, moving $q \mapsto \delta(q, c)$, and **accepts** if it ends in F. The language it accepts is $L(M)$; languages accepted by some DFA are **regular**.

The state set is the machine's entire memory, so a DFA is the right model for anything with bounded memory: a vending machine, a protocol handshake, a lexer, a digital circuit with flip-flops. Figure 30.1 shows a three-state DFA that reads a binary numeral from the most significant bit and accepts exactly the multiples of 3. Its states are the three equivalence classes of "same remainder mod 3" from Ch. 29. Reading bit b turns a value v into $2v + b$, so the remainder r becomes $(2r + b) \bmod 3$.

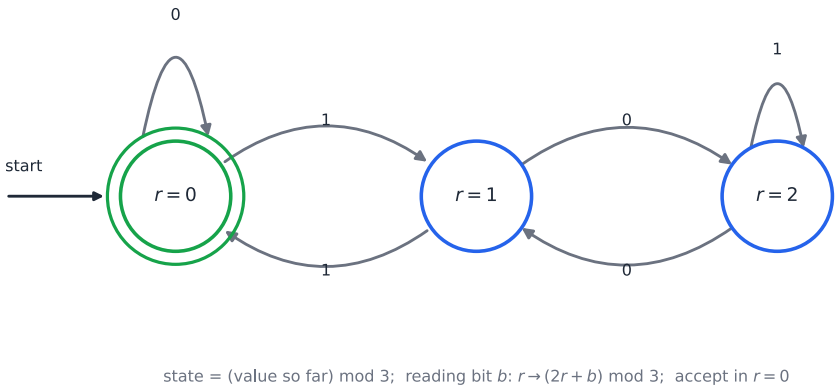

Figure 30.1 — A DFA for "divisible by 3". The double ring marks the accepting state. Trace `110` *(six):* $0 \to 1 \to 0 \to 0$*, accept. Trace* `111` *(seven):* $0 \to 1 \to 0 \to 1$*, reject.*

How much can a finite memory do? Not much, and the proof is the pigeonhole principle from Ch. 28.

Theorem 30.1 — Counting needs unbounded memory

The language $L = \{0^n 1^n : n \geq 0\}$ (some zeros followed by the *same number* of ones) is not regular.

Proof. Suppose a DFA M with k states accepts L. Feed it the $k + 1$ strings $\varepsilon, 0, 00, \ldots, 0^k$ and record the state after each. There are $k + 1$ strings and only k states, so two of them, say 0^i and 0^j with $i < j$, leave M in the same state q. From q, the machine's future depends only on the rest of the input. Append 1^i: the string $0^i 1^i \in L$ must be accepted, so reading 1^i from q ends in an accepting state. But $0^j 1^i$ also reaches q and then reads the same 1^i, so it is accepted too, though $j \neq i$ means $0^j 1^i \notin L$. Contradiction. □

The same argument proves that no DFA checks balanced parentheses, which is why compilers need a stack (a pushdown automaton, the next rung) to parse code. Its general form, the **pumping lemma**, is a standard tool for proving languages non-regular.

Turing machines

Turing's model gives a finite control unlimited scratch space.

Turing machine

A Turing machine has a finite set of states, including a start state and a halting state, and a tape of cells extending without bound, each holding a symbol (blank, written $\lrcorner$, by default). A head sits over one cell. At each step the machine reads the symbol under the head and, according to a finite table $\delta(q, s) = (q', s', D)$, switches to state q', writes s', and moves one cell left or right ($D \in \{L, R\}$). It **halts** if it reaches the halting state. On some inputs it may run forever.

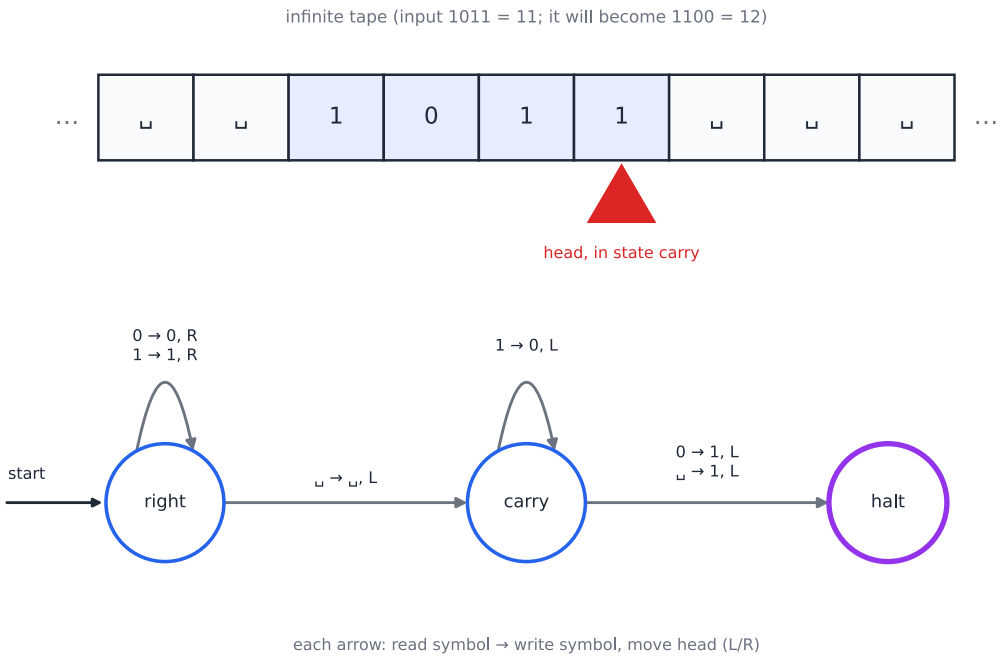

Figure 30.2 — A three-state Turing machine that adds 1 to a binary number. In state right *it runs to the end of the input; in state* carry *it walks back, turning trailing 1s into 0s, until it can write a single 1. The head is shown mid-carry on input 1011.*

This looks absurdly primitive, but every algorithm anyone has written down can be compiled into such a table. Two facts make the model central:

- **Universality.** There is a single Turing machine U that takes as input the description $\langle M \rangle$ of any machine M plus an input w, and simulates M on w. This is a stored-program computer, described nine years before the first one was built.
- **The Church–Turing thesis.** Every procedure that a human or a physical machine can carry out step by step can be done by a Turing machine. This is not a theorem (it relates a mathematical object to an informal idea), but every alternative model ever proposed, from lambda calculus to cellular automata to the programming language you use, has turned out to be equivalent.

Decidable, recognisable and the halting problem

> **Decidable and recognisable**
>
> A language L is **decidable** if some Turing machine halts on every input, accepting exactly the strings in L. It is **recognisable** if some machine accepts exactly the strings in L, but may run forever on strings outside it.

The difference matters. To recognise "programs that halt", just run the program and say yes if it stops. If it never stops, you never answer. The question is whether something cleverer always answers.

> **Theorem 30.2 — The halting problem is undecidable (Turing, 1936)**
>
> The language $\mathrm{HALT} = \{\langle M, w\rangle : M \text{ halts on input } w\}$ is recognisable but not decidable.

Proof. It is recognisable: the universal machine simulates M on w and accepts if the simulation halts.

Suppose, for contradiction, that a machine H decides it: $H(\langle M\rangle, w)$ always halts, answering *yes* if M halts on w and *no* otherwise. Build a new machine D that, on input $\langle M\rangle$:

1. runs $H(\langle M\rangle, \langle M\rangle)$, asking whether M halts when fed its own description;
2. if H says *yes*, loops forever; if H says *no*, halts.

D is a legitimate machine because H always halts. Now run D on its own description $\langle D\rangle$.

- If D halts on $\langle D\rangle$, then $H(\langle D\rangle, \langle D\rangle)$ said *yes*, so by step 2 D loops forever. Contradiction.
- If D loops forever on $\langle D\rangle$, then H said *no*, so by step 2 D halts. Contradiction.

Either way we reach a contradiction, so no such H exists. □

This is **diagonalisation**. List all machines down the side of a table and all inputs across the top, and write in each cell whether that machine halts on that input. D is built to disagree with the diagonal: on input $\langle M_i\rangle$ it does the opposite of what M_i does on $\langle M_i\rangle$. So D differs from every row, yet D is supposed to be a row. It is Cantor's proof that the reals are uncountable, turned into a statement about programs.

What the theorem does and does not say

It does not say you can never tell whether a *particular* program halts: for `while True: pass` you obviously can. It says no single algorithm is right about *every* program. A practical tool can answer "halts", "loops" or "don't know" and be useful, as long as it is allowed to say "don't know".

Reductions: undecidability spreads

Once you have one unsolvable problem, you can find many by **reduction**. Problem A reduces to problem B, written $A \le B$, if a computable function f turns every instance x of A into an instance $f(x)$ of B with the same answer. Then a solver for B would solve A, so if A is undecidable, so is B.

For example, "does program P ever print `hello`?" is undecidable. Given $\langle M, w\rangle$, build the program that silently simulates M on w (with all output suppressed) and then prints `hello`. It prints `hello` exactly when M halts on w. A `hello`-detector would therefore decide HALT.

Pushing this idea to its limit gives a theorem that should worry anyone who writes analysis tools.

Rice's theorem (1953)

Let S be any property of the *function a program computes* (its input-output behaviour, not its text), such that some programs have it and some do not. Then "does program P have property S?" is undecidable.

"Does this program ever divide by zero?", "does it compute the same function as that one?", "does it meet its specification?" are all undecidable in general. This is why the first mystery of Ch. 29 can have no complete mechanical solution.

? The machine that could not prove itself

Turing's diagonal trick looks a lot like the sentence "this statement is not provable". Five years earlier, Kurt Gödel had used that sentence to show that any consistent formal system rich enough for arithmetic leaves some true statements unprovable. Are the two results the same theorem in different clothes, and can one be derived from the other? The story is in Ch. 65 and Ch. 68.

Efficient computation: P and NP

Decidable is not the same as practical. A problem whose best algorithm takes 2^n steps is decidable, but at $n = 300$ it is as good as unsolvable. Complexity theory sorts decidable problems by how their cost grows (the growth-rate language is from Ch. 26).

P and NP

A decision problem is in **P** if some algorithm solves it in time $O(n^k)$ for a fixed k, where n is the input length. It is in **NP** if every *yes*-instance has a **certificate** of polynomial length that a polynomial-time **verifier** can check: the verifier accepts (x, c) for some c exactly when x is a *yes*-instance.

Satisfiability (SAT: does this formula have an assignment making it true?) is in NP, because the certificate is the assignment and checking it takes one pass over the formula. Sorting, shortest paths (Ch. 27) and, since 2002, primality testing are in P. Every problem in P is in NP (the verifier can ignore the certificate and solve the problem), so P $\subseteq$ NP. Whether the inclusion is strict is the open question.

Polynomial-time reductions, $A \le_p B$, are reductions computed in polynomial time. A problem B is **NP-hard** if every problem in NP reduces to it, and **NP-complete** if it is also in NP. An NP-complete problem is a hardest problem in NP: a polynomial algorithm for *one* of them gives a polynomial algorithm for *all* of NP.

Cook–Levin theorem (1971–73)

SAT is NP-complete.

The idea of the proof is to write the entire run of a polynomial-time verifier, tape cell by tape cell and step by step, as a giant but polynomial-size Boolean formula that is satisfiable exactly when some certificate makes the verifier accept. We state it without proof. Once SAT was known to be hard, Richard Karp showed in 1972 that 21 classic problems were NP-complete too, by chains of reductions. Here is one link of such a chain, proved in full.

Let $G = (V, E)$ be a graph. A set $S \subseteq V$ is **independent** if no edge joins two vertices of S; it is a **vertex cover** if every edge has at least one endpoint in S; it is a **clique** if every two vertices of S are joined by an edge.

Theorem 30.3 — Three faces of one problem

For any graph $G = (V, E)$ with $|V| = n$ and any $S \subseteq V$:

1. S is independent in G if and only if $V \setminus S$ is a vertex cover of G;
2. S is independent in G if and only if S is a clique in the complement graph $\bar{G}$ (same vertices, an edge exactly where G has none).

Hence "does G have an independent set of size $\ge k$?", "does G have a vertex cover of size $\le n - k$?" and "does $\bar{G}$ have a clique of size $\ge k$?" have the same answer, and each problem reduces to the others in polynomial time.

Proof. (1) Suppose S is independent and take any edge uv. Not both of u, v lie in S, so at least one lies in $V \setminus S$: the complement covers every edge. Conversely, if $V \setminus S$ covers every edge, no edge can have both endpoints in S, so S is independent.

(2) Two distinct vertices $u, v \in S$ are non-adjacent in G exactly when they are adjacent in $\bar{G}$. So "no pair in S is adjacent in G" and "every pair in S is adjacent in $\bar{G}$" are the same statement.

The reductions are the maps $(G, k) \mapsto (G, n - k)$ and $(G, k) \mapsto (\bar{G}, k)$. The first is free; the second writes down $\binom{n}{2}$ adjacency bits, which takes $O(n^2)$ time. $\square$

A classic reduction sends 3-SAT to Independent Set (by a gadget that turns each clause into a triangle); combined with Theorem 30.3 this makes Clique and Vertex Cover NP-complete as well. Thousands of problems are now known to be NP-complete: scheduling, timetabling, circuit layout, protein folding models, Sudoku on $n^2 \times n^2$ grids, and the integer programs of Ch. 49. They stand or fall together.

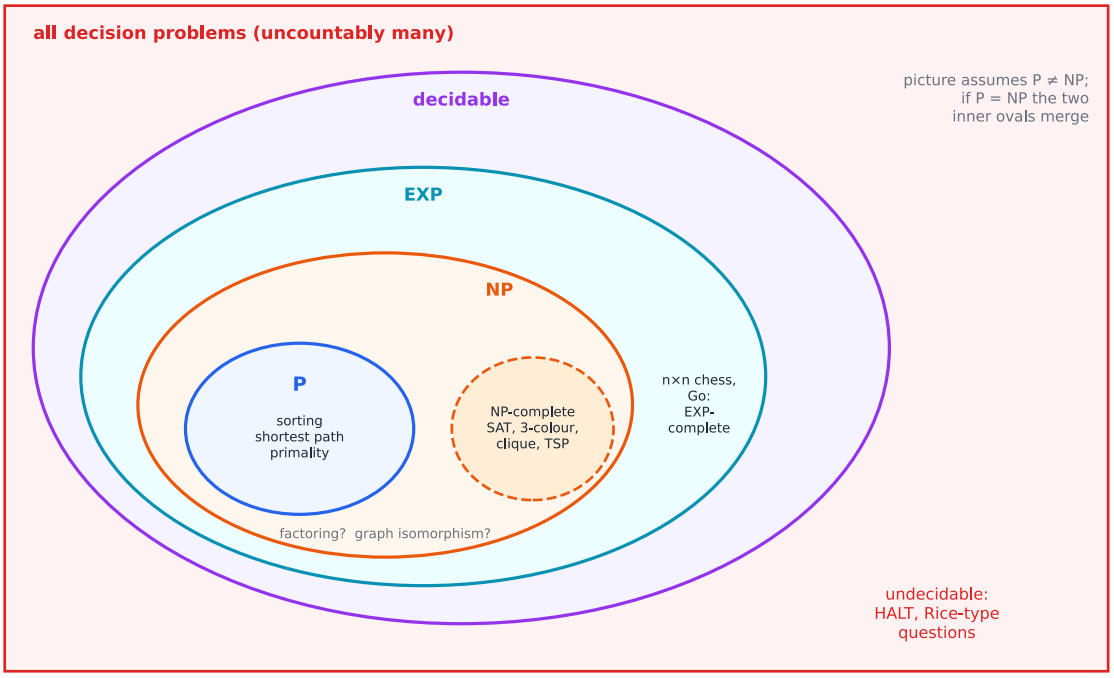

Figure 30.3 — The landscape as most researchers believe it to be. We know $\mathrm{P} \subseteq \mathrm{NP} \subseteq \mathrm{EXP}$ *and, by a diagonal argument,* $\mathrm{P} \neq \mathrm{EXP}$. *Every other boundary in the picture inside the decidable region is unproved.*

> **? The million-dollar inclusion**
>
> Is $\mathrm{P} = \mathrm{NP}$? The Clay Mathematics Institute has offered US$1,000,000 for an answer since 2000. Strangely, much of modern life is built on betting that the answer is no: if every efficiently checkable problem were efficiently solvable, the one-way functions behind online banking could not exist. Why cryptography needs hardness, and which hardness it needs, is Ch. 77.

30.4 The algorithm

Simulating machines

A DFA is a loop over the input with one table lookup per symbol: linear time and constant memory, which is why regular expressions (compiled to automata) are fast. A Turing machine simulator is barely longer. The tape is a dictionary, so it grows in both directions on demand. Notice the `max_steps` argument: a simulator *must* have one, and Theorem 30.2 says that no clever replacement for it exists.

```
def run_tm(rules, tape, state="right", head=0, halt="halt", max_steps=10_000):
    tape = dict(enumerate(tape))
    for step in range(max_steps):
        if state == halt:
            return "".join(tape[i] for i in sorted(tape)).strip("_"), step
        state, write, move = rules[state, tape.get(head, "_")]
        tape[head] = write
        head += 1 if move == "R" else -1
    return None, max_steps          # gave up: maybe it never halts

inc = {("right", "0"): ("right", "0", "R"), ("right", "1"): ("right", "1", "R"),
       ("right", "_"): ("carry", "_", "L"),
       ("carry", "1"): ("carry", "0", "L"), ("carry", "0"): ("halt", "1", "L"),
       ("carry", "_"): ("halt", "1", "L")}
print(run_tm(inc, "1011"), run_tm(inc, "111"))   # ('1100', 8) ('1000', 8)
```

Verifying versus searching

Here is the asymmetry at the heart of NP, in code. A formula in conjunctive normal form is a list of clauses; literal `3` means x_3 and `-3` means $\neg x_3$.

```
from itertools import product

def verify(clauses, bits):                    # O(total formula length)
    return all(any(bits[abs(l) - 1] == (l > 0) for l in c) for c in clauses)

def brute_sat(clauses, n):                    # O(2^n * formula length)
    for bits in product([False, True], repeat=n):
        if verify(clauses, bits):
            return bits
    return None

F = [(1, 2, 3), (-1, -2), (-1, -3), (-2, -3), (-1, 2), (1, -3)]
print(brute_sat(F, 3))                        # (False, True, False)
```

`verify` reads the formula once. `brute_sat` may call it 2^n times. Real SAT solvers (DPLL and its descendant, conflict-driven clause learning) prune the search brilliantly and solve industrial instances with millions of variables, but on carefully built hard families every known algorithm still takes exponential time.

The program you cannot write

Theorem 30.2, written as Python, is short enough to memorise.

```
def halts(program_source, input_data):
    ...                               # suppose someone hands you this, always correct

def contrarian(source):
    if halts(source, source):
        while True:
            pass                      # loop forever
    return "halted"

# contrarian(<source code of contrarian>) can neither halt nor loop.
```

Whatever body you write for `halts`, `contrarian` run on its own source code proves it wrong. In practice, analysis tools accept this and choose a side: **sound** tools (which never miss a real bug but raise false alarms) or **complete** ones (which never raise false alarms but miss bugs). Rice's theorem says you cannot have both and also always answer.

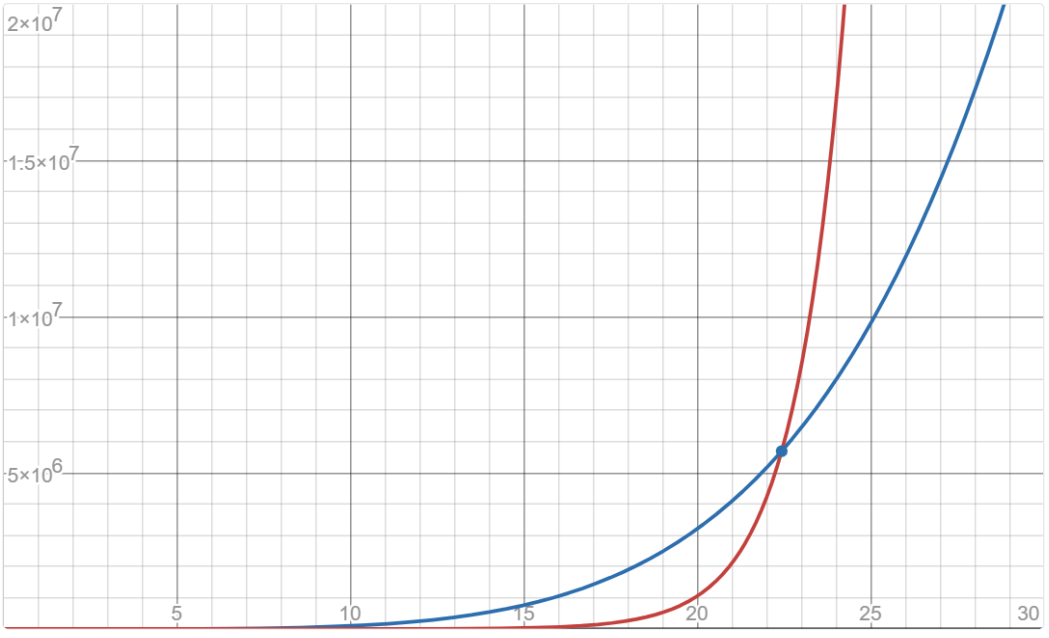
Failure cases

- **Confusing worst case with typical case.** NP-completeness is a worst-case statement. Many instances of NP-complete problems are easy, and SAT solvers exploit that every day.
- **Forgetting the encoding.** "Polynomial" means polynomial in the *length of the input*. Trial division tests whether N is prime in about $\sqrt{N}$ steps, which looks polynomial, but the input is $d \approx \log_{10} N$ digits long, so $\sqrt{N} \approx 10^{d/2}$ is exponential in the input length.

30.5 The experiment

Polynomial versus exponential

Every polynomial is eventually beaten by every exponential, but "eventually" can be far away. The graph compares n^5 with 2^n.



An algorithm costing 2^n beats one costing n^5 until $n \approx 22.4$; after that it loses, and the gap explodes.

Change the exponent 5 to 10: the crossover moves out to $n \approx 58.8$ (widen to `right=70` and `top=10^{18}` to see it, and move the label point). This is the honest caveat of complexity theory. An n^{10} algorithm is "efficient" in theory and useless in practice, while a 1.001^n algorithm is "inefficient" and fine for any n you will ever meet. The theory is about the shape of growth, not about this afternoon's run time.

The cliff in random 3-SAT

Generate random 3-SAT formulas with n variables and m clauses, each clause three distinct variables with random signs. With few clauses, almost every formula is satisfiable. With many, almost none is. The surprise is how sharply one regime gives way to the other. The script below brute-forces every formula over all 2^n assignments at once, using numpy.

```
import numpy as np
import matplotlib.pyplot as plt

N = 12            # knob: number of variables (each +1 doubles the work)
TRIALS = 200      # knob: random formulas per ratio
RATIOS = np.arange(1.0, 8.01, 0.25)   # clauses per variable, m/n
rng = np.random.default_rng(1)

# every assignment of N Boolean variables, as rows of a 2^N x N table
A = ((np.arange(2**N)[:, None] >> np.arange(N)) & 1).astype(bool)

def satisfiable(m):
    """Random 3-SAT with m clauses; brute force over all 2^N assignments."""
    var = np.array([rng.choice(N, 3, replace=False) for _ in range(m)])
    neg = rng.random((m, 3)) < 0.5
    alive = np.ones(2**N, dtype=bool)
    for v, s in zip(var, neg):
        alive &= (A[:, v] ^ s).any(axis=1)   # clause = OR of 3 literals
        if not alive.any():
            return False
    return True

frac = [np.mean([satisfiable(int(round(r * N))) for _ in range(TRIALS)]) for r in RATIOS]
for r, f in zip(RATIOS, frac):
    print(f"m/n = {r:4.2f}   P(satisfiable) = {f:.2f}")

plt.plot(RATIOS, frac, "o-")
plt.axvline(4.27, ls="--", color="grey")
plt.xlabel("clauses per variable  m/n")
plt.ylabel("fraction satisfiable")
plt.title(f"random 3-SAT, n = {N}")
plt.show()
```

With the default knobs it runs in a few seconds. Every formula is satisfiable up to $m/n = 3$, the fraction is 0.74 at $m/n = 4.25$, it crosses one half near $m/n \approx 4.8$, and it is down to about 0.04 by $m/n = 7$. The dashed line marks 4.27, where the transition is believed to sit for very large n.

Things to try:

1. Run with `N = 8`, then `N = 14`. The drop gets steeper and slides toward the dashed line as N grows. Estimate where it crosses one half for each N.
2. Time each call of `satisfiable` and plot the average time against m/n. The cost is not monotone: under-constrained formulas are satisfied at once, over-constrained ones die after a few clauses, and the hardest ones cluster near the cliff.
3. Switch to 2-SAT (two variables per clause). Where is the cliff now? Unlike 3-SAT, 2-SAT is in P, and its threshold can be computed exactly.

30.6 The challenge

No answers are given.

1. **Intuition.** A program has 1 KB of memory and no other storage. Explain why "does it halt on this input?" *is* decidable for it, and estimate how many steps a decider might need. Why does this not contradict Theorem 30.2?
2. **Derivation.** Use a pigeonhole argument in the style of Theorem 30.1 to prove that the language of palindromes over $\{0, 1\}$ is not regular. Then design a DFA with 5 states that accepts binary numerals divisible by 5, and prove that no DFA with fewer states can do it.
3. **Implementation.** The **busy beaver** $\mathrm{BB}(n)$ is the largest number of steps any halting n-state, two-symbol Turing machine takes when started on a blank tape. Extend `run_tm` to enumerate every 2-state machine (each table entry is a choice of write symbol, move and next state or halt) and find $\mathrm{BB}(2)$ by experiment. Why can no program compute $\mathrm{BB}(n)$ for every n?
4. **Open investigation.** In 2024 a large online collaboration proved, with a computer-checked proof, that $\mathrm{BB}(5) = 47{,}176{,}870$. Some 6-state machines are known to behave like Collatz-type iterations. Write a simulator for a 6-state machine of your own design that mimics the Collatz map on unary or binary numbers, and investigate: what would proving that your machine halts actually require?

30.7 Loose threads

The challenge question has an answer, and it is yes. Some problems no program can ever solve, whatever the hardware, the language or the century. The halting problem is the first, proved by making a program argue with itself, and Rice's theorem spreads the damage to every non-trivial question about what programs do. A simple count shows that these are not rare exceptions. Almost every problem is unsolvable, because there are only countably many programs.

Then the chapter drew a second frontier inside the solvable world, between P and NP, and left it exactly where mathematics leaves it: unresolved. That is not a gap in this book. It is a gap in human knowledge.

What we did not tell you:

- **Why logic breaks in the same place.** The diagonal trick that kills the halting problem also limits proof itself. The first mystery points to Ch. 65 and Ch. 68.
- **What hardness is good for.** If P were equal to NP, modern cryptography would collapse; it is built on problems believed hard on average, which is a stronger demand than NP-hardness. The second mystery points to Ch. 77.
- **Whether coins help.** Every algorithm in this chapter was deterministic.

> **? Does randomness buy speed?**
>
> Some problems have fast randomised algorithms that flip coins and are wrong with probability below 2^{-100}, while no equally fast deterministic algorithm is known. Primality testing was one of them for 25 years until a deterministic method appeared in 2002. Is randomness ever *really* necessary for efficiency, or can it always be faked? Many researchers believe the second, and the reason has to do with pseudorandom generators: see Ch. 81.

Simple rules running for a long time also turn up in nature and in games: Conway's Game of Life can simulate a universal Turing machine, so even "will this pattern ever die out?" is undecidable. That lead is followed in Ch. 86.

Track B — Probability, Uncertainty, and Information

> **Level 2 — Specializations.** The mathematics of randomness, prediction, communication, and decision-making under uncertainty.

Suggested reading order for Track B. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 19 — Probability
- Ch. 20 — Statistical Analysis
- Ch. 21 — Random Processes
- Ch. 24 — Computational Mathematics

Chapters

Ch.	Chapter	What it explores
31	Probability: The Science of Uncertainty	Conditional probability, Bayes' theorem, independence, inequalities, limit theorems.
32	The Art of Counting Random Worlds	Advanced combinatorics, random variables, distributions, tail bounds.
33	Information Theory: Measuring the Unknown	Entropy, mutual information, KL divergence, coding, compression.
34	Random Walks and Markov Worlds	Markov chains, stationary distributions, mixing times, hitting times.
35	Bayesian Thinking and Statistical Inference	Bayesian inference, likelihood, estimators, hypothesis testing, model selection.
36	Stochastic Processes: When Randomness Evolves	Poisson processes, Brownian motion, martingales, stochastic calculus.
37	Causal Inference: Correlation Is Not Destiny	Causal graphs, interventions, counterfactuals, confounding, experimental design.
38	Monte Carlo: Computing with Randomness	Sampling, simulation, variance reduction, Markov chain Monte Carlo.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 31 — Probability: The Science of Uncertainty

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19, Ch. 20 · **Leads to:** Ch. 32, Ch. 35, Ch. 38 · **Related:** Ch. 33, Ch. 97 **Reading time:** ~25 min

31.1 The hook

In September 1990 a reader sent a puzzle to Marilyn vos Savant's column in *Parade* magazine. You are on a game show facing three closed doors. Behind one is a car; behind the other two, goats. You pick door 1. The host, who knows where the car is, opens door 3 and shows you a goat. He then offers you the chance to switch to door 2. Should you?

Vos Savant said yes: switching wins two times in three. The magazine reportedly received around ten thousand letters in reply, many from people with doctorates, a large share of them telling her she was wrong. Two doors are left, they said, so it must be fifty-fifty. Paul Erdős, one of the most prolific mathematicians of the century, is said to have stayed unconvinced until he watched a computer simulation.

Now change one detail. The host does *not* know where the car is. He opens one of the two doors you did not pick at random, and it happens to show a goat. Everything you can see is identical: you chose door 1, door 3 is open, a goat is standing there, door 2 is closed. Yet now switching wins exactly half the time.

Same doors, same goat, same view, different answer. If that bothers you, good. It means you have found the central fact of this chapter: **a probability is not a property of the world you see. It depends on how you came to see it.** The answer to "should I switch?" depends on a question that seems to have nothing to do with doors: *what was the host's rule?*

The second half of the chapter asks a matching question about long runs. A casino does not know whether the next spin of its roulette wheel will win or lose, yet it can predict its takings for the year to within a fraction of a percent. Somewhere between one spin and a million, uncertainty turns into near-certainty. Where does that happen, how fast, and can it fail? It can, and you will watch it fail in Figure 31.2.

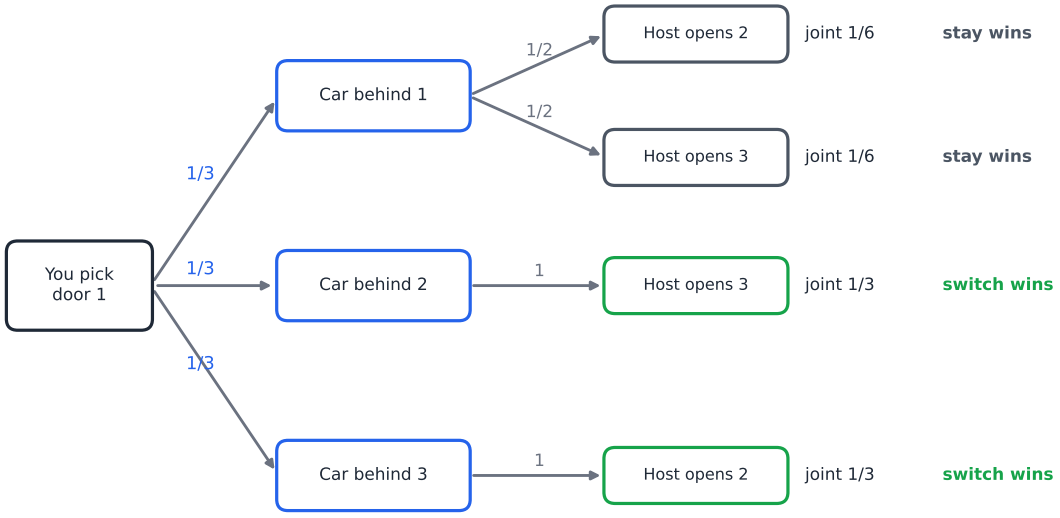
31.2 The big idea

Think of probability as **bookkeeping for ignorance**. Before the host acts you have a ledger: one third of your belief on each door. Every observation is a new entry. Conditioning on an event does not change the world. It deletes the parts of your ledger that the observation rules out and rescales what remains, so that it sums to one again.

The catch is that an observation is an event in the *full* story, host's behaviour included, and not just in the picture of the doors. "Door 3 shows a goat" is one event when the host chose door 3 on purpose because it hid a goat. It is a different event when he picked door 3 by chance and got lucky. Each version deletes a different part of the ledger:

- **Knowing host.** If the car is behind door 2, he is *forced* to open door 3. If the car is behind door 1, he opens door 3 only half the time. So seeing door 3 opened is twice as likely in the "car behind 2" world. That is evidence, and it pushes belief towards door 2.
- **Ignorant host.** He opens door 3 half the time whatever is behind door 1 or door 2, so the opening alone tells you nothing. Only the goat matters, and the goat rules out door 3 alone, leaving doors 1 and 2 equal.

The probability tree in Figure 31.1 makes this mechanical. Every path from the root to a leaf is one complete story, and its probability is the product of the branch probabilities. Conditioning means keeping the leaves that agree with what you saw and renormalising.



Given 'host opens 3': stay wins with 1/6, switch wins with 1/3 -> P(switch wins) = (1/3)/(1/6 + 1/3) = 2/3

Figure 31.1 — The knowing-host game as a tree. The leaves consistent with "host opens door 3" carry joint probability 1/6 (you were right first time) and 1/3 (the car is behind door 2). Renormalised, switching wins 2/3.

The analogy for the second half. A single coin toss is like one voter in an election: unpredictable. A million tosses are like the national result, which polls predict well. The law of large numbers says the average of many independent random quantities settles down to its expectation. The central limit theorem says how the remaining wobble is shaped (a bell curve) and how big it is (it shrinks like $1/\sqrt{n}$). Both are covered in the core (§20.5, with proofs in Appendix E.4–E.5). This chapter pushes on what the core left soft. In what sense does the average "settle"? What guarantees it? What breaks it?

31.3 The mathematics

Conditional probability, the law of total probability and Bayes' theorem are developed in §19.2 and §19.3. Independence is in §19.4, and Markov's and Chebyshev's inequalities are in §19.9. We use all of them freely.

Result 1: the host's rule decides the answer

Generalise the host. Let $C \in \{1, 2, 3\}$ be the car's door, uniform. You pick door 1. If the car is behind door 1, the host can open either goat door. Say he opens door 3 with probability q and door 2 with probability $1 - q$. If the car is behind door 2 or 3, he must open the other goat door. Let O_3 be the event "host opens door 3".

Monty Hall with a biased host

For the knowing host with preference $q \in [0, 1]$,

$$P(C = 2 \mid O_3) = \frac{1}{1+q}, \qquad P(C = 1 \mid O_3) = \frac{q}{1+q}.$$

For the ignorant host, who opens door 2 or 3 at random, $P(C = 2 \mid O_3,\ \text{goat}) = \tfrac{1}{2}$.

Proof. By the law of total probability,

$$P(O_3) = P(O_3 \mid C = 1)P(C = 1) + P(O_3 \mid C = 2)P(C = 2) + P(O_3 \mid C = 3)P(C = 3) = \frac{q}{3} + \frac{1}{3} + 0.$$

Bayes' theorem gives

$$P(C = 2 \mid O_3) = \frac{P(O_3 \mid C = 2)P(C = 2)}{P(O_3)} = \frac{1/3}{(q+1)/3} = \frac{1}{1+q}.$$

For the ignorant host, $P(O_3 \mid C = c) = \tfrac{1}{2}$ for every c. The goat is seen exactly when $C \neq 3$. So $P(O_3 \cap \{\text{goat}\} \cap \{C = c\}) = \tfrac{1}{6}$ for $c = 1, 2$ and 0 for $c = 3$. Renormalising, doors 1 and 2 get $\tfrac{1}{2}$ each. □

With $q = \tfrac{1}{2}$, the usual host, switching wins $\tfrac{2}{3}$. Even in the worst case, $q = 1$ (a host who always opens door 3 when he can), switching wins $\tfrac{1}{2}$. It is never worse than staying. If he opens door 2 instead, the mirror-image formula is $1/(2 - q)$, which is also at least $\tfrac{1}{2}$. So "always switch" is a dominant strategy, whatever the host's taste in doors. And the ignorant-host answer is not a special value of q at all: it is a different event in a different sample space.

Common Pitfall — conditioning on what you saw instead of what happened

"Two doors remain, so it's 50–50" quietly assumes the ignorant-host model. The data ("door 3 is open with a goat") cannot settle which model is true. Only the *protocol* can. The same trap appears in the boy–girl paradox, in survivorship bias, and in every observational study where the way the data were collected depends on the outcome (Ch. 37).

Independence is more fragile than it looks

Events A, B, C can be independent in pairs without being independent together. Toss two fair bits X, Y and let $Z = X \oplus Y$ (exclusive-or). Every pair is independent: for instance $P(X = 1, Z = 1) = P(X = 1, Y = 0) = \tfrac{1}{4} = P(X = 1)P(Z = 1)$. But any two of them determine the third, so $P(X = 1, Y = 1, Z = 1) = 0 \neq \tfrac{1}{8}$. This is not a curiosity. It is the principle behind the one-time pad and RAID-5 parity: one parity bit tells you nothing on its own, yet together with the other bits it tells you everything. The definition of mutual independence in §19.4 needs the product rule for *every* subfamily for exactly this reason.

Independence can also appear or disappear when you condition. Two independent fair dice are no longer independent once you are told their sum is 7. Two strongly correlated alarm signals can become independent once you know whether there really is a fire. Conditioning is the single most powerful operation in probability, and the most dangerous.

Result 2: Jensen's inequality

Markov and Chebyshev turn means and variances into tail bounds. The next inequality is the one that information theory (Ch. 33) is built on.

Jensen's inequality

If φ is convex and X and $\varphi(X)$ have finite expectations, then

$$\varphi\big(E[X]\big) \le E\big[\varphi(X)\big].$$

For concave φ the inequality reverses. If φ is strictly convex, equality holds only when X is almost surely constant.

Proof. Let $\mu = E[X]$. A convex function lies above each of its supporting lines. So there is a slope m (the derivative at μ if it exists, otherwise any subgradient) such that

$$\varphi(x) \ge \varphi(\mu) + m(x - \mu) \quad \text{for all } x.$$

Put $x = X$ and take expectations. Linearity gives $E[\varphi(X)] \geq \varphi(\mu) + m(E[X] - \mu) = \varphi(\mu)$. If φ is strictly convex, the inequality between the curve and the line is strict for $x \neq \mu$. Equality in expectation then forces $X = \mu$ with probability one. □

Choosing φ gives a family of classics:

$\varphi(x)$	Jensen says	Reading
x^2	$E[X]^2 \leq E[X^2]$	variance is non-negative
e^x	$e^{E[X]} \leq E[e^X]$	the MGF is never below e^{μ} (the seed of Chernoff bounds, Ch. 32)
$\log x$ (concave)	$E[\log X] \leq \log E[X]$	geometric mean $\leq$ arithmetic mean; entropy $\leq \log$(alphabet size)
$1/x$ on $x > 0$	$1/E[X] \leq E[1/X]$	average travel time at random speeds is worse than the time at the average speed

A second workhorse is **Cauchy–Schwarz**, $|E[XY]| \leq \sqrt{E[X^2]E[Y^2]}$. It follows because $E[(X - tY)^2] \geq 0$ for every real t, so this quadratic in t has a non-positive discriminant. Applied to the centred variables, it shows that the correlation coefficient of §20.3 always lies in $[-1, 1]$.

Result 3: averages settle, almost surely

The weak law of large numbers (Appendix E.4) says that for each fixed $\varepsilon > 0$,

$$P\big(|\bar{X}_n - \mu| > \varepsilon\big) \to 0, \qquad \bar{X}_n = \frac{1}{n}\sum_{i=1}^{n} X_i.$$

Read it carefully. It is a statement about each *single* n: at a large time, a large deviation is unlikely. It does not say that any particular run of the experiment eventually stays close to μ. A run could, in principle, wander away rarely but infinitely often. The **strong law** rules that out. It is a statement about whole sample paths:

$$P\Big(\lim_{n\to\infty} \bar{X}_n = \mu\Big) = 1.$$

The tool that turns "rarely" into "only finitely often" is short enough to prove in full.

First Borel–Cantelli lemma

If $A_1, A_2, \ldots$ are events with $\sum_n P(A_n) < \infty$, then with probability one only finitely many of the A_n occur.

Proof. "Infinitely many A_n occur" is the event $\bigcap_N \bigcup_{n \geq N} A_n$. For every N it is contained in $\bigcup_{n \geq N} A_n$, so by the union bound

$$P(\text{infinitely many } A_n) \leq \sum_{n \geq N} P(A_n) \xrightarrow[N\to\infty]{} 0,$$

because the tail of a convergent series tends to zero. □

Now the strong law, under an extra assumption that keeps the proof to a few lines.

Strong law of large numbers (finite fourth moment)

Let $X_1, X_2, \ldots$ be i.i.d. with mean μ and $E[(X_1 - \mu)^4] = \kappa < \infty$. Then $\bar{X}_n \to \mu$ with probability one.

Proof. Put $Y_i = X_i - \mu$, so $E[Y_i] = 0$ and $E[Y_i^2] = \sigma^2$. Expand $E[(Y_1 + \cdots + Y_n)^4]$ as a sum of terms $E[Y_iY_jY_kY_l]$. By independence and $E[Y_i] = 0$, any term containing an index exactly once vanishes. What survives is the n terms $E[Y_i^4] = \kappa$ and the terms $E[Y_i^2Y_j^2] = \sigma^4$ with $i \neq j$. There are $\binom{4}{2} = 6$ ways to choose which two of the four positions hold i, and $\binom{n}{2}$ unordered pairs $\{i, j\}$, giving $3n(n-1)$ such terms. Hence

$$E\Big[\Big(\sum_{i=1}^{n} Y_i\Big)^4\Big] = n\kappa + 3n(n-1)\sigma^4 \leq Kn^2, \qquad K = \kappa + 3\sigma^4.$$

Markov's inequality applied to the fourth power gives, for any $\varepsilon > 0$,

$$P\big(|\bar{X}_n - \mu| > \varepsilon\big) = P\Big(\Big(\sum Y_i\Big)^4 > n^4\varepsilon^4\Big) \leq \frac{Kn^2}{n^4\varepsilon^4} = \frac{K}{\varepsilon^4 n^2}.$$

The right side is summable in n. By Borel–Cantelli, with probability one $|\bar{X}_n - \mu| > \varepsilon$ happens only finitely often. Apply this with $\varepsilon = 1/m$ for $m = 1, 2, \ldots$. A countable union of probability-zero events has probability zero, so with probability one, for every m, $|\bar{X}_n - \mu| \leq 1/m$ for all large n. That is $\bar{X}_n \to \mu$. □

Notice why Chebyshev alone was not enough. It gives a bound of order $1/n$, and $\sum 1/n$ diverges, so Borel–Cantelli cannot use it. Raising the power from 2 to 4 buys a $1/n^2$ bound, and that is summable. Exponential bounds, which buy e^{-cn}, are the business of Ch. 32.

? The strong law with nothing but a mean

Our proof needed a finite fourth moment. Kolmogorov's strong law needs only $E|X| < \infty$: no variance, no fourth moment, nothing else. The proof truncates the variables, controls what was cut off, and needs a rigorous account of what "with probability one" means for an infinite sequence of coin tosses. That rebuilding of probability on measure theory is the subject of Ch. 97.

When averages refuse to settle

Every one of these laws needs $E|X| < \infty$. The standard **Cauchy** distribution, with density $f(x) = \dfrac{1}{\pi(1+x^2)}$, is symmetric about zero, yet $\int |x| f(x)\,dx$ diverges logarithmically. It has no mean. It is not exotic: it is the distribution of $\tan\Theta$ for a uniformly random angle Θ, so it describes where a randomly aimed beam from a lighthouse hits the shore. Its characteristic function is $e^{-|\omega|}$, so the average of n independent copies has characteristic function $\left(e^{-|\omega|/n}\right)^n = e^{-|\omega|}$. **The average of n Cauchy samples is again standard Cauchy.** Averaging a million of them is no better than taking one.

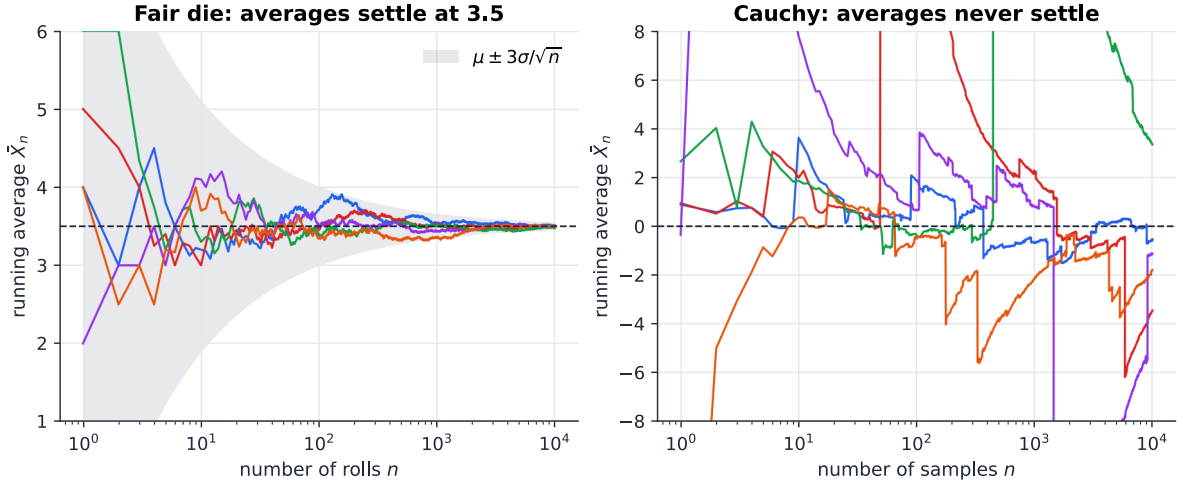


Figure 31.2 — Left: five runs of the running average of a fair die, closing in on 3.5 inside the $\pm 3\sigma/\sqrt{n}$ envelope. Right: five runs of the running average of standard Cauchy samples. Each time a single huge sample arrives, the average jumps, and it never settles.

The central limit theorem (§20.5) completes the finite-variance story. The wobble $\bar{X}_n - \mu$ is approximately $\mathcal{N}(0, \sigma^2/n)$, which is the grey envelope in Figure 31.2. It is a statement about *shape*: it tells you the distribution of the error at typical scales, $\pm$ a few $\sigma/\sqrt{n}$. It does not reliably tell you about errors far out in the tails. That distinction will matter a great deal in the next chapter.

31.4 The algorithm

The law of large numbers is an algorithm in disguise. **To estimate a probability, simulate and count.** If I_k is the indicator that trial k produced the event, then $\hat{p}_n = \frac{1}{n}\sum I_k$ converges to p. The questions an engineer must answer are *how many trials*, and *how do I accumulate the answer without numerical trouble*.

```
import numpy as np

def estimate(trial, n, rng):
    """Monte Carlo estimate of P(event) with a CLT confidence half-width."""
    mean, m2 = 0.0, 0.0                     # Welford's running mean and sum of squares
    for k in range(1, n + 1):
        x = float(trial(rng))               # 1.0 if the event happened, else 0.0
        d = x - mean
        mean += d / k
        m2 += d * (x - mean)
    var = m2 / (n - 1)
    return mean, 1.96 * np.sqrt(var / n)    # ~95 % interval: mean +- half-width
```

Welford's update avoids the cancellation of the naive formula $\frac{1}{n}\sum x^2 - \bar{x}^2$, which can lose every significant digit when the variance is tiny compared with the mean squared. Each step costs $O(1)$ time and $O(1)$ memory, so the estimator can run on a stream that never ends.

How many trials? To get $|\hat{p} - p| \le \varepsilon$ with failure probability at most δ:

- *Chebyshev* (a guarantee): $\mathrm{Var}(\hat{p}) \le \frac{1}{4n}$, so $n \ge \dfrac{1}{4\delta\varepsilon^2}$. For $\varepsilon = 0.01$ and $\delta = 0.05$ that is 50 000 trials.
- *CLT* (an approximation): $n \approx \dfrac{z^2}{4\varepsilon^2}$ with $z = 1.96$, about 9 604 trials, five times fewer.

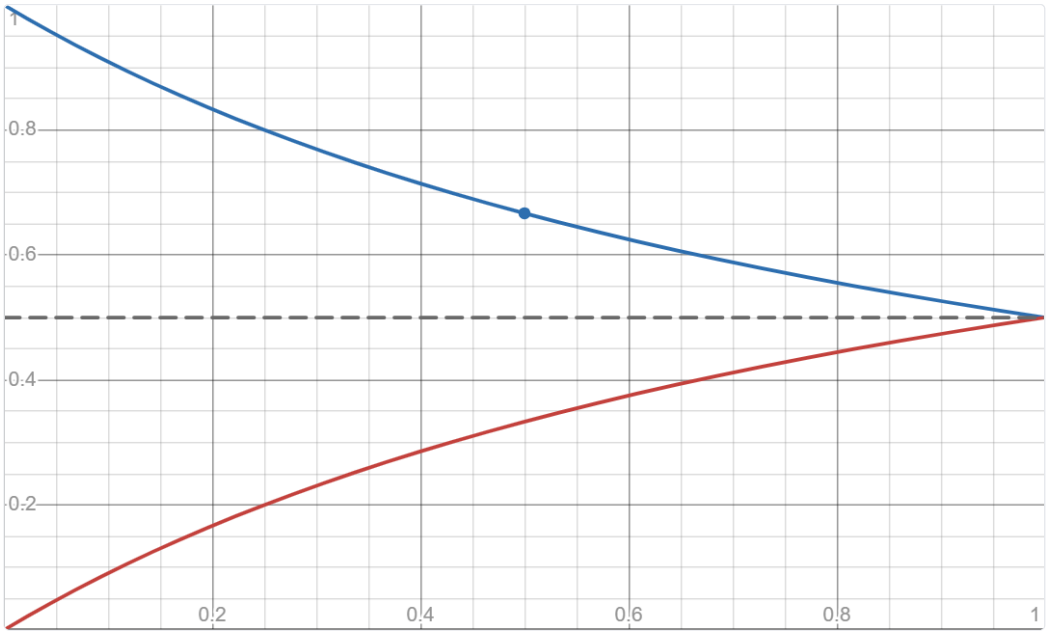
The gap between a rigorous bound and an approximate one is a recurring theme. In Ch. 32 the Chernoff–Hoeffding bound closes most of it, giving a guarantee with $\log(1/\delta)$ in place of $1/\delta$.

Failure cases.

1. *Rare events.* The relative error of $\hat{p}$ is about $1/\sqrt{np}$. To estimate $p = 10^{-6}$ to $\pm 10\,\%$ at 95 % confidence you need roughly 4×10^8 trials. Bit-error-rate testing at 10^{-12} is impossible by brute force. That is why importance sampling exists (Ch. 38).
2. *Heavy tails.* If the quantity being averaged has infinite variance, the $1/\sqrt{n}$ rate is gone. If it has no mean, as in Figure 31.2, there is nothing to converge to.
3. *Hidden dependence.* A poor random-number generator, or trials that share state, quietly break the "independent" in i.i.d. The estimate then converges to the wrong answer with great confidence.

31.5 The experiment

First, see the host-bias formula $1/(1+q)$ from Result 1. The horizontal axis is q, the probability that the knowing host opens door 3 when he has a choice.



Probability that switching wins (blue) and that staying wins (red) as the host's door preference q varies. The curves meet only at $q = 1$. Add the line `y=\frac{1}{2-x}` (switching wins when the host opened door 2 instead) and check that it too never drops below the dashed line at $1/2$. Then change the fixed point to the q you think a real host might have.

Now simulate the game itself. The knobs are at the top.

```
import numpy as np

DOORS = 3           # try 10 or 100: the host opens all but one other door
HOST_KNOWS = True   # False: host opens doors at random (games showing the car are discarded)
Q = 0.5             # knowing host, car behind your door: chance he leaves the lowest-numbered other door shut
TRIALS = 100_000
rng = np.random.default_rng(1)

stay = switch = kept = 0
for _ in range(TRIALS):
    car, pick = rng.integers(DOORS), 0
    others = [d for d in range(DOORS) if d != pick]
    if HOST_KNOWS:
        if car == pick:
            closed = others[0] if rng.random() < Q else rng.choice(others[1:])
        else:
            closed = car                    # he must keep the car hidden
    else:
        closed = rng.choice(others)         # the door left shut, chosen blindly
        if car not in (pick, closed):       # he revealed the car: game void
            continue
    kept += 1
    stay += (car == pick)
    switch += (car == closed)

print(f"games kept: {kept}")
print(f"P(win | stay)   = {stay / kept:.4f}")
print(f"P(win | switch) = {switch / kept:.4f}")
print(f"theory, usual knowing host: switch wins {(DOORS - 1) / DOORS:.4f}")
```

Things to try. Set `DOORS = 100` with `HOST_KNOWS = True`: switching wins about 99 % of the time, and the puzzle stops feeling paradoxical. Set `HOST_KNOWS = False` and watch both answers fall to $1/2$, while `games kept` drops to about $2/\text{DOORS}$ of the trials: most games are thrown away because the blind host exposed the car. Then plot the running estimate of `switch / kept` against the number of games on log axes. Does its wobble shrink like $1/\sqrt{n}$?

31.6 The challenge

1. **Intuition.** A test for a disease affecting 1 in 1000 people is 99 % sensitive and has a 5 % false-positive rate. Before computing anything, guess the probability that a person who tests positive is ill. Then explain, using only the idea of "deleting the impossible parts of the ledger", why the true answer is so much smaller than most people guess. What changes if the person was tested *because* they had symptoms?
2. **Derivation.** In the n-door knowing-host game, the host opens k goat doors ($1 \le k \le n-2$) chosen uniformly from those available, and you then switch to a uniformly random closed door other than yours. Derive the probability that switching wins, and show that it is always larger than $1/n$.
3. **Implementation.** Write a function that takes any finite probability tree (nested lists of `(probability, label, subtree)`) and an observed event, given as a predicate on root-to-leaf paths, and returns the posterior distribution over leaves. Use it to reproduce Result 1 for both hosts and the boy–girl paradox ("at least one is a boy" versus "the elder is a boy").

4. **Open investigation.** For the running average of a symmetric distribution with tails $P(|X| > x) \sim x^{-\alpha}$, explore by simulation for which α the average seems to converge, at what rate, and to what *shape* of fluctuation. What happens near $\alpha = 1$ and near $\alpha = 2$? Can you guess a scaling law $n^{\beta(\alpha)}$ that makes the fluctuations look the same at every n?

31.7 Loose threads

This chapter treated probability as a calculus of belief updates and long-run averages. In doing so it took several things on trust.

We assumed the host's rule was known. In real problems it never is. A doctor does not know the exact false-positive rate, and a radar does not know the clutter statistics. The honest response is to put a probability distribution on the unknown rule itself and let the data update *that*.

> **? What if you do not know the host's rule?**
>
> Suppose you play the game many times against the same host and do not know his q. Each game you see which door he opens. Can you learn q, and how should your decision to switch change as you learn? Treating q itself as random, with a prior that the data sharpen into a posterior, is Bayesian inference, the subject of Ch. 35.

We proved the strong law with a fourth moment, and the general proof was left for later. We also saw that Chebyshev gives deviation probabilities falling only like $1/n$, while the true probabilities in a coin-tossing experiment fall far faster. For 1000 fair tosses, Chebyshev bounds the chance that the fraction of heads is outside $[0.45, 0.55]$ by 0.1. The truth is about 0.0014.

> **? Exponentially unlikely**
>
> The probability that the average of n coin tosses is off by more than ε does not fall like $1/n$. It falls like e^{-cn}, and the constant c has an exact value that depends on ε. Where does the exponential come from, and what is c? Chernoff's method in Ch. 32 gives the bound. The identity of c, a quantity that measures how *distinguishable* two coins are, waits in Ch. 33.

Finally, the Cauchy distribution showed that averaging can fail outright. Between "finite variance, Gaussian fluctuations" and "no mean, no convergence" lies a whole zoo of heavy-tailed limits, the stable laws. They govern network traffic bursts, financial returns and impulsive noise. Their story continues with processes that evolve in time in Ch. 36, and the computational consequences of rare events in Ch. 38.

Chapter 32 — The Art of Counting Random Worlds

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19, Ch. 31 · **Leads to:** Ch. 33, Ch. 34, Ch. 38 · **Related:** Ch. 28, Ch. 26 **Reading time:** ~25 min

32.1 The hook

A load balancer sends each of 1000 incoming requests to one of 1000 servers, chosen uniformly at random and independently. It is the simplest possible policy, with no coordination and no state. Three questions decide whether it is good enough.

1. **How many servers sit idle?** One might guess "hardly any, since there is one request per server". The answer is about 368, more than a third of the fleet.
2. **How busy is the busiest server?** The average load is exactly 1. The maximum is usually 5 or 6, and that maximum sets your latency tail.
3. **How many requests until every server has received at least one?** Not 1000, and not 2000. It takes about 7485 on average.

Now make one small change. For each request, pick *two* random servers and send it to the less loaded of the pair. The busiest server's load drops from about 5 or 6 to 3, almost every time. One extra random probe per request is enough to tame the maximum.

Each of these numbers is a property of an astronomically large set of equally likely "worlds": 1000^{1000} ways to assign the requests. Nobody can list them. Yet the answers come out in a few lines of algebra. This chapter is about how: counting random worlds *without enumerating them*, and bounding the rare worlds where things go badly wrong. It ends with a piece of magic. We will prove that certain objects exist by showing that a random one works, without ever constructing one.

32.2 The big idea

Two ideas do almost all the work.

Idea 1: break a count into indicators and add expectations. To find the expected number of idle servers, do not attempt the distribution of that number. It is horrible, because the servers' states are dependent. Instead, attach to each server a little switch I_j that reads 1 if server j is idle. The count is $\sum_j I_j$, and expectation is linear *whether or not the switches are independent*. So you need only $P(I_j = 1)$ for one server, multiplied by 1000. Linearity of expectation (§19.9) is the most underrated theorem in probability. It ignores dependence completely.

Idea 2: the average is not enough; bound the tails. "On average 7485 requests" does not tell an engineer how often it takes 10 000. The tail of the distribution is where systems fail: the server that overflows, the hash bucket that degrades to a linked list, the noise spike that flips a bit. Chapter 19 gave Markov's and Chebyshev's inequalities, which bound tails from the mean and variance alone. They are honest but weak. For sums of many independent pieces, a cleverer use of Markov's inequality gives bounds that decay *exponentially*. That is the **Chernoff bound**, and it is the reason randomized systems can be made reliable.

The analogy. Think of the random world as a city of 1000^{1000} houses and a property as a colour painted on some of them. Linearity of expectation lets you count the colour by asking one typical house at a time. Tail bounds tell you that the strange houses, the ones far from typical, are so rare that a random visitor essentially never finds one. The probabilistic method turns this round: if the strange houses are rare enough, then *most* houses are normal, and in particular a normal house *exists*.

32.3 The mathematics

Counting rules (permutations, combinations, inclusion–exclusion) are in §19.1 and treated in depth in Ch. 28. The binomial, geometric and Poisson families are in §19.6. Here we use them as tools.

Indicators at work

Idle servers. Throw m balls into n bins. Server j is idle when every ball misses it, so $P(I_j = 1) = (1 - 1/n)^m$ and

$$E[\#\text{idle}] = n\Big(1 - \frac{1}{n}\Big)^m \approx ne^{-m/n}.$$

With $m = n = 1000$ this is 367.7, close to $n/e = 367.9$. More generally, the load of one bin is $\text{Binomial}(m, 1/n)$, which for large n is close to $\text{Poisson}(m/n)$. With $m = n$, about 36.8 % of bins hold 0 balls, 36.8 % hold 1, 18.4 % hold 2, 6.1 % hold 3, and 1.5 % hold 4. This is the **Poisson paradigm**: many rare, weakly dependent events produce Poisson counts.

Fixed points. Shuffle a deck of n cards. How many cards end up where they started? Let I_k indicate that card k is fixed, so $P(I_k = 1) = 1/n$ and $E[\#\text{fixed}] = n \cdot \frac{1}{n} = 1$. The answer is one, for every n, even though the events are dependent (if $n - 1$ cards are fixed, so is the last). The chance of *no* fixed point, a derangement, tends to $\sum_k (-1)^k/k! = 1/e \approx 0.368$. Inclusion–exclusion gives that (Ch. 28); the Poisson paradigm predicts it at once.

Result 1: the coupon collector

Coupon collector

Draw uniformly from n coupon types until every type has appeared. The number of draws T satisfies

$$E[T] = nH_n = n\Big(1 + \frac{1}{2} + \cdots + \frac{1}{n}\Big) = n\ln n + \gamma n + O(1),$$

where $\gamma \approx 0.5772$, and for every $c > 0$

$$P\big(T > n\ln n + cn\big) \le e^{-c}.$$

Proof of the mean. Split the collection into stages. Stage i starts when you hold $i-1$ distinct types and ends when you get a new one. During stage i each draw is new with probability $p_i = (n-i+1)/n$, independently of the past. So the length T_i of stage i is geometric with mean $1/p_i$ (§19.9). By linearity,

$$E[T] = \sum_{i=1}^{n} \frac{n}{n-i+1} = n\sum_{k=1}^{n}\frac{1}{k} = nH_n.$$

Proof of the tail. $T > t$ means some type is still missing after t draws. Type j is missing with probability $(1-1/n)^t \le e^{-t/n}$, using $1-x \le e^{-x}$. By the union bound over the n types,

$$P(T > t) \le n e^{-t/n}.$$

Put $t = n\ln n + cn$: the bound becomes $n \cdot e^{-\ln n - c} = e^{-c}$. $\square$

For $n = 1000$: $E[T] = 7485.5$, and $P(T > 9908) \le e^{-3} \approx 0.05$. The stages are independent, so their variances add: $\mathrm{Var}(T) = \sum (1-p_i)/p_i^2 \le n^2 \sum 1/k^2 < \pi^2 n^2/6$. That gives a standard deviation below 1283. The collector's time is concentrated in a window of width $O(n)$ around $n\ln n$. The last few coupons are the expensive ones: the final stage alone takes n draws on average.

The birthday bound, made general

The birthday calculation of Example 19.5 gives the exact chance that k random labels from M are all distinct, $\prod_{i<k}(1 - i/M)$. Apply $1 - x \le e^{-x}$ to each factor:

$$P(\text{no collision}) \le \exp\Big(-\sum_{i=0}^{k-1}\frac{i}{M}\Big) = \exp\Big(-\frac{k(k-1)}{2M}\Big).$$

This bound is also an excellent approximation while $k \ll M$. It says collisions become likely once k is of order $\sqrt{2M\ln 2} \approx 1.18\sqrt{M}$. For $M = 365$ that is 22.5; for 64-bit random identifiers, about 5×10^9. A hash with b output bits gives only about $b/2$ bits of collision resistance. That is why SHA-256, and not a 128-bit hash, is used where collisions must be infeasible (Ch. 77).

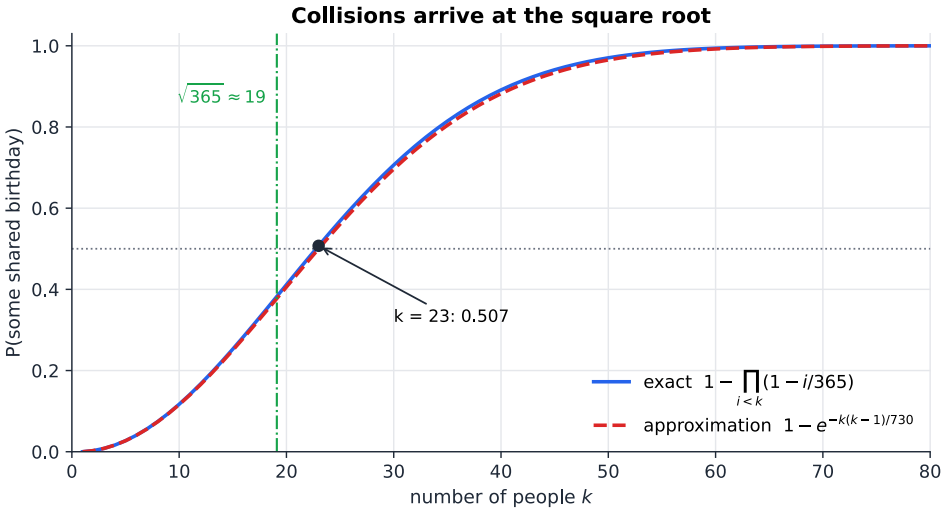

Figure 32.1 — Probability of a shared birthday among k people, exact (blue) and the exponential approximation (red, dashed). The curve passes $1/2$ at $k = 23$, just after $\sqrt{365} \approx 19$: collisions arrive at the square root of the space size.

Result 2: the Chernoff bound

Markov's inequality, $P(Y \ge a) \le E[Y]/a$ for $Y \ge 0$, is weak on its own. The trick is to apply it to e^{sX} rather than to X. For any $s > 0$, $X \ge a$ if and only if $e^{sX} \ge e^{sa}$, so

$$P(X \ge a) \le e^{-sa}\,E\big[e^{sX}\big] = e^{-sa}M_X(s),$$

with the moment-generating function of §19.9. The bound holds for every $s > 0$, so we may choose the best one. When X is a sum of independent pieces, the MGF *factors*, and that is where the exponential decay comes from.

Chernoff bound for sums of independent Bernoulli variables

Let $X = \sum_{i=1}^{n} X_i$ with independent $X_i \sim \text{Bernoulli}(p_i)$ and $\mu = E[X] = \sum p_i$. For every $\delta > 0$,

$$P\big(X \geq (1+\delta)\mu\big) \leq \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\mu},$$

and for $0 < \delta \leq 1$ this implies $P\big(X \geq (1+\delta)\mu\big) \leq e^{-\delta^2\mu/3}$.

Proof. Each factor of the MGF is $E[e^{sX_i}] = 1 - p_i + p_i e^s = 1 + p_i(e^s - 1) \leq \exp\big(p_i(e^s-1)\big)$, using $1 + x \leq e^x$. By independence,

$$M_X(s) = \prod_{i=1}^{n} E\big[e^{sX_i}\big] \leq \exp\big(\mu(e^s - 1)\big).$$

Hence, for every $s > 0$,

$$P\big(X \geq (1+\delta)\mu\big) \leq \exp\big(\mu(e^s-1) - s(1+\delta)\mu\big).$$

The exponent is minimised where its derivative $\mu e^s - (1+\delta)\mu$ vanishes, at $s = \ln(1+\delta) > 0$. Substituting gives $\exp\big(\mu\delta - \mu(1+\delta)\ln(1+\delta)\big)$, which is the first bound. For the second, we need $(1+\delta)\ln(1+\delta) \geq \delta + \delta^2/3$ on $[0,1]$. Let $g(\delta) = (1+\delta)\ln(1+\delta) - \delta - \delta^2/3$. Then $g(0) = 0$ and $g'(\delta) = \ln(1+\delta) - \frac{2}{3}\delta$. This is concave, zero at 0, and positive at $\delta = 1$ ($\ln 2 - \frac{2}{3} > 0$), so $g' \geq 0$ on $[0,1]$ and therefore $g \geq 0$. $\square$

The lower tail has a matching bound, $P(X \leq (1-\delta)\mu) \leq e^{-\delta^2\mu/2}$. A close cousin, **Hoeffding's inequality**, handles any independent variables confined to intervals $[a_i, b_i]$:

$$P\big(X - E[X] \geq t\big) \leq \exp\!\left(-\frac{2t^2}{\sum_i (b_i - a_i)^2}\right).$$

How much better is this than Chebyshev? Toss 100 fair coins and ask for at least 75 heads.

Bound	Value for $P(X \geq 75)$
Markov, μ/a	0.67
Chebyshev, $\sigma^2/(a-\mu)^2$	0.04
Chernoff, $\delta = \frac{1}{2}$, $e^{-\delta^2\mu/3}$	0.016
Chernoff, $\left(e^{\delta}/(1+\delta)^{1+\delta}\right)^{\mu}$	0.0045
Hoeffding, $e^{-2t^2/n}$ with $t = 25$	3.7×10^{-6}
Chernoff with the exact Bernoulli MGF (no $1+x \leq e^x$ step)	2.1×10^{-6}
True value	2.8×10^{-7}

The crude Chernoff forms are built for small p_i, where $1 + x \leq e^x$ is nearly tight. For fair coins it is better to keep the exact factor $(\frac{1}{2} + \frac{1}{2}e^s)^n$ and optimise s directly. That is the bottom bound row, and the blue curve in Figure 32.2. On a log scale, it runs parallel to the true tail: it has the right *exponential rate*, missing only a polynomial prefactor. Chebyshev and Markov fall hopelessly behind.

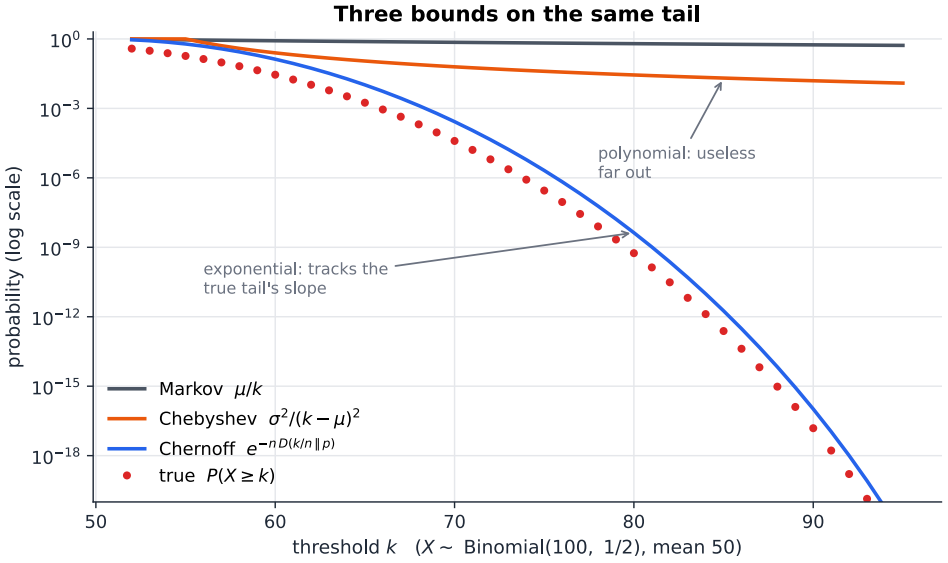

Figure 32.2 — Upper bounds on $P(X \geq k)$ for $X \sim \text{Binomial}(100, \frac{1}{2})$. Markov and Chebyshev decay polynomially. The optimised Chernoff bound decays at the same exponential rate as the truth (red dots).

Max load. The Chernoff bound answers the hook's second question. A bin's load is a sum of n Bernoulli$(1/n)$ variables with $\mu = 1$. For large $1 + \delta = k$ the bound is roughly $(e/k)^k$. A union bound over n bins shows that the maximum load exceeds k with small probability once $(e/k)^k \ll 1/n$. Solving gives $k \approx \dfrac{\ln n}{\ln \ln n}$, so the maximum grows, but extraordinarily slowly. A matching lower bound shows that this is the true order.

Result 3: the probabilistic method

Colour each edge of the complete graph K_N red or blue. A **monochromatic** K_k is a set of k vertices whose $\binom{k}{2}$ connecting edges all have the same colour. Ramsey's theorem (Ch. 28) says that for N large enough, every colouring has one. The Ramsey number $R(k,k)$ is the least such N. How large must N be?

> **Erdős's lower bound (1947)**
>
> If $\binom{N}{k}2^{1-\binom{k}{2}} < 1$, then some 2-colouring of K_N has no monochromatic K_k, so $R(k,k) > N$. In particular $R(k,k) > 2^{k/2}$ for all $k \geq 3$.

Proof. Colour every edge independently red or blue with probability $\frac{1}{2}$ each. A fixed set S of k vertices is monochromatic with probability $2 \cdot 2^{-\binom{k}{2}}$: all red or all blue. By the union bound over the $\binom{N}{k}$ choices of S,

$$P(\text{some monochromatic } K_k) \leq \binom{N}{k} 2^{1-\binom{k}{2}} < 1.$$

So with positive probability the random colouring has *no* monochromatic K_k. A positive-probability event cannot be empty, so such a colouring exists. For the explicit bound, take $N = \lfloor 2^{k/2} \rfloor$ and use $\binom{N}{k} \leq N^k/k!$:

$$\binom{N}{k} 2^{1-\binom{k}{2}} \leq \frac{2^{k^2/2}}{k!} 2^{1-k(k-1)/2} = \frac{2^{1+k/2}}{k!} < 1 \quad (k \geq 3). \qquad \square$$

Read that proof again. It proves that a colouring of K_{32} with no monochromatic K_{10} exists, and the sharper condition reaches K_{100}. Yet it gives no way to find one other than "try random colourings". Nobody knows an explicit construction that comes close. This is the **probabilistic method**: to show that an object with a property exists, show that a random object has the property with positive probability.

> **? The exponential gap in Ramsey theory**
>
> The probabilistic method gives $R(k,k) > 2^{k/2} = (\sqrt{2})^k$. A simple counting argument (Erdős–Szekeres, 1935) gives $R(k,k) < 4^k$. For almost ninety years neither base could be improved. In 2023 the upper base was finally pushed below 4, by a tiny amount. Is the truth $(\sqrt{2})^k$, 4^k, or something in between? Even $R(5,5)$ is known only to lie between 43 and 46. This is a famous **open problem**. Ch. 28 describes the battlefield, and Ch. 98 discusses how such problems are attacked.

32.4 The algorithm

The probabilistic method has an algorithmic twin: if a random choice is good with probability p, then trying repeatedly finds a good one in $1/p$ attempts on average. Here is the idea on a classic optimisation problem, **MAX-CUT**: split the vertices of a graph into two sides so that as many edges as possible cross.

Put each vertex on a random side. Each edge crosses with probability $\frac{1}{2}$, so by linearity the expected cut is $m/2$ for a graph with m edges. Hence a cut of at least $m/2$ *exists*. No cut can exceed m, so this is a $\frac{1}{2}$-approximation. **Derandomisation by conditional expectations** turns the coin flips into decisions. Place vertices one at a time, each on the side that keeps the conditional expected cut at least $m/2$:

```
def greedy_cut(n, edges):
    """Deterministic cut with at least half the edges, via conditional expectations."""
    side = [None] * n
    nbrs = [[] for _ in range(n)]
    for u, v in edges:
        nbrs[u].append(v); nbrs[v].append(u)
    for v in range(n):
        # Edges to still-unplaced vertices cross with prob. 1/2 either way, so only
        # the already-placed neighbours matter: join the side that cuts more of them.
        on0 = sum(1 for w in nbrs[v] if side[w] == 0)
        on1 = sum(1 for w in nbrs[v] if side[w] == 1)
        side[v] = 1 if on0 >= on1 else 0
    cut = sum(1 for u, v in edges if side[u] != side[v])
    return side, cut
```

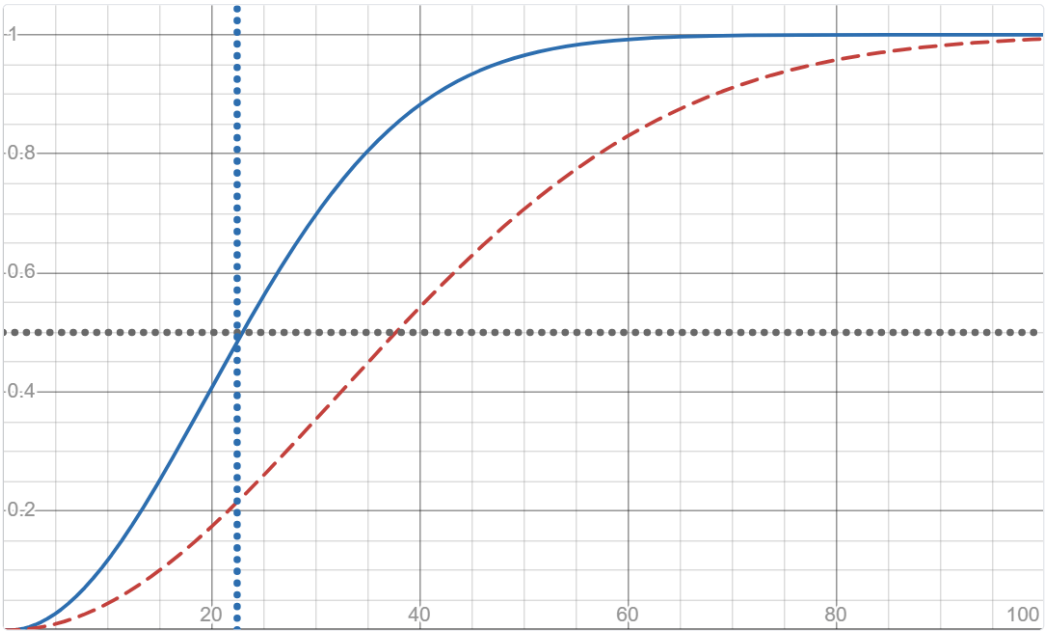
The running time is $O(n+m)$. The guarantee is cut $\geq m/2$ always, with no probability left. The invariant is that the conditional expectation, over the vertices not yet placed, never drops below $m/2$. At the end nothing is random any more, so the actual cut is at least $m/2$.

Load balancing in practice. Random assignment is $O(1)$ per request and needs no shared state, but the $\ln n / \ln \ln n$ maximum load grows with the fleet. The *two-choice* rule costs one extra probe and cuts the maximum to $\ln \ln n / \ln 2 + O(1)$. That is an exponential improvement, and real systems from Nginx to distributed caches use it.

Failure cases. Union bounds become useless when the events are many and not rare (the bound exceeds 1). Chernoff bounds need *independence*, or at least something close to it: a fault that hits all servers at once is not a sum of independent indicators. Linearity of expectation never fails, but an expectation can be dominated by rare catastrophic worlds. The *expected* load of a bin is always 1, yet that says nothing about the maximum.

32.5 The experiment

The birthday approximation, with the space size M as a knob:



Collision probability for k random labels drawn from $M = 365$ (blue) and $M = 1000$ (red). The dotted vertical line marks the 50 % point $\sqrt{2M \ln 2}$. Change 365 to 10000: how far does the curve move? Then check that the 50 % point moves like $\sqrt{M}$ and not like M.

Now simulate balls into bins, with one and two choices, and the coupon collector:

```
import numpy as np

N = 1000          # servers (bins) and requests (balls); try 100, 10_000, 100_000
TRIALS = 200
CHOICES = 2       # 1 = purely random, 2 = power of two choices, try 3
rng = np.random.default_rng(7)

def max_load(n, d):
    load = np.zeros(n, dtype=int)
    for _ in range(n):
        cand = rng.integers(0, n, d)              # d random candidate servers
        load[cand[np.argmin(load[cand])]] += 1    # send to the least loaded
    return load.max(), np.sum(load == 0)

res = np.array([max_load(N, CHOICES) for _ in range(TRIALS)])
print(f"{CHOICES} choice(s): max load histogram {np.bincount(res[:, 0])}")
print(f"mean idle servers {res[:, 1].mean():.1f}   (one-choice theory n/e = {N / np.e:.1f})")

def coupon(n):
    seen, t = np.zeros(n, bool), 0
    while not seen.all():
        seen[rng.integers(0, n, 4 * n)] = True    # draw in blocks for speed...
        t += 4 * n
    return t                                       # ...so t overshoots by < 4n

H = np.sum(1 / np.arange(1, N + 1))
print(f"coupon collector: coarse simulation {np.mean([coupon(N) for _ in range(20)]):.0f}, theory n*H_n = {N * H:.0f}")
print(f"one-choice max-load scale ln n/ln ln n = {np.log(N) / np.log(np.log(N)):.2f}")
```

With `CHOICES = 1` and `N = 1000` you should see maximum loads of 4 to 8, mostly 5 or 6. With `CHOICES = 2` nearly every trial gives 3. Push `N` to 100 000 (be patient) and see how little the two-choice maximum moves. The `coupon` function is deliberately coarse. Rewrite it to count draws one at a time, compare its average with nH_n, and plot the histogram of $(T - n \ln n)/n$. Its shape does not depend on n. What is it?

32.6 The challenge

1. **Intuition.** Linearity of expectation says the expected number of fixed points of a random permutation is 1 for every n. Without computing, explain why the *variance* of that number should also be close to 1 for large n, and why that fits the Poisson paradigm.
2. **Derivation.** Using the Chernoff bound, show that if $m = n \ln n$ balls are thrown into n bins, then with probability tending to 1 every bin holds between $\frac{1}{2} \ln n$ and $3 \ln n$ balls. Explain why "many balls per bin" behaves so differently from "one ball per bin".
3. **Implementation.** Write a randomised algorithm that, given N and k, searches for a 2-colouring of K_N with no monochromatic K_k by sampling random colourings and repairing violations. Find a colouring of K_{17} with no monochromatic K_4. What happens when you try K_{18}, and why?
4. **Open investigation.** In the two-choice process, what if the second choice is not independent but correlated with the first, for instance a neighbour in a ring of servers? Measure the maximum load as a function of n. Does the $\ln \ln n$ behaviour survive? Which kinds of correlation destroy it?

32.7 Loose threads

We proved that the Chernoff bound has the right exponential *rate*, but we left one thing unnamed. When we kept the exact MGF of a fair coin and optimised, we got $P(X \geq an) \leq e^{-nD}$ for a number D that depends on a and on the coin's bias. For $a = 0.75$ and a fair coin, $D \approx 0.131$ nats per toss. That number is not an accident of the algebra.

> **? What is the exponent?**
>
> The optimised Chernoff exponent for n tosses of a p-coin, asked to show a fraction a of heads, is
>
> $$D = a \ln \frac{a}{p} + (1-a) \ln \frac{1-a}{1-p}.$$
>
> It is zero when $a = p$, it is never negative, and it is not symmetric in a and p. It measures how hard it is to mistake a p-coin for an a-coin. It is a *distance between probability distributions*, and it is the central quantity of Ch. 33.

The coupon collector is a random walk on the complete graph: each draw "visits" a uniformly random type, and T is the time to visit everything. On a ring, a grid or a social network, the walk can only move to neighbours, and the time to visit everything, the **cover time**, can be far larger.

> **? Covering a graph**
>
> A random walk on a cycle of n nodes takes about $n^2/2$ steps to visit every node, compared with $n \ln n$ for the complete graph. A walk on a two-dimensional grid (a torus) of n nodes takes about $\frac{1}{\pi} n (\ln n)^2$. Why do these exponents and logarithms appear, and how is the cover time linked to the eigenvalues of the graph? The answers live in Ch. 34.

We also stated, without proof, that two random choices cut the maximum load from $\ln n / \ln \ln n$ to $\ln \ln n / \ln 2$. The proof follows the fraction of bins with load at least i: that fraction roughly *squares* at each level, which gives a doubly exponential decay. For practical versions, such as the one in the open investigation above, only partial answers are known. Finally, the probabilistic method only ever gave us existence. Turning "a random object works" into "here is one" is sometimes easy (conditional expectations), sometimes very hard (explicit Ramsey graphs), and sometimes equivalent to deep questions about whether randomness helps computation at all (Ch. 81).

Chapter 33 — Information Theory: Measuring the Unknown

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19, Ch. 21, Ch. 31, Ch. 32 · **Leads to:** Ch. 80, Ch. 35, Ch. 79 · **Related:** Ch. 30, Ch. 34 **Reading time:** ~25 min

33.1 The hook

Think of a whole number between 1 and 1 000 000. I will find it with twenty yes/no questions. Each answer halves the remaining candidates, and $2^{20} = 1\,048\,576$ is just over a million. Twenty questions is also the best possible: nineteen answers can only tell apart $2^{19} = 524\,288$ cases, so some numbers would share the same answers. So "a number up to a million" contains about twenty *bits* of uncertainty.

Now change the game. I roll a loaded six-sided die whose faces come up with probabilities $0.35, 0.20, 0.15, 0.12, 0.10, 0.08$. You must find the face by yes/no questions, and we play thousands of rounds. Six outcomes need three questions if you treat them equally. But you can do better *on average* by asking about the likely faces first. How much better? Is there a floor that no questioning strategy can beat?

There is, and it is the same floor that limits every compression program ever written. Zip a file of English text and it typically shrinks to about a third of its size. Zip the zipped file and almost nothing happens. Zip a file of truly random bytes and it gets slightly *bigger*. Something in the data is being used up, and once it is gone no clever algorithm can squeeze further. In 1948 Claude Shannon gave that something a name, a formula and a unit. He also proved two theorems that have governed every modem, disk drive and phone since: one for how far data can be compressed, and one for how fast it can be sent through noise.

This chapter measures the unknown. By the end you will know the exact floor for the loaded die (2.396 questions per roll), a simple algorithm that gets within 0.06 of it, and why the rest of the gap cannot be closed one roll at a time.

33.2 The big idea

Information is surprise. Learning that an event of probability p happened tells you $\log_2(1/p)$ bits. A fair coin landing heads is 1 bit. A one-in-a-million event is about 20 bits, exactly the twenty questions above. An event you were sure of tells you nothing. The logarithm is forced on us by one requirement: for *independent* events, surprises should add, $\log \frac{1}{pq} = \log \frac{1}{p} + \log \frac{1}{q}$.

Entropy is average surprise. The entropy of a random variable is the surprise you expect before you look. It has three readings that turn out to be the same number:

1. the average number of yes/no questions an optimal player needs to identify the outcome;
2. the average number of bits per symbol an optimal compressor needs;
3. how *spread out* the distribution is: zero for a certainty, maximal for a uniform distribution.

Mutual information is shared surprise. If Y is a noisy measurement of X, then seeing Y removes some of your uncertainty about X. The amount removed is the information Y carries about X. It is symmetric: X tells you exactly as much about Y as Y tells you about X. Figure 33.2 draws this as a Venn diagram.

KL divergence is the price of being wrong. If the world follows p but you designed your code (or your bets, or your model) for q, you waste $D(p\|q)$ extra bits per symbol. That one quantity turns out to be the exponent in the Chernoff bound of Ch. 32, and it measures how quickly an experiment can tell p from q.

The analogy. Entropy is to information what energy is to physics: a conserved currency that can be moved around, converted between forms and lost, but never created by processing. Shannon borrowed the word from thermodynamics, reportedly on von Neumann's advice. The resemblance is not only in the name.

33.3 The mathematics

Logarithms are base 2 (bits) unless written ln (nats; 1 nat $= 1/\ln 2 \approx 1.443$ bits). By convention $0 \log 0 = 0$.

Entropy, joint and conditional entropy

For a discrete random variable X with PMF $p(x)$,

$$H(X) = -\sum_{x} p(x) \log p(x) = E\Big[\log \frac{1}{p(X)}\Big].$$

For a pair, $H(X,Y) = -\sum_{x,y} p(x,y) \log p(x,y)$. The conditional entropy is $H(Y \mid X) = \sum_x p(x) H(Y \mid X = x)$, the average remaining uncertainty about Y once X is known.

The **chain rule** follows by taking logarithms of $p(x,y) = p(x)p(y \mid x)$ and averaging:

$$H(X,Y) = H(X) + H(Y \mid X).$$

The uncertainty of a pair is the uncertainty of the first, plus what remains about the second once the first is known.

For a coin with $P(\text{heads}) = p$, the entropy is the **binary entropy function**

$$H_b(p) = -p \log p - (1-p) \log (1-p),$$

plotted in Figure 33.1. It is 1 bit at $p = \frac{1}{2}$, 0 at $p = 0$ or 1, and $H_b(0.11) \approx 0.5$: a coin that lands heads 11 % of the time carries half a bit per toss.

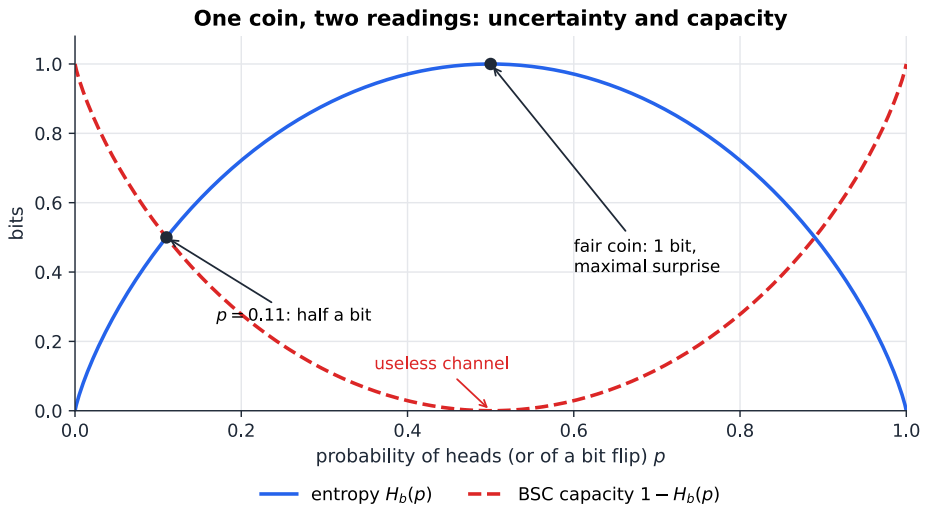

Figure 33.1 — The binary entropy $H_b(p)$ (blue) and, dashed, $1 - H_b(p)$: the capacity of a channel that flips each bit with probability p. A channel that flips half its bits is useless; one that flips all of them is perfect (just invert).

Result 1: Gibbs' inequality and the maximum of entropy

Kullback–Leibler divergence

For PMFs p and q on the same alphabet, with $q(x) > 0$ wherever $p(x) > 0$,

$$D(p\|q) = \sum_x p(x) \log \frac{p(x)}{q(x)}.$$

Gibbs' inequality

$D(p\|q) \geq 0$, with equality if and only if $p = q$.

Proof. Take expectations under p over the support of p. The logarithm is strictly concave, so Jensen's inequality (§31.3) gives

$$-D(p\|q) = E_p\left[\log \frac{q(X)}{p(X)}\right] \leq \log E_p\left[\frac{q(X)}{p(X)}\right] = \log \sum_{x:\, p(x)>0} q(x) \leq \log 1 = 0.$$

Equality in Jensen requires $q(X)/p(X)$ to be constant on the support of p, and equality in the last step requires that support to carry all of q's mass. Together these force $q = p$. □

Two consequences follow at once.

- **Entropy is at most** $\log(\text{alphabet size})$**.** Take q uniform on n symbols. Then $0 \leq D(p\|q) = \log n - H(p)$, so $H(X) \leq \log n$, with equality only for the uniform distribution. The fair die is the hardest die to guess.
- **Mutual information is non-negative.** Define

$$I(X;Y) = D\big(p_{XY} \,\|\, p_X p_Y\big) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)p(y)} \;\geq 0,$$

with equality exactly when X and Y are independent. Expanding the logarithm gives the Venn-diagram identities of Figure 33.2:

$$I(X;Y) = H(X) - H(X \mid Y) = H(Y) - H(Y \mid X) = H(X) + H(Y) - H(X,Y).$$

Since $I \geq 0$, we get $H(X \mid Y) \leq H(X)$: *on average, learning something never increases uncertainty*. A single surprising observation can leave you more confused. On average it cannot.

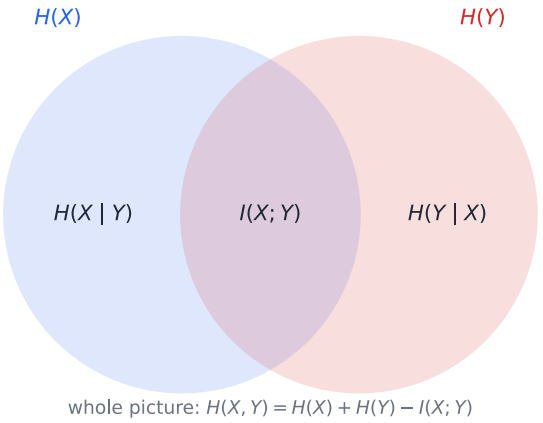

Figure 33.2 — How the entropies of two variables fit together. The overlap is the mutual information. Each circle minus the overlap is a conditional entropy. The union is the joint entropy. (For three or more variables the picture breaks: the central region can be negative.)

Worked Example 33.1 — A noisy binary link

A bit X, equally likely 0 or 1, is sent through a **binary symmetric channel** that flips it with probability $\varepsilon = 0.11$. How much information does the received bit Y carry about X?

Step 1. Y is also uniform, so $H(Y) = 1$ bit.

Step 2. Given X, the output is the input flipped with probability 0.11, so $H(Y \mid X) = H_b(0.11) = 0.500$ bit.

Step 3. $I(X;Y) = H(Y) - H(Y \mid X) = 1 - 0.500 = 0.500$ bit.

Each channel use delivers half a bit, even though 89 % of the bits arrive intact. The other half bit is eaten by our not knowing *which* bits flipped. Shannon showed that $1 - H_b(\varepsilon)$ is the channel's **capacity**: the largest rate at which bits can be sent with an error probability as small as you like. That claim is far from obvious, and we hold it back for later.

Result 2: prefix codes, Kraft, and the source coding bound

A **prefix code** assigns each symbol a binary codeword so that no codeword is the beginning of another. A stream of codewords can then be decoded left to right with no separators: read bits until they match a codeword, output its symbol, and repeat. Every prefix code is a binary tree whose leaves are the symbols (Figure 33.3).

Kraft inequality

Codeword lengths $\ell_1, \dots, \ell_n$ are achievable by a binary prefix code if and only if

$$\sum_{i=1}^{n} 2^{-\ell_i} \le 1.$$

Proof. Read a codeword $c = c_1 c_2 \dots c_\ell$ as the binary fraction $0.c_1 c_2 \dots c_\ell$ and attach to it the interval $[0.c_1 \dots c_\ell,\ 0.c_1 \dots c_\ell + 2^{-\ell})$. These are exactly the numbers in $[0, 1)$ whose binary expansion begins with c. If no codeword is a prefix of another, the intervals are disjoint. They all lie in $[0, 1)$, so their lengths $2^{-\ell_i}$ sum to at most 1. Conversely, given lengths satisfying the inequality, sort them so that $\ell_1 \le \ell_2 \le \dots$ and lay intervals of length $2^{-\ell_i}$ end to end from 0. Each starts at a multiple of its own length (all earlier lengths are larger powers of $\tfrac{1}{2}$), so its left endpoint has an exact ℓ_i-bit binary expansion. Take that expansion as the codeword. Disjoint intervals mean no prefixes. □

Source coding bound (Shannon, 1948)

Every prefix code for X has expected length $L = \sum p_i \ell_i \ge H(X)$. There is a prefix code with $L < H(X) + 1$.

Proof. Lower bound. Let $Z = \sum_j 2^{-\ell_j} \le 1$ and define the PMF $r_i = 2^{-\ell_i}/Z$. Then $\ell_i = \log \frac{1}{r_i} - \log Z$, and

$$L - H(X) = \sum_i p_i \ell_i + \sum_i p_i \log p_i = \sum_i p_i \log \frac{p_i}{r_i} - \log Z = D(p \| r) + \log \frac{1}{Z} \ge 0,$$

because both terms are non-negative (Gibbs, and $Z \le 1$).

Upper bound. Choose $\ell_i = \lceil \log(1/p_i) \rceil$. Then $2^{-\ell_i} \le p_i$, so $\sum 2^{-\ell_i} \le 1$, and Kraft supplies a prefix code with these lengths. Since $\ell_i < \log(1/p_i) + 1$, we get $L < H(X) + 1$. □

The proof says more than the statement. Equality $L = H$ needs $p_i = 2^{-\ell_i}$ exactly, so every probability must be a power of $\tfrac{1}{2}$. And $L - H$ is a KL divergence: *the redundancy of a code is the divergence between the true distribution and the distribution the code implicitly assumes*.

For the loaded die of the hook, $H = 2.396$ bits. A fixed 3-bit code wastes 0.60 bits per roll. The Shannon code with lengths $\lceil \log(1/p_i) \rceil$ averages 2.95. The Huffman code of the next section achieves 2.45.

The Chernoff exponent, named

Ch. 32 left a number unexplained. For $X \sim \text{Binomial}(n, p)$ and $a > p$, keep the exact MGF in the Chernoff bound:

$$P(X \geq an) \leq \min_{s>0} e^{-san}\left(1 - p + pe^{s}\right)^{n}.$$

Setting the derivative of the exponent to zero gives $e^{s} = \dfrac{a(1-p)}{p(1-a)}$, which exceeds 1 when $a > p$. Substituting, $1 - p + pe^{s} = \dfrac{1-p}{1-a}$, and the bound becomes

$$P(X \geq an) \leq \exp\!\left(-n\left[a \ln \frac{a}{p} + (1-a)\ln \frac{1-a}{1-p}\right]\right) = e^{-n\,D(a\|p)},$$

with D in nats, where $D(a\|p)$ is the divergence between a Bernoulli(a) and a Bernoulli(p) coin. The chance that a p-coin *impersonates* an a-coin for n tosses decays at a rate equal to the divergence of the impostor from the truth. For $a = 0.75$ and $p = 0.5$ the rate is 0.131 nats per toss, the slope of the blue curve in Figure 32.2. The bound is tight in the exponent: Cramér's theorem (and its generalisation, Sanov's theorem) says no better exponent is possible.

Divergence is not symmetric. $D(0.5\|0.9) = 0.737$ bits but $D(0.9\|0.5) = 0.531$ bits. If the coin is really fair, the balanced stretches it produces quickly rule out a 0.9-coin. If it really is a 0.9-coin, ruling out "fair" takes longer. So D is not a distance in the geometric sense, and that asymmetry has consequences in statistics, machine learning and hypothesis testing (Ch. 35).

> **? The capacity claim**
>
> Worked Example 33.1 said a channel flipping 11 % of bits can carry half a bit per use with an error rate *as small as you like*. Repetition codes do not come close: to drive errors to zero they send the rate to zero. Shannon's proof of the noisy-channel coding theorem picks a code *at random*, the probabilistic method of Ch. 32 again, and shows that its average error vanishes. Why does a random code work, and why did it take until the 1990s (turbo and LDPC codes) to build practical codes that come close to capacity? See Ch. 80.

33.4 The algorithm

Huffman's algorithm (1952). Repeatedly merge the two least probable symbols into a single node whose probability is their sum, until one node remains. The merge history is the code tree. Label each left branch 0 and each right branch 1.

```
import heapq, itertools

def huffman(probs):
    """probs: dict symbol -> probability. Returns dict symbol -> codeword string."""
    tie = itertools.count()                     # breaks ties so tuples always compare
    heap = [(p, next(tie), {s: ""}) for s, p in probs.items()]
    heapq.heapify(heap)
    if len(heap) == 1:
        return {s: "0" for s in probs}
    while len(heap) > 1:
        p0, _, c0 = heapq.heappop(heap)         # the two least likely subtrees
        p1, _, c1 = heapq.heappop(heap)
        merged = {s: "0" + w for s, w in c0.items()}
        merged.update({s: "1" + w for s, w in c1.items()})
        heapq.heappush(heap, (p0 + p1, next(tie), merged))
    return heap[0][2]

die = {"A": .35, "B": .20, "C": .15, "D": .12, "E": .10, "F": .08}
code = huffman(die)
print(code, sum(die[s] * len(w) for s, w in code.items()))   # average length 2.45
```

For the loaded die the merges are $F + E = 0.18$, $D + C = 0.27$, $0.18 + B = 0.38$, $0.27 + A = 0.62$, and finally 1.00. The likely faces A and B get 2-bit codewords and the rest get 3 bits. The average is 2.45 bits per roll, only 0.054 above the entropy.

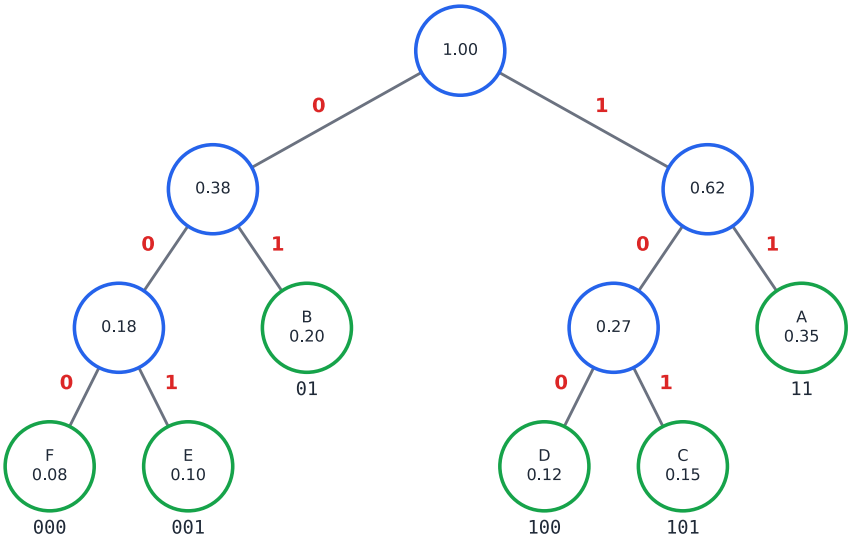

Figure 33.3 — The Huffman tree for the loaded die. Read a codeword from the root down: F is 000, A is 11. Likely symbols sit near the root.

Complexity. With a binary heap, each of the $n - 1$ merges costs $O(\log n)$, for $O(n \log n)$ in total. Decoding walks the tree one bit at a time, or uses a lookup table indexed by the next few bits.

Optimality. Among all prefix codes for a given distribution, Huffman's has the smallest expected length. The proof is an exchange argument: in some optimal tree, the two least likely symbols are siblings at the deepest level, so merging them first loses nothing. You are asked to complete it in the challenge.

Failure cases.

1. *Skewed sources.* A binary source with $P(1) = 0.01$ has entropy $H_b(0.01) = 0.081$ bits. But Huffman on single symbols must spend at least 1 bit per symbol, over twelve times the floor. The cure is to code *blocks* of k symbols, which brings the overhead down to below $1/k$ bits per symbol, or to use arithmetic coding, which effectively allows fractional codeword lengths.
2. *Wrong model.* Huffman is optimal for the probabilities you give it. Coding with q when the truth is p costs $H(p) + D(p\|q)$ bits per symbol on average, which is the KL divergence again as a price. For the loaded die, the ideal code for a fair die (an average of $\log_2 6 = 2.585$ bits) wastes $D(p\|\text{uniform}) = 0.189$ bits per roll.
3. *Ignoring memory.* Letter frequencies alone give English about 4.1 bits per letter. But letters are not independent: after "q" comes "u". Shannon's 1951 experiments with human predictors estimated the true rate of English at around 1 bit per letter. Huffman on single letters cannot see that. Context-modelling compressors can.

33.5 The experiment

The binary entropy and the divergence from a fair coin, with fixed numbers you can edit:

Blue: $H_b(x)$. Red: $D(x\|0.5)$, the cost of believing a fair coin when the true bias is x. Green (dashed): $D(0.5\|x)$, the reverse. The red and green curves differ: KL divergence is not symmetric. Replace every 0.5 by 0.9 to see the divergences from a biased coin, and find where each one is zero.

Now measure the entropy of real text and compare three compressors: the entropy floor for independent letters, a Huffman code, and zlib, which exploits repetition and context.

```
import zlib, heapq, itertools
from collections import Counter
import numpy as np

TEXT = open(__file__).read() * 1     # try: a novel from a text file, or "ab" * 5000
ORDER = 1                            # 1 = letters; 2 = pairs of letters as symbols

symbols = [TEXT[i:i + ORDER] for i in range(0, len(TEXT) - ORDER + 1, ORDER)]
counts = Counter(symbols)
p = np.array(list(counts.values()), float) / len(symbols)
H = -np.sum(p * np.log2(p)) / ORDER                    # bits per character

tie = itertools.count()
heap = [(c, next(tie), 0) for c in counts.values()]    # (weight, tiebreak, cost so far)
heapq.heapify(heap); total = 0
while len(heap) > 1:                                   # total bits = sum of merged weights
    a, _, _ = heapq.heappop(heap); b, _, _ = heapq.heappop(heap)
    total += a + b; heapq.heappush(heap, (a + b, next(tie), 0))
huff = total / len(TEXT)

z = 8 * len(zlib.compress(TEXT.encode(), 9)) / len(TEXT)
print(f"characters {len(TEXT)}, distinct symbols {len(counts)}")
print(f"entropy (order {ORDER})  {H:.3f} bits/char")
print(f"Huffman              {huff:.3f} bits/char")
print(f"zlib                 {z:.3f} bits/char   (raw ASCII: 8)")
```

The script compresses its own source code by default. Then try `TEXT = "ab" * 5000`: the letter entropy is a full 1 bit per character, yet zlib needs almost nothing, because the string is perfectly predictable. Try `ORDER = 2` on a long English text and watch the per-character entropy fall. Then try random text, `"".join(np.random.choice(list("abcdefgh"), 10000))`, where zlib cannot beat 3 bits per character. What does that tell you about the difference between "the entropy of the letters" and "the entropy of the text"?

33.6 The challenge

1. **Intuition.** A biased coin with $P(\text{heads}) = 0.9$ has entropy 0.469 bits. Explain in words, without formulas, how a sequence of 1000 such tosses could be stored in about 470 bits, and why any scheme that stores *every* possible sequence in 470 bits must fail on some sequences.
2. **Derivation.** Prove that among all distributions on $\{0, 1, 2, \dots\}$ with mean μ, the geometric distribution has the largest entropy. Use Gibbs' inequality with a well-chosen q, and find the maximum entropy as a function of μ.
3. **Implementation.** Complete the exchange-argument proof that Huffman codes are optimal. Then implement **canonical Huffman** coding, where only the codeword *lengths* are transmitted, together with an encoder and decoder that round-trip a file. Measure the header overhead as a fraction of the file size.
4. **Open investigation.** Estimate the entropy rate of English in bits per character as the context length k grows ($k = 0, 1, 2, \dots$), using frequency counts from a large text, and plot the estimate against k. Why does it eventually start to *fall too fast*, below any plausible true value? How would you design an estimator that does not fool itself? (Modern language models give the best-known estimates, and they still disagree.)

33.7 Loose threads

Entropy as defined here is an average over a probability distribution. It says nothing about a *single* string. The string 0101 . . . 01 and a string of fair coin flips of the same length have the same letter frequencies and the same order-0 entropy. Yet one has a ten-character description ("01, 500 times") and the other has no description much shorter than itself.

> **? The information in one object**
>
> The *Kolmogorov complexity* of a string is the length of the shortest program that prints it. It captures exactly the intuition above, and for typical outputs of a random source it matches entropy. But it is **uncomputable**: no algorithm can find the shortest program for every string. Why not, and what does that say about the limits of compression and of science itself? The answer is a diagonal argument from Ch. 30.

We proved $H \le L < H + 1$ one symbol at a time, and we noted that coding blocks drives the overhead to zero. Behind that remark is a much stronger fact. Long sequences from a source with entropy H almost all lie in a "typical set" of about 2^{nH} sequences, each with probability close to 2^{-nH}. This is the **asymptotic equipartition property**, a law of large numbers for surprise. The same idea makes random channel codes work, which is why the capacity mystery above lives in Ch. 80.

Everything here was discrete. For continuous variables, $-\int f \log f$ (the *differential* entropy) behaves strangely. It can be negative, and it changes when you change units. Yet differences of it, such as mutual information, remain perfectly meaningful. The Gaussian maximises differential entropy for a given variance (§20.4), and that one fact leads to $C = B \log_2(1 + \text{SNR})$, the most famous formula in communications.

> **? Choosing beliefs by maximising ignorance**
>
> If all you know about a quantity is its mean, which distribution should you assume? Gibbs' inequality suggests an answer: the one with *maximum entropy*, the least committal belief consistent with the facts. Is that a principle of logic, a convenient habit, or a disguised prior? The debate, and when maximum entropy agrees with Bayes' rule, is taken up in Ch. 35.

Chapter 34 — Random Walks and Markov Worlds

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 10, Ch. 19, Ch. 21 · **Leads to:** Ch. 36, Ch. 38, Ch. 53 · **Related:** Ch. 27, Ch. 87 **Reading time:** ~30 min

34.1 The hook

A man leaves a bar and walks home along a long straight street. He is too drunk to remember where he is going, so at every corner he tosses a mental coin and steps one block left or one block right. Will he ever get back to the bar's door?

Yes, with probability one. He will return, and return again, infinitely often. But here is the first twist: the *expected* time until his first return is infinite. He is certain to come back, and on average he takes forever to do it.

Now let the drunk loose in a city grid, where at every corner he picks one of four directions. He still returns with probability one. Finally, give him wings. A drunk bird flapping randomly through a three-dimensional lattice of air returns to its starting point with probability only about 0.34. Two-thirds of the time it is lost forever. The mathematician Shizuo Kakutani summarized it in one line: a drunk man will find his way home, but a drunk bird may get lost forever.

Why should the number of dimensions decide between "certainly comes back" and "probably never does"? Nothing in the rule changed: one random step at a time, no memory of the past.

Hold that question. Here are two more that look unrelated.

The shuffle. You riffle-shuffle a deck of 52 cards. How many shuffles until the deck is "random"? Three shuffles leave it almost perfectly ordered in a statistical sense. Four is no better. Then, between five and nine shuffles, the deck's distance from random collapses from nearly total to nearly nothing, and the folklore answer "seven" sits in the middle of the fall. Not a gradual improvement: a cliff.

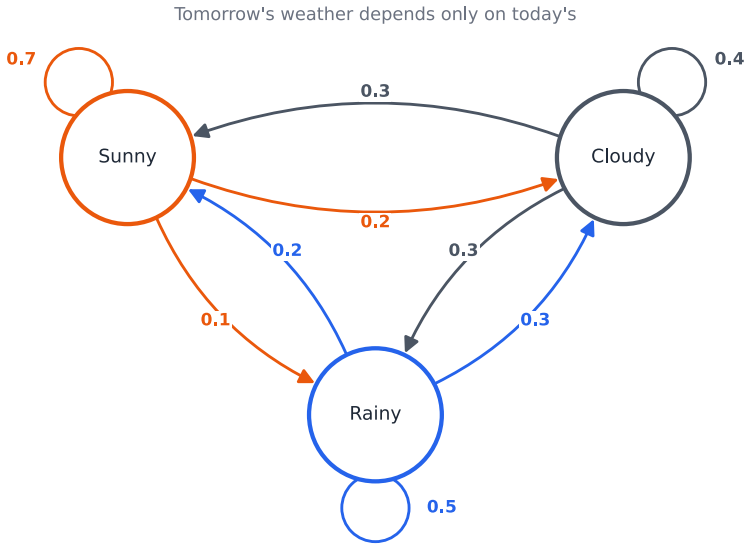
The search engine. In 1998 two students ranked the web by imagining a bored surfer clicking links at random, forever, and asking what fraction of time the surfer spends on each page. That fraction, PageRank, is a number that the surfer's starting page has no influence on at all.

All three stories are about the same object: a system that jumps between states with probabilities that depend only on where it is now. This chapter builds that object, proves the theorem that makes PageRank work, computes when gamblers go broke, and leaves the drunk bird and the seven shuffles hanging, because their full answers need tools the next chapters supply.

34.2 The big idea

Forget the past; keep the present. A Markov chain is a random process with amnesia. To predict tomorrow you need today, and nothing earlier. That single restriction turns an impossibly rich object (a whole random history) into something you can write on a napkin: a table of probabilities "from state i, go to state j with probability P_{ij}".

Here is the napkin for a toy weather model.



The weather chain. Each arrow carries the probability of tomorrow's state given today's; the arrows leaving any state sum to 1.

Run the chain for a long time and two things happen.

1. **The start is forgotten.** Whether today is Sunny or Rainy, the probability that it is Sunny 30 days from now is the same number. The chain "mixes".
2. **The long-run fractions settle.** Over a year, the fraction of Sunny days converges to a fixed value, the *stationary distribution*. That fraction is also the probability of Sunny on a single day far in the future.

The analogy that carries the whole chapter is **ink in water**. Put a drop of ink (all the probability) on one state. Each step, the ink in every state splits along the arrows in the proportions P_{ij}. Ink is never created or destroyed: probability is conserved. After enough steps the ink is spread in a fixed pattern that the flow no longer changes. That pattern is the stationary distribution, and how fast the ink spreads is the mixing time.

Three questions organise everything:

- **Where does the ink end up?** (stationary distributions)
- **How fast does it get there?** (mixing times)
- **When does a single particle first reach a target?** (hitting times)

The drunk on the street is the same story with infinitely many states, one per street corner. There the ink never settles: it spreads thinner and thinner forever. That is why the drunk always returns yet takes infinite expected time, and the escape of the bird is the same spreading, faster in more dimensions.

34.3 The mathematics

Chains and their matrices

Markov chain

A sequence of random variables $X_0, X_1, X_2, \dots$ taking values in a countable state space S is a (time-homogeneous) **Markov chain** with **transition matrix** $\mathbf{P}$ if

$$P(X_{n+1} = j \mid X_n = i,\ X_{n-1} = i_{n-1}, \dots, X_0 = i_0) = P_{ij}$$

for all n and all histories. The matrix is **row-stochastic**: $P_{ij} \geq 0$ and $\sum_j P_{ij} = 1$ for each row i.

For the weather chain, with states ordered (Sunny, Cloudy, Rainy),

$$\mathbf{P} = \begin{bmatrix} 0.7 & 0.2 & 0.1 \\ 0.3 & 0.4 & 0.3 \\ 0.2 & 0.3 & 0.5 \end{bmatrix}.$$

Write the distribution of X_n as a row vector $\boldsymbol{\mu}_n$, with $(\boldsymbol{\mu}_n)_j = P(X_n = j)$. Conditioning on the state at time n (the law of total probability from Ch. 19) gives

$$(\boldsymbol{\mu}_{n+1})_j = \sum_i (\boldsymbol{\mu}_n)_i P_{ij} \quad \Longrightarrow \quad \boldsymbol{\mu}_{n+1} = \boldsymbol{\mu}_n \mathbf{P}, \qquad \boldsymbol{\mu}_n = \boldsymbol{\mu}_0 \mathbf{P}^n.$$

The entry $(\mathbf{P}^n)_{ij}$ is the probability of going from i to j in exactly n steps. Everything about the chain's distribution is a question about matrix powers, which Ch. 10 §10.4 already taught you to compute by eigen-decomposition. (Ch. 10 writes probability vectors as columns and uses the transposed, column-stochastic matrix; the two conventions are the same mathematics. Probabilists use rows.)

Stationary distributions

Stationary distribution

A probability row vector $\boldsymbol{\pi}$ ($\pi_j \geq 0$, $\sum_j \pi_j = 1$) is **stationary** for $\mathbf{P}$ if

$$\boldsymbol{\pi}\mathbf{P} = \boldsymbol{\pi}.$$

If $X_0 \sim \boldsymbol{\pi}$ then $X_n \sim \boldsymbol{\pi}$ for every n.

So $\boldsymbol{\pi}$ is a left eigenvector of $\mathbf{P}$ with eigenvalue 1. Such an eigenvalue always exists: $\mathbf{P}\mathbf{1} = \mathbf{1}$ because rows sum to one, and a matrix and its transpose share eigenvalues.

For the weather chain, $\boldsymbol{\pi}\mathbf{P} = \boldsymbol{\pi}$ is three linear equations, one redundant. Taking the first two with the normalisation:

$$\begin{aligned} 0.7\pi_S + 0.3\pi_C + 0.2\pi_R &= \pi_S, \\ 0.2\pi_S + 0.4\pi_C + 0.3\pi_R &= \pi_C, \\ \pi_S + \pi_C + \pi_R &= 1, \end{aligned} \qquad \Longrightarrow \qquad \boldsymbol{\pi} = \left(\tfrac{21}{46},\ \tfrac{13}{46},\ \tfrac{12}{46}\right) \approx (0.457,\ 0.283,\ 0.261).$$

In the long run it is sunny 45.7 % of days. The remaining eigenvalues of $\mathbf{P}$ are $(3 \pm \sqrt{3})/10 \approx 0.473$ and 0.127; we will see in a moment that the larger of these controls the speed.

Two things can go wrong, and the convergence theorem must rule both out.

- **Reducible chains.** If the state space splits into pieces that cannot reach each other, there is one stationary distribution per closed piece, and where you end up depends on where you started. A chain is **irreducible** if every state can reach every other.
- **Periodic chains.** The two-state chain that swaps deterministically, $\mathbf{P} = \left[\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right]$, has stationary distribution $(\tfrac{1}{2}, \tfrac{1}{2})$, yet started in state 1 it is in state 1 at even times and state 2 at odd times. $\boldsymbol{\mu}_n$ oscillates forever. A chain is **aperiodic** if returns to each state are not locked to multiples of some period $d > 1$. Its eigenvalue -1 is the culprit: it has modulus one, so it never decays.

The convergence theorem, with a proof

To measure how far a distribution is from equilibrium we use the **total variation distance**

$$d_{TV}(\boldsymbol{\mu}, \boldsymbol{\nu}) = \tfrac{1}{2} \sum_j |\mu_j - \nu_j| = \max_{A \subseteq S} |\mu(A) - \nu(A)|,$$

the largest disagreement the two distributions can have about the probability of any event. It lies between 0 and 1.

The general theorem says: a finite, irreducible, aperiodic chain has a unique stationary distribution and $\boldsymbol{\mu}_0\mathbf{P}^n \to \boldsymbol{\pi}$ from every start. We prove a version with a clean, quantitative argument due to Doeblin and Dobrushin. The key quantity is the **contraction coefficient**

$$\delta(\mathbf{P}) = \max_{i,k} d_{TV}\big(\mathbf{P}_{i\cdot},\ \mathbf{P}_{k\cdot}\big),$$

the largest total-variation distance between two rows of $\mathbf{P}$. It measures how much the chain's next step still "remembers" which state it came from.

Contraction theorem

For any two probability vectors $\boldsymbol{\mu}, \boldsymbol{\nu}$,

$$d_{TV}(\boldsymbol{\mu}\mathbf{P}, \boldsymbol{\nu}\mathbf{P}) \le \delta(\mathbf{P})\, d_{TV}(\boldsymbol{\mu}, \boldsymbol{\nu}).$$

If $\delta(\mathbf{P}) < 1$ (in particular, if every entry of $\mathbf{P}$ is at least $\varepsilon > 0$ on an N-state space, which gives $\delta \le 1 - N\varepsilon$), then $\mathbf{P}$ has exactly one stationary distribution $\boldsymbol{\pi}$, and for every start

$$d_{TV}(\boldsymbol{\mu}_0\mathbf{P}^n, \boldsymbol{\pi}) \le \delta(\mathbf{P})^n.$$

Proof. **Step 1: split the difference.** Let $a = d_{TV}(\boldsymbol{\mu}, \boldsymbol{\nu})$; if $a = 0$ there is nothing to prove. The vector $\boldsymbol{\mu} - \boldsymbol{\nu}$ sums to zero, so its positive part and negative part each have total mass a. Normalise them: $\boldsymbol{\mu} - \boldsymbol{\nu} = a(\boldsymbol{\alpha} - \boldsymbol{\beta})$ with $\boldsymbol{\alpha}, \boldsymbol{\beta}$ probability vectors.

Step 2: push through one step. By linearity $\boldsymbol{\mu}\mathbf{P} - \boldsymbol{\nu}\mathbf{P} = a(\boldsymbol{\alpha}\mathbf{P} - \boldsymbol{\beta}\mathbf{P})$, so $d_{TV}(\boldsymbol{\mu}\mathbf{P}, \boldsymbol{\nu}\mathbf{P}) = a\, d_{TV}(\boldsymbol{\alpha}\mathbf{P}, \boldsymbol{\beta}\mathbf{P})$.

Step 3: bound by rows. Since $\sum_i \alpha_i = \sum_k \beta_k = 1$,

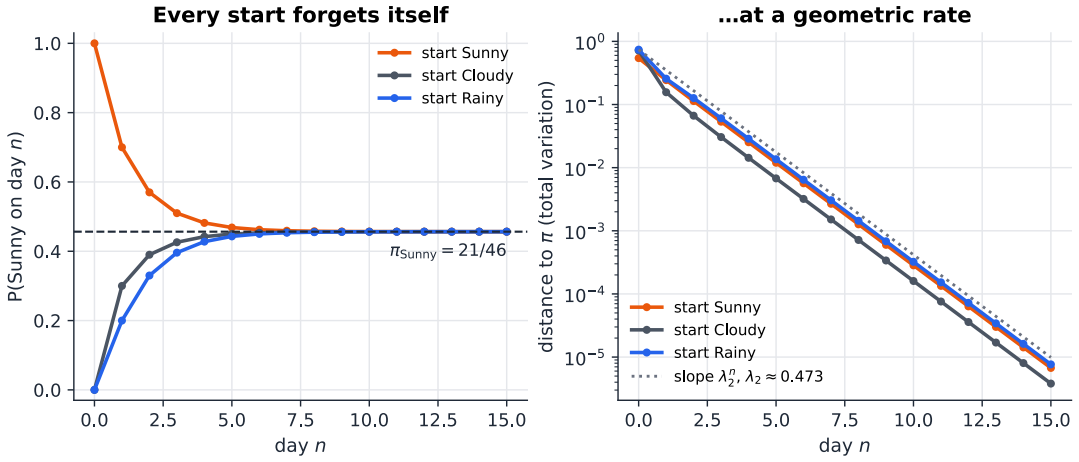
$$\boldsymbol{\alpha}\mathbf{P} - \boldsymbol{\beta}\mathbf{P} = \sum_i \alpha_i \mathbf{P}_{i\cdot} - \sum_k \beta_k \mathbf{P}_{k\cdot} = \sum_{i,k} \alpha_i \beta_k \big(\mathbf{P}_{i\cdot} - \mathbf{P}_{k\cdot}\big).$$

Take half the ℓ_1 norm and use the triangle inequality: $d_{TV}(\boldsymbol{\alpha}\mathbf{P}, \boldsymbol{\beta}\mathbf{P}) \le \sum_{i,k} \alpha_i\beta_k\, d_{TV}(\mathbf{P}_{i\cdot}, \mathbf{P}_{k\cdot}) \le \delta(\mathbf{P})$. This proves the inequality.

Step 4: the bound on δ. For two rows, $d_{TV}(\mathbf{p}, \mathbf{q}) = 1 - \sum_j \min(p_j, q_j)$ (because $|p - q| = p + q - 2\min(p, q)$). If every entry is at least ε, each minimum is at least ε and $\delta \le 1 - N\varepsilon$.

Step 5: existence, uniqueness, convergence. If $\delta < 1$ the map $\boldsymbol{\mu} \mapsto \boldsymbol{\mu}\mathbf{P}$ is a contraction on the closed set of probability vectors, so the sequence $\boldsymbol{\mu}_0\mathbf{P}^n$ is Cauchy and converges to a fixed point (the contraction-mapping argument of Ch. 22). Two fixed points $\boldsymbol{\pi}, \boldsymbol{\pi}'$ would satisfy $d_{TV}(\boldsymbol{\pi}, \boldsymbol{\pi}') \le \delta\, d_{TV}(\boldsymbol{\pi}, \boldsymbol{\pi}')$, forcing equality. Finally $d_{TV}(\boldsymbol{\mu}_0\mathbf{P}^n, \boldsymbol{\pi}) = d_{TV}(\boldsymbol{\mu}_0\mathbf{P}^n, \boldsymbol{\pi}\mathbf{P}^n) \le \delta^n d_{TV}(\boldsymbol{\mu}_0, \boldsymbol{\pi}) \le \delta^n$. ∎

For the weather chain the smallest entry is 0.1, giving the crude guarantee $\delta \le 1 - 3(0.1) = 0.7$; computing the row distances directly gives $\delta = 0.5$. Either way the distance to equilibrium at least halves every day. The truth is a little better still:



Left: the probability of a sunny day n days ahead, from three different starting days. Right: total-variation distance to $\boldsymbol{\pi}$ on a log scale; the lines are straight with slope set by the second eigenvalue $\lambda_2 = (3 + \sqrt{3})/10 \approx 0.473$.

What about chains where some entries are zero, like a random walk on a sparse graph? If the chain is irreducible and aperiodic, then some power $\mathbf{P}^m$ has all entries positive (a fact from number theory about the return times), and you apply the theorem to $\mathbf{P}^m$. This is the general convergence theorem.

The straight lines in the figure come from the eigen-decomposition. If $\mathbf{P}$ is diagonalisable with eigenvalues $1 = \lambda_1 > |\lambda_2| \ge \cdots$, then $\boldsymbol{\mu}_0\mathbf{P}^n = \boldsymbol{\pi} + \sum_{k \ge 2} c_k \lambda_k^n \mathbf{v}_k$, and the distance decays like $|\lambda_2|^n$. The quantity $1 - |\lambda_2|$ is the **spectral gap**. Big gap, fast mixing.

Reversibility: the shortcut to $\boldsymbol{\pi}$

Solving $\boldsymbol{\pi}\mathbf{P} = \boldsymbol{\pi}$ for a million-state chain is expensive. For an important class of chains there is a shortcut.

Detailed balance

If a probability vector $\boldsymbol{\pi}$ satisfies $\pi_i P_{ij} = \pi_j P_{ji}$ for all i, j, then $\boldsymbol{\pi}$ is stationary.

Proof. Sum the detailed-balance equation over i: $\sum_i \pi_i P_{ij} = \pi_j \sum_i P_{ji} = \pi_j$. ∎

Detailed balance says that in equilibrium the *flow* of probability from i to j equals the flow back, edge by edge. Such chains are called **reversible**: a film of the chain in equilibrium looks statistically the same run backwards.

The most important reversible chain is the **random walk on a graph**: from vertex v, move to a uniformly chosen neighbour, so $P_{vw} = 1/\deg(v)$ for each edge vw. Try $\pi_v = \deg(v)/(2|E|)$: then $\pi_v P_{vw} = 1/(2|E|) = \pi_w P_{wv}$. Detailed balance holds, so a random walker on any connected graph spends time at each vertex in proportion to its degree. Well-connected vertices are visited more, a first hint of why random walks can rank things.

Hitting times and the gambler's ruin

Now follow one particle instead of the ink. The **hitting time** of a set A is $\tau_A = \min\{n \geq 0 : X_n \in A\}$. The workhorse for computing anything about τ_A is **first-step analysis**: condition on the first move, and the Markov property hands you a linear system.

Gambler's ruin

A gambler bets one unit on a fair coin each round, starting with k units, and stops on reaching 0 (ruin) or N (target). Then

$$P(\text{reach } N \text{ before } 0) = \frac{k}{N}, \qquad E[\text{number of bets}] = k(N-k).$$

Proof. Let h_k be the probability of reaching N first from fortune k. After one bet the fortune is $k \pm 1$ with probability $\frac{1}{2}$ each, and the future is a fresh game from there, so

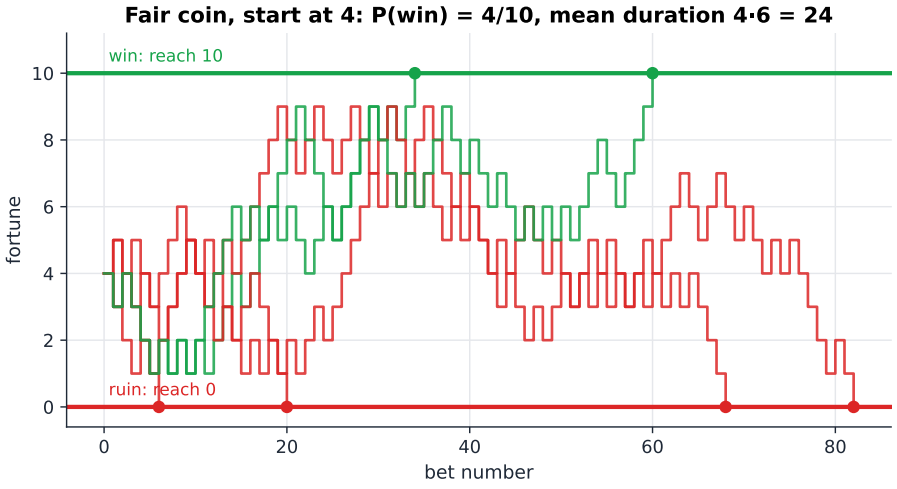
$$h_k = \tfrac{1}{2} h_{k+1} + \tfrac{1}{2} h_{k-1}, \qquad h_0 = 0,\ h_N = 1.$$

Rearranged, $h_{k+1} - h_k = h_k - h_{k-1}$: the differences are constant, so h_k is linear, and the boundary values give $h_k = k/N$.

For the duration, let m_k be the expected number of bets from k. One bet is always made, then the game continues from $k \pm 1$:

$$m_k = 1 + \tfrac{1}{2} m_{k+1} + \tfrac{1}{2} m_{k-1}, \qquad m_0 = m_N = 0.$$

Now the second difference is constant: $m_{k+1} - 2m_k + m_{k-1} = -2$. A quadratic with second difference -2 is $-k^2 + bk + c$; the boundary conditions give $c = 0$, $b = N$, so $m_k = k(N-k)$. ∎



Six games starting from 4 units with target 10. On average 4 in 10 games are won, and a game lasts 24 bets. Individual games vary enormously in length.

Look at the duration formula again. Start in the middle, $k = N/2$, and the expected game length is $N^2/4$: a random walk needs about N^2 steps to travel distance N. Distance grows like the *square root* of time. This $\sqrt{n}$ law is the fingerprint of every diffusive process, and it reappears as the envelope of Brownian motion in Ch. 36.

The same algebra with a biased coin (win probability p, $q = 1-p$, $r = q/p \neq 1$) gives

$$P(\text{reach } N \text{ before } 0) = \frac{1 - r^k}{1 - r^N}.$$

At a roulette-like $p = 0.49$, a gambler who starts with 50 and wants to double to 100 succeeds only about 12 % of the time, against 50 % for a fair coin. A 2 % edge, compounded over the long journey a random walk takes, becomes crushing.

Two more facts about hitting times, stated without proof:

- **Kac's formula.** For an irreducible chain with stationary $\boldsymbol{\pi}$, the expected time to return to state i, starting from i, is $1/\pi_i$. In the weather chain a rainy day recurs on average every $46/12 \approx 3.83$ days. First-step analysis also gives the expected wait for rain starting from a sunny day: $20/3 \approx 6.67$ days.
- **Recurrence on the infinite line.** The fair walk on $\mathbb{Z}$ has no stationary distribution (the ink spreads forever). Letting $N \to \infty$ in the gambler's ruin, the chance of escaping to $+N$ before returning to 0 from $k = 1$ is $1/N \to 0$, so the walker returns with probability one. Yet the expected return time is infinite: Kac's formula with every $\pi_i = 0$ gives $1/0$. The hook's first paradox is just this.

? The drunk bird

On $\mathbb{Z}^d$ the simple random walk returns to its start with probability one for $d = 1, 2$ (Pólya, 1921) but only with probability about 0.3405 for $d = 3$. The gambler's-ruin trick only works in one dimension. The real proof turns the question into whether the sum $\sum_n P(X_{2n} = 0)$ diverges, and computing $P(X_{2n} = 0) \sim c\, n^{-d/2}$ needs Fourier analysis on the lattice (Ch. 16) or, in the continuum, the Green's function of the Laplacian, which behaves like $1/r$ in three dimensions (Ch. 89). Why should the dimension of space, and not the coin, decide whether you get home?

Mixing times

The convergence theorem says *that* the ink spreads. The practical question is *how long* to wait.

Mixing time

$$t_{\text{mix}}(\varepsilon) = \min\left\{ n : \max_{i \in S} d_{TV}\left(\mathbf{P}^n_{i,\cdot}, \boldsymbol{\pi}\right) \le \varepsilon \right\},$$

the number of steps after which, from the *worst* starting state, the chain is within ε of equilibrium. By convention $t_{\text{mix}} = t_{\text{mix}}(1/4)$.

For the weather chain, after one day the worst start (Rainy) is still at distance 0.257; after two days every start is below 0.127. So $t_{\text{mix}} = 2$ days. Weather forgets fast.

For reversible chains the spectral gap gives two-sided bounds, roughly

$$\frac{1}{\text{gap}} - 1 \;\lesssim\; t_{\text{mix}} \;\lesssim\; \frac{1}{\text{gap}} \ln \frac{1}{\pi_{\min}},$$

up to constants. The logarithm on the right matters: a chain on $52!$ states can still mix in a handful of steps if its gap is not tiny.

? Seven shuffles and the cliff

Bayer and Diaconis (1992) computed the exact distance to uniform for riffle-shuffling 52 cards: 1.000 after four shuffles, then $0.924,\ 0.614,\ 0.334,\ 0.167,\ 0.085$ after five to nine. For n cards the drop happens near $\tfrac{3}{2}\log_2 n$ shuffles and gets sharper as n grows. This sudden collapse is the **cutoff phenomenon**. Eigenvalues alone predict smooth geometric decay, so they cannot explain a cliff. Which chains have cutoff, and why, is a major open problem: Peres's "product condition" is necessary, fails to be sufficient in general, and has been proven sufficient only for special families such as birth-and-death chains. Ch. 38 shows why the answer matters every time someone runs a Markov chain Monte Carlo sampler and asks when to stop.

34.4 The algorithm

PageRank by power iteration

The random surfer of the hook follows a link chosen uniformly from the current page. Two defects stop this from being a well-behaved chain: some pages have no outgoing links (the surfer is stuck), and the web is not irreducible (some regions cannot be left). The fix is to add **teleportation**: with probability d (the damping factor, classically 0.85) follow a random link; with probability $1 - d$ jump to a page chosen uniformly from all n. The new transition matrix is

$$\mathbf{G} = d\,\mathbf{P} + (1 - d)\,\frac{1}{n}\mathbf{1}\mathbf{1}^{\mathsf{T}},$$

and every entry of $\mathbf{G}$ is at least $(1 - d)/n > 0$. Every entry positive means the contraction theorem of §34.3 applies directly: a unique stationary distribution exists, and iteration converges to it from any start. In fact the same proof, applied with the rank-one teleport term, gives $\delta(\mathbf{G}) \le d$, so the error shrinks by at least 0.85 per sweep, independent of the size of the web.

```
import numpy as np

def pagerank(links, n, d=0.85, tol=1e-10, max_iter=1000):
    """links: dict page -> list of pages it links to. Returns the stationary vector."""
    x = np.full(n, 1.0 / n)
    for it in range(max_iter):
        new = np.full(n, (1 - d) / n)          # teleport: every page gets (1-d)/n
        dangling = 0.0
        for i in range(n):
            out = links.get(i, [])
            if out:
                share = d * x[i] / len(out)
                for j in out:
                    new[j] += share
            else:
                dangling += d * x[i]            # page with no links: jump anywhere
        new += dangling / n
        if np.abs(new - x).sum() < tol:
            return new, it + 1
        x = new
    return x, max_iter

print(pagerank({0: [1, 2], 1: [2], 2: [0], 3: [2]}, 4))
```

On the four-page web A→{B, C}, B→C, C→A, D→C, it converges in 47 sweeps to

$$\boldsymbol{\pi} \approx (0.373,\ 0.196,\ 0.394,\ 0.0375).$$

Page C wins: three pages point to it. Page A comes second although only one page links to it, because that one page is C, the most important page. Importance is inherited from who links to you, which is exactly what $\boldsymbol{\pi} = \boldsymbol{\pi}\mathbf{G}$ says. Page D, which nobody links to, gets only the teleport share $(1-d)/n = 0.0375$.

Cost. Each sweep touches every link once, so it costs $O(n + |E|)$, never forming the dense matrix $\mathbf{G}$. To reach error ε you need about $\ln \varepsilon / \ln d$ sweeps: about 140 for $\varepsilon = 10^{-10}$ in the worst case, usually far fewer. Compare a direct solve of $\boldsymbol{\pi}(\mathbf{I} - \mathbf{G}) = \mathbf{0}$ at $O(n^3)$ for a dense matrix: hopeless for billions of pages.

Stability. Each sweep maps probability vectors to probability vectors, so errors cannot grow, and nothing is ever divided by a small number. Round-off drift in the total mass can be removed by renormalising $\mathbf{x}$ to sum to 1 after each sweep.

Failure cases

- **Periodic chains.** Without teleportation, power iteration on a bipartite graph oscillates forever, exactly like the two-state swap. The cure is either teleportation or a **lazy** chain $\frac{1}{2}(\mathbf{I} + \mathbf{P})$, which has the same $\boldsymbol{\pi}$ and no negative eigenvalues.
- **Small spectral gap.** If $d \to 1$ the guarantee $\delta \le d$ degrades, and on webs with weakly connected clusters $|\lambda_2|$ approaches 1: convergence becomes painfully slow, and the answer becomes hypersensitive to small changes in the links. This is one reason $d = 0.85$ rather than 0.99.
- **Simulating instead of iterating.** Estimating $\boldsymbol{\pi}$ by running a single surfer and counting visits also works (the ergodic theorem, the Markov-chain cousin of Ch. 21 §21.7), but the error falls like $1/\sqrt{\text{steps}}$, inflated by the correlation between successive states. The slower the chain mixes, the more steps each "independent" sample costs.

34.5 The experiment

Part 1: the weather in your terminal

The script below simulates the weather chain for 2000 days, compares the running fraction of sunny days with $\pi_S = 21/46$, and plots the distance to equilibrium.

```
import numpy as np
import matplotlib.pyplot as plt

# ---- knobs ---------------------------------------------------------------
P = np.array([[0.7, 0.2, 0.1],      # Sunny  -> (Sunny, Cloudy, Rainy)
              [0.3, 0.4, 0.3],      # Cloudy -> ...
              [0.2, 0.3, 0.5]])     # Rainy  -> ...
start = 2          # 0 = Sunny, 1 = Cloudy, 2 = Rainy
days = 2000        # length of one simulated history
seed = 1
# --------------------------------------------------------------------------

w, V = np.linalg.eig(P.T)                    # left eigenvectors of P
pi = np.real(V[:, np.argmin(abs(w - 1))]); pi /= pi.sum()
lam = sorted(abs(w))[-2]
print("stationary pi  :", np.round(pi, 4))
print("second |eigval|:", round(lam, 4))

rng = np.random.default_rng(seed)
x, path = start, []
for _ in range(days):
    path.append(x)
    x = rng.choice(3, p=P[x])                # one Markov step
path = np.array(path)
running = np.cumsum(path == 0) / np.arange(1, days + 1)
print("simulated fraction Sunny:", round(running[-1], 4))

mu, tv = np.eye(3)[start], []
for n in range(30):
    tv.append(0.5 * abs(mu - pi).sum()); mu = mu @ P

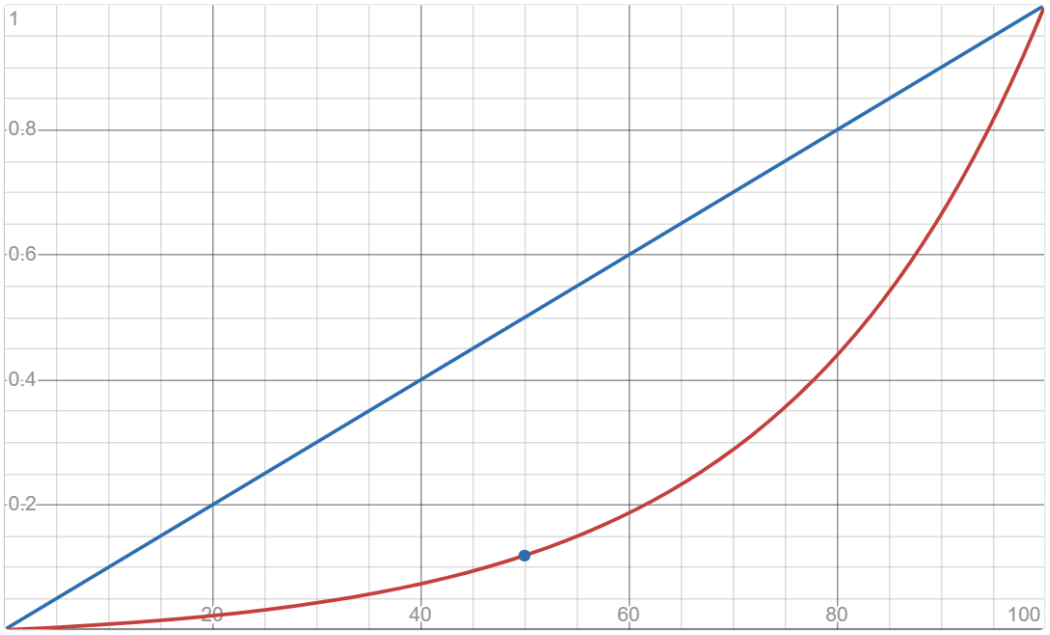
fig, (a, b) = plt.subplots(1, 2, figsize=(10, 3.5))
a.plot(running); a.axhline(pi[0], ls="--", c="k")
a.set(xscale="log", xlabel="day", ylabel="running fraction Sunny")
b.semilogy(tv, "o-"); b.semilogy(tv[0] * lam ** np.arange(30), "k:")
b.set(xlabel="day n", ylabel="TV distance to pi")
plt.tight_layout(); plt.show()
```

With the knobs as given it prints $\boldsymbol{\pi} \approx (0.4565, 0.2826, 0.2609)$, $|\lambda_2| \approx 0.4732$, and a simulated sunny fraction of about 0.47. Things to change:

1. **Make the weather sticky.** Set the diagonal to 0.98 and spread 0.01 to each other state. The stationary distribution becomes uniform, but $|\lambda_2|$ jumps to 0.97. Watch the running average wander for hundreds of days before it settles. Same $\boldsymbol{\pi}$, very different mixing.
2. **Break aperiodicity.** Use the cyclic chain Sunny→Cloudy→Rainy→Sunny with probability 1. The distance curve stops decaying. Which eigenvalues have modulus 1 now?
3. **Break irreducibility.** Make Rainy absorbing (row $[0, 0, 1]$). What is $\boldsymbol{\pi}$, and does the running fraction of sunny days still converge to it?
4. Increase `days` by factors of 10 and check that the simulation error shrinks roughly like $1/\sqrt{\text{days}}$.

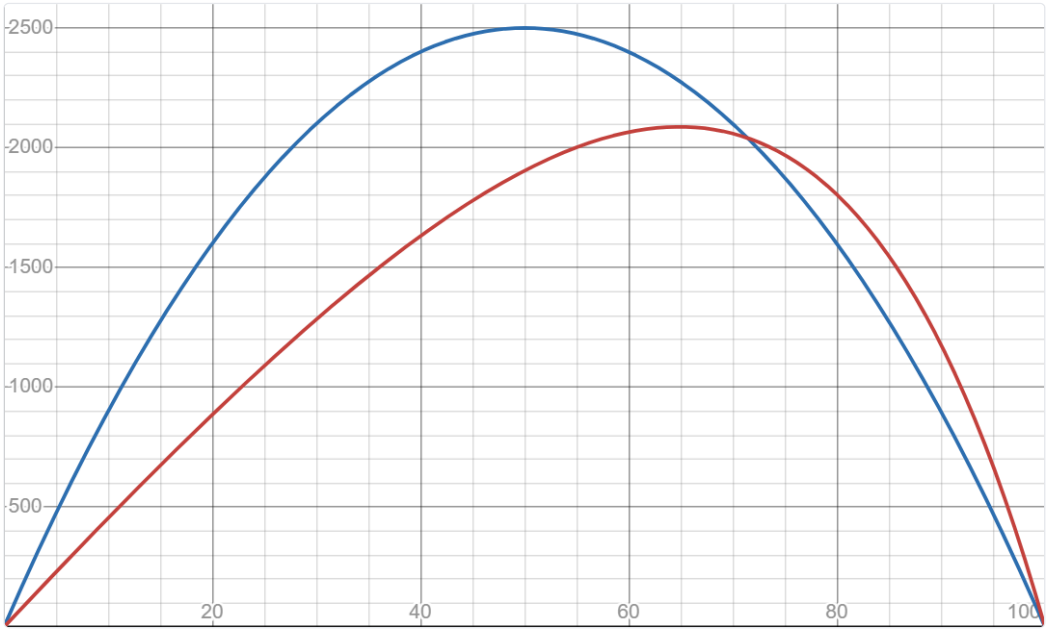
Part 2: the casino's edge

The probability of reaching 100 before 0, as a function of the starting fortune x, for a fair coin (blue) and a coin with $p = 0.49$ (red):



Doubling 50 to 100: a fair coin succeeds half the time; a 2 % edge cuts it to 12 %.

Change $0.51/0.49$ to $0.52/0.48$, or change the target 100 (in both places, and in the fair line) to 1000. How small must the edge be before the red curve starts to look like the blue line? The expected game lengths tell the same story: from 50, the fair game lasts $50 \cdot 50 = 2500$ bets on average, the $p = 0.49$ game about 1904 bets. The house edge does not just tilt the outcome; it ends the game sooner.



Expected number of bets before the game ends, fair (blue) and $p = 0.49$ (red). The red formula is $k/(q-p) - \frac{N}{q-p} \cdot \frac{1-r^k}{1-r^N}$; the 0.02 is $q - p$.

34.6 The challenge

1. **Intuition.** A random walk on a connected graph has stationary distribution proportional to degree. A random walk on a *directed* graph does not, in general. Construct a three-vertex directed graph where the vertex with the most incoming links is *not* the most visited, and explain in words what the walker is doing.
2. **Derivation.** For the biased gambler's ruin, derive $h_k = (1 - r^k)/(1 - r^N)$ from the recurrence $h_k = p\,h_{k+1} + q\,h_{k-1}$. Then let $N \to \infty$ and find the probability that a gambler with a favourable coin ($p > \tfrac{1}{2}$) starting with k units is *never* ruined.
3. **Implementation.** Write a function that estimates $t_{\text{mix}}(1/4)$ for any transition matrix by computing $\max_i d_{TV}(\mathbf{P}^n_{i\cdot}, \boldsymbol{\pi})$ for increasing n. Apply it to the lazy random walk on a cycle of n vertices for $n = 10, 20, 40, 80$ and fit the growth law. Is it closer to n, n^2 or $n \ln n$?
4. **Open investigation.** Take the four-page web of §34.4 and add one page that links only to itself and to A. How does each page's rank change as d goes from 0.5 to 0.99? Can a page owner raise their own rank by adding outgoing links, removing them, or creating a ring of pages that link to each other? Search for the strongest manipulation you can find with, say, three extra pages. (No closed-form answer is known for the general problem of optimal "link farms".)

34.7 Loose threads

This chapter worked almost entirely with finite chains in discrete time, where matrices and eigenvalues do the heavy lifting. Several doors were left shut on purpose.

> **? Can you build a chain for any target?**
>
> Here everything ran forward: given $\mathbf{P}$, find $\boldsymbol{\pi}$. Turn it around. Suppose you want samples from a distribution $\boldsymbol{\pi}$ on a space far too large to enumerate, known only up to a normalising constant: every configuration of a million-spin magnet, or every value of a model's parameters given data. Detailed balance hints that you could *design* a chain whose stationary distribution is exactly $\boldsymbol{\pi}$, using only ratios π_j/π_i, and then just run it. That recipe, Metropolis–Hastings, is one of the most important algorithms of the twentieth century. How it works, and how to tell when it has run long enough, is in Ch. 38. The posterior distributions of Ch. 35 are its main customers.

Other threads:

- **Continuous time and continuous space.** Shrink the step and the step size of the random walk together, with steps of size $\sqrt{\Delta t}$ every Δt, and the walk becomes Brownian motion. The gambler's-ruin answers survive the limit. Why they survive, and the strange calculus that results, is Ch. 36.
- **Chains with choices.** If, in each state, you may *choose* the transition matrix and you collect rewards, you have a Markov decision process. The stationary-distribution machinery becomes Bellman's equation: Ch. 52 and Ch. 53.
- **Random walks as a lens on networks.** Hitting times between vertices behave like effective resistances in an electrical network with a resistor on every edge, a link that runs both ways and is developed with graph Laplacians in Ch. 27 and Ch. 87.
- **The entropy of a chain.** A stationary chain produces information at a definite rate, $-\sum_i \pi_i \sum_j P_{ij} \log_2 P_{ij}$ bits per step. Why that is the right number for compressing its output is a question for Ch. 33.

Chapter 35 — Bayesian Thinking and Statistical Inference

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19, Ch. 20 · **Leads to:** Ch. 37, Ch. 38, Ch. 91 · **Related:** Ch. 33, Ch. 41 **Reading time:** ~30 min

35.1 The hook

The perfect fab line. A new production line has made its first 20 chips, and all 20 pass the test. Your manager wants a number for the datasheet: the defect rate. The textbook estimator from Ch. 20, the maximum-likelihood estimate, is $0/20 = 0$. Zero defects. Would you print "defect rate: 0 %" and promise every customer a perfect part? Nobody would. But if not zero, then what, and on what grounds?

The sunrise. Pierre-Simon Laplace asked a version of the same question in 1814. Suppose all you know is that the sun has risen every day for 5000 years, about 1,826,213 days. What is the probability that it rises tomorrow? He gave an exact number, and the method behind it is the one that rescues the fab line.

The almost-significant coin. A colleague tosses a coin 100 times and gets 60 heads. The two-sided p-value for "the coin is fair" is 0.057: just short of the conventional 0.05, "nearly significant", the sort of result that gets written up as "a trend toward bias". A second analyst looks at the same 100 tosses and reports that the data favour the coin being fair, by a small margin. Same data, opposite leaning. One of them must have made a mistake?

Neither did. They answered different questions. This chapter is about the difference: what it means to *learn* a parameter from data, how prior knowledge enters (it always does, openly or not), and why the most common number in science, the p-value, is not the probability that a hypothesis is true. By the end you will compute the fab line's defect rate, Laplace's sunrise, and the Bayes factor for the coin, and you will see the coin dispute become a full-blown paradox as the sample grows.

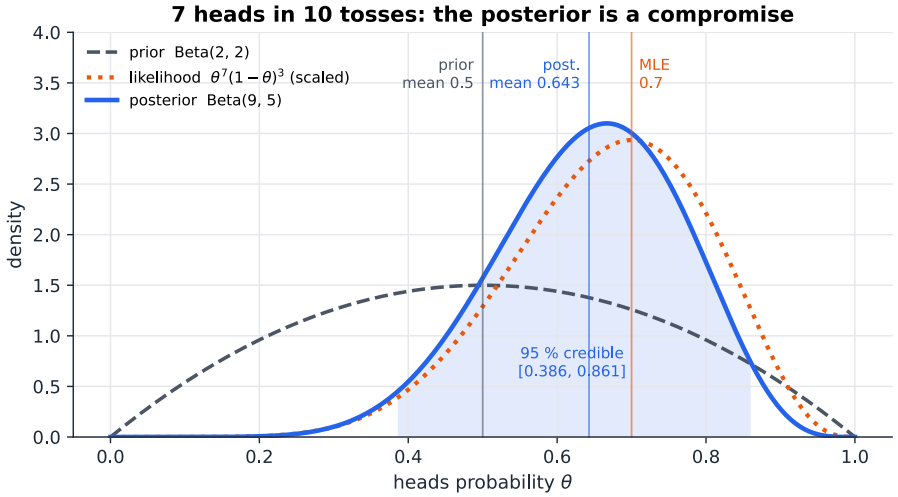
35.2 The big idea

Treat the unknown as random. In Ch. 19 §19.3, Bayes' theorem updated the probability of an *event*: is the patient ill, is the bit a 1? Bayesian inference applies the same rule to a *parameter*: the heads probability θ of a coin, the defect rate of a line, the resistance of a sensor. Before data, your knowledge of θ is a distribution, the **prior**. Data arrive. The rule

$$\text{posterior} \;\propto\; \text{likelihood} \times \text{prior}$$

turns the prior into the **posterior**: everything you now know about θ, as a full distribution rather than a single number.

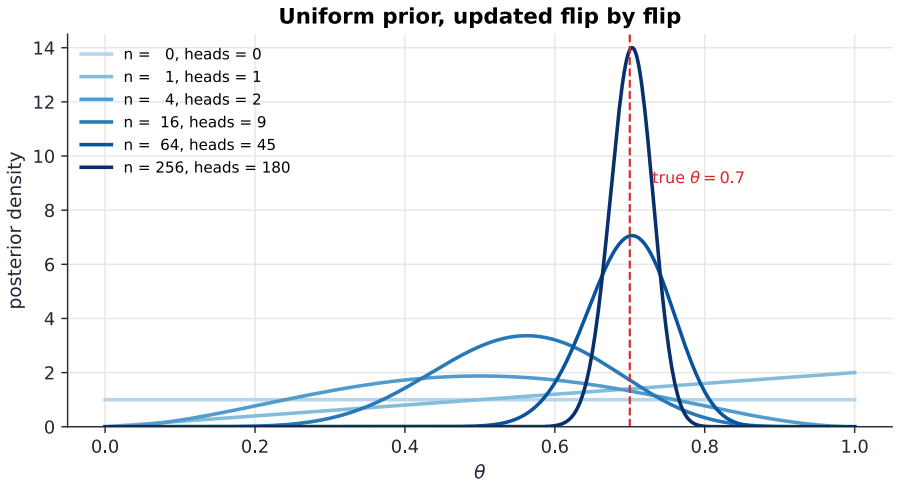
The analogy is a **detective's suspect board**. Before evidence, each suspect has some plausibility. Each clue raises the plausibility of the suspects it fits and lowers the others, in proportion to how well it fits (the likelihood). The detective never jumps to "the butler did it, probability 1" on one clue, and never refuses to update. With enough clues, detectives with different initial hunches end up agreeing.



Seven heads in ten tosses. A mild prior centred at 0.5 (grey) meets the likelihood (orange, peaking at the MLE 0.7). The posterior (blue) sits between them, narrower than either, with its central 95 % shaded.

Three consequences make the method worth learning.

1. **Uncertainty comes for free.** The posterior's width says how much you know. Twenty perfect chips do not prove a zero defect rate; they rule out large rates and leave small ones plausible.
2. **Learning is sequential.** Today's posterior is tomorrow's prior. You can update after every chip, every toss, every radar return, and the result is the same as updating once with all the data.
3. **Data eventually win.** As the sample grows, the likelihood becomes sharp and the prior's influence fades.



A flat prior updated by tosses of a coin with true $\theta = 0.7$. After 256 tosses the posterior is a narrow spike near the truth.

The price is that you must say what you believed before seeing data. Critics call that subjective. Bayesians reply that every method makes such assumptions; this one writes them down where they can be argued with.

35.3 The mathematics

Posterior, likelihood and evidence

Let data D have probability (or density) $p(D \mid \theta)$ given a parameter θ. Read as a function of θ with D fixed, this is the **likelihood** $L(\theta) = p(D \mid \theta)$ of Ch. 20 §20.6. With a prior density $p(\theta)$, Bayes' theorem for densities gives

$$p(\theta \mid D) = \frac{p(D \mid \theta)\, p(\theta)}{p(D)}, \qquad p(D) = \int p(D \mid \theta)\, p(\theta)\, d\theta.$$

The denominator $p(D)$, the **evidence** or **marginal likelihood**, does not depend on θ: it only normalises the posterior. It will matter enormously when we compare models.

The coin: conjugacy

Model n tosses as independent Bernoulli(θ) trials with k heads. The likelihood is $L(\theta) = \binom{n}{k}\theta^k(1-\theta)^{n-k}$. For the prior choose the **Beta distribution**

$$p(\theta) = \frac{\theta^{a-1}(1-\theta)^{b-1}}{B(a,b)}, \quad 0 < \theta < 1, \qquad B(a,b) = \int_0^1 t^{a-1}(1-t)^{b-1}dt = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}.$$

Its mean is $a/(a+b)$. The parameters behave like pseudo-counts: $a-1$ imagined heads and $b-1$ imagined tails. Beta$(1,1)$ is uniform, Beta$(2,2)$ is a gentle hump at 0.5, Beta$(50,50)$ is a confident belief that the coin is nearly fair.

Beta–binomial conjugacy

With prior $\theta \sim \text{Beta}(a,b)$ and k heads in n tosses,

$$\theta \mid D \;\sim\; \text{Beta}(a+k,\; b+n-k),$$

and the posterior mean is a weighted average of the prior mean and the MLE $\hat\theta = k/n$:

$$E[\theta \mid D] = \frac{a+k}{a+b+n} = \underbrace{\frac{a+b}{a+b+n}}_{\text{weight on prior}} \cdot \frac{a}{a+b} + \underbrace{\frac{n}{a+b+n}}_{\text{weight on data}} \cdot \frac{k}{n}.$$

Proof. Multiply likelihood and prior and drop every factor free of θ:

$$p(\theta \mid D) \propto \theta^k(1-\theta)^{n-k} \cdot \theta^{a-1}(1-\theta)^{b-1} = \theta^{(a+k)-1}(1-\theta)^{(b+n-k)-1}.$$

This is the kernel of Beta$(a+k, b+n-k)$, and a density is determined by its kernel, since the constant is fixed by integrating to 1. The mean of a Beta(α,β) is $\alpha/(\alpha+\beta)$; the weighted-average form follows by writing $a+k = (a+b)\frac{a}{a+b} + n\frac{k}{n}$. ∎

A prior is **conjugate** to a likelihood when the posterior stays in the prior's family. Updating then reduces to bookkeeping: add heads to a, tails to b. The weight on the data, $n/(a+b+n)$, tends to 1: the prior counts as $a+b$ observations' worth of opinion, and real observations outnumber it eventually.

For the figure, Beta$(2,2)$ and 7 heads in 10 give Beta$(9,5)$: posterior mean $9/14 \approx 0.643$, between the prior mean 0.5 and the MLE 0.7. The central 95 % **credible interval** is $[0.386,\ 0.861]$, and $P(\theta > 0.5 \mid D) \approx 0.867$.

Prediction and the rule of succession

The question you usually care about is not "what is θ" but "what happens next". The **posterior predictive** probability averages over everything θ could be.

Predictive probability and the rule of succession

Under the model above, the probability that toss $n+1$ is a head is the posterior mean:

$$P(\text{head on toss } n+1 \mid D) = \int_0^1 \theta\, p(\theta \mid D)\, d\theta = \frac{a+k}{a+b+n}.$$

With a uniform prior ($a = b = 1$) this is **Laplace's rule of succession**, $\dfrac{k+1}{n+2}$.

Proof. Condition on θ: given θ, the next toss is a head with probability θ, independently of the past. By the law of total probability over the posterior, $P(\text{head} \mid D) = E[\theta \mid D]$, and conjugacy gives the value. ∎

Now the hook's first two puzzles fall.

- **Sunrise.** $k = n = 1{,}826{,}213$: $P(\text{sunrise}) = \frac{n+1}{n+2} \approx 1 - 5.5 \times 10^{-7}$. Laplace himself added that anyone who understands the physics of the solar system would be far more confident: the uniform prior encodes ignorance, and he was not ignorant.
- **Fab line.** $k = 0$ defects in $n = 20$ with a uniform prior on the defect rate: the posterior is $\text{Beta}(1, 21)$, the chance that the next chip is defective is $1/22 \approx 4.5\,\%$, and the 95 % upper credible bound on the rate is $1 - 0.05^{1/21} \approx 13.3\,\%$. That is an honest datasheet line: "no failures in 20; rate below about 13 % with 95 % credibility." Engineers know its frequentist cousin as the **rule of three**: with zero failures in n trials, the 95 % upper confidence bound is about $3/n$ (exactly $1 - 0.05^{1/20} \approx 13.9\,\%$ here).

Three estimators, three losses

If you must report one number, which one? The posterior offers several.

- **MLE**, $\arg\max_\theta L(\theta)$: ignores the prior. For the coin, k/n.
- **MAP** (maximum a posteriori), $\arg\max_\theta p(\theta \mid D)$: the posterior's peak. For $\text{Beta}(\alpha, \beta)$ with $\alpha, \beta > 1$ it is $(\alpha - 1)/(\alpha + \beta - 2)$; for $\text{Beta}(9, 5)$, $8/12 \approx 0.667$. With a uniform prior MAP equals MLE.
- **Posterior mean**, $E[\theta \mid D]$: 0.643 for $\text{Beta}(9, 5)$.

Which is "best" depends on what an error costs you, and decision theory makes this precise.

The posterior mean minimises expected squared error

For any estimate c computed from the data,

$$E\big[(\theta - c)^2 \mid D\big] = \operatorname{Var}(\theta \mid D) + \big(E[\theta \mid D] - c\big)^2,$$

so the posterior expected squared loss is minimised exactly by $c = E[\theta \mid D]$.

Proof. Write $m = E[\theta \mid D]$ and expand $(\theta - c)^2 = (\theta - m)^2 + 2(\theta - m)(m - c) + (m - c)^2$. Take the posterior expectation: the first term gives the posterior variance, the middle term vanishes because $E[\theta - m \mid D] = 0$ and $m - c$ is a constant given D, and the last term is constant. ∎

The same argument applied to absolute error $|\theta - c|$ picks out the posterior **median**, and a 0–1 loss on small intervals picks out the MAP. There is no loss-free notion of the best estimate. Notice also what the theorem says about the MLE: it is not the minimum-MSE answer once you believe anything about θ. Estimators that pull the MLE toward a prior value are called **shrinkage** estimators, and they can beat the MLE on mean squared error even under frequentist rules, a fact that shocked statisticians when Stein proved a version of it in 1956.

Credible intervals versus confidence intervals

A 95 % **credible interval** contains θ with posterior probability 0.95: a statement about θ, given the data you saw. A 95 % **confidence interval** (Ch. 20 §20.7) is produced by a procedure that captures the true θ in 95 % of repeated experiments: a statement about the procedure, not about this particular interval. In large samples with mild priors the two nearly coincide numerically, which is why they are so often confused. In small samples, and especially at boundaries like zero defects, they can differ substantially.

Testing hypotheses: the Bayes factor

To compare two hypotheses H_0 and H_1, apply Bayes' theorem to the hypotheses themselves:

$$\underbrace{\frac{P(H_0 \mid D)}{P(H_1 \mid D)}}_{\text{posterior odds}} = \underbrace{\frac{p(D \mid H_0)}{p(D \mid H_1)}}_{\text{Bayes factor } B_{01}} \times \underbrace{\frac{P(H_0)}{P(H_1)}}_{\text{prior odds}}.$$

The **Bayes factor** is the part supplied by the data. Each $p(D \mid H)$ is a marginal likelihood: the probability of the data averaged over that hypothesis's prior on its parameters.

For the 60-heads coin, take $H_0 : \theta = \frac{1}{2}$ and $H_1 : \theta \sim \text{Uniform}(0, 1)$, "the coin is biased, by an amount I cannot predict". Then

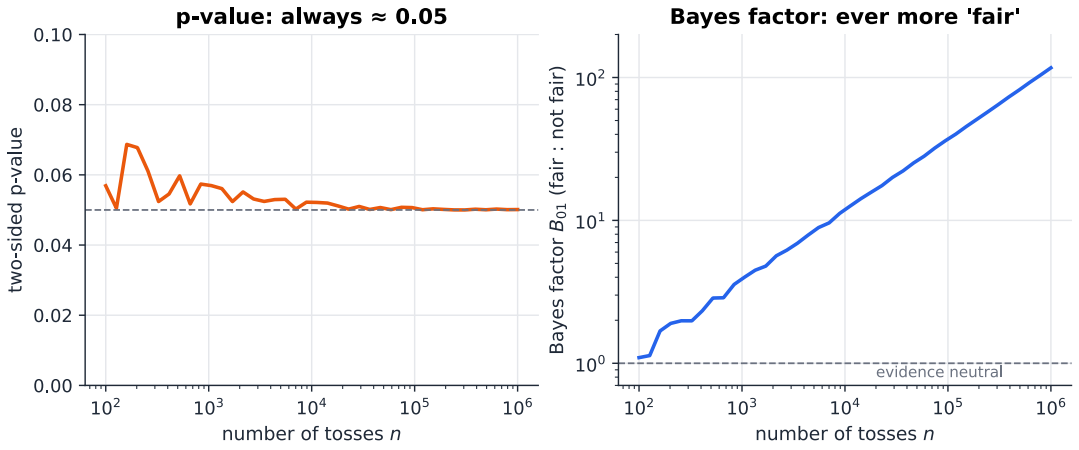
$$p(D \mid H_0) = \binom{100}{60} 2^{-100} \approx 0.01084,$$

and under H_1, integrating the binomial against the uniform prior with the Beta integral,

$$p(D \mid H_1) = \int_0^1 \binom{n}{k} \theta^k (1-\theta)^{n-k} d\theta = \binom{n}{k} \frac{k!\,(n-k)!}{(n+1)!} = \frac{1}{n+1} = \frac{1}{101} \approx 0.00990.$$

So $B_{01} \approx 0.01084 \times 101 \approx 1.10$. The data favour "fair" by about 10 %: essentially no evidence either way. Meanwhile the exact two-sided p-value is 0.057. The second analyst of the hook was right, and so was the first. The p-value asks "how surprising are data this extreme *if* H_0 is true?" The Bayes factor asks "how much better does H_0 predict the data than H_1 does?" Sixty heads is mildly surprising under a fair coin, but it is *also* unimpressive under a vague H_1, which spreads its bets over every θ from 0 to 1 and so predicts any particular count poorly.

Now hold the p-value fixed near 0.05 and let the sample grow, by choosing $k \approx n/2 + 0.98\sqrt{n}$ heads (a z-score of 1.96). The p-value stays at 0.05 forever. The Bayes factor does not.



Every experiment on the left is "just significant at 5 %". On the right, the same data favour the fair coin more and more strongly: $B_{01} \approx 1.1$ *at* $n = 100$, 3.7 *at* $n = 1000$, 117 *at* $n = 10^6$.

This is **Lindley's paradox** (1957). The reason is the $\sqrt{n}$ in the z-score: an excess of $0.98\sqrt{n}$ heads is a *shrinking fraction* $0.98/\sqrt{n}$ of the tosses, so the observed frequency closes in on $\frac{1}{2}$, which is exactly what H_0 predicts and what a uniform H_1 finds unremarkable. A small p-value in a huge sample can signal a tiny real effect, a tiny bias in the experiment, or nothing, and the Bayes factor rate of growth, roughly $\sqrt{n}$, measures how differently the two philosophies weigh that.

> **Common Pitfall — the p-value is not $P(H_0 \mid D)$**
>
> "$p = 0.04$, so there is a 4 % chance the null hypothesis is true" is wrong. A p-value is computed assuming H_0 is true; it cannot also be the probability that H_0 is true. Converting it into $P(H_0 \mid D)$ needs a prior and an alternative, as above. The Neyman–Pearson framework of Ch. 20 §20.8 controls error *rates* over repeated tests; it never claims to say how likely a single hypothesis is.

Model selection and the automatic Occam's razor

The same machinery compares whole models. Given models $M_1, M_2, \ldots$ with their own parameters, the evidence $p(D \mid M) = \int p(D \mid \theta, M) p(\theta \mid M)\, d\theta$ rewards fit but punishes flexibility. A model with many parameters spreads its prior probability over a huge space of possible datasets, so it assigns relatively little probability to the one you observed, unless it needed that flexibility. Simple models that predict sharply and are right win. This is Occam's razor, derived rather than assumed.

For large n and d parameters, a Laplace approximation of the evidence integral gives the **Bayesian information criterion**

$$\ln p(D \mid M) \approx \ln L(\hat{\theta}) - \frac{d}{2} \ln n,$$

stated here without proof: log-likelihood at the best fit, minus a penalty of $\frac{1}{2} \ln n$ per parameter. Compare polynomial fits of degree 1 and 5 to 50 noisy points and BIC will usually prefer degree 1 unless the curvature is real, exactly the overfitting guard that Ch. 20 §20.9 achieves with residual analysis.

> **? Where should the prior come from?**
>
> Everything here assumed a prior, and the Bayes factor is notoriously sensitive to it: replace the uniform H_1 by Beta(50, 50) ("biased, but only slightly") and B_{01} for 60 heads drops from 1.10 to 0.52, so the same data now favour "biased" by two to one. Is there an "objective" prior that represents ignorance? The uniform prior is not it: uniform in θ is not uniform in θ^2 or in the log-odds, so "ignorance" depends on the parametrisation. Harold Jeffreys proposed $p(\theta) \propto \sqrt{I(\theta)}$, built from the Fisher information, which gives the same answer in every parametrisation. For the coin it is Beta$(\frac{1}{2}, \frac{1}{2})$. Why the square root of Fisher information, and what geometry makes it invariant, is the doorway to information geometry (Ch. 59, with Fisher information and KL divergence from Ch. 33). Whether any prior can truly represent ignorance is still argued.

35.4 The algorithm

Conjugate priors are a gift that the real world rarely gives. Change the coin to a logistic-regression model of chip failure versus temperature, and the posterior has no closed form. The universal fallback in one or two dimensions is the **grid posterior**: evaluate prior times likelihood on a grid of θ values and normalise numerically.

```
GRID-POSTERIOR(data, log_prior, log_lik, grid θ_1..θ_G with spacing Δ)
  for g = 1..G:
      s_g ← log_prior(θ_g) + log_lik(data | θ_g)      # work in logs
  s_max ← max_g s_g
  for g = 1..G:
      w_g ← exp(s_g − s_max)                          # largest weight is exactly 1
  Z ← Δ · Σ_g w_g
  return posterior density w_g / Z,  log-evidence  s_max + ln Z
```

Numerical stability. The likelihood of 10 000 tosses is a product of 10 000 numbers below one, around 10^{-3000}, which underflows to zero in double precision (smallest positive double about 10^{-308}). Two rules fix this: add log-likelihoods instead of multiplying likelihoods, and subtract the maximum before exponentiating (the **log-sum-exp** trick). The returned log-evidence is exact up to the grid's quadrature error, which is what Bayes factors need.

Cost. One likelihood evaluation per grid point: $O(Gn)$ for n data points. That is trivial in one dimension. In d dimensions a grid with G points per axis has G^d points: 100 points per axis and $d = 10$ parameters is 10^{20} evaluations. This **curse of dimensionality** is why grids die beyond three or four parameters and why the rest of modern Bayesian computation exists.

Streaming updates. When a conjugate prior is available, the opposite extreme holds: the update is $O(1)$ per observation. A monitoring system tracking a defect rate keeps two counters (a, b) and increments one per chip, never storing the data.

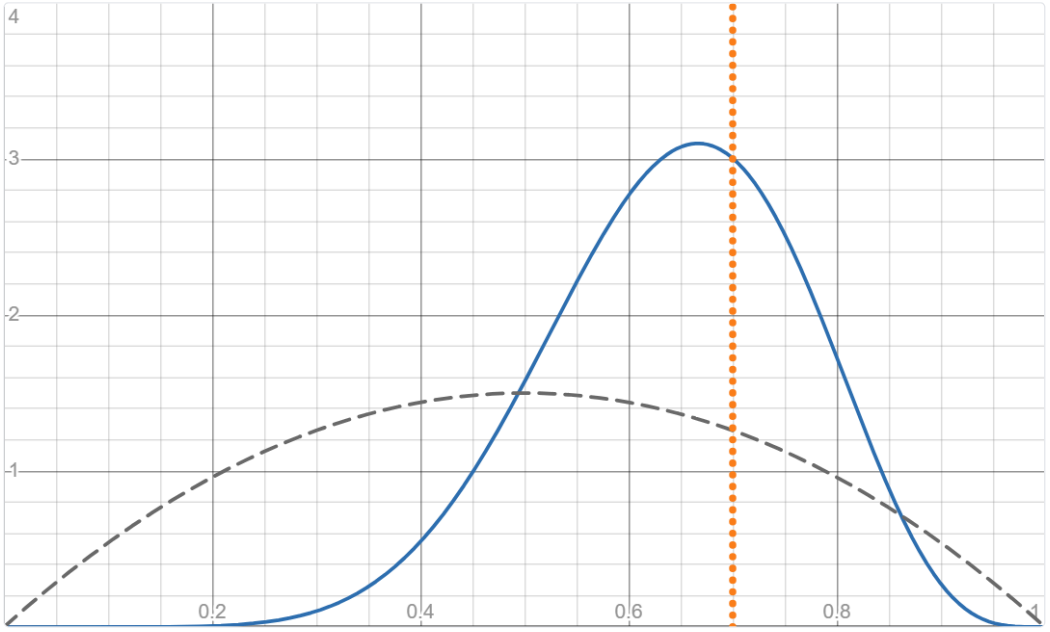
Failure cases.

- *Improper priors in Bayes factors.* A "flat prior on the whole real line" is fine for estimation (the posterior is usually proper) but makes the evidence $p(D \mid H_1)$ defined only up to an arbitrary constant. Bayes factors computed with improper priors are meaningless.
- *Grids that miss the mass.* With lots of data the posterior is a spike of width about $1/\sqrt{n}$. A grid too coarse to resolve it, or one placed where the spike is not, returns confident nonsense. Always check the posterior visibly fits inside the grid.
- *Prior–data conflict.* If a confident prior and the data disagree sharply, the posterior can land between them, where neither has support. That is a symptom worth reporting, not hiding.

35.5 The experiment

Part 1: drag the posterior

The posterior $\mathrm{Beta}(9, 5)$ for 7 heads in 10 tosses under a $\mathrm{Beta}(2, 2)$ prior, with the prior in grey:



Posterior (blue), prior (grey) and the MLE 0.7 *(orange). The blue curve is* $\mathrm{Beta}(a + k,\ b + n - k)$ *with* $a = b = 2$, $k = 7$, $n = 10$.

Edit the numbers. The two blue parameters are $a + k$ and $b + n - k$; the grey ones are a and b. Try:

1. **More data, same frequency.** Replace $9, 5$ by $72, 32$ (70 heads in 100) and change `top` to 10. The posterior narrows like $1/\sqrt{n}$ and the prior stops mattering.
2. **A stubborn prior.** Set the prior to $\mathrm{Beta}(30, 30)$ (grey 30, 30) and the posterior to $\mathrm{Beta}(37, 33)$. Seven heads in ten barely move it. How many tosses at 70 % does it take before the posterior mean passes 0.65?
3. **Zero defects.** Set the posterior to $\mathrm{Beta}(1, 21)$ and the prior to $\mathrm{Beta}(1, 1)$. This is the fab line. Most of the mass sits below 0.1, none of it at exactly zero.

Part 2: a grid posterior you can break

```
import numpy as np
import matplotlib.pyplot as plt

# ---- knobs ----------------------------------------------------------------
true_theta = 0.7      # the coin's real heads probability (hidden from the analyst)
n_flips    = 30       # how many tosses we observe
a, b       = 2, 2     # Beta(a, b) prior; try (1,1), (20,20), (1,10)
seed       = 0
# ---------------------------------------------------------------------------

rng = np.random.default_rng(seed)
data = rng.random(n_flips) < true_theta
k = int(data.sum())

theta = np.linspace(0.0005, 0.9995, 2000)          # grid over the parameter
dth = theta[1] - theta[0]
log_prior = (a - 1) * np.log(theta) + (b - 1) * np.log(1 - theta)
log_lik = k * np.log(theta) + (n_flips - k) * np.log(1 - theta)
log_post = log_prior + log_lik
post = np.exp(log_post - log_post.max())            # subtract max: no underflow
post /= post.sum() * dth                            # normalise numerically

mean = (theta * post).sum() * dth
cdf = np.cumsum(post) * dth
lo, hi = theta[np.searchsorted(cdf, 0.025)], theta[np.searchsorted(cdf, 0.975)]
print(f"heads {k}/{n_flips}   MLE {k/n_flips:.3f}   MAP {theta[post.argmax()]:.3f}")
print(f"posterior mean {mean:.3f}  (exact {(a+k)/(a+b+n_flips):.3f})")
print(f"95% credible interval [{lo:.3f}, {hi:.3f}]")
print(f"P(theta > 0.5 | data) = {post[theta > 0.5].sum()*dth:.3f}")

prior = np.exp(log_prior - log_prior.max()); prior /= prior.sum() * dth
plt.plot(theta, prior, "--", label="prior")
plt.plot(theta, post, label="posterior")
plt.axvline(true_theta, color="k", ls=":", label="true theta")
plt.xlabel("theta"); plt.ylabel("density"); plt.legend(); plt.show()
```

With the default knobs it reports 20 heads in 30, posterior mean 0.647 (matching the exact conjugate answer), a 95 % credible interval of about $[0.48,\ 0.80]$, and $P(\theta > 0.5 \mid D) \approx 0.96$. Things to try:

1. Set `n_flips = 100000` and remove the `- log_post.max()`. Watch the posterior turn into `nan`: that is underflow, live.
2. Replace the Beta prior by a *bimodal* one, say `log_prior = np.log(np.exp(-((theta-0.2)/0.05)**2) + np.exp(-((theta-0.8)/0.05)**2))`. No conjugate formula exists now, but the grid does not care. How much data does it take for one hump to win?
3. Run 1000 seeds and count how often the 95 % credible interval contains `true_theta`. Is it 95 %? Does the answer depend on the prior?

35.6 The challenge

1. **Intuition.** Two engineers estimate the same defect rate. One updates after every chip; the other waits for the whole batch of 500 and updates once. Explain without algebra why they must end with the same posterior, and name a situation in which a real analysis could break this equivalence.
2. **Derivation.** Show that the Gamma distribution is a conjugate prior for the rate λ of a Poisson count: with prior $\text{Gamma}(\alpha, \beta)$ (density $\propto \lambda^{\alpha-1} e^{-\beta\lambda}$) and counts $x_1, \dots, x_n$, find the posterior and write its mean as a weighted average of the prior mean and the sample mean. Interpret α and β as pseudo-data.
3. **Implementation.** Extend the grid code to two parameters: a Gaussian with unknown mean μ and standard deviation σ, observed through 20 noisy voltage readings. Plot the joint posterior as a contour map, then the marginal posterior of μ. Measure how runtime grows when you go from 100×100 to 400×400 grid points, and predict what three parameters would cost.
4. **Open investigation.** Lindley's paradox used a uniform alternative. For a fixed p-value of 0.05, how does the growth of B_{01} with n depend on the prior under H_1? Try $\text{Beta}(c, c)$ for several c, and a prior that shrinks with n. Is there a prior that makes the Bayes factor and the p-value agree at every sample size, and would you be willing to use it? (Statisticians still disagree about what the right reconciliation is.)

35.7 Loose threads

The chapter stayed with one or two parameters and friendly priors on purpose. The frontier starts exactly where it stopped.

> **? The integral you cannot do**
>
> Every posterior here was either conjugate or small enough for a grid. A model with 50 parameters has a posterior whose normalising integral $p(D) = \int p(D \mid \theta) p(\theta)\, d\theta$ is a 50-dimensional integral that no grid and no formula can touch. Yet modern science computes such posteriors routinely. The trick is to stop computing the posterior and start *sampling* from it, using a Markov chain built so that its stationary distribution is the posterior (Ch. 34 supplies the convergence theorem). The normalising constant cancels out of every step. How to build that chain, and why the evidence $p(D)$ remains hard even after the posterior becomes easy, is Ch. 38.

? What if the model is wrong?

As $n \to \infty$ the posterior concentrates at the true parameter and becomes Gaussian with width $1/\sqrt{nI(\theta)}$, so Bayesian and frequentist intervals agree. This is the Bernstein–von Mises theorem, and it needs conditions, including that the true distribution is in the model family. If the coin's tosses are secretly correlated, the posterior still concentrates, confidently, on the parameter that makes the wrong model least wrong in the KL sense of Ch. 33. The precise statement, its failures in infinite-dimensional models, and the measure-theoretic machinery needed even to state it are in Ch. 97.

Other threads:

- **Inference is not intervention.** A posterior that says "chips made on Tuesday fail more" tells you nothing about what would happen if you moved production off Tuesdays. Learning causes from data needs extra structure: Ch. 37.
- **Inverse problems.** Deblurring an image or reconstructing a CT scan is Bayesian inference with millions of parameters, where the prior is what makes the problem solvable at all: Ch. 91.
- **Beliefs about other people's beliefs.** When the parameter you are inferring is another player's private information and they know you are inferring it, Bayes' rule becomes a strategic tool: Ch. 41.
- **Filtering.** Updating the belief about a *moving* state, one measurement at a time, with the posterior as the next prior, is the Kalman filter when everything is Gaussian. It is Bayes' rule running on a Markov chain.

Chapter 36 — Stochastic Processes: When Randomness Evolves

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19, Ch. 21, Ch. 34 · **Leads to:** Ch. 38, Ch. 89, Ch. 97 · **Related:** Ch. 13, Ch. 54, Ch. 92 **Reading time:** ~30 min

36.1 The hook

The bus that is always late. The timetable says buses come "every 10 minutes on average". They are not scheduled; they arrive at random, independently of each other, at an average rate of one per 10 minutes. You walk to the stop at a random moment. How long do you expect to wait?

The obvious answer is 5 minutes: on average you land halfway through a 10-minute gap. The correct answer is 10 minutes. And if you ask how long the gap you landed in lasts, from the bus before you to the bus after you, the answer is 20 minutes, twice the average gap. Every passenger, every day, experiences gaps twice as long as the timetable's average. No one is lying, and no buses are behaving strangely.

The integral that will not behave. Let $W(t)$ be a random signal that wanders like the pen of a seismograph, the Brownian motion of Ch. 21 §21.5. Ordinary calculus says $\int_0^t W\,dW = \frac{1}{2}W(t)^2$, by the same rule that gives $\int x\,dx = \frac{1}{2}x^2$. Compute the integral numerically, as a limit of Riemann sums, the way engineers compute every integral. You get

$$\int_0^t W\,dW = \tfrac{1}{2}W(t)^2 - \tfrac{1}{2}t.$$

An extra term, $-t/2$, appears out of nowhere, and it does not shrink as the grid gets finer. Worse, if you evaluate the Riemann sum at the midpoint of each interval instead of the left end, you get the classical answer back. For ordinary functions the evaluation point never matters in the limit. Here it changes the answer.

The investment that grows and shrinks. A stock model widely used in finance says the expected value of an investment grows by 65 % over ten years. In the same model, about 59 % of investors lose money over those ten years. Both statements are correct.

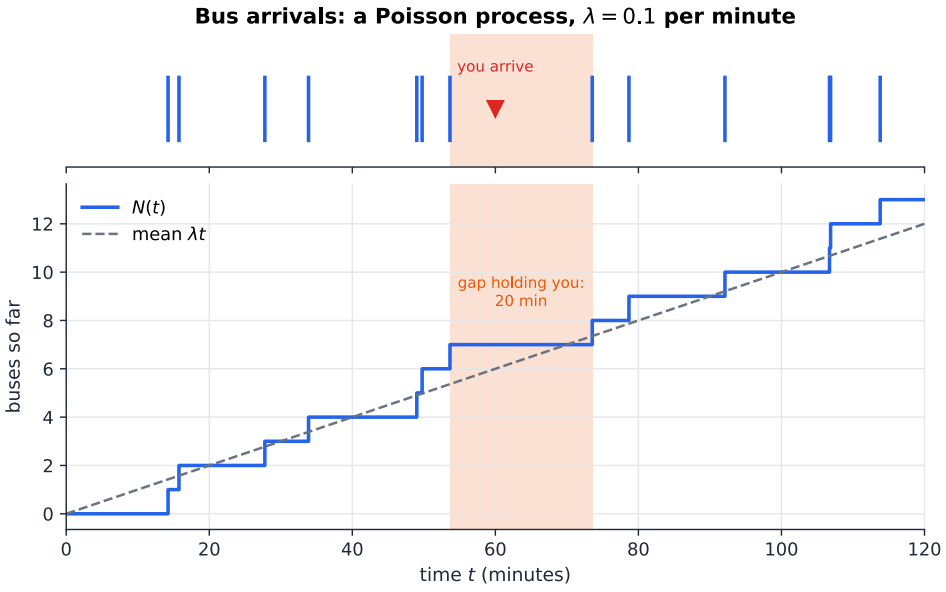
All three surprises come from one fact: when randomness accumulates in time, its *fluctuations* have rules of their own, and those rules are not the rules of smooth functions. This chapter builds the two fundamental random processes, the Poisson process (random events) and Brownian motion (random wandering), introduces the martingale (the mathematical fair game), and opens the door to stochastic calculus. It resolves the bus, the integral and the investment. It leaves some deeper doors shut.

36.2 The big idea

Randomness that adds up. A random variable is one roll of a die. A stochastic process is a whole history of rolls, indexed by time, where what happens later can build on what happened earlier. Core Ch. 21 studied processes through their averages: means, autocorrelations, spectra. This chapter studies their *paths*: what does one realisation actually look like, when does it first cross a line, how do you integrate against it?

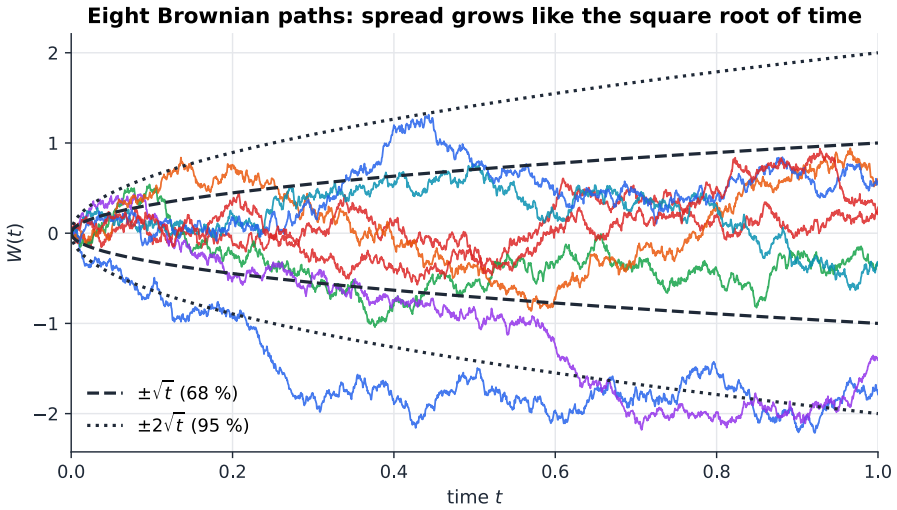
Two building blocks cover a surprising amount of the world.

- **Counting random events: the Poisson process.** Photons hitting a detector, packets arriving at a router, decays of radioactive atoms, buses. Each tiny time slot has a tiny independent chance of an event. Paths are staircases that jump by one at random times.
- **Accumulating random nudges: Brownian motion.** A pollen grain kicked by water molecules, the phase of a free-running oscillator, the integrated error of a gyroscope. Each instant adds an independent, tiny, symmetric nudge. Paths are continuous but jagged at every scale.



Top: arrival times of a Poisson process with rate 0.1 *per minute. Bottom: the count* $N(t)$ *against its mean* λt*. A passenger arriving at* $t = 60$ *falls into the longest gap in sight: long gaps are easier to land in.*

The analogy for both is **a drunk with a stopwatch**. In Ch. 34 the drunk took one step per tick. Now let the ticks get faster and the steps smaller. If each step is a rare "jump" that happens with small probability, you get the Poisson process. If every tick produces a step of size $\sqrt{\Delta t}$, you get Brownian motion. That square root is the whole secret: in a time Δt a Brownian path moves about $\sqrt{\Delta t}$, which is *much larger* than Δt when Δt is small. The path's velocity, displacement over time, is about $1/\sqrt{\Delta t}$ and blows up. The path has no velocity anywhere. That is why calculus has to be rebuilt.



Eight sample paths of standard Brownian motion. The dashed and dotted curves are $\pm\sqrt{t}$ and $\pm 2\sqrt{t}$: at each time about 68 % and 95 % of paths lie inside them.

The third idea is a lens rather than a process. A **martingale** is a fair game: a process whose expected future value, given everything you know now, is its present value. Martingales are the reason gambling systems cannot beat a fair casino, and they turn hard questions about random paths (when, where, how likely) into one line of algebra.

36.3 The mathematics

The Poisson process

Poisson process

A counting process $N(t)$, $t \geq 0$, with $N(0) = 0$, is a **Poisson process of rate** λ if

1. it has independent increments: counts in disjoint time intervals are independent;
2. it has stationary increments: the distribution of $N(t+s) - N(t)$ depends only on s;
3. in a short interval of length h, $P(\text{one event}) = \lambda h + o(h)$ and $P(\text{two or more}) = o(h)$.

Condition 3 says events are rare and arrive one at a time. From these three local rules a global formula follows.

Poisson counts

$$P\big(N(t) = k\big) = \frac{(\lambda t)^k}{k!} e^{-\lambda t}, \qquad k = 0, 1, 2, \ldots$$

Proof. Let $p_k(t) = P(N(t) = k)$. To have k events at time $t + h$, either there were k at time t and none in $(t, t+h]$, or $k-1$ and exactly one, or fewer and at least two. By independent increments and rule 3,

$$p_k(t+h) = p_k(t)(1 - \lambda h) + p_{k-1}(t)\,\lambda h + o(h).$$

Subtract $p_k(t)$, divide by h and let $h \to 0$:

$$p_0'(t) = -\lambda p_0(t), \qquad p_k'(t) = -\lambda p_k(t) + \lambda p_{k-1}(t) \quad (k \geq 1),$$

with $p_0(0) = 1$, $p_k(0) = 0$. The first equation gives $p_0(t) = e^{-\lambda t}$. For the rest, substitute $p_k(t) = q_k(t) e^{-\lambda t}$: the system becomes $q_k' = \lambda q_{k-1}$ with $q_0 = 1$, $q_k(0) = 0$, so $q_1 = \lambda t$, $q_2 = (\lambda t)^2/2$, and by induction $q_k = (\lambda t)^k / k!$. ∎

This is a system of linear ODEs of the type solved in Ch. 11, and the answer is the Poisson distribution of Ch. 19 §19.6. Two consequences follow at once.

- **Gaps are exponential.** The time T_1 to the first event satisfies $P(T_1 > t) = P(N(t) = 0) = e^{-\lambda t}$: exponential with mean $1/\lambda$. By independent, stationary increments, every later gap is the same and independent (Ch. 20 §20.4).
- **No memory.** $P(T > s + t \mid T > s) = e^{-\lambda(s+t)} / e^{-\lambda s} = e^{-\lambda t}$. Having already waited s minutes tells you nothing about the remaining wait.

The bus paradox, resolved

Memorylessness answers the first half of the hook immediately. You arrive at a random time. Whatever happened before, the time until the next bus is exponential with mean $1/\lambda = 10$ minutes. Looking backwards, the time since the last bus is (for large t) also exponential with mean 10 minutes, by the same argument run in reverse. The gap you are in averages $10 + 10 = 20$ minutes.

Why is that not a contradiction with an average gap of 10 minutes? Because you do not pick a gap at random; you pick a *moment* at random, and a gap twice as long contains twice as many moments. This is **length-biased sampling**. If gaps have density $f(x)$, the gap containing a random moment has density proportional to $x f(x)$:

$$f_{\text{seen}}(x) = \frac{x f(x)}{E[X]}, \qquad E[X_{\text{seen}}] = \frac{E[X^2]}{E[X]} = E[X] + \frac{\operatorname{Var}(X)}{E[X]}.$$

For exponential gaps $E[X^2] = 2/\lambda^2$, so $E[X_{\text{seen}}] = 2/\lambda = 20$ minutes. The formula shows the paradox is general: the gap you experience exceeds the average gap by $\operatorname{Var}(X)/E[X]$. Only perfectly regular buses ($\operatorname{Var} = 0$) give the naive answer. The same effect is why your friends have more friends than you on average, and why sampled classes look more crowded than the average class size.

Two more facts, stated without proof, make Poisson processes easy to work with. **Superposition:** merging independent Poisson streams of rates λ_1 and λ_2 gives a Poisson stream of rate $\lambda_1 + \lambda_2$. **Thinning:** keeping each event independently with probability p gives a Poisson stream of rate $p\lambda$. Together they explain why aggregated traffic from many independent sources looks Poisson even when no single source is.

Brownian motion: the square-root law

Ch. 21 §21.5 defined the Wiener process. We use the standard version, $\sigma = 1$: $W(0) = 0$, independent increments, $W(t+s) - W(t) \sim \mathcal{N}(0, s)$, continuous paths. Two properties drive everything.

Scaling. For any $c > 0$, the process $\frac{1}{\sqrt{c}} W(ct)$ is again a standard Brownian motion (its increments are Gaussian with variance $cs/c = s$). Zoom in on a Brownian path by a factor c in time and $\sqrt{c}$ in space and it looks statistically identical. The path is a random fractal, and $\operatorname{Var} W(t) = t$ means it typically sits within $\pm\sqrt{t}$ of zero, the envelope in the figure above. This is the continuum version of the gambler's-ruin observation in Ch. 34 that a walk needs N^2 steps to travel N.

Quadratic variation. Chop $[0, t]$ into n intervals of length $\Delta t = t/n$ with increments ΔW_k.

Quadratic variation of Brownian motion

$$Q_n = \sum_{k=1}^{n} (\Delta W_k)^2 \;\longrightarrow\; t \qquad \text{in mean square as } n \to \infty.$$

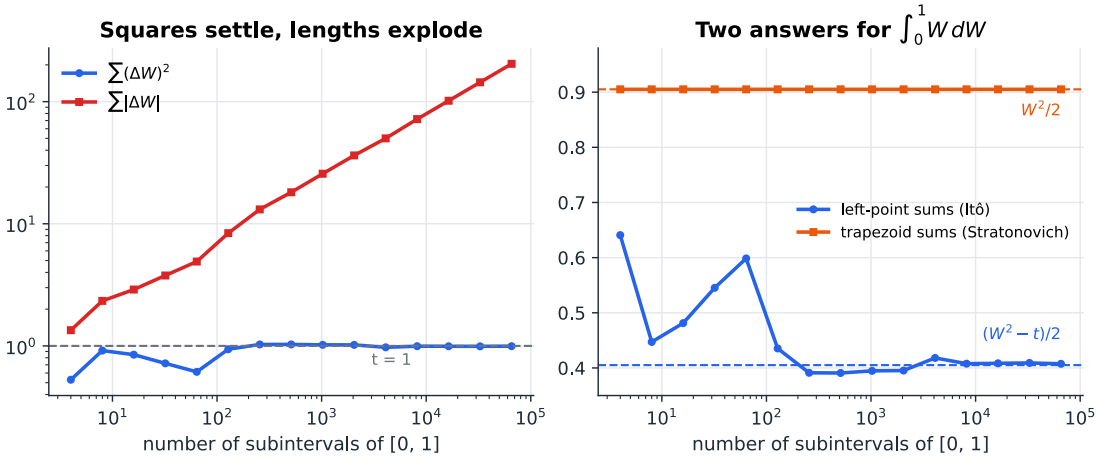
Proof. Each $\Delta W_k \sim \mathcal{N}(0, \Delta t)$, so $E[(\Delta W_k)^2] = \Delta t$ and, using $E[Z^4] = 3$ for a standard Gaussian Z, $\operatorname{Var}\left((\Delta W_k)^2\right) = 3\Delta t^2 - \Delta t^2 = 2\Delta t^2$. The increments are independent, so

$$E[Q_n] = n\,\Delta t = t, \qquad \operatorname{Var}(Q_n) = n \cdot 2\Delta t^2 = \frac{2t^2}{n} \to 0.$$

Hence $E[(Q_n - t)^2] = \operatorname{Var}(Q_n) \to 0$. ∎

For any differentiable function f, the same sum $\sum (\Delta f_k)^2 \approx \sum f'(t_k)^2 \Delta t^2 \le \max|f'|^2\, t\, \Delta t \to 0$. Smooth functions have zero quadratic variation; Brownian motion has quadratic variation exactly t, *deterministically*, even though every increment is random. The squares of the random kicks add up to a clock.

There is a sting in the tail. Since $Q_n \le \max_k |\Delta W_k| \cdot \sum_k |\Delta W_k|$, and $\max_k |\Delta W_k| \to 0$ by continuity while $Q_n \to t > 0$, the total length $\sum_k |\Delta W_k|$ must go to infinity. A Brownian path has **infinite length** on every interval. In fact (Paley, Wiener and Zygmund, 1933) it is differentiable at no point at all.



Left: on one path over $[0, 1]$, the sum of squared increments settles at $t = 1$ while the sum of absolute increments grows without bound. Right: left-point Riemann sums of $\int_0^1 W\, dW$ converge to $\frac{1}{2}(W^2 - t)$; trapezoid sums give $\frac{1}{2}W^2$.

Martingales: the mathematics of fair games

Martingale

A process $M(t)$ with $E|M(t)| < \infty$ is a **martingale** with respect to the information $\mathcal{F}_s$ available at time s (the history of the process up to s) if

$$E\big[M(t) \mid \mathcal{F}_s\big] = M(s) \qquad \text{for all } s \le t.$$

The best prediction of the future value is the present value. Examples:

- $W(t)$: given the past, $W(t) = W(s) + [W(t) - W(s)]$ and the bracket is independent with mean zero.
- $N(t) - \lambda t$: the Poisson count minus its expected growth, the "surprise" part of the arrivals.
- $W(t)^2 - t$, which deserves a proof because it is the engine of what follows.

$W(t)^2 - t$ is a martingale

For $s \le t$, $E\big[W(t)^2 - t \mid \mathcal{F}_s\big] = W(s)^2 - s$.

Proof. Write $W(t) = W(s) + D$ with $D = W(t) - W(s) \sim \mathcal{N}(0, t-s)$ independent of $\mathcal{F}_s$. Then $W(t)^2 = W(s)^2 + 2W(s)D + D^2$. Conditionally on $\mathcal{F}_s$, $W(s)$ is known, $E[D] = 0$ and $E[D^2] = t - s$, so $E[W(t)^2 \mid \mathcal{F}_s] = W(s)^2 + t - s$. Subtract t. ∎

The power of martingales comes from a theorem we state without proof.

Optional stopping (one version)

If M is a martingale, τ is a stopping time (a random time whose occurrence by time t is decided by the history up to t), and $M(t \wedge \tau)$ stays bounded, then $E[M(\tau)] = E[M(0)]$.

Now watch it redo Ch. 34's gambler's ruin, in continuous time and in two lines. Let Brownian motion start at 0 and stop at the first time τ it hits $-a$ or $+b$. Let $p = P(\text{hit } b \text{ first})$. Since W is a martingale,

$$0 = E[W(\tau)] = p\,b - (1-p)\,a \quad\Longrightarrow\quad p = \frac{a}{a+b}.$$

Since $W^2 - t$ is a martingale (with a limiting argument for the unbounded t),

$$0 = E[W(\tau)^2 - \tau] = p\,b^2 + (1-p)\,a^2 - E[\tau] \quad\Longrightarrow\quad E[\tau] = ab.$$

These are exactly k/N and $k(N-k)$ from the discrete game with $a = k$, $b = N - k$, now with no recurrences at all.

? The gambler who always wins

Bet 1 on a fair coin. If you lose, double the bet; keep doubling until you win once, then stop. You are certain to stop, and when you do you are up exactly 1. Your fortune is a martingale, it started at 0, and at the stopping time it equals 1, so $E[M(\tau)] = 1 \neq 0$. Optional stopping fails. The boundedness condition was violated (your losses before the win are unbounded, and you need infinite credit). Exactly which conditions make "you cannot beat a fair game" true, and the measure-theoretic notion of conditional expectation needed to state them precisely, are the business of Ch. 97.

Stochastic integrals: where the extra term comes from

We want to make sense of $\int_0^t H(s)\,dW(s)$: the accumulated effect of random kicks dW scaled by a time-varying gain H. A Brownian path has infinite length, so the classical Riemann–Stieltjes integral does not exist. Itô's idea was to *choose* the left endpoint and define

$$\int_0^t H\,dW = \lim_{n\to\infty} \sum_{k=0}^{n-1} H(t_k)\big(W(t_{k+1}) - W(t_k)\big),$$

the limit taken in mean square. The left endpoint is not arbitrary: it means the gain is decided *before* the kick arrives, which is how any causal system, a controller, a trader, a filter, actually operates.

The Itô integral of W

$$\int_0^t W\,dW = \tfrac{1}{2}W(t)^2 - \tfrac{1}{2}t.$$

Proof. Write $W_k = W(t_k)$ and $\Delta W_k = W_{k+1} - W_k$. The algebraic identity $b^2 - a^2 = 2a(b-a) + (b-a)^2$ with $a = W_k$, $b = W_{k+1}$ gives

$$W_k\,\Delta W_k = \tfrac{1}{2}\big(W_{k+1}^2 - W_k^2\big) - \tfrac{1}{2}(\Delta W_k)^2.$$

Sum over k. The first part telescopes to $\frac{1}{2}\big(W(t)^2 - W(0)^2\big) = \frac{1}{2}W(t)^2$. The second part is $-\frac{1}{2}Q_n$, and $Q_n \to t$ in mean square by the quadratic-variation theorem. ∎

The proof shows exactly where ordinary calculus breaks. For a smooth function the $(\Delta)^2$ terms add up to zero and you get $\frac{1}{2}W^2$. For Brownian motion they add up to t. Evaluate at the midpoint (or average the endpoints, the trapezoid rule) and the cross term is gone: $\frac{1}{2}(W_k + W_{k+1})\Delta W_k = \frac{1}{2}(W_{k+1}^2 - W_k^2)$ exactly, which telescopes to $\frac{1}{2}W^2$. That is the **Stratonovich** integral. The two differ by half the quadratic variation, and the right-hand panel of the figure above shows the two Riemann sums converging to the two answers on one simulated path.

The Itô choice buys one beautiful property: an Itô integral is a martingale with mean zero. Indeed $E[\frac{1}{2}W(t)^2 - \frac{1}{2}t] = \frac{1}{2}t - \frac{1}{2}t = 0$. The classical answer $\frac{1}{2}W^2$ has mean $t/2$, so it would have the system gaining on average from kicks it could not anticipate.

Itô's lemma: the new chain rule

The same bookkeeping, applied to any smooth function $f(W)$, gives the fundamental theorem of stochastic calculus. Taylor-expand one step:

$$\Delta f = f'(W)\,\Delta W + \tfrac{1}{2}f''(W)(\Delta W)^2 + \cdots.$$

In ordinary calculus the second term is negligible. Here $(\Delta W)^2$ sums to Δt, so it survives, while higher terms ($|\Delta W|^3 \sim \Delta t^{3/2}$) vanish. The mnemonic is $(dW)^2 = dt$, $dt\,dW = 0$, $(dt)^2 = 0$.

Itô's lemma (stated)

If X satisfies $dX = a\,dt + b\,dW$ and $f(t,x)$ is twice continuously differentiable, then

$$df(t,X) = \Big(\frac{\partial f}{\partial t} + a\frac{\partial f}{\partial x} + \frac{1}{2}b^2\frac{\partial^2 f}{\partial x^2}\Big)dt + b\frac{\partial f}{\partial x}\,dW.$$

The extra $\frac{1}{2}b^2 f''$ is the Itô correction. With $f = x^2$ and $X = W$ ($a = 0, b = 1$) it reproduces $d(W^2) = 2W\,dW + dt$, the theorem above in differential form.

The investment paradox, resolved

The standard model for a price, a population, or any quantity whose random fluctuations are proportional to its size is **geometric Brownian motion**:

$$dS = \mu S\,dt + \sigma S\,dW, \qquad S(0) = S_0.$$

Naively, divide by S and integrate: $\ln S$ should grow like $\mu t + \sigma W$. Itô's lemma with $f = \ln x$ ($f' = 1/x$, $f'' = -1/x^2$, $a = \mu S$, $b = \sigma S$) says otherwise:

$$d(\ln S) = \Big(\mu - \tfrac{1}{2}\sigma^2\Big)dt + \sigma\,dW \quad\Longrightarrow\quad S(t) = S_0\exp\Big(\big(\mu - \tfrac{1}{2}\sigma^2\big)t + \sigma W(t)\Big).$$

Two different growth rates now coexist. The **mean** grows at rate μ: $E[S(t)] = S_0 e^{\mu t}$, using $E[e^{\sigma W}] = e^{\sigma^2 t/2}$. The **typical path** (the median, and the long-run growth of almost every path) grows at the smaller rate $\mu - \frac{1}{2}\sigma^2$.

With the hook's numbers, $\mu = 0.05$ per year and $\sigma = 0.4$, over $t = 10$ years: $E[S]/S_0 = e^{0.5} \approx 1.65$, a 65 % expected gain. But $\mu - \frac{1}{2}\sigma^2 = -0.03$, so the median is $e^{-0.3} \approx 0.74$ and

$$P\big(S(10) < S_0\big) = P\Big(W(10) < \frac{0.3}{0.4}\Big) = \Phi\Big(\frac{0.3}{0.4\sqrt{10}}\Big) \approx 0.594,$$

so about 59 % to 60 % of paths lose money. The mean is dragged up by a few enormous winners. Volatility is not just risk around a trend: it *lowers* the trend that a typical path follows, by exactly the Itô correction $\frac{1}{2}\sigma^2$. Engineers meet the same effect as the gap between average power and the power of the average in log-normal fading channels.

36.4 The algorithm

Simulating a Poisson process

The exponential-gap property gives an exact $O(\text{number of events})$ algorithm: draw $E_1, E_2, \dots \sim \text{Exponential}(\lambda)$ and set $T_k = E_1 + \cdots + E_k$ until $T_k > T$. An exponential sample is $-\ln(U)/\lambda$ with U uniform on $(0, 1]$.

When the rate varies in time, $\lambda(t) \le \lambda_{\max}$, use **thinning** (Lewis–Shedler, 1979):

```
THINNING(λ(·), λ_max, T)
  t ← 0, events ← []
  loop:
      t ← t − ln(U₁)/λ_max           # next candidate of a rate-λ_max process
      if t > T: return events
      if U₂ ≤ λ(t)/λ_max: append t   # keep it with probability λ(t)/λ_max
```

It is exact, by the thinning property of §36.3. Its efficiency is the average of $\lambda(t)/\lambda_{\max}$: a sharply peaked rate wastes most candidates.

Simulating Brownian motion and SDEs

On a grid $t_k = k\,\Delta t$, Brownian motion is exact at the grid points: $W_{k+1} = W_k + \sqrt{\Delta t}\,Z_k$ with $Z_k \sim \mathcal{N}(0,1)$ independent. For a stochastic differential equation $dX = a(X)\,dt + b(X)\,dW$, the analogue of Euler's method (Ch. 22) is **Euler–Maruyama**:

$$X_{k+1} = X_k + a(X_k)\,\Delta t + b(X_k)\sqrt{\Delta t}\,Z_k.$$

Note the left-point evaluation of b: this scheme converges to the *Itô* solution. Its accuracy has two different orders.

- **Strong order $\frac{1}{2}$**: the error on each individual path, $E|X_N - X(T)|$, shrinks like $\Delta t^{1/2}$. Halving the error needs four times the steps.
- **Weak order 1**: the error in expectations, $|E[g(X_N)] - E[g(X(T))]|$, shrinks like Δt.

If you only need averages (a price, a mean error), the cheaper weak order is what counts, and Monte Carlo sampling error, which falls like $1/\sqrt{\text{paths}}$, usually dominates.

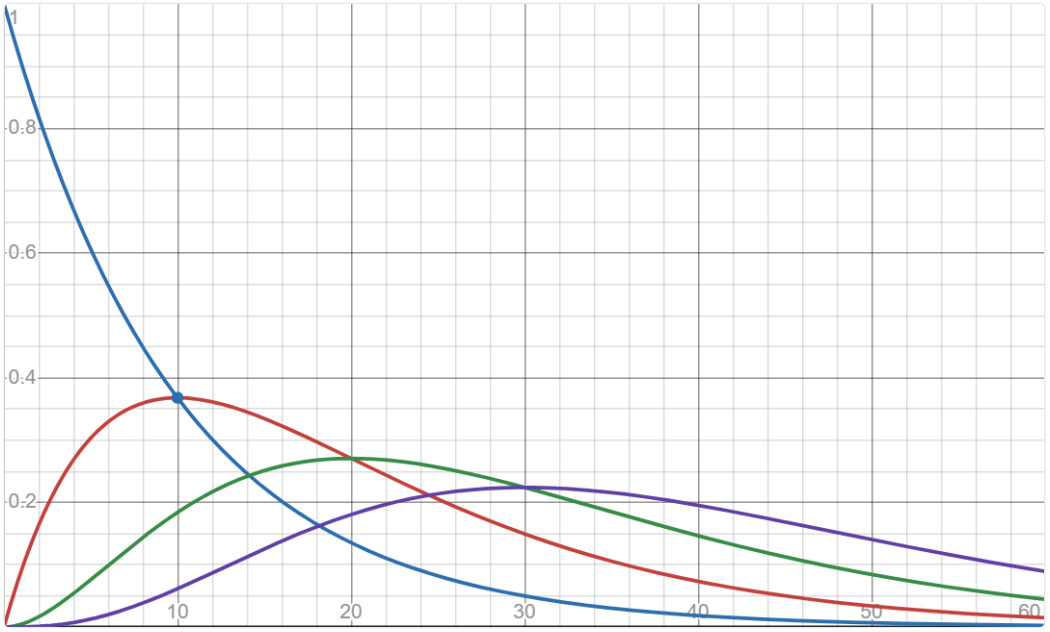
Failure cases.

- *Wrong calculus.* Evaluate b at the midpoint, or use a deterministic ODE solver with the noise treated as an ordinary input signal, and you silently solve the Stratonovich equation instead. For geometric Brownian motion that shifts the growth rate by $\frac{1}{2}\sigma^2$.
- *Positivity.* A geometric Brownian motion is always positive, but an Euler–Maruyama step $S(1 + \mu\Delta t + \sigma\sqrt{\Delta t}Z)$ goes negative whenever $Z < -(1 + \mu\Delta t)/(\sigma\sqrt{\Delta t})$. With coarse steps and high volatility this happens. Simulate $\ln S$ instead, where the scheme is exact.
- *Shared randomness.* To compare two step sizes on the same path, the coarse increments must be sums of the fine ones. Drawing fresh random numbers for each resolution compares different paths and hides the convergence.

36.5 The experiment

Part 1: waiting for the bus

The probability of exactly k buses in the first t minutes, for $k = 0, 1, 2, 3$ and rate $\lambda = 0.1$ per minute:



$P(N(t) = k)$ for $k = 0$ (blue) to 3 (red, green, purple). Each curve for $k \geq 1$ peaks at $t = k/\lambda$, where the expected count equals k.

At $t = 10$ the blue curve reads $e^{-1} \approx 0.368$: more than a third of the time you see *no* bus in a full average gap. Change every 0.1 to 0.2 (a bus every 5 minutes on average) and confirm the peaks move to half the times. Then add the curve for $k = 4$, `y=\frac{(0.1x)^{4}}{24}e^{-0.1x}`, and check where it peaks.

Part 2: the investment paradox in 20 000 paths

The script simulates geometric Brownian motion by Euler–Maruyama and by the exact Itô solution, and checks the Itô integral of the hook along the way.

```
import numpy as np
import matplotlib.pyplot as plt

# ---- knobs --------------------------------------------------------------
mu, sigma = 0.05, 0.4     # drift and volatility of dS = mu S dt + sigma S dW
T, steps  = 10.0, 250     # horizon (years) and Euler–Maruyama steps
paths     = 20000         # number of simulated paths
seed      = 36
# -------------------------------------------------------------------------

rng = np.random.default_rng(seed)
dt = T / steps
dW = rng.normal(0.0, np.sqrt(dt), (paths, steps))

S = np.ones(paths)                        # Euler–Maruyama, S(0) = 1
for k in range(steps):
    S = S + mu * S * dt + sigma * S * dW[:, k]
W_T = dW.sum(axis=1)
S_exact = np.exp((mu - 0.5 * sigma**2) * T + sigma * W_T)   # Ito's formula

print(f"mean   S(T): EM {S.mean():.3f}  exact {S_exact.mean():.3f}  theory {np.exp(mu*T):.3f}")
print(f"median S(T): EM {np.median(S):.3f}  exact {np.median(S_exact):.3f}"
      f"  theory {np.exp((mu-0.5*sigma**2)*T):.3f}")
print(f"fraction of paths that lost money: {(S_exact < 1).mean():.3f}")
print(f"EM paths below zero: {(S < 0).sum()}")

W = np.concatenate([np.zeros((paths, 1)), dW.cumsum(axis=1)], axis=1)
ito = (W[:, :-1] * dW).sum(axis=1)        # left-point sums for int W dW
print(f"mean Ito sum {ito.mean():+.3f}   mean (W^2 - T)/2 {((W_T**2 - T)/2).mean():+.3f}")

plt.hist(np.log(S_exact), bins=80, density=True, alpha=0.6, label="log S(T) exact")
plt.axvline(mu * T, color="r", label="log of mean")
plt.axvline((mu - 0.5 * sigma**2) * T, color="k", ls="--", label="mean of log")
plt.xlabel("log S(T)"); plt.legend(); plt.show()
```

With the default knobs it prints a mean near 1.63 (theory 1.65), a median near 0.73 (theory 0.74), and a loss fraction near 0.60. The mean of the Itô sums is close to zero, as a martingale's must be. Things to try:

1. **Crank the volatility.** Set `sigma = 1.0` and `steps = 10`. Count the Euler–Maruyama paths that go negative. Then raise `steps` and watch them disappear.

2. **Find the break-even volatility.** For $\mu = 0.05$, what σ makes exactly half the paths lose money? Predict it from $\mu - \frac{1}{2}\sigma^2 = 0$ first.
3. **Switch calculus.** Replace the left-point sum by the trapezoid sum `0.5*(W[:, :-1] + W[:, 1:]) * dW`. What is its mean now, and why is it $T/2$?
4. **Watch the mean misbehave.** Increase `T` to 50 with `sigma = 0.4`. The sample mean of `S_exact` starts to undershoot the theory badly. Why does estimating $E[S]$ from samples get harder as the distribution becomes more skewed?

36.6 The challenge

1. **Intuition.** Buses on a real route tend to bunch: a late bus picks up more passengers, slows down, and the next bus catches it up. Does bunching make the passenger's experienced gap longer or shorter than the Poisson value of $2/\lambda$? Argue from the formula $E[X] + \mathrm{Var}(X)/E[X]$ without computing anything.
2. **Derivation.** Let $N(t)$ be a Poisson process of rate λ. Show that $(N(t) - \lambda t)^2 - \lambda t$ is a martingale. Then use Itô's lemma to find $d\big(e^{\theta W(t) - \theta^2 t/2}\big)$ and show that this exponential is a martingale for every real θ.
3. **Implementation.** Implement Euler–Maruyama for the Ornstein–Uhlenbeck process $dX = -\alpha X\,dt + \sigma\,dW$ of Ch. 21. Measure the strong error at $T = 1$ against the exact solution driven by the same Brownian increments, for $\Delta t = 2^{-4}, \dots, 2^{-12}$, and confirm the order $\frac{1}{2}$ on a log-log plot. Do you actually see order $\frac{1}{2}$, or something better, and why might this particular equation be special?
4. **Open investigation.** Brownian motion started at the centre of a square first hits the boundary at a random point. Simulate that exit point and estimate its distribution along the edges. Then put a "temperature" g on the boundary (say 1 on one edge, 0 on the others), and estimate $E[g(\text{exit point})]$ for many starting points. Compare the resulting map with the steady-state heat distribution from Ch. 13 §13.6. How does the Monte Carlo error scale with the number of paths, and how badly does the time-step bias near the boundary spoil it?

36.7 Loose threads

The last challenge hints at the deepest connection this chapter has kept off the page.

> **? Brownian motion knows the heat equation**
>
> Run Brownian paths from a point x and average a function of where they are at time t: $u(t, x) = E[f(x + W(t))]$. This average satisfies the heat equation $\partial u/\partial t = \frac{1}{2}\,\partial^2 u/\partial x^2$ of Ch. 13, exactly. With killing, drift and boundaries added, every linear parabolic PDE and every Laplace boundary-value problem has a "random walker" solution, the Feynman–Kac formula. Why should a diffusing particle and a diffusing temperature obey the same law, and what does that mean for solving PDEs in a thousand dimensions where grids are hopeless? The answer starts in Ch. 89.

> **? Itô or Stratonovich?**
>
> Mathematics gave two consistent calculi that disagree by $\frac{1}{2}$ of the quadratic variation. Which one does nature use? A physical noise source is never truly white: it has a tiny correlation time. Smooth the noise, solve the ordinary differential equation, then let the correlation time go to zero, and the answer converges to the *Stratonovich* solution (the Wong–Zakai theorem). Yet finance, filtering and biology routinely use Itô. When is each correct, and what goes wrong when a model is built with the wrong one? The physics of noise-driven systems is taken up in Ch. 92.

Other threads:

- **Why the paths exist at all.** Defining a process with continuous but nowhere-differentiable paths, and making "conditional expectation given the past" precise, needs measure theory. The construction of Brownian motion, filtrations and the full martingale theory are in Ch. 97.
- **Simulation as a tool.** Every expectation in this chapter can be estimated by simulating paths. Doing that efficiently, with variance reduction and multilevel tricks that exploit the strong and weak orders, is Ch. 38.
- **Deciding under evolving randomness.** Choosing when to stop, invest or switch while a stochastic process unfolds is optimal stopping and stochastic control: Ch. 51 and Ch. 54.
- **Back to the walk.** Poisson jumps plus Brownian wandering, plus Markov chains in continuous time, cover nearly every stochastic model used in engineering. The discrete-time roots are in Ch. 34.

Chapter 37 — Causal Inference: Correlation Is Not Destiny

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 19 (conditional probability, independence), Ch. 20 (correlation, two-sample statistics) · **Leads to:** Ch. 38, Ch. 53 · **Related:** Ch. 35, Ch. 27, Ch. 48 **Reading time:** ~30 min

37.1 The hook

In 1986 a group of urologists in London compared two ways of removing kidney stones: open surgery (call it treatment A) and a newer keyhole procedure (treatment B). They had 700 patients, 350 on each treatment. The headline numbers were these:

	Treatment A (open)	Treatment B (keyhole)
All patients	273/350 = **78%** success	289/350 = **83%** success

Keyhole surgery wins, clearly. It is also cheaper and less painful. Case closed?

Now split the same 700 patients by the size of their stone:

	Treatment A (open)	Treatment B (keyhole)
Small stones	81/87 = **93%**	234/270 = **87%**
Large stones	192/263 = **73%**	55/80 = **69%**
All patients	273/350 = **78%**	289/350 = **83%**

Treatment A is better for small stones. Treatment A is better for large stones. Treatment B is better overall. No arithmetic error is hiding anywhere; you can check every fraction. This is **Simpson's paradox**, and it is not a curiosity. It turns up in admissions data, drug trials and A/B tests every week.

So which treatment should *you* choose if you walk in with a kidney stone of unknown size? Most people say A, because it wins in every group. Now consider a second story with *exactly the same numbers*. Replace "stone size" by "blood pressure measured one week after the treatment": low versus high. Treatment A is better among patients who ended up with low blood pressure, and better among those who ended up with high blood pressure, and worse overall. Which do you choose now?

This time the right answer is B, and the aggregate table is the one to trust. Same numbers, opposite answers.

That should be disturbing. It means that **no amount of staring at the data can tell you whether to aggregate or split**. The answer depends on something that is not in the table: *how the variables cause one another*. Stone size influences which treatment a doctor picks and also how well any treatment works. Post-treatment blood pressure is something the treatment itself changes. One is a confounder, the other is a mediator, and the difference lives entirely in the arrows.

This chapter is about those arrows: how to draw them, how to compute with them, and how to answer the question every engineer, doctor and policymaker actually cares about. Not "what do I see when X is large?" but "what *happens* if I *make* X large?"

37.2 The big idea

Seeing versus doing

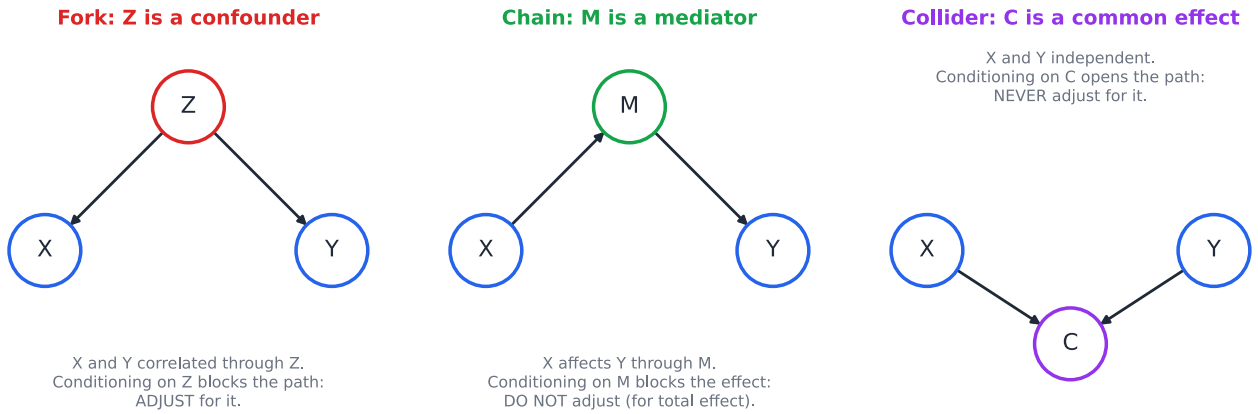
A barometer's needle falls before a storm. The correlation is excellent, and you can use it to predict rain. But if you grab the needle and push it down, no storm arrives. Observing a low reading and *forcing* a low reading are different operations, and probability theory as taught in Ch. 19 has symbols only for the first.

Conditional probability $P(\text{storm} \mid \text{needle low})$ answers: *among the days on which the needle happened to be low, how often did a storm follow?* Those days were selected by nature, and nature lowered the needle *because* the air pressure was dropping. The question we want, $P(\text{storm} \mid do(\text{needle low}))$, asks: *if I reach into the world and set the needle, overriding whatever normally sets it, how often does a storm follow?* The new symbol $do(\cdot)$ is the whole subject in four letters.

Draw the arrows

The tool that makes *do* precise is a **causal graph**: a directed acyclic graph (DAG) with one node per variable and an arrow $A \to B$ whenever A is one of the things that directly determines B.

Three tiny graphs, built from three variables, explain almost everything.

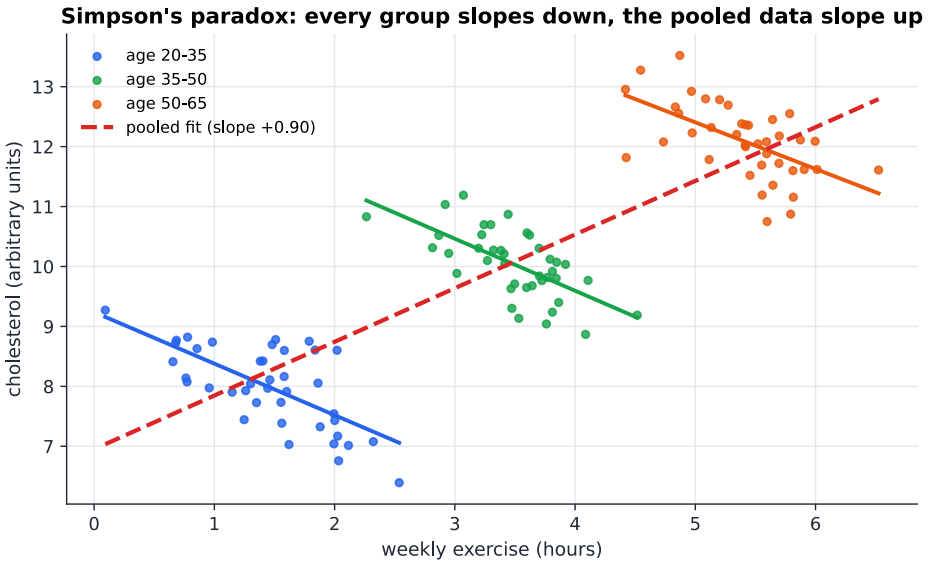


The three junctions. In a fork the middle node is a common cause; in a chain it passes an effect along; in a collider it is a common effect. Conditioning on the middle node closes the first two paths and opens the third.

- **Fork** ($X \leftarrow Z \rightarrow Y$). Stone size Z pushes doctors toward open surgery X and independently lowers success Y. X and Y become correlated even if X did nothing. Compare like with like, within each level of Z, and the spurious part disappears. Z is a **confounder**: adjust for it.
- **Chain** ($X \rightarrow M \rightarrow Y$). Treatment X changes blood pressure M, which changes recovery Y. If you compare only patients with the same M you have frozen the very channel through which X works, and you will under-count its effect. M is a **mediator**: for the total effect, leave it alone.
- **Collider** ($X \rightarrow C \leftarrow Y$). Talent X and good looks Y are independent in the population, but Hollywood casts people who have enough of one or the other, C. Among actors, the talented ones seem less attractive. Nothing about talent affects looks; you created the correlation by looking only at $C = 1$. This is **Berkson's paradox**, and colliders are the reason that "control for everything" is terrible advice.

Simpson's paradox, drawn

Here is the same phenomenon with continuous variables. Within each age group, more exercise goes with lower cholesterol. But older people both exercise more (in this invented population, retirees with time on their hands) and have higher cholesterol. Pool the groups and the slope flips sign.

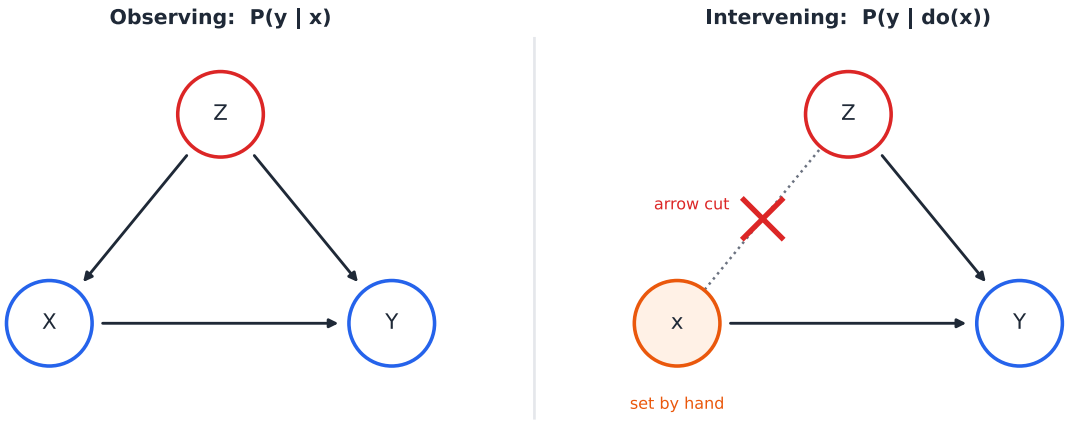


Simpson's paradox in a scatter plot: the within-group slopes are about -0.8, the pooled slope is about $+0.9$. Age is a fork, so the within-group lines tell the causal story.

Whether the coloured lines or the red dashed line is "right" is not a statistical question. If age causes both exercise and cholesterol, the coloured lines are right. If (absurdly) exercise caused aging, age would be a mediator and the dashed line would be the total effect. The data are identical in both worlds.

The surgery

How do we compute $P(y \mid do(x))$? The answer is beautifully mechanical. *Intervening on X means cutting every arrow that points into X*, because whatever used to determine X no longer does: you do. Everything else in the world keeps working as before.



Graph surgery. Observing X keeps the arrow $Z \to X$, so seeing X tells you something about Z. Setting X cuts that arrow; Z keeps its natural distribution.

In the mutilated graph, X carries no information about Z. So the only route by which x can change Y is the direct arrow. That is what we want to measure, and it is what a randomized trial measures, because a coin flip is a way of performing the surgery in the real world.

37.3 The mathematics

Structural causal models

Structural causal model (SCM)

An SCM consists of exogenous "noise" variables $U_1, \dots, U_n$, mutually independent with distribution $P(\mathbf{u})$, and endogenous variables $V_1, \dots, V_n$ each determined by a **structural equation**

$$V_i = f_i\big(\mathrm{pa}(V_i),\, U_i\big),$$

where $\mathrm{pa}(V_i)$ are the **parents** of V_i in a directed acyclic graph G.

Each structural equation is an *assignment*, not an algebraic identity: $Y := 2X + U_Y$ says "nature computes Y from X", and you may not rearrange it into an equation for X. Because the graph is acyclic and the noises are independent, the joint distribution factorizes along the graph:

$$P(v_1, \dots, v_n) = \prod_{i=1}^{n} P\big(v_i \mid \mathrm{pa}(v_i)\big).$$

This is the chain rule of Ch. 19 with most conditioning variables dropped, which is what the graph's missing arrows promise.

Intervention

The intervention $do(X = x)$ replaces the structural equation for X by the constant assignment $X := x$ and leaves every other equation unchanged. The **interventional distribution** $P(\mathbf{v} \mid do(x))$ is the distribution of the modified model. Graphically: delete all arrows into X.

Since only one factor changes, the modified model factorizes as the original one with X's factor removed. This is the **truncated factorization**:

$$P(\mathbf{v} \mid do(x)) = \prod_{i:\, V_i \neq X} P\big(v_i \mid \mathrm{pa}(v_i)\big)\Big|_{X = x}.$$

Result 1: the adjustment formula

Take the kidney-stone graph: $Z \to X$, $Z \to Y$, $X \to Y$. The observational joint is $P(z)P(x \mid z)P(y \mid x, z)$.

Adjustment for a confounder

If Z is the only common cause of X and Y (graph $Z \to X \to Y$, $Z \to Y$), then

$$P(y \mid do(x)) = \sum_{z} P(y \mid x, z)\, P(z).$$

Proof. By truncated factorization, the post-intervention joint of (Z, Y) is $P(z)\,P(y \mid x, z)$: the factor $P(x \mid z)$ is gone and x is fixed. Summing over z gives the result. ■

Compare it with plain conditioning, which by the law of total probability is

$$P(y \mid x) = \sum_{z} P(y \mid x, z)\, P(z \mid x).$$

The two formulas differ in one symbol: $P(z)$ versus $P(z \mid x)$. Conditioning weights each stratum by how common it is *among the people who got x*; intervention weights it by how common it is *in the population*. When X and Z are dependent, which is what makes Z a confounder, the weights differ.

The kidney stones, settled

Small stones are $357/700 = 0.51$ of patients, large ones 0.49. Adjusting:

$$P(\text{success} \mid do(A)) = 0.931 \times 0.51 + 0.730 \times 0.49 = 0.833,$$
$$P(\text{success} \mid do(B)) = 0.867 \times 0.51 + 0.688 \times 0.49 = 0.779.$$

Treatment A is better by about 5 percentage points. The raw comparison went the other way because doctors gave A to 77% of the large-stone (hard) cases but only 24% of the small-stone (easy) cases. A was handed the difficult patients.

For the blood-pressure story the graph is $X \to M \to Y$ (possibly with $X \to Y$ too). There are no arrows into X, so surgery changes nothing and $P(y \mid do(x)) = P(y \mid x)$: the aggregate table is the causal answer. Splitting by M would compute something else, a "controlled direct effect", which is a legitimate quantity but not the one a patient choosing a treatment needs.

Result 2: why randomization works

Randomization identifies the causal effect

If X is assigned by an independent random device R (so its structural equation is $X := f_X(R)$ with R independent of everything else, and X has no other parents), then

$$P(y \mid do(x)) = P(y \mid x).$$

Proof. Write $\mathbf{V}'$ for all variables other than X and R. Because R is a parent of X only, the factorization of the joint is

$$P(r, x, \mathbf{v}') = P(r)\, P(x \mid r) \prod_{V_i \in \mathbf{V}'} P\big(v_i \mid \mathrm{pa}(v_i)\big),$$

and no factor in the product mentions r. Summing over r gives $P(x) \prod_i P(v_i \mid \mathrm{pa}(v_i))$, and dividing by $P(x)$,

$$P(\mathbf{v}' \mid x) = \prod_{V_i \in \mathbf{V}'} P\big(v_i \mid \mathrm{pa}(v_i)\big)\Big|_{X = x}.$$

That is exactly the truncated factorization for $P(\mathbf{v}' \mid do(x))$. Summing both sides over everything except Y gives the claim. ■

The proof is short, but the idea is one of the great inventions of the twentieth century. R. A. Fisher's randomized field trials in the 1920s did not need to know what the confounders were. The coin cuts *all* incoming arrows at once, including the ones nobody thought of. That is why randomized controlled trials (RCTs) are the gold standard, and why "we controlled for age, sex and income" is always weaker: it cuts only the arrows you remembered.

Result 3: conditioning on a collider manufactures correlation

Collider bias, Gaussian case

Let $X, Y \sim \mathcal{N}(0,1)$ be independent and $C = X + Y + U$ with $U \sim \mathcal{N}(0,1)$ independent. Then, conditional on C,

$$\mathrm{Corr}(X, Y \mid C) = -\tfrac{1}{2}.$$

Proof. The vector (X, Y, C) is jointly Gaussian with covariance matrix

$$\mathbf{\Sigma} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 3 \end{pmatrix}.$$

For jointly Gaussian vectors, the conditional covariance of (X, Y) given C is the Schur complement $\mathbf{\Sigma}_{11} - \mathbf{\Sigma}_{12}\mathbf{\Sigma}_{22}^{-1}\mathbf{\Sigma}_{21}$ (the same formula that drives the Kalman filter mentioned in Ch. 21):

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \frac{1}{3}\begin{pmatrix} 1 \\ 1 \end{pmatrix}\begin{pmatrix} 1 & 1 \end{pmatrix} = \begin{pmatrix} 2/3 & -1/3 \\ -1/3 & 2/3 \end{pmatrix}.$$

The conditional correlation is $(-1/3)/(2/3) = -1/2$, and it does not depend on the value of C. ■

Two independent causes become *strongly* anticorrelated once you look within a slice of their common effect. If you knew C exactly with no noise ($U = 0$), the correlation would be -1: knowing X would pin down Y.

The back-door criterion

The three junctions combine into one rule for general graphs. A **path** between X and Y is any sequence of edges, ignoring direction. It is **blocked** by a set $\mathbf{Z}$ if it contains a fork or chain whose middle node is in $\mathbf{Z}$, or a collider whose middle node is *not* in $\mathbf{Z}$ (and has no descendant in $\mathbf{Z}$). A **back-door path** is a path from X to Y that starts with an arrow *into* X.

Back-door adjustment (Pearl, 1993)

If a set $\mathbf{Z}$ contains no descendant of X and blocks every back-door path from X to Y, then

$$P(y \mid do(x)) = \sum_{\mathbf{z}} P(y \mid x, \mathbf{z})\, P(\mathbf{z}).$$

Result 1 is the special case of a single fork. The rule tells you, by inspecting the graph alone, which variables to put in your regression or stratification. It also tells you when *no* set of measured variables works, for instance when the confounder is unmeasured. Then other tricks are needed: the **front-door criterion** (adjust through a fully observed mediator), or an **instrumental variable** (something that nudges X but touches Y only through X, like a lottery for school places).

? Can the arrows be read off the data?

Everything above assumed someone handed you the graph. With two variables, $X \to Y$ and $Y \to X$ produce the same family of joint distributions, so data alone cannot orient that edge. Yet with three or more variables, colliders leave a fingerprint (independent parents that become dependent when you condition on the child) and some arrows *can* be discovered from passive observation. How much of a causal graph is learnable, and with how much data, is an active research area built on conditional-independence tests; its information-theoretic core, conditional mutual information, is in Ch. 33.

The ladder of causation

Judea Pearl organizes causal questions into three rungs.

1. **Association**, $P(y \mid x)$: *what does seeing x tell me?* Statistics and machine learning live here.
2. **Intervention**, $P(y \mid do(x))$: *what if I do x?* Experiments, policies, control.
3. **Counterfactuals**, $P(y_{x'} \mid x, y)$: *I did x and saw y; what would have happened had I done x'?* Regret, blame, explanation, legal liability.

Each rung needs strictly more knowledge than the one below. The adjustment formula climbs from rung 1 to rung 2 using only the graph. Rung 3 needs the structural equations themselves, because it reasons about *this particular individual*, whose noise terms have already been revealed.

Counterfactual (abduction, action, prediction)

To compute what Y would have been had X been x', given evidence $\mathbf{e}$:

1. **Abduction.** Use $\mathbf{e}$ to infer the exogenous variables $\mathbf{U}$ (or their posterior $P(\mathbf{u} \mid \mathbf{e})$).
2. **Action.** Apply $do(X = x')$.
3. **Prediction.** Run the modified model with the inferred $\mathbf{U}$ and read off Y.

A linear counterfactual

Let $Z := U_Z$, $X := Z + U_X$, $Y := 2X + 3Z + U_Y$. We observe one unit with $(Z, X, Y) = (1, 2, 9)$. Abduction: $U_Z = 1$, $U_X = 1$, $U_Y = 9 - 4 - 3 = 2$. Action: set $X := 0$. Prediction: $Y = 0 + 3 \cdot 1 + 2 = 5$. Had this unit received $X = 0$, its outcome would have been 5, not 9.

In a linear model, the counterfactual difference $9 - 5 = 4 = 2 \times 2$ is the same for every unit. In nonlinear models it is not, and the population distribution of counterfactuals is usually *not* identifiable even from perfect experimental data.

? The questions no experiment can answer

"Did the drug *cause* this patient's recovery?" is a rung-3 question: the probability that she would not have recovered without it. Even an infinitely large RCT gives only bounds on it. Remarkably, the sharpest bounds come from a *linear program* over the unknown response types, and the bounds' tightness is governed by LP duality. That machinery is in Ch. 48.

Experimental design in one page

If you *can* intervene, do. A randomized experiment estimates the **average treatment effect**

$$\text{ATE} = E[Y \mid do(X = 1)] - E[Y \mid do(X = 0)]$$

by the difference of sample means $\bar{Y}_1 - \bar{Y}_0$, an unbiased estimator by Result 2. Its variance, from the two-sample results of Ch. 20, is $\sigma_1^2/n_1 + \sigma_0^2/n_0$. For a binary outcome near 50% success, $\sigma^2 \approx 0.25$, and detecting a 10-point improvement with the usual 5% significance and 80% power needs about

$$n = \frac{2\,(z_{0.975} + z_{0.8})^2\,\sigma^2}{\Delta^2} = \frac{2\,(1.96 + 0.84)^2 (0.25)}{0.1^2} \approx 392$$

patients per arm. Two design ideas sharpen this:

- **Blocking** (stratified randomization): randomize *within* levels of a known prognostic variable such as stone size. The estimator stays unbiased and its variance drops, because between-block variation no longer enters, exactly the stratification trick from Monte Carlo in Ch. 24.
- **Blinding**: neither patient nor assessor knows the arm, so expectations cannot open a new path $X \to$ belief $\to Y$.

37.4 The algorithm

Suppose the graph is drawn and the back-door criterion has given you an adjustment set $\mathbf{Z}$. Two classical estimators turn observational records $(x_i, \mathbf{z}_i, y_i)$, $i = 1, \dots, N$, into an estimate of the ATE.

Stratification (direct adjustment). Estimate the adjustment formula term by term:

```
def ate_stratified(x, z, y):
    """x: 0/1 treatment, z: hashable stratum label, y: outcome (numpy arrays)."""
    ate = 0.0
    for s in np.unique(z):
        m = (z == s)
        if x[m].all() or not x[m].any():
            raise ValueError(f"stratum {s} has only one arm: positivity fails")
        ate += (y[m & (x == 1)].mean() - y[m & (x == 0)].mean()) * m.mean()
    return ate
```

Inverse propensity weighting (IPW). Let $e(\mathbf{z}) = P(X = 1 \mid \mathbf{z})$ be the **propensity score**. Then

$$E[Y \mid do(X = 1)] = E\left[\frac{X\,Y}{e(\mathbf{Z})}\right], \qquad E[Y \mid do(X = 0)] = E\left[\frac{(1 - X)\,Y}{1 - e(\mathbf{Z})}\right].$$

To see the first, condition on $\mathbf{Z}$: $E[XY \mid \mathbf{z}] = P(X = 1 \mid \mathbf{z})\,E[Y \mid X = 1, \mathbf{z}] = e(\mathbf{z})\,E[Y \mid X = 1, \mathbf{z}]$. Divide by $e(\mathbf{z})$ and average over $P(\mathbf{z})$, and you have the adjustment formula. IPW builds a *pseudo-population* in which every treated patient counts $1/e$ times: a patient who received treatment despite having only a 10% chance of it stands in for ten patients like her. In that pseudo-population treatment is independent of $\mathbf{Z}$, just as in a trial.

Cost and scaling. Stratification costs $O(N)$ after grouping, but the number of strata grows as k^d for d covariates with k levels each. With ten binary covariates there are already 1024 cells, most of them nearly empty. Rosenbaum and Rubin's theorem (1983) rescues us: if $\mathbf{Z}$ is a valid adjustment set, so is the single number $e(\mathbf{Z})$. You can fit e by logistic regression and then stratify on it, match on it, or weight by it. One dimension instead of d.

Failure cases. Each of these breaks the estimate silently, with no error message.

1. **Positivity violations.** If some stratum contains only treated (or only untreated) units, the adjustment formula needs a quantity the data never show. In IPW this appears as $e \approx 0$ or 1 and enormous weights.
2. **Unmeasured confounding.** No estimator can adjust for a variable you did not record.
3. **Bad controls.** Adjusting for a mediator removes part of the effect; adjusting for a collider (or a descendant of one) *creates* bias. "Add every available covariate to the regression" can make the answer worse.

> **? Why do the weights explode?**
>
> IPW is an importance-sampling estimator in disguise: you have samples from the world as it is (doctors choosing), and you reweight them by a likelihood ratio to estimate an average in a world that does not exist (a coin choosing). When a propensity approaches 0 the estimator remains unbiased, yet its variance can grow without bound and a single patient can dominate the answer. Why that happens, and how to diagnose it with an *effective sample size*, is the subject of importance sampling in Ch. 38. The same reweighting lets a reinforcement-learning agent evaluate a policy it has never run, in Ch. 53.

37.5 The experiment

The script below builds a small world with a known answer. Severity Z makes doctors more likely to treat ($Z \to X$) and makes recovery less likely ($Z \to Y$). The treatment truly raises recovery probability by 10 points. Run it, then try to break each estimator.

```
import numpy as np
rng = np.random.default_rng(1)

N      = 100_000   # patients
EFFECT = 0.10      # true causal effect of treatment on recovery probability
CONF   = 0.60      # how strongly severity drives treatment choice (0 = none)
HARM   = 0.30      # how much severity lowers recovery

def world(randomize):
    Z = rng.random(N) < 0.5                        # severe case?
    if randomize:
        X = rng.random(N) < 0.5                    # coin flip: do(X)
    else:
        X = rng.random(N) < 0.5 + CONF * (Z - 0.5) # doctors treat the severe
    pY = 0.5 + EFFECT * X - HARM * Z
    Y = rng.random(N) < pY
    return Z, X, Y

Z, X, Y = world(randomize=False)
naive = Y[X].mean() - Y[~X].mean()

adj = 0.0                                          # back-door adjustment
for z in (False, True):
    s = Z == z
    adj += (Y[s & X].mean() - Y[s & ~X].mean()) * s.mean()

e = 0.5 + CONF * (Z - 0.5)                         # propensity score P(X=1|Z)
ipw = np.mean(X * Y / e) - np.mean((~X) * Y / (1 - e))

Zr, Xr, Yr = world(randomize=True)
rct = Yr[Xr].mean() - Yr[~Xr].mean()

print(f"true effect      {EFFECT:+.3f}")
print(f"naive difference {naive:+.3f}")
print(f"adjusted for Z   {adj:+.3f}")
print(f"IPW estimate     {ipw:+.3f}")
print(f"randomized trial {rct:+.3f}")
```

With the settings shown, one run prints a naive difference of about -0.085 (its expected value is exactly -0.08): a treatment that helps every patient *looks harmful*, because doctors aim it at the patients most likely to do badly. The adjusted and IPW estimates come out near $+0.09$ and the randomized trial near $+0.10$, each within sampling error of the truth.

Things to change:

- Set `CONF = 0`. Doctors now ignore severity, the arrow $Z \to X$ disappears, and the naive estimate becomes correct. Confounding needs *both* arrows of the fork.
- Set `CONF = 0.99`. Propensities become 0.005 and 0.995. Change the seed a few times and watch the IPW estimate wander far more than the stratified one. Then set `CONF = 1.0` and see the stratified estimator fail on an empty arm: positivity in action.
- Add a collider. Inside the randomized branch, compute `C = Xr | (Yr & (rng.random(N) < 0.3))` (a unit enters a follow-up study if treated, or sometimes if recovered) and recompute `rct` using only units with `C` true. A perfect experiment, ruined by whom you chose to look at.

37.6 The challenge

1. **Intuition.** A study finds that hospitalized patients with disease A rarely have disease B, and concludes that A protects against B. Draw a causal graph in which A and B are independent in the population yet negatively associated among hospital patients. Which junction is responsible, and what single change to the study design would remove the effect?

2. **Derivation.** For the front-door graph $X \to M \to Y$ with an unobserved confounder U pointing into both X and Y (and no other arrows), use truncated factorization to show that

$$P(y \mid do(x)) = \sum_{m} P(m \mid x) \sum_{x'} P(y \mid m, x')\, P(x').$$

Explain in words why M must be fully observed and must intercept every directed path from X to Y.

3. **Implementation.** Extend the experiment to three binary confounders Z_1, Z_2, Z_3, each pushing both treatment and outcome. Implement (a) stratification over all eight cells and (b) IPW with a propensity fitted by logistic regression via a few iterations of Newton's method (using only numpy). Compare their errors over 200 repetitions at $N = 500$ and $N = 50\,000$. At what point does stratification begin to suffer from empty cells?

4. **Open investigation.** In a linear-Gaussian SCM, the arrow direction between two variables cannot be learned from data. It can be learned if the noise is *non-Gaussian*, because only in the causal direction is the residual independent of the input. Simulate $Y := X + U$ with X and U uniform, regress both ways, and measure how dependent the residual is on the regressor (for example by the correlation between their squares). How does your ability to tell the directions apart degrade as the noise becomes more Gaussian, say a sum of k uniforms with growing k? There is no clean formula for the sample size you need; find out empirically.

37.7 Loose threads

This chapter gave you the grammar of causation and quietly skipped several hard parts.

- **Where do the graphs come from?** We assumed the arrows. In practice they come from domain knowledge, from experiments, and partly from data. How far data alone can go is the first mystery of 37.3; its toolkit of conditional-independence tests and conditional mutual information is in Ch. 33.
- **Is the back-door criterion the whole story?** No. Pearl's **do-calculus** is a set of three rewriting rules that turn a *do*-expression into an ordinary probability whenever that is possible at all, and it is known to be *complete*: if the rules fail, the effect is not identifiable from the graph. The completeness proof is well beyond this chapter.
- **What about rung 3?** Counterfactual quantities like the probability that a treatment was *necessary* are generally only partially identified. The second mystery of 37.3 points to the linear programs that compute their sharpest bounds, in Ch. 48.
- **Why reweighting is fragile.** The mystery of 37.4: IPW is importance sampling, and it degrades badly when propensities approach 0 or 1. The diagnosis is in Ch. 38, and the reinforcement-learning version (off-policy evaluation) in Ch. 53.

The kidney-stone table will never look the same again. Every pair of correlated numbers you meet now comes with a question attached: *which arrows made this?*

Chapter 38 — Monte Carlo: Computing with Randomness

> **Level 2 · Track B — Probability, Uncertainty, and Information Builds on:** Ch. 24 (§24.6 Monte Carlo methods), Ch. 19, Ch. 34 (stationary distributions) · **Leads to:** Ch. 35, Ch. 71, Ch. 90 · **Related:** Ch. 37, Ch. 81, Ch. 92 **Reading time:** ~30 min

38.1 The hook

In 1946 the mathematician Stanisław Ulam was recovering from an illness and playing a lot of solitaire. He wanted to know the chance that a randomly shuffled deck could be played out to the end. He tried the combinatorics and got nowhere: too many cases. Then a lazier, better idea arrived. *Just play a hundred games and count the wins.* He mentioned it to John von Neumann, who saw at once that the same trick would answer questions about neutrons diffusing through the core of a bomb, questions nobody could solve on paper. They needed a code name for a secret method that ran on chance. Nicholas Metropolis suggested the casino where Ulam's uncle liked to gamble: **Monte Carlo**.

You have met the basic idea already in Ch. 24, §24.6: an expectation $\mu = E[f(\mathbf{X})]$ is estimated by an average of f over random samples, the error falls as $\sigma/\sqrt{N}$ whatever the dimension, and variance-reduction tricks (antithetic pairs, control variates, stratification, importance sampling) shrink σ. That chapter treated Monte Carlo as an *integrator*. This one is about the hard part it took for granted.

Every Monte Carlo estimate begins with "draw $\mathbf{X}_1, \dots, \mathbf{X}_N$ from p". But what if you cannot draw from p?

Here is the situation that changed science. In 1953 Metropolis, the Rosenbluths and the Tellers wanted the average energy of a liquid: a few hundred hard disks in a box, in thermal equilibrium. Statistical mechanics says the probability of a configuration $\mathbf{x}$ (all the positions together, a point in a space of hundreds of dimensions) is

$$p(\mathbf{x}) = \frac{e^{-E(\mathbf{x})/kT}}{Z}, \qquad Z = \int e^{-E(\mathbf{x})/kT}\, d\mathbf{x}.$$

The energy $E(\mathbf{x})$ is easy to compute for any configuration. The normalizing constant Z is an integral over hundreds of dimensions: computing it is *harder* than the problem you started with. And without Z you do not even know p, only something proportional to it.

Modern Bayesian statistics lives in exactly this trap. A posterior (Ch. 35) is likelihood times prior divided by the evidence, and the evidence is an integral nobody can do. You can evaluate the shape of the distribution at any point you like, but you cannot normalize it, cannot invert its CDF, and in a hundred dimensions cannot even find where most of its mass lies.

So here is the question this chapter answers:

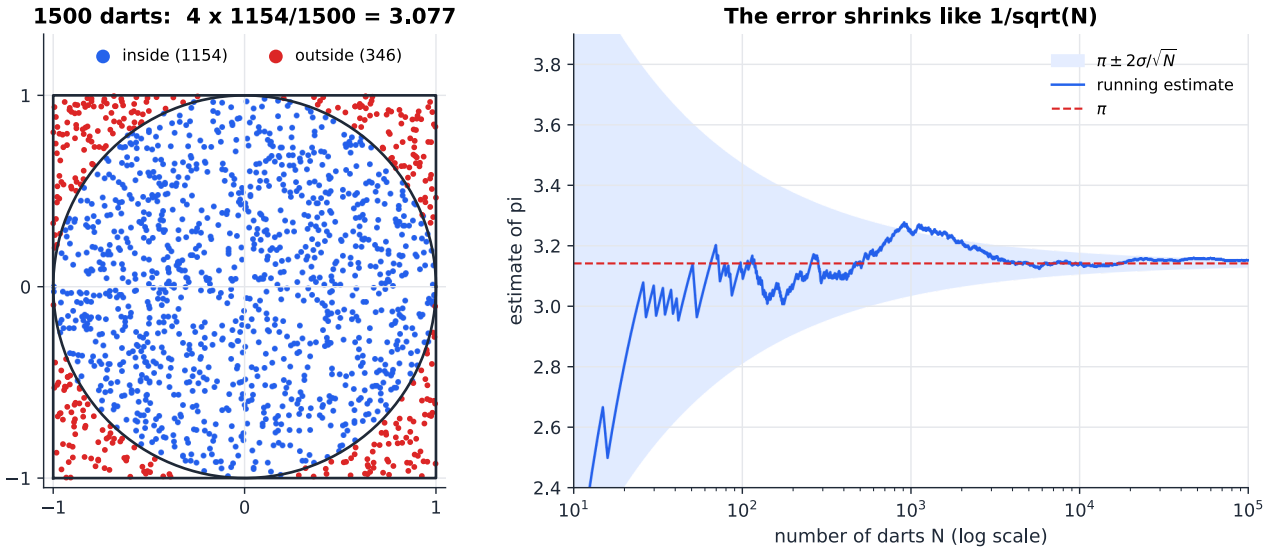
How do you draw samples from a probability distribution that you can evaluate only up to an unknown constant, in a space with hundreds of dimensions?

The answer, found on a 1950s computer called MANIAC, is a random walk with one carefully designed rule. It is one of the most cited algorithms of the twentieth century.

38.2 The big idea

Darts first

Throw darts uniformly at the square $[-1, 1]^2$. The fraction that land inside the unit circle estimates the area ratio $\pi/4$.



Estimating π with darts. Each dart is a Bernoulli trial with success probability $\pi/4$, so the estimate $4 \times (\text{hits}/N)$ has standard deviation $1.64/\sqrt{N}$: two correct digits need about 10^4 darts, three need about 10^6.

This works because we *can* sample the square uniformly, and the circle sits comfortably inside it, so most darts are useful. Two things go wrong when we try the same trick on a hard distribution.

The target hides. In a 100-dimensional space, the mass of a typical distribution is concentrated in a region that is an absurdly small fraction of any box you could draw around it. The volume of the unit ball in d dimensions, as a fraction of its enclosing cube, is $\pi^{d/2}/\big(2^d\,\Gamma(d/2+1)\big)$: 79% for $d=2$, 0.25% for $d=10$, and about 2×10^{-70} for $d=100$. Uniform darts almost never land anywhere interesting.

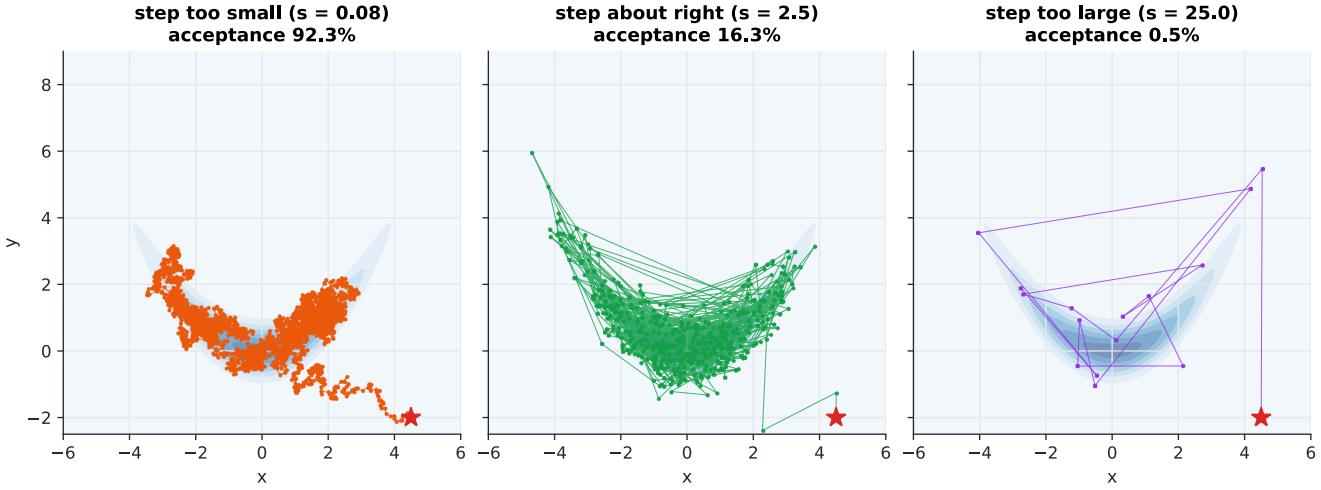
The target is unnormalized. We can compute $\tilde{p}(\mathbf{x}) = Z\,p(\mathbf{x})$ but not Z.

The hiker in the fog

Imagine a hiker on a foggy mountain range who can read only an altimeter showing the local "height" $\tilde{p}(\mathbf{x})$. She wants to spend time at each place in proportion to its height, so that a log of where she has been is a sample from p. She cannot see the landscape. She follows one rule:

> Propose a random step. If it goes uphill, take it. If it goes downhill, take it only with probability (new height)/(old height); otherwise stay put and record the current position again.

She never needs the total volume of the mountain range, only *ratios* of heights, and in a ratio the unknown Z cancels. She drifts uphill toward the mass, but keeps occasionally stepping down, so she does not just sit on the summit; she explores the slopes in exactly the right proportions. This is the **Metropolis algorithm**. Each recorded position depends on the previous one, so her log is a **Markov chain**, the object of Ch. 34, and we will design that chain so that its stationary distribution is p.



Three Metropolis chains of 3000 steps on the same banana-shaped density, all starting at the red star. Tiny steps are almost always accepted but crawl; huge steps are almost always rejected, so the chain freezes for hundreds of steps at a time; a moderate step explores the whole density.

Notice that the best-looking chain accepts only about one proposal in six. A high acceptance rate is not the goal; *exploration* is.

38.3 The mathematics

Sampling when you can: inverse transform and rejection

If X has a CDF F you can invert, then $F^{-1}(U)$ with U uniform has CDF F (inverse-transform sampling, Ch. 19). That covers the exponential, the Rayleigh, the Cauchy. For everything else, the first general tool is rejection.

Rejection sampling

Let $\tilde{p}\ge 0$ be an unnormalized target with $\int \tilde{p} = Z$, and let q be a density you can sample, with $\tilde{p}(\mathbf{x}) \le M\,q(\mathbf{x})$ for all $\mathbf{x}$. Repeat: draw $\mathbf{Y}\sim q$ and $U\sim\mathcal{U}(0,1)$; accept $\mathbf{Y}$ if $U \le \tilde{p}(\mathbf{Y})/\big(Mq(\mathbf{Y})\big)$. Then accepted values have density exactly $p=\tilde{p}/Z$, and each trial is accepted with probability Z/M.

Proof. For any set A,

$$P(\mathbf{Y}\in A,\ \text{accept}) = \int_A q(\mathbf{y})\,\frac{\tilde{p}(\mathbf{y})}{Mq(\mathbf{y})}\,d\mathbf{y} = \frac{1}{M}\int_A \tilde{p}(\mathbf{y})\,d\mathbf{y}.$$

Taking A to be the whole space gives $P(\text{accept}) = Z/M$. Dividing, $P(\mathbf{Y}\in A \mid \text{accept}) = \frac{1}{Z}\int_A \tilde{p}$, which is p. ∎

Geometrically, you throw darts uniformly under the curve Mq and keep those that fall under $\tilde{p}$: the π experiment with a smarter box. For a standard half-normal target, $\tilde{p}(x) = e^{-x^2/2}$ on $x\ge0$, with an Exp(1) proposal the best envelope constant gives an acceptance rate of $\sqrt{\pi/(2e)} = 0.760$. Very good.

Now the bad news. Take the target $\mathcal{N}(\mathbf{0},\mathbf{I}_d)$ and a proposal only slightly wider, $\mathcal{N}(\mathbf{0},\sigma^2\mathbf{I}_d)$. The ratio p/q is largest at the origin, where it equals σ^d, so the acceptance rate is σ^{-d}. With $\sigma=1.2$ and $d=100$: $1.2^{-100}\approx 1.2\times10^{-8}$. One accepted sample per hundred million tries, for a proposal that is "only" 20% too wide. **Rejection sampling dies exponentially with dimension.**

Importance sampling, revisited

Ch. 24 introduced importance sampling: draw from q, weight by $w = p/q$. When p is known only up to Z, use the **self-normalized** estimator

$$\hat{\mu} = \frac{\sum_{i=1}^{N} \tilde{w}_i \, f(\mathbf{X}_i)}{\sum_{i=1}^{N} \tilde{w}_i}, \qquad \tilde{w}_i = \frac{\tilde{p}(\mathbf{X}_i)}{q(\mathbf{X}_i)}, \quad \mathbf{X}_i \sim q.$$

Both numerator and denominator are Monte Carlo averages: divided by N, the numerator tends to $Z\mu$ and the denominator to Z. So Z cancels and $\hat{\mu} \to \mu$. The price is a small bias of order $1/N$ (a ratio of unbiased estimators is not unbiased), which is usually negligible.

The deeper problem is the one the effective sample size $\mathrm{ESS} = (\sum w_i)^2 / \sum w_i^2$ from Ch. 24 diagnoses. For large N, $\mathrm{ESS}/N \approx (E_q[w])^2 / E_q[w^2]$. In the same Gaussian example (target $\mathcal{N}(\mathbf{0}, \mathbf{I}_d)$, proposal $\mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I}_d)$), a direct Gaussian integral gives $E_q[w^2] = \left(\sigma^2 / \sqrt{2\sigma^2 - 1}\right)^d$. With $\sigma = 1.2$:

Dimension d	1	10	100
ESS/N	0.95	0.61	0.0074

At $d = 100$, a million weighted samples are worth about 7400 independent ones, and the situation gets exponentially worse from there. A handful of samples carry nearly all the weight. This is the same degeneracy that makes inverse propensity weighting fragile in Ch. 37: a patient with a tiny propensity is a sample with a huge weight.

Both independent-sampling methods fail for the same reason: they propose blindly, from a fixed q that knows nothing about where the target's mass is. The fix is to let each proposal depend on where you are now.

Markov chains that sample

A Markov chain on a continuous space is described by a **transition kernel** $K(\mathbf{x} \to \mathbf{y})$: the density of the next state $\mathbf{y}$ given the current state $\mathbf{x}$. A density π is **stationary** for K if a chain started in π stays in π:

$$\int \pi(\mathbf{x}) \, K(\mathbf{x} \to \mathbf{y}) \, d\mathbf{x} = \pi(\mathbf{y}) \quad \text{for all } \mathbf{y}.$$

(We write π for the target in this section, as is traditional in MCMC; it has nothing to do with 3.14159.) Checking this integral equation directly is hard. A local condition is much easier.

Detailed balance implies stationarity

If $\pi(\mathbf{x}) \, K(\mathbf{x} \to \mathbf{y}) = \pi(\mathbf{y}) \, K(\mathbf{y} \to \mathbf{x})$ for all $\mathbf{x}, \mathbf{y}$, then π is stationary for K.

Proof. Integrate both sides over $\mathbf{x}$:

$$\int \pi(\mathbf{x}) K(\mathbf{x} \to \mathbf{y}) \, d\mathbf{x} = \pi(\mathbf{y}) \int K(\mathbf{y} \to \mathbf{x}) \, d\mathbf{x} = \pi(\mathbf{y}),$$

because $K(\mathbf{y} \to \cdot)$ is a probability density and integrates to 1. ∎

Detailed balance says the *flow* of probability from $\mathbf{x}$ to $\mathbf{y}$ equals the flow back. A chain in equilibrium, filmed and played backwards, looks statistically the same; such chains are called **reversible**. Stationarity only requires the net flow into each state to balance; detailed balance asks for balance across every single pair, which is stronger but checkable one pair at a time.

Metropolis–Hastings

Now design a kernel with detailed balance for a target we know only as $\tilde{\pi} = Z\pi$. Start from any proposal density $q(\mathbf{y} \mid \mathbf{x})$, such as a Gaussian step around $\mathbf{x}$, and accept the proposal with probability

$$\alpha(\mathbf{x}, \mathbf{y}) = \min\left(1, \; \frac{\tilde{\pi}(\mathbf{y}) \, q(\mathbf{x} \mid \mathbf{y})}{\tilde{\pi}(\mathbf{x}) \, q(\mathbf{y} \mid \mathbf{x})}\right).$$

If the proposal is rejected, the chain stays at $\mathbf{x}$ (and $\mathbf{x}$ is recorded again: this repetition is essential). Only the ratio $\tilde{\pi}(\mathbf{y})/\tilde{\pi}(\mathbf{x}) = \pi(\mathbf{y})/\pi(\mathbf{x})$ appears, so **the normalizing constant is never needed**. For a symmetric proposal, $q(\mathbf{x} \mid \mathbf{y}) = q(\mathbf{y} \mid \mathbf{x})$, the q's cancel and we recover the hiker's rule: that is Metropolis's original 1953 algorithm, and Hastings generalized it to asymmetric proposals in 1970.

Metropolis–Hastings satisfies detailed balance

The Metropolis–Hastings kernel $K(\mathbf{x} \to \mathbf{y}) = q(\mathbf{y} \mid \mathbf{x}) \, \alpha(\mathbf{x}, \mathbf{y})$ for $\mathbf{y} \neq \mathbf{x}$, plus a point mass at $\mathbf{x}$ for rejections, satisfies detailed balance with respect to π. Hence π is stationary.

Proof. The point mass at $\mathbf{x}$ only ever connects $\mathbf{x}$ to itself, and detailed balance is trivial when $\mathbf{y} = \mathbf{x}$. For $\mathbf{y} \neq \mathbf{x}$, write $a = \pi(\mathbf{x}) q(\mathbf{y} \mid \mathbf{x})$ and $b = \pi(\mathbf{y}) q(\mathbf{x} \mid \mathbf{y})$, so that $\alpha(\mathbf{x}, \mathbf{y}) = \min(1, b/a)$ and $\alpha(\mathbf{y}, \mathbf{x}) = \min(1, a/b)$. Then

$$\begin{aligned} \pi(\mathbf{x}) K(\mathbf{x} \to \mathbf{y}) &= a \, \min(1, b/a) = \min(a, b), \\ \pi(\mathbf{y}) K(\mathbf{y} \to \mathbf{x}) &= b \, \min(1, a/b) = \min(a, b). \end{aligned}$$

The two flows are equal. ∎

The proof is three lines, and it explains the strange-looking formula. The acceptance probability is the *largest* one that equalizes the two flows: whichever direction is "overused" by the proposal gets throttled down to match the other.

Stationarity is not yet enough; the chain must also *reach* π from wherever it starts, and its time averages must converge. The relevant result, stated here without proof, extends the ergodic theorem for finite chains in Ch. 34:

Ergodic theorem for MCMC (stated)

If the chain is **irreducible** (from any start it can reach any set of positive π-probability) and **aperiodic**, and π is stationary, then for any f with $E_\pi|f| < \infty$ and almost any starting point,

$$\frac{1}{N}\sum_{t=1}^{N} f(\mathbf{X}_t) \longrightarrow E_\pi[f(\mathbf{X})] \quad \text{as } N \to \infty.$$

A Gaussian random-walk proposal on a target that is positive everywhere satisfies both conditions. So the algorithm is *correct*. Whether it is *fast* is another matter entirely.

The price of dependence

Successive MCMC samples are correlated, so N of them carry less information than N independent draws. Let ρ_k be the lag-k autocorrelation of the sequence $f(\mathbf{X}_t)$ in equilibrium. A calculation like the one for the variance of a sample mean of a stationary process (Ch. 21) gives, for large N,

$$\operatorname{Var}\left(\frac{1}{N}\sum_{t=1}^{N} f(\mathbf{X}_t)\right) \approx \frac{\sigma_f^2}{N}\,\tau, \qquad \tau = 1 + 2\sum_{k=1}^{\infty}\rho_k.$$

The **integrated autocorrelation time** τ is the number of chain steps that are worth one independent sample, and N/τ is the effective sample size of the chain. For a chain whose correlations decay geometrically, $\rho_k = \rho^k$, the sum is $\tau = (1+\rho)/(1-\rho)$: with $\rho = 0.9$, $\tau = 19$; with $\rho = 0.99$, $\tau = 199$.

This is where the step size bites. Tiny steps are accepted, but successive states are nearly identical, $\rho \approx 1$, and τ is huge. Huge steps are rejected, the chain repeats itself, $\rho \approx 1$ again. In between lies a sweet spot. For a random-walk Metropolis sampler on a d-dimensional Gaussian-like target, Roberts, Gelman and Gilks (1997) showed that as $d \to \infty$ the optimal proposal scale is about $2.38/\sqrt{d}$ times the target's standard deviation, which gives an acceptance rate of **0.234**. In low dimensions the optimum is higher (about 0.44 in one dimension). These are rules of thumb, not laws; the experiment below finds a different optimum for a curved target.

? How long is long enough?

The ergodic theorem promises convergence but not a speed. How many steps until a chain started at the red star has "forgotten" its start? For a finite chain the answer is governed by the gap between the largest and second-largest eigenvalue of its transition matrix (Ch. 34). For a sampler on a continuous space the transition kernel is an *operator*, its spectrum can be continuous, and bounding its gap is a genuinely hard problem in operator theory. The tools are in Ch. 90; for most real posteriors, nobody knows the answer.

Gibbs sampling in one paragraph

If you can sample each coordinate from its conditional distribution given all the others, $\pi(x_i \mid \mathbf{x}_{-i})$, then cycling through the coordinates and replacing each with a fresh conditional draw is a Metropolis–Hastings chain whose acceptance probability is exactly 1 (put $q = \pi(x_i \mid \mathbf{x}_{-i})$ into α and the ratio equals 1). That is **Gibbs sampling**, the workhorse behind early Bayesian software and image restoration. It shines when conditionals are simple and fails when coordinates are strongly correlated, because moving one axis at a time along a narrow diagonal ridge is like walking down a corridor sideways.

38.4 The algorithm

Random-walk Metropolis in its entirety:

```
def metropolis(log_target, x0, step, n, rng):
    x = np.asarray(x0, float); lp = log_target(x)
    chain = np.empty((n, x.size)); accepted = 0
    for t in range(n):
        y = x + step * rng.normal(size=x.size)      # symmetric Gaussian proposal
        lp_y = log_target(y)
        if np.log(rng.random()) < lp_y - lp:        # accept with prob min(1, ratio)
            x, lp = y, lp_y; accepted += 1
        chain[t] = x                                # record x even after a rejection
    return chain, accepted / n
```

Four engineering details matter more than they look.

1. **Work in logarithms.** In a hundred dimensions, $\tilde\pi(\mathbf{x})$ can be 10^{-300} and underflow to zero, making every ratio $0/0$. Compare $\log U$ with $\log\tilde\pi(\mathbf{y}) - \log\tilde\pi(\mathbf{x})$ instead. The `min(1, ·)` is implicit: if the difference is positive, the test always passes.
2. **Record rejections.** A common bug is to append only accepted states. That silently samples the wrong distribution, overweighting regions where moves are easy.
3. **Cost.** One target evaluation per step, $O(d)$ arithmetic for the proposal. The real cost is the number of steps, which is $N_{\text{eff}} \times \tau$, and τ for random-walk Metropolis typically grows like d (the step must shrink like $1/\sqrt{d}$, and a diffusion needs (distance/step)^2 steps to cross the target).
4. **Burn-in and diagnostics.** Early samples remember the starting point; discard them. Then check convergence, imperfectly: run several chains from dispersed starting points and compare their within-chain and between-chain variances (the Gelman–Rubin statistic $\hat R$, which should be close to 1), and estimate τ from the autocorrelations.

Failure cases.

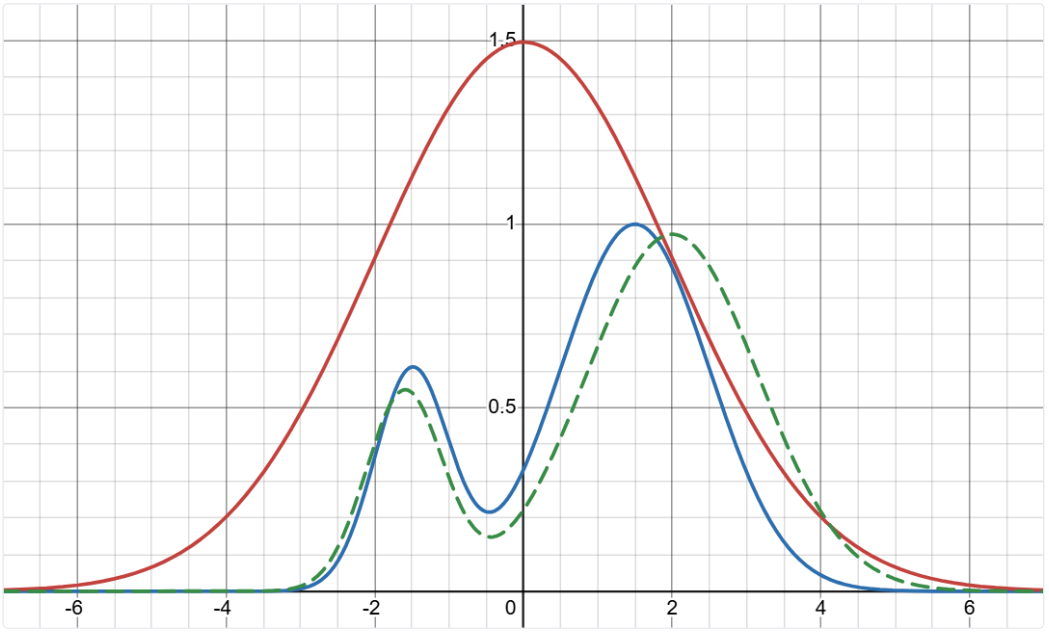
- **Multimodality.** If the target has two peaks separated by a valley of near-zero density, a random walk may never cross it. Every diagnostic computed from a single chain will look perfect, and the answer will be wrong by a factor of two. Several chains from different starts are the only cheap defence, and they are not a proof.
- **Bad scaling.** If the target is narrow in one direction and wide in another, an isotropic step that suits the narrow direction crawls along the wide one. The fix is to rescale the proposal by an estimate of the target's covariance (adaptive Metropolis).
- **Heavy tails and sharp ridges.** Curved, funnel-shaped posteriors (common in hierarchical Bayesian models) have regions where no single step size works.

> **? The trick of adding momentum**
>
> Random-walk Metropolis diffuses, so it needs about d steps to cross a d-dimensional target. **Hamiltonian Monte Carlo** gives each sample an imaginary momentum, lets it slide frictionlessly over the landscape $-\log\tilde{\pi}$ for a while, and then applies an accept/reject test. It can make long, nearly always accepted moves, and the number of steps it needs grows only about like $d^{1/4}$. Why does it work? Because Hamilton's equations preserve volume in phase space and conserve energy, so the Metropolis ratio is almost exactly 1; and the integrator that keeps those properties under discretization is not the obvious one. The physics, including symplectic structure, is in Ch. 92.

38.5 The experiment

Rejection sampling: fit the envelope

The blue curve below is an unnormalized bimodal target $\tilde{p}(x)$, with area $Z \approx 3.259$. The red curve is the envelope $M\,q(x)$ with $q = \mathcal{N}(0, 2^2)$ and $M = 7.5$. Rejection sampling is valid only if red lies above blue everywhere, and its acceptance rate is Z/M, about 43% here.



Rejection sampling with a Gaussian envelope. The dashed green curve is the acceptance probability $\tilde{p}/(Mq)$; it must stay below 1.

Change the `7.5` (in both the red and green lines) to `5` and find where the envelope dips below the target: there the sampler would produce too few samples, silently. The smallest valid M is about 7.29, set by the point $x = 2$. Then change the proposal width: replace `/8` by `/2` and `2\sqrt{2\pi}` by `\sqrt{2\pi}` (standard deviation 1). Push M as high as you like; the green curve still crosses 1 far out on the right, because the target's tail $e^{-(x-1.5)^2/2}$ eventually beats $e^{-x^2/2}$. A proposal with lighter tails than the target can never be fixed by a bigger constant.

Metropolis on the banana

The script samples the banana density of the figure in 38.2, whose true means are $E[x^2] = 4$ and $E[y] = 1$. It reports the acceptance rate and an effective sample size computed from the autocorrelation of y.

```
import numpy as np
rng = np.random.default_rng(0)

STEP   = 1.0       # proposal step size: try 0.1, 1.0, 3.0, 10.0
N      = 50_000    # chain length
BURN   = 1_000     # samples discarded at the start
START  = (4.5, -2.0)

def log_target(x, y):
    """Unnormalized log density of a curved 'banana'. True E[y] = 1."""
    return -x**2 / 8 - (y - 0.25 * x**2)**2 / (2 * 0.5**2)

def metropolis(n, step, start):
    chain = np.empty((n, 2))
    cur = np.array(start, float); lp = log_target(*cur); acc = 0
    for i in range(n):
        prop = cur + step * rng.normal(size=2)      # symmetric proposal
        lp_prop = log_target(*prop)
        if np.log(rng.random()) < lp_prop - lp:     # accept w.p. min(1, ratio)
            cur, lp = prop, lp_prop; acc += 1
        chain[i] = cur
    return chain, acc / n

def ess(v, max_lag=2000):
    """Effective sample size from the autocorrelation of one coordinate."""
    v = v - v.mean(); n = len(v); tau = 1.0
    for k in range(1, max_lag):
        rho = np.dot(v[:-k], v[k:]) / np.dot(v, v)
        if rho < 0.05: break
        tau += 2 * rho
    return n / tau

chain, acc = metropolis(N, STEP, START)
y = chain[BURN:, 1]
print(f"acceptance rate  {acc:.2f}")
print(f"estimate of E[y] {y.mean():.3f}   (true 1.000)")
print(f"estimate of E[x^2] {np.mean(chain[BURN:, 0]**2):.3f} (true 4.000)")
print(f"effective sample size for y: {ess(y):.0f} out of {len(y)}")
```

With `STEP = 1.0` one run accepts 40% of proposals and estimates $E[y] \approx 1.05$ with an effective sample size of roughly 500 out of 49 000: each independent-equivalent sample costs about 100 steps. Things to try:

- Sweep `STEP` through 0.1, 1.0, 2.5, 5.0, 10.0 and tabulate acceptance against ESS. On this curved target the best ESS comes at steps between about 2.5 and 5, with acceptance rates of only 6–16%, well below the textbook 0.234. Why might a two-dimensional banana prefer bold steps?
- With `STEP = 0.1` the acceptance rate is above 90% and the ESS collapses to a few dozen. Plot `chain[:, 1]` against step number to *see* the slow wander.
- Set `BURN = 0` and `N = 2000`, and compare estimates from `START = (4.5, -2.0)` with `START = (0, 0)`. How many steps does the start keep influencing the answer?
- Replace the banana by two well-separated Gaussian bumps centred at $(\pm 4, 0)$ and run from one of them. Look at the fraction of time spent on each side. Then run five chains from different starts.

38.6 The challenge

1. **Intuition.** A colleague runs Metropolis, keeps only the accepted proposals ("the rejected ones were never real samples") and finds the histogram too spread out compared with the known answer. Explain, without equations, which regions of the target are over-represented by this mistake, and why.

2. **Derivation.** For the independence sampler, a Metropolis–Hastings chain whose proposal $q(\mathbf{y})$ ignores the current state, write down the acceptance probability in terms of the importance weights $w(\mathbf{x}) = \tilde{\pi}(\mathbf{x})/q(\mathbf{x})$. Then show that if $w \le M$ everywhere, every step accepts with probability at least Z/M, and relate this to the acceptance rate of rejection sampling with the same envelope.

3. **Implementation.** Write a Gibbs sampler for the bivariate Gaussian with unit variances and correlation r, using the conditionals $x \mid y \sim \mathcal{N}(ry,\, 1 - r^2)$ and $y \mid x \sim \mathcal{N}(rx,\, 1 - r^2)$. Measure the lag-1 autocorrelation of the x-chain for $r = 0.5, 0.9, 0.99$ and compare it with r^2. Then implement random-walk Metropolis on the same target and find, for $r = 0.99$, the step size that maximizes ESS per target evaluation. Which method wins?

4. **Open investigation.** Take the bimodal target $\tilde{\pi}(x) = e^{-(x-a)^2/2} + e^{-(x+a)^2/2}$ and a Gaussian random-walk proposal with step 1. Measure, by simulation, the average number of steps before a chain started at $+a$ first crosses $x = 0$, for $a = 1, 2, 3, 4, 5$. How does it grow with a? Try to explain the growth with a barrier-height argument, and then design a modification (tempering, larger occasional jumps, or anything you invent) that makes the crossing time grow polynomially instead. There is no universal recipe for multimodal targets in high dimension.

38.7 Loose threads

The hook asked how to sample from a distribution known only up to a constant, in hundreds of dimensions. Metropolis–Hastings answers it: build a Markov chain whose only contact with the target is through ratios, prove detailed balance in three lines, and let the ergodic theorem turn the chain's time averages into expectations. What the chapter did not answer is how *well* this works.

- **Speed.** The first mystery: we proved the chain converges, but not how fast. Mixing-time bounds for continuous-space chains come from the spectral gap of an operator, in Ch. 90. The finite-state version is in Ch. 34.

- **Better proposals.** The second mystery: Hamiltonian Monte Carlo replaces blind diffusion by physics, and why its energy-conserving, volume-preserving dynamics are exactly what the acceptance test needs is a story about symplectic geometry, in Ch. 92.
- **Where does the randomness come from?** Every line of code above calls `rng.random()`, which is a deterministic program. Why a deterministic sequence can stand in for true chance, and how to tell when it cannot, is the subject of Ch. 81.
- **The constant we threw away.** MCMC never computes Z, yet in Bayesian model comparison (Ch. 35) Z *is* the answer: the evidence for a model. Estimating it requires further machinery (thermodynamic integration, nested sampling, annealed importance sampling).
- **Light transport.** Path tracing in computer graphics estimates an integral over all light paths in a scene. The same importance sampling, and even Metropolis itself (Metropolis light transport), turn up in Ch. 71.

? Is randomness necessary at all?

Quasi-Monte Carlo (Ch. 24) replaced random points by carefully spread deterministic ones and gained almost a factor of $\sqrt{N}$ in accuracy. Can a Markov chain be "derandomized" the same way? Can every randomized algorithm be replaced by a deterministic one with only polynomial slowdown? The second question is the famous open problem whether $\mathsf{BPP} = \mathsf{P}$, and the evidence for and against it runs through Ch. 81.

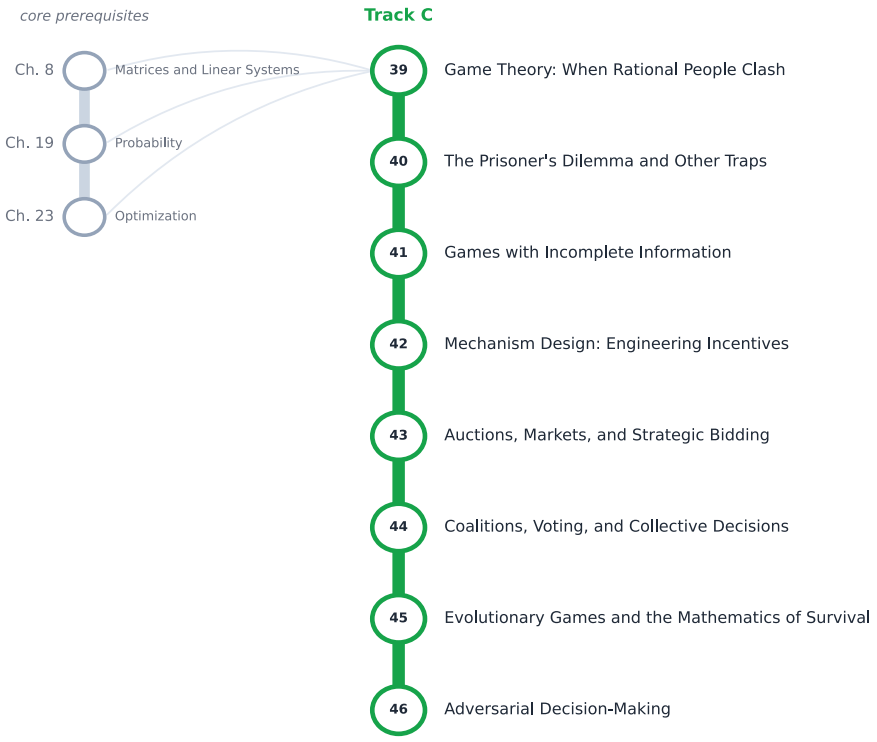
Track C — Game Theory and Strategic Intelligence

> **Level 2 — Specializations.** What happens when the thing you are optimizing against can think back.



Suggested reading order for Track C. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 8 — Matrices and Linear Systems
- Ch. 19 — Probability
- Ch. 23 — Optimization

Chapters

Ch.	Chapter	What it explores
39	Game Theory: When Rational People Clash	Normal-form games, dominant strategies, Nash equilibrium.
40	The Prisoner's Dilemma and Other Traps	Cooperation, repeated games, social dilemmas, evolutionary stability.
41	Games with Incomplete Information	Bayesian games, beliefs, signaling, screening.
42	Mechanism Design: Engineering Incentives	Social choice, incentive compatibility, truthful mechanisms.
43	Auctions, Markets, and Strategic Bidding	Auction formats, revenue, allocation, market design.
44	Coalitions, Voting, and Collective Decisions	Cooperative games, Shapley value, voting systems, bargaining.
45	Evolutionary Games and the Mathematics of Survival	Replicator dynamics, evolutionary stable strategies, population games.
46	Adversarial Decision-Making	Minimax, zero-sum games, regret, robust strategies.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 39 — Game Theory: When Rational People Clash

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 8, Ch. 19, Ch. 23 · **Leads to:** Ch. 40, Ch. 41, Ch. 46 · **Related:** Ch. 30, Ch. 48, Ch. 58 **Reading time:** ~25 min

39.1 The hook

Here is a game you can play with a lecture hall, a mailing list, or a newspaper's readership. Everybody writes down a whole number from 0 to 100. The winner is whoever comes closest to **two thirds of the average** of all the numbers. That's the whole game.

Take a minute and pick your number before reading on.

Most people start like this: "If everyone picks at random, the average is about 50, so I should say 33." A sharper player thinks one step further: "But everyone else will reason the same way and say 33, so I should say 22." The next player says 15, then 10, and the staircase keeps going down. Where does it stop?

A cold argument says: at zero. Two thirds of any average of numbers between 0 and 100 can be at most $66.\overline{6}$, so a guess above 67 is never better than a guess of 67, whatever anyone else does. A player who knows nobody guesses above 67 knows the target is at most $\frac{2}{3} \cdot 66.\overline{6} \approx 44.4$. Then 29.6, 19.8, 13.2, and so on. Each round of "I know that you know that I know..." shrinks the upper bound by another factor of $\frac{2}{3}$, and the only number that survives every round is 0.

Now the twist. When this game is played with real people, the winner almost never picked 0. Averages land somewhere in the twenties or thirties, and the person who guessed 0, the "perfectly rational" one, loses badly. Being right about rationality is not the same as being right about people.

Keep that tension in mind, because it runs through this whole track. Once you start optimizing against something that can think back, the best move stops being a property of the problem and becomes a property of what everyone believes about everyone else. In Ch. 23 the objective function sat still while you climbed it. Here it moves, because the other players are climbing too.

A second example, which we will come back to: a penalty kick in football. The kicker shoots left or right, and the keeper has to dive left or right before seeing the ball. If the kicker always goes left, a keeper who has done any homework always dives left. If the keeper always dives left, the kicker shoots right. Neither of them can be predictable, and yet each has to *choose*. What does a rational choice even mean when being predictable is exactly what loses?

By the end of this chapter you will be able to compute the answer to that question, down to the percentage. You will also see why the answer is stranger than it first looks.

39.2 The big idea

The basic move of game theory is to stop asking "what is the best action?" and ask "what is the best action **given what the others do**?" That conditional best choice is a **best response**. The central idea of the subject is then almost too simple to state:

> A situation is stable when every player is already playing a best response to everyone else.

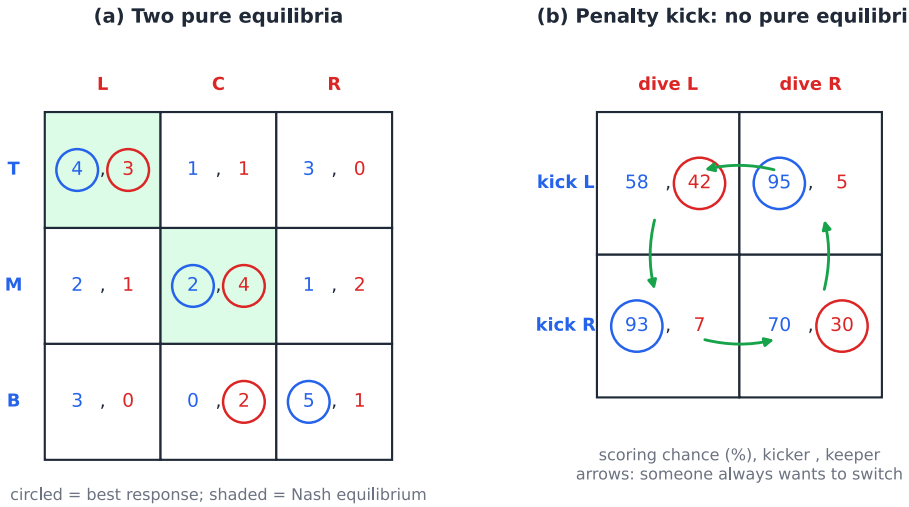
Nobody, looking back, wishes they had done something different, given what the others actually did. That's a **Nash equilibrium**: a profile of choices with no regrets.

An analogy helps. Picture a crowded beach on a hot afternoon. Everyone has spread a towel somewhere, and each person picked their spot given where the others already were: not too close to the loud group, not too far from the water. Once everyone is settled, nobody wants to get up and move. That doesn't make the arrangement *good* (maybe everyone would be happier if the loud group moved), but it is *stable*. Equilibrium is a statement about stability, not about how good the outcome is. Ch. 40 builds an entire chapter on how far apart those two ideas can be.

There are two ways to find stable outcomes, and they correspond to the two examples in the hook.

Elimination. Some choices are bad *no matter what* the others do. Throw them away. Once they're gone, other choices that used to be reasonable may become bad no matter what, so throw those away too. The 2/3 game is pure elimination: the staircase 100, 67, 44, 30, ... is a chain of "nobody sensible would ever..." arguments.

Mixing. In the penalty kick, nothing can be eliminated. Every pure action is a best response to *something*, and every pure action is beaten by *something*. The way out is to choose at random, with probabilities tuned so precisely that the opponent gains nothing from knowing them. The kicker cannot hide the probabilities, only the outcome of the coin flip. That turns out to be enough.



Best responses marked by circles: blue for the row player (largest in its column), red for the column player (largest in its row). A cell with both circles is a pure Nash equilibrium. In the penalty kick the circles never meet; the arrows show that from any cell, one of the players wants to switch.

39.3 The mathematics

Games in normal form

Normal-form game

A **game in normal form** consists of

- a finite set of **players** $N = \{1, \dots, n\}$;
- for each player i a set of **pure strategies** S_i;
- for each player a **payoff function** $u_i : S_1 \times \cdots \times S_n \to \mathbb{R}$.

A **strategy profile** is $s = (s_1, \dots, s_n)$. We write s_{-i} for everyone's choices except player i's, so $s = (s_i, s_{-i})$.

With two players and finite strategy sets, the whole game fits into two matrices. Let player 1 (the **row player**) have strategies indexed by $i = 1, \dots, m$ and player 2 (the **column player**) by $j = 1, \dots, n$. The payoffs are a_{ij} and b_{ij}, giving the **bimatrix** $(\mathbf{A}, \mathbf{B})$ that you see in the figure: each cell lists "row payoff, column payoff". If $\mathbf{A} + \mathbf{B} = \mathbf{0}$, what one player wins the other loses: a **zero-sum** game. The penalty kick, measured in scoring probability, is zero-sum after a shift (the keeper's payoff is $1-$ the kicker's), and that's all zero-sum requires.

Payoffs are utilities, not money. The only thing that matters about them is how a player ranks outcomes and lotteries over outcomes. That last part is a real assumption (von Neumann–Morgenstern expected utility), and we use it every time we average payoffs over randomness.

Dominance

Strict dominance

Strategy s_i **strictly dominates** s_i' if $u_i(s_i, s_{-i}) > u_i(s_i', s_{-i})$ for **every** s_{-i}. A strategy that is strictly dominated by some other strategy is never a best response, so a rational player never uses it.

In the left matrix of the figure, compare the column player's options C and R. Column C pays $(1, 4, 2)$ against rows (T, M, B); column R pays $(0, 2, 1)$. C is better in every row, so R is strictly dominated and the column player will never play it. Once R is gone, look at the row player: row T now pays $(4, 1)$ against (L, C), and row B pays $(3, 0)$. With R deleted, T strictly dominates B. Two rounds of elimination shrink the 3×3 game to a 2×2 core:

	L	C
T	$(4, 3)$	$(1, 1)$
M	$(2, 1)$	$(2, 4)$

This is **iterated elimination of strictly dominated strategies** (IESDS), the same procedure as the $2/3$ staircase. It's not free, though. The first round only needs the column player to be rational. The second round needs the row player to *know* the column player is rational. A third round would need the column player to know that the row player knows it, and so on. IESDS to depth k needs rationality to be "known" k levels deep. The $2/3$ game in a real lecture hall shows what happens when the hierarchy breaks off after one or two levels.

Nash equilibrium

Best response and Nash equilibrium

The **best-response set** of player i to s_{-i} is

$$\mathrm{BR}_i(s_{-i}) = \arg\max_{s_i \in S_i} u_i(s_i, s_{-i}).$$

A profile s^* is a **(pure) Nash equilibrium** if $s_i^* \in \mathrm{BR}_i(s_{-i}^*)$ for every player i, that is,

$$u_i(s_i^*, s_{-i}^*) \;\geq\; u_i(s_i, s_{-i}^*) \quad \text{for all } i \text{ and all } s_i \in S_i.$$

In a bimatrix game this is a finger exercise. Circle the largest a_{ij} in each column (the row player's best response to column j) and the largest b_{ij} in each row (the column player's best response to row i). Every cell with two circles is a pure equilibrium. The left game has two: (T, L) with payoffs $(4, 3)$ and (M, C) with payoffs $(2, 4)$. The players disagree about which one they prefer, and nothing in the definition says which one will happen. That *equilibrium selection* problem comes back again and again.

How do dominance and equilibrium fit together? The next result says elimination is safe: it never throws away a stable outcome.

IESDS preserves Nash equilibria

If s^* is a Nash equilibrium of a finite game, then no strategy s_i^* in it is ever deleted by iterated elimination of strictly dominated strategies.

Proof. Suppose the claim fails, and look at the **first** round in which some equilibrium strategy, say s_i^*, is deleted. It is deleted because some strategy t_i that is still present strictly dominates it against every profile of opponents' strategies that is still present. Since this is the first round to delete any part of s^*, all of s_{-i}^* is still present. Dominance then gives

$$u_i(t_i, s_{-i}^*) > u_i(s_i^*, s_{-i}^*),$$

which says s_i^* is not a best response to s_{-i}^*. That contradicts s^* being an equilibrium. ∎

So if IESDS leaves only one profile, that profile is the unique Nash equilibrium. (The argument shows every equilibrium survives, so at most one exists; the surviving profile is an equilibrium because every strategy that could beat it has been deleted for good reason. Checking that last step carefully is a nice exercise.) In the $2/3$ game, IESDS (with weak dominance in the first round) leaves only "everyone says 0".

When no pure equilibrium exists: mixed strategies

The penalty kick has no cell with two circles. Let's write it in scoring probabilities, with rows the kicker's choice and columns the keeper's dive:

$$\mathbf{S} = \begin{pmatrix} 0.58 & 0.95 \\ 0.93 & 0.70 \end{pmatrix}.$$

The numbers are illustrative, but they're in the range that studies of professional penalties report. Shooting to the side the keeper dives to still scores sometimes, and shooting to the open side almost always scores. The kicker maximizes $\mathbf{S}$, and the keeper minimizes it.

Mixed strategy

A **mixed strategy** for player i is a probability distribution σ_i over S_i. For a two-player game, row mixes are vectors $\mathbf{x} \in \Delta_m = \{\mathbf{x} \geq 0,\ \sum_i x_i = 1\}$ and column mixes are $\mathbf{y} \in \Delta_n$. The expected payoffs are

$$u_1(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\mathsf{T}} \mathbf{A} \mathbf{y}, \qquad u_2(\mathbf{x}, \mathbf{y}) = \mathbf{x}^{\mathsf{T}} \mathbf{B} \mathbf{y}.$$

A **mixed Nash equilibrium** is a pair $(\mathbf{x}^*, \mathbf{y}^*)$ in which each mix is a best response to the other.

Expected values here are the ordinary expectations of Ch. 19, with the players' coin flips independent. The bilinear form $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y}$ is all the linear algebra we need. The key structural fact about mixed equilibria is short to prove and it does all the work in practice.

Indifference principle (support lemma)

Let $(\mathbf{x}^*, \mathbf{y}^*)$ be a mixed Nash equilibrium, and let $v_1 = u_1(\mathbf{x}^*, \mathbf{y}^*)$. Then every pure strategy i with $x_i^* > 0$ earns exactly v_1 against $\mathbf{y}^*$:

$$(\mathbf{A}\mathbf{y}^*)_i = v_1 \quad \text{whenever } x_i^* > 0, \qquad (\mathbf{A}\mathbf{y}^*)_k \leq v_1 \text{ for all } k.$$

The same holds for player 2.

Proof. Write $w_k = (\mathbf{A}\mathbf{y}^*)_k$ for the payoff of pure row k against $\mathbf{y}^*$, and $w_{\max} = \max_k w_k$. Playing the pure row with the largest w_k is one of player 1's options, and since $\mathbf{x}^*$ is a best response, $v_1 \geq w_{\max}$. On the other hand,

$$v_1 = \sum_k x_k^* w_k \leq \sum_k x_k^* w_{\max} = w_{\max}.$$

So $v_1 = w_{\max}$, and the inequality in the middle holds with equality. That means $\sum_k x_k^*(w_{\max} - w_k) = 0$. Each term is a nonnegative weight times a nonnegative gap, so each term is zero: wherever $x_k^* > 0$ we must have $w_k = w_{\max} = v_1$. ∎

Read that theorem backwards and it becomes a recipe, along with the surprising core of mixed play. **In a mixed equilibrium, you randomize so that the *other* player is indifferent.** The keeper's probabilities aren't chosen to make the keeper happy. They're chosen to leave the kicker with nothing to exploit.

Solving the penalty kick

Let the kicker shoot left with probability p and the keeper dive left with probability q. Neither pure profile is stable, so both must mix, and by the indifference principle each must make the other indifferent.

Keeper's q makes the kicker indifferent between shooting left and right:

$$0.58q + 0.95(1-q) = 0.93q + 0.70(1-q) \implies 0.25 = 0.60q \implies q = \tfrac{5}{12} \approx 0.417.$$

Kicker's p makes the keeper indifferent between diving left and right:

$$0.58p + 0.93(1-p) = 0.95p + 0.70(1-p) \implies 0.23 = 0.60p \implies p = \tfrac{23}{60} \approx 0.383.$$

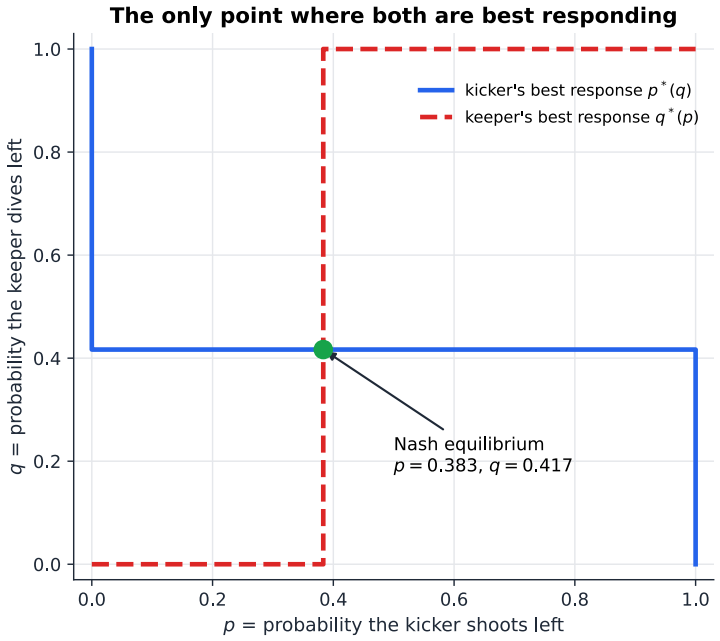
The scoring probability at equilibrium is $0.95 - 0.37 \cdot \frac{5}{12} \approx 0.796$, the same whichever way the kicker shoots, as the theorem promised.

For any 2×2 game with no pure equilibrium, the same two lines of algebra give a closed form. For the row player's payoffs a_{ij}, the column mix that makes rows indifferent is

$$q^* = \frac{a_{22} - a_{12}}{a_{11} - a_{12} - a_{21} + a_{22}},$$

and symmetrically for p^* using b_{ij}. Notice something odd: **the keeper's equilibrium probability depends only on the kicker's payoffs.** If the kicker gets better at shooting left (raise a_{11}), the kicker's own mix doesn't change at all. The keeper's does. People find this hard to believe the first time, and the experiment section lets you test it.

The best-response curves make it visible. The kicker's best response is a step function of q: shoot left if $q < 5/12$, right if $q > 5/12$, anything at all if $q = 5/12$. The keeper's best response is a step function of p. The two staircases cross at one point only.



Each curve is one player's best response to the other's mix. The only point lying on both is the mixed Nash equilibrium $(p, q) = (23/60,\ 5/12)$.

The left game of the figure has a mixed equilibrium too, on top of its two pure ones. The same algebra on the 2×2 core gives $\mathbf{x}^* = (3/5,\ 2/5)$ over (T, M) and $\mathbf{y}^* = (1/3,\ 2/3)$ over (L, C), with payoffs $(2,\ 2.2)$. That is *worse for both players* than either pure equilibrium. The players randomize to stay unexploitable, and they sometimes miscoordinate as a result.

Does an equilibrium always exist?

The penalty kick had no pure equilibrium but did have a mixed one. Is that luck?

Nash (1950)

Every finite game, with finitely many players and finitely many pure strategies each, has at least one Nash equilibrium in mixed strategies.

We won't prove it here. The idea, though, is clean. Collect all players' mixes into one point σ of a product of simplices, a compact convex set. Define a continuous map f that nudges each player's mix toward strategies that do better than the current mix. A fixed point $f(\sigma) = \sigma$ is a profile where no nudge helps, which is exactly an equilibrium. Then a theorem from topology guarantees that the fixed point exists.

? A theorem that promises without delivering

Nash's proof uses Brouwer's fixed-point theorem: every continuous map of a disc (or simplex, or ball) into itself fixes some point. The proof tells you an equilibrium *exists* but gives you no way to find it, and nobody knows how to make it constructive at a cost that stays polynomial. Why must a continuous map of a disc fix a point, while a map of an annulus need not? The answer is topological, and it's waiting in Ch. 58.

For **zero-sum** games there is an older and sharper result. Von Neumann's minimax theorem (1928) says

$$\max_{\mathbf{x}\in\Delta_m}\ \min_{\mathbf{y}\in\Delta_n}\ \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} \;=\; \min_{\mathbf{y}\in\Delta_n}\ \max_{\mathbf{x}\in\Delta_m}\ \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y}.$$

The number in the middle, 0.796 for the penalty kick, is the **value** of the game. In zero-sum games, equilibrium is the same thing as security: each side guarantees itself the value, however clever the opponent is. The general-sum game on the left has no such guarantee.

Fix $\mathbf{y}$ and the inner maximum is a linear program, and so is the outer minimization. That's no accident: the minimax theorem and linear-programming duality are two views of the same fact, which is why a zero-sum game can be solved with the simplex method of Ch. 23. The duality side of the story is Ch. 48, and the adversarial side is Ch. 46.

39.4 The algorithm

Pure equilibria. For an $m \times n$ bimatrix, compute the column maxima of $\mathbf{A}$ and the row maxima of $\mathbf{B}$, then check each cell. That costs $O(mn)$, which is optimal, since you have to look at every payoff anyway.

Mixed equilibria: support enumeration. The indifference principle turns equilibrium-finding into linear algebra *once you guess the supports*. Fix a set I of rows and a set J of columns that will get positive probability. For a nondegenerate game, $|I| = |J| = k$. Then solve two square linear systems:

- find $\mathbf{y}$ on J with $\sum_j y_j = 1$ that makes every row in I earn the same v_1;
- find $\mathbf{x}$ on I with $\sum_i x_i = 1$ that makes every column in J earn the same v_2.

Accept the pair if both mixes are nonnegative and no pure strategy *outside* the support does better than v_1 (resp. v_2).

```
import itertools
import numpy as np

def support_enumeration(A, B, tol=1e-9):
    """All Nash equilibria of a nondegenerate bimatrix game (A: row payoffs, B: column payoffs)."""
    m, n = A.shape
    found = []
    for k in range(1, min(m, n) + 1):
        for I in itertools.combinations(range(m), k):
            for J in itertools.combinations(range(n), k):
                # column mix y on J makes row indifferent on I; row mix x on I makes column indifferent on J
                My = np.block([[A[np.ix_(I, J)], -np.ones((k, 1))], [np.ones((1, k)), np.zeros((1, 1))]])
                Mx = np.block([[B[np.ix_(I, J)].T, -np.ones((k, 1))], [np.ones((1, k)), np.zeros((1, 1))]])
                rhs = np.r_[np.zeros(k), 1.0]
                try:
                    sy, sx = np.linalg.solve(My, rhs), np.linalg.solve(Mx, rhs)
                except np.linalg.LinAlgError:
                    continue
                x, y = np.zeros(m), np.zeros(n)
                x[list(I)], y[list(J)] = sx[:k], sy[:k]
                if x.min() < -tol or y.min() < -tol:
                    continue
                # no profitable deviation outside the support
                if (A @ y).max() <= sy[k] + tol and (x @ B).max() <= sx[k] + tol:
                    found.append((x.round(4), y.round(4)))
    return found

A = np.array([[4, 1, 3], [2, 2, 1], [3, 0, 5]])
B = np.array([[3, 1, 0], [1, 4, 2], [0, 2, 1]])
for x, y in support_enumeration(A, B):
    print(x, y)
```

On the 3×3 game of the figure it prints exactly three equilibria: (T, L), (M, C), and the mix $\mathbf{x} = (0.6, 0.4, 0)$, $\mathbf{y} = (0.333, 0.667, 0)$. No support involving B or R survives, which matches the dominance argument.

Complexity. For each k there are $\binom{m}{k}\binom{n}{k}$ support pairs, and each costs a $k \times k$ solve. Summed over k, that's $\binom{m+n}{m}$ support pairs, exponential in the game's size. Ten strategies each already means about 185,000 pairs. Smarter pivoting methods (Lemke–Howson, a cousin of the simplex method of Ch. 23) find *one* equilibrium much faster on typical games, but there are known games where they take exponentially many pivots.

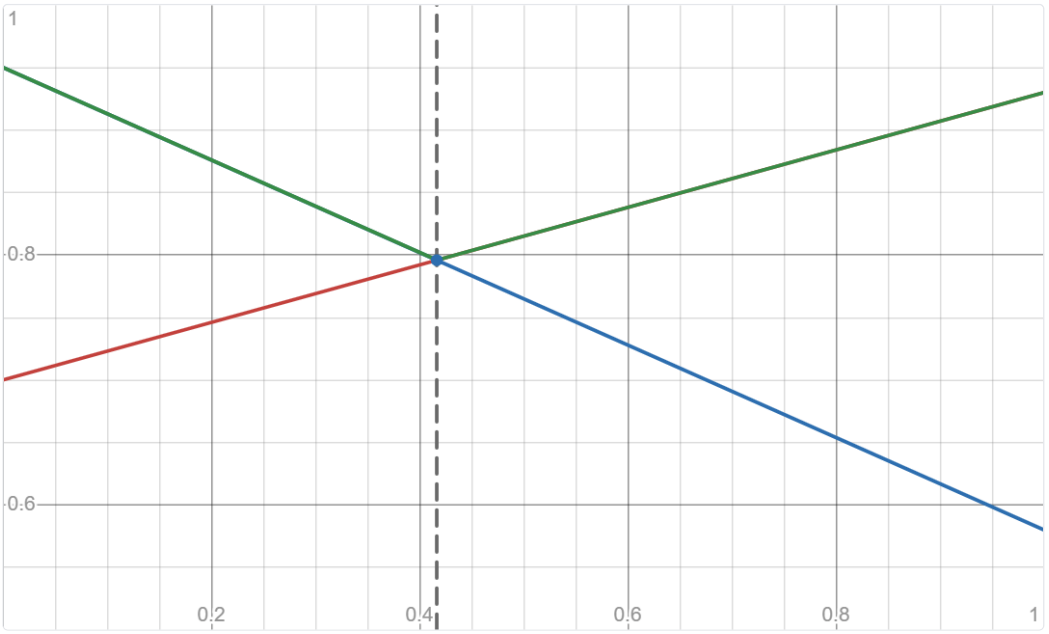
Failure cases.

- *Degenerate games* (ties in payoffs, or a mixed strategy with k-element support whose best responses number more than k) can have a whole continuum of equilibria. The square systems then become singular, and the code above silently skips the continuum.
- *Numerical tolerance.* An equilibrium probability of 10^{-12} is either a rounding error or a real but tiny weight. The test `x.min() < -tol` has to decide which, and the choice of `tol` changes the answer on badly scaled payoffs.
- *Zero-sum games* don't need any of this: they reduce to a single linear program and are solvable in polynomial time.

> **? Hard to find, easy to check**
>
> Checking a proposed equilibrium takes one matrix–vector product. Finding one in a general two-player game is **PPAD-complete** (Daskalakis–Goldberg–Papadimitriou, Chen–Deng, 2006): as hard as any problem whose answer is guaranteed by a "follow the path to its end" parity argument. Nobody believes it can be done in polynomial time, but nobody can prove that either. What PPAD is, and why "a solution is guaranteed to exist" doesn't make a problem easy, belongs to Ch. 30.

39.5 The experiment

Drag the indifference point. The graph shows the kicker's scoring probability as a function of the keeper's mix q (horizontal axis). The blue line is "shoot left", the red line is "shoot right", and the thick green curve is the kicker's best, the upper envelope. The keeper wants to sit where that envelope is lowest, which is the crossing point.



The kicker's scoring chance against a keeper who dives left with probability x; the keeper picks the lowest point of the green envelope, $x = 5/12$.

Change the **0.58** in both the blue and green lines to 0.70 (the kicker gets better at hitting a covered left corner). Where does the crossing move, and whose equilibrium mix just changed? Then change **0.95** to 0.85 and watch what happens when the crossing slides near $x = 0$ or $x = 1$. When the lines stop crossing inside $[0, 1]$, one shot dominates the other and the mixed equilibrium disappears.

Watch players learn. Equilibrium is a static notion. Do players who don't know any game theory ever reach it? In **fictitious play** (Brown, 1951), each player best-responds to the *empirical frequency* of the opponent's past actions, as if the opponent were a fixed coin.

```
import numpy as np
import matplotlib.pyplot as plt

# Scoring probability: rows = kicker (L, R), columns = keeper (L, R).
S = np.array([[0.58, 0.95],
              [0.93, 0.70]])          # KNOB: change these four numbers
rounds = 5000                          # KNOB: how long they learn
kick_counts = np.array([1.0, 0.0])     # KNOB: initial "memories"
dive_counts = np.array([0.0, 1.0])

p_hist, q_hist = [], []
for t in range(rounds):
    q = dive_counts / dive_counts.sum()       # kicker's belief about the keeper
    p = kick_counts / kick_counts.sum()       # keeper's belief about the kicker
    kick = np.argmax(S @ q)                   # kicker maximises scoring chance
    dive = np.argmin(p @ S)                   # keeper minimises it
    kick_counts[kick] += 1
    dive_counts[dive] += 1
    p_hist.append(kick_counts[0] / kick_counts.sum())
    q_hist.append(dive_counts[0] / dive_counts.sum())

print(f"long-run: kicker shoots left {p_hist[-1]:.3f}, keeper dives left {q_hist[-1]:.3f}")
fig, ax = plt.subplots(figsize=(7, 4))
ax.semilogx(p_hist, label="kicker: fraction left")
ax.semilogx(q_hist, label="keeper: fraction left")
ax.axhline(23/60, ls=":", c="grey"); ax.axhline(5/12, ls=":", c="grey")
ax.set_xlabel("round"); ax.set_ylabel("empirical frequency"); ax.legend()
plt.show()
```

After 5,000 rounds the frequencies come out at about 0.386 and 0.425, closing in on $23/60$ and $5/12$ slowly and with a sawtooth. Each player, round by round, is completely predictable (it's an `argmax`!), yet the *frequencies* approach the equilibrium mix. Things to try:

- Increase `rounds` to 10^5. How fast does the error shrink?
- Replace `S` with a non-zero-sum game by giving the keeper its own payoff matrix (and `argmax` for both). Try the coordination core of the left figure.
- Try Shapley's 3×3 game, where the row player gets $\left(\begin{smallmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{smallmatrix}\right)$ and the column player gets $\left(\begin{smallmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{smallmatrix}\right)$. Watch whether the frequencies settle down.

39.6 The challenge

1. **Intuition.** In the penalty kick, the kicker practises and her accuracy into a covered right corner rises from 0.70 to 0.80. Without calculating, decide which player's equilibrium mix changes and in which direction. Then explain in one paragraph why a player's improvement shows up in the *opponent's* behaviour.

2. **Derivation.** For the 2/3 game with n players choosing real numbers in $[0, 100]$, show that "everyone chooses 0" is the unique Nash equilibrium. Then change the rule to "closest to $\frac{2}{3}$ of the average **plus 10**", and find the new equilibrium and the number of elimination rounds it takes to get there to within 0.1.

3. **Implementation.** Extend `support_enumeration` to detect degenerate cases: report when a square system is singular *and* the game has a pure strategy that ties with the support's payoff. Test it on the game $\mathbf{A} = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 2 \end{smallmatrix}\right)$, $\mathbf{B} = \left(\begin{smallmatrix} 1 & 1 \\ 2 & 0 \end{smallmatrix}\right)$ and describe the full set of equilibria you find.

4. **Open investigation.** Generate random $n \times n$ bimatrix games with independent uniform payoffs and count their Nash equilibria (pure and mixed) for $n = 2, \dots, 8$. How does the average count grow with n? How often is it exactly one? Then compare with how often fictitious play converges on the same games. Is there a simple property of a random game that predicts when learning succeeds?

39.7 Loose threads

This chapter gave you the core vocabulary (strategies, payoffs, dominance, best responses, Nash equilibrium, mixing) and one genuinely useful tool, the indifference principle. Along the way it stepped around several holes.

- **Existence without construction.** Nash's theorem guarantees an equilibrium, but its proof is a fixed-point argument that doesn't tell you where the fixed point is. Why that argument works at all is topology (Ch. 58). Why turning it into an algorithm seems to need exponential time is complexity theory (Ch. 30).
- **Which equilibrium?** The left game has three equilibria. The theory as built here can't say which one players will reach. History, focal points, learning dynamics and evolution all have a say. Ch. 40 and Ch. 45 start to break the tie.
- **The 2/3 game was not "solved".** Real people stop after one or two levels of reasoning. The equilibrium predicts that *everyone* plays 0, and it fails as a forecast even though every individual step of the argument is valid. Models of bounded "level-k" reasoning take that failure seriously.
- **Everyone knew the payoffs.** The kicker knew the keeper's matrix and vice versa. Take that away, so that you don't know whether the other player is strong or weak, honest or bluffing, and you need beliefs about *types*. That's Ch. 41.
- **Mixed strategies are strange.** Does a professional kicker really flip a mental coin? One modern reading says the probabilities describe the *opponent's uncertainty* about you rather than your own randomness. That reading becomes precise once beliefs are on the table in Ch. 41.

> **? Why does learning sometimes fail?**
>
> Fictitious play converges to the mixed equilibrium in every two-player zero-sum game (Robinson, 1951). In Shapley's 3×3 game from the experiment it cycles forever, with longer and longer runs, and the frequencies never settle. What separates games where simple learning finds equilibrium from games where it can't is a story about dynamics on the simplex, told in Ch. 45 and Ch. 46.

Chapter 40 — The Prisoner's Dilemma and Other Traps

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 39, Ch. 10, Ch. 19 · **Leads to:** Ch. 41, Ch. 45 · **Related:** Ch. 34, Ch. 46, Ch. 52 **Reading time:** ~25 min

40.1 The hook

Your laptop and your neighbour's phone share one Wi-Fi channel. When both want to transmit, the 802.11 protocol tells each of them to wait a random number of slots first, drawn from a *contention window*, and to double that window after every collision. It's a polite protocol: everyone backs off, collisions stay rare, and the channel stays busy with useful traffic.

Now suppose you edit your driver so that it always uses the smallest possible window. Against polite neighbours you win nearly every race for the channel, and your throughput jumps. This isn't hypothetical; papers in the early 2000s measured exactly this kind of "greedy" MAC misbehaviour. So why doesn't everyone do it? If *everyone* does it, every slot is a collision, the doubling rule never gets a chance to work, and the whole channel collapses. Each of you is better off cheating whatever the others do, and all of you together are worse off when everyone cheats.

That structure has a name, and a famous story. Two suspects are held in separate cells. Each is offered a deal: testify against the other and walk free, unless the other also testifies, in which case both get a reduced sentence. If both stay silent, the police can only convict them of something minor. Whatever your partner does, testifying shortens *your* sentence. So both testify, and both serve far longer than if they had kept quiet.

Overfishing, arms races, price wars, antibiotic overuse, doping in sport, climate negotiations, and every group project where someone coasts: the same pattern appears again and again. Individual rationality, applied carefully and correctly, leads to collective disaster.

Yet the real world is full of cooperation. Wi-Fi mostly works. Neighbouring fishing villages sometimes manage their stocks for centuries. In 1980 the political scientist Robert Axelrod invited game theorists to submit computer programs to play the dilemma against each other, two hundred rounds a match. The winner was the shortest program submitted, four lines long, written by Anatol Rapoport: *cooperate first, then do whatever the other player did last time*. Axelrod ran the tournament again with 62 entrants who knew the result. Tit-for-tat won again.

How can a strategy that never beats any opponent head-to-head (it can at best tie) win the whole tournament? And how can cooperation survive when defection is always individually better? The answer lies in one variable the one-shot story hides: **the future**.

40.2 The big idea

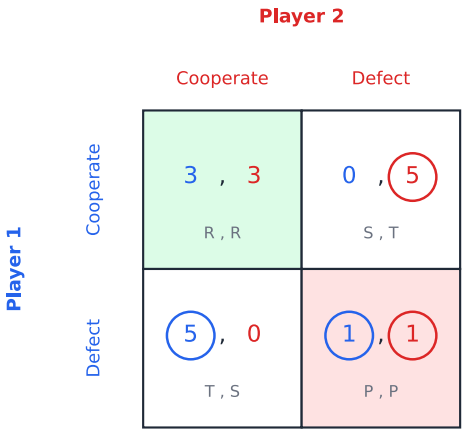
The prisoner's dilemma is a trap because the game is played **once**. Defecting has no consequences beyond the current payoff. Repeat the game, so the same two players meet again and again, and today's choice becomes a message about tomorrow. A defection can be punished, and cooperation can be rewarded. Whether that's enough depends on how much the players care about what comes next.

Think of a restaurant on a highway versus one in your own neighbourhood. The highway diner can serve bad food to travellers it will never see again. The neighbourhood café can't, because its customers come back, or don't. Same incentives, same people. The only difference is the **shadow of the future**. Game theorists measure it with a single number, the discount factor $\delta \in [0, 1)$: the weight of tomorrow's payoff relative to today's, or equivalently the probability that there will be a tomorrow at all.

The big idea of this chapter in one line:

> Cooperation is sustainable when the long-run gain from continued cooperation outweighs the one-time gain from betrayal, and that comparison has an exact threshold in δ.

The second big idea is about *populations* rather than pairs. Instead of asking what a rational player should do, ask which behaviours **survive** when strategies reproduce in proportion to their payoffs. A strategy that can't be invaded by a small group of mutants is *evolutionarily stable*. Remarkably, the answers from rationality and from evolution often coincide, and the places where they don't are where the most interesting biology and engineering happen.



Why it is a trap

T > R	temptation beats reward
P > S	punishment beats being the sucker
R > P	mutual cooperation beats mutual defection
green	what both would choose together
red	the only Nash equilibrium
circles	best responses: Defect, every time

The canonical numbers $T = 5$, $R = 3$, $P = 1$, $S = 0$. Every best-response circle falls on Defect, so mutual defection (red) is the only equilibrium, though both players prefer mutual cooperation (green).

40.3 The mathematics

The one-shot dilemma

Prisoner's dilemma

A symmetric 2×2 game with actions Cooperate (C) and Defect (D) and row-player payoffs

	C	D
C	R	S
D	T	P

is a **prisoner's dilemma** if $T > R > P > S$ (Temptation, Reward, Punishment, Sucker). For repeated play one also asks $2R > T + S$, so that taking turns exploiting each other is worse than steady cooperation.

The analysis takes one line. Against C, defecting gives $T > R$; against D, defecting gives $P > S$. So **D strictly dominates C**, and by the result of Ch. 39 the unique Nash equilibrium is (D, D) with payoffs (P, P). But (C, C) gives (R, R) with $R > P$ for both. The equilibrium is **Pareto-dominated**: some other outcome is better for everybody.

That's the precise sense of "trap". Nash equilibrium is a statement about stability, and stability has nothing to do with efficiency.

Other traps in the same family

Changing the order of T, R, P, S gives a small zoo of social dilemmas, each with its own personality.

- **Stag hunt** ($R > T \geq P > S$): hunting the stag together pays most, but hunting a hare alone is safe. Both (C, C) and (D, D) are equilibria. The trap is *trust*: cooperation is stable, but risky if you doubt your partner.
- **Chicken / Hawk–Dove** ($T > R > S > P$): two drivers head at each other. Swerving is humiliating, but crashing is worst. The pure equilibria are "one swerves, one doesn't", and there's a mixed equilibrium in which crashes happen with positive probability.
- **Public goods** (n players): each player can contribute 1 to a pot that is multiplied by r (with $1 < r < n$) and shared equally. A unit you contribute returns only $r/n < 1$ to you, so not contributing is strictly dominant, even though full contribution pays everyone $r > 1$ instead of 0. With $n = 4$ and $r = 1.6$, each contributed unit costs you 1 and returns you 0.4. This is the n-player prisoner's dilemma, and it's the mathematics behind "the tragedy of the commons".

Finitely repeated: the future doesn't help

Repeat the dilemma a known, finite number of times K, adding up the payoffs. Surely the shadow of the future helps now?

Unravelling

In the prisoner's dilemma repeated a commonly known finite number of times K, every subgame-perfect equilibrium has both players defecting in every round.

Proof. We go by backward induction on the number of rounds left. A subgame-perfect equilibrium must be an equilibrium of every subgame, starting from any history.

Last round. Whatever happened before, round K is a one-shot prisoner's dilemma, since no future follows to reward or punish anything. D strictly dominates C, so both defect, whatever the history.

Inductive step. Suppose that from round $k + 1$ onward both players defect regardless of history. Then nothing a player does in round k changes what happens later, so round k is strategically a one-shot game plus a constant. Again D strictly dominates C, so both defect in round k, whatever the history. By induction, both defect in every round. ■

The "known" in "known finite" is doing all the work. If the horizon is uncertain, so that after each round the game continues with probability δ, there is no last round to start the unravelling from.

Infinitely repeated: thresholds for cooperation

Now let the game continue forever, with discounted payoffs

$$U_i = \sum_{t=0}^{\infty} \delta^t \, u_i(a^t), \qquad 0 \le \delta < 1.$$

It helps to compare **average** payoffs $(1-\delta)U_i$, which are on the same scale as one round: steady cooperation has average R.

A strategy in the repeated game is a rule mapping every history to an action, an enormous object. Two simple ones:

- **Grim trigger**: cooperate until the opponent defects once, then defect forever.
- **Tit-for-tat (TFT)**: cooperate in round 0, then copy the opponent's previous move.

When grim trigger sustains cooperation

Both players using grim trigger is a Nash equilibrium of the infinitely repeated prisoner's dilemma if and only if

$$\delta \;\ge\; \delta^{*} = \frac{T-R}{T-P}.$$

Proof. Against grim trigger, the opponent's behaviour depends only on whether you have ever defected. Before your first defection, cooperating forever gives

$$U_{\text{coop}} = R + \delta R + \delta^2 R + \cdots = \frac{R}{1-\delta}.$$

Suppose instead you first defect in some round t_0. Discounting is time-consistent, so it is enough to compare from t_0 onward. In round t_0 you get T. From then on the opponent defects forever, and your best reply to permanent defection is to defect too, earning P per round. So the best deviation gives

$$U_{\text{dev}} = T + \delta P + \delta^2 P + \cdots = T + \frac{\delta P}{1-\delta}.$$

Cooperation is a best response if and only if $U_{\text{coop}} \ge U_{\text{dev}}$. Multiply by $1-\delta > 0$:

$$R \;\ge\; (1-\delta)T + \delta P \iff \delta(T-P) \;\ge\; T - R \iff \delta \;\ge\; \frac{T-R}{T-P}.$$

By symmetry the same holds for the other player. ∎

With the canonical numbers, $\delta^{*} = (5-3)/(5-1) = \tfrac{1}{2}$. If there's at least a 50% chance of meeting again, the threat of permanent punishment keeps both players honest.

Tit-for-tat is more forgiving, which makes it harder to check. Against TFT, any deviation that eventually returns to cooperation gets punished only once. Two deviations matter: defecting forever (average payoff $(1-\delta)T + \delta P$, same as above) and **alternating** D, C, D, C, ..., which against TFT produces the outcome sequence $(D,C),(C,D),(D,C),\ldots$ with payoffs $T, S, T, S, \ldots$. Its value is $(T+\delta S)/(1-\delta^2)$, and comparing with $R/(1-\delta)$ gives $R(1+\delta) \ge T + \delta S$. Both together give the condition

$$\delta \;\ge\; \max\left\{ \frac{T-R}{T-P},\; \frac{T-R}{R-S} \right\} = \max\left\{ \tfrac{1}{2},\; \tfrac{2}{3} \right\} = \tfrac{2}{3}$$

for the canonical payoffs. This is Axelrod's condition for TFT to be "collectively stable". Forgiveness has a price: a slightly longer shadow of the future is needed.

? Why is it enough to check one deviation at a time?

In both proofs we quietly compared cooperation against a *handful* of deviations, while a repeated-game strategy can deviate in infinitely many, history-dependent ways. The justification is the **one-shot deviation principle**: with discounting, a strategy profile is subgame perfect if and only if no player gains by deviating in a single period and then returning to the plan. It is Bellman's principle of optimality in disguise, and it is proved in Ch. 52.

Too many equilibria

Here's the uncomfortable sequel. Once δ is large, grim trigger can sustain not only (C,C) forever but almost *any* pattern: cooperate on even rounds only, or let one player exploit the other two rounds out of three. The **folk theorem** (so called because everyone knew it before anyone published it) says that, for δ close enough to 1, every feasible average payoff pair that gives each player strictly more than their punishment payoff P is a subgame-perfect equilibrium outcome.

Repetition fixes the problem of *no* good equilibria by creating *infinitely many* equilibria. The theory explains how cooperation is possible. It doesn't explain why it happens, or which form it takes.

Evolutionary stability

Change the question. Suppose a large population plays the stage game in random pairs, and strategies that earn more spread (by imitation, learning, or reproduction). Write $u(\sigma,\tau)$ for the payoff of strategy σ against τ.

Evolutionarily stable strategy (Maynard Smith and Price, 1973)

A strategy σ is an **ESS** if, for every mutant strategy $\mu \neq \sigma$, either

1. $u(\sigma, \sigma) > u(\mu, \sigma)$, or
2. $u(\sigma, \sigma) = u(\mu, \sigma)$ and $u(\sigma, \mu) > u(\mu, \mu)$.

The intuition: a small fraction ε of mutants appears. They mostly meet residents. Condition 1 says the residents do strictly better in those meetings. If there is a tie there, condition 2 says the residents do better in the rare meetings with mutants. Either way, the mutants shrink.

Every ESS is a symmetric Nash equilibrium (condition 1 or 2 implies $u(\sigma, \sigma) \geq u(\mu, \sigma)$), but not every equilibrium is an ESS. In the one-shot prisoner's dilemma, ALL-D is an ESS: $u(D, D) = P > S = u(C, D)$.

The **Hawk–Dove** game is the classic example where evolution predicts a mix. Two animals contest a resource worth V. Hawks fight; doves posture and retreat. A fight costs the loser C, and we assume $C > V$. The row player's payoffs are

	H	D
H	$\frac{V-C}{2}$	V
D	0	$\frac{V}{2}$

The Hawk–Dove ESS

If $C > V > 0$, the strategy "play Hawk with probability $p^* = V/C$" is the unique ESS of the Hawk–Dove game.

Proof. Let $u(x, y)$ be the expected payoff of a player who plays Hawk with probability x against one who plays Hawk with probability y:

$$u(x, y) = xy\,\frac{V - C}{2} + x(1 - y)V + (1 - x)(1 - y)\,\frac{V}{2}.$$

Equilibrium. Against $y = p^*$, Hawk earns $p^*\frac{V-C}{2} + (1 - p^*)V$ and Dove earns $(1 - p^*)\frac{V}{2}$. Their difference is $\frac{1}{2}\big(p^*(V - C) + (1 - p^*)V\big) = \frac{1}{2}(V - p^*C) = 0$. So every x earns the same against p^*, and condition 1 holds with equality for every mutant.

Stability. So we need condition 2 for every mutant $m \neq p^*$. Because u is linear in its first argument,

$$u(p^*, m) - u(m, m) = (p^* - m)\,\frac{\partial u}{\partial x}(\cdot, m) = (p^* - m) \cdot \frac{V - mC}{2} = \frac{C}{2}\,(p^* - m)^2 > 0,$$

using $V = p^*C$. Condition 2 holds, so p^* is an ESS. Pure Hawk isn't an ESS (Dove does better against it, $0 > \frac{V-C}{2}$), and pure Dove isn't either ($V > \frac{V}{2}$); a different mix $x \neq p^*$ isn't even a best reply to itself, so it can't be an ESS. ■

With $V = 2$ and $C = 10$, a fifth of contests are played by hawks. Notice how the indifference principle from Ch. 39 reappears, now holding a *population* in balance rather than a single player's coin.

What about the *repeated* dilemma? Is tit-for-tat an ESS? Here is where the story gets slippery.

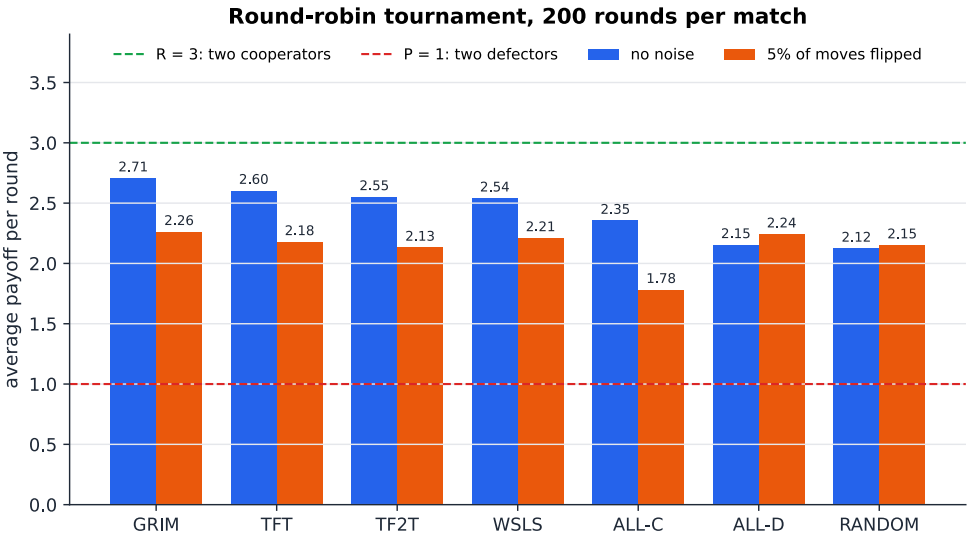
? Tit-for-tat can't hold the fort

In a population of TFT players, a mutant that always cooperates (ALL-C) earns exactly the same against TFT, and exactly the same against itself. Neither ESS condition holds, so ALL-C can drift in unopposed. Once there are enough ALL-C players, ALL-D can invade by exploiting them. Cooperation then collapses, and TFT can return. Populations may cycle between cooperation and defection forever. Whether these cycles are real, and what they look like, needs dynamics, not just stability conditions: the **replicator equation** of Ch. 45.

40.4 The algorithm

There are two computational questions, and they need different tools.

Simulation: who wins a tournament? A round-robin tournament of k strategies, each match L rounds long, costs $O(k^2 L)$ moves. Every strategy is a function from the pair of histories (mine, theirs) to an action. Deterministic strategies make it exact; noisy ones need repeated runs and averages, with the usual $1/\sqrt{N}$ Monte Carlo error.



A small Axelrod-style tournament (each strategy meets every other and its own twin, 200 rounds, averaged over 20 runs). Without noise the "nice" strategies (never defect first) take the top four places. With 5% of moves flipped by accident, every nice strategy loses ground, ALL-C is exploited, and ALL-D climbs to near the top.

Two lessons in that chart deserve to be stated carefully, because they're not what people expect.

1. **The winner depends on the field.** In this field GRIM edges out TFT, mostly because GRIM punishes RANDOM forever while TFT keeps forgiving it. In Axelrod's fields TFT won. No strategy is best against every population, since the best reply depends on who else is there. That's Ch. 39 all over again.
2. **Noise is brutal to reciprocity.** One accidental defection between two TFT players starts an echo: C/D, D/C, C/D, ... until another error breaks it. Two GRIM players never recover at all.

Exact analysis: memory-one strategies as Markov chains. If a strategy looks only at the last round, it is four numbers: the probabilities $(p_{CC}, p_{CD}, p_{DC}, p_{DD})$ of cooperating after each outcome (own move first). TFT is $(1, 0, 1, 0)$. *Win-stay, lose-shift* (WSLS, also called Pavlov) repeats its move after a good outcome (R or T) and switches after a bad one, giving $(1, 0, 0, 1)$. Two memory-one players drive a **Markov chain** on the four outcomes CC, CD, DC, DD. With execution errors the chain is irreducible, and the long-run payoff is the stationary distribution $\boldsymbol{\pi}$ (the left eigenvector of the transition matrix for eigenvalue 1, as in Ch. 10 and Ch. 34) dotted with the payoff vector.

```
import numpy as np

T, R, P, S = 5, 3, 1, 0

def long_run(p, q, eps=0.01):
    """Long-run payoffs of two memory-one strategies.
    p, q: probability of cooperating after the last outcome (CC, CD, DC, DD), seen from each player's side."""
    p = (1 - eps) * np.asarray(p) + eps * (1 - np.asarray(p))   # execution errors
    q = (1 - eps) * np.asarray(q) + eps * (1 - np.asarray(q))
    q = q[[0, 2, 1, 3]]                    # player 2 sees CD as DC and vice versa
    M = np.zeros((4, 4))
    for s in range(4):
        a, b = p[s], q[s]
        M[s] = [a * b, a * (1 - b), (1 - a) * b, (1 - a) * (1 - b)]
    w, V = np.linalg.eig(M.T)              # stationary distribution = left eigenvector for eigenvalue 1
    pi = np.real(V[:, np.argmin(abs(w - 1))]); pi /= pi.sum()
    return pi @ [R, S, T, P], pi @ [R, T, S, P]

TFT, WSLS, ALLD, GTFT = [1, 0, 1, 0], [1, 0, 0, 1], [0, 0, 0, 0], [1, 1/3, 1, 1/3]
for name, s in [("TFT", TFT), ("WSLS", WSLS), ("GTFT", GTFT), ("ALL-D", ALLD)]:
    print(f"{name:5s} vs itself: {long_run(s, s)[0]:.3f}   vs ALL-D: {long_run(s, ALLD)[0]:.3f}")
```

With a 1% error rate, two TFT players average only 2.250, exactly $(R + S + T + P)/4$, because errors leave them wandering uniformly over all four outcomes. Two WSLS players average 2.951, and two players of *generous* TFT (forgive a defection with probability $1/3$) average 2.970. The price of being nice shows up against ALL-D: TFT keeps 1.020, GTFT 0.693, WSLS only 0.535.

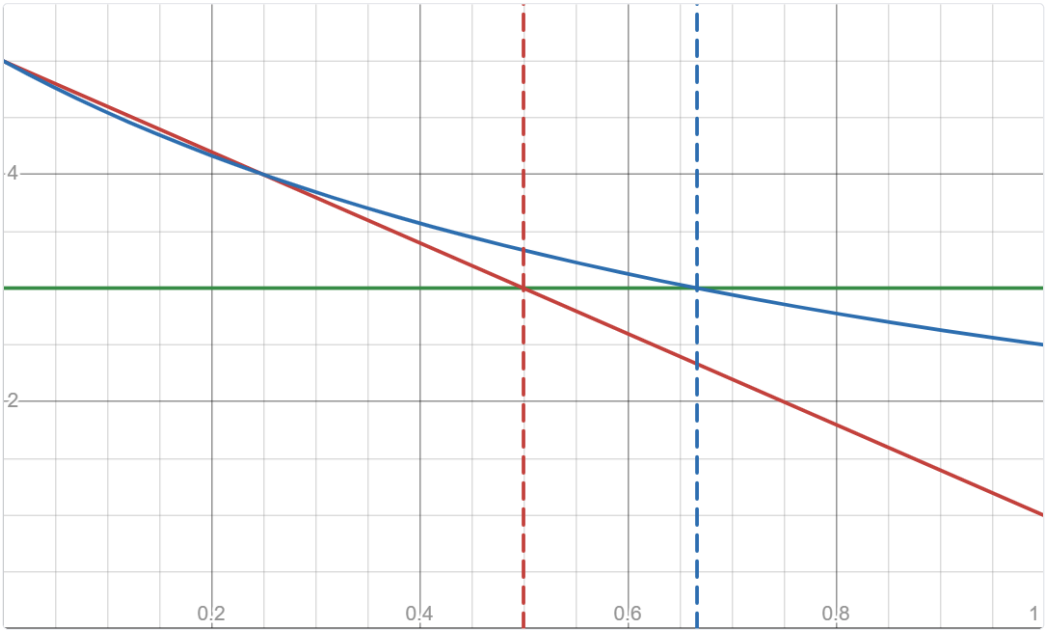
Cost and stability. The exact method costs one 4×4 eigenproblem per pair, independent of the match length, which is far cheaper than simulation. It does fail in one place. With `eps=0`, chains like TFT vs TFT are *reducible* (they get stuck in CC forever, or in an echo), the eigenvalue 1 is repeated, and "the" stationary distribution depends on the starting state. `np.linalg.eig` then returns an arbitrary vector in that eigenspace. Keep a small positive error rate, or handle the starting state explicitly.

? A strategy that dictates your score

In 2012, the physicist Freeman Dyson and computer scientist William Press found memory-one strategies that let one player **unilaterally** force a linear relation between the two long-run scores, for example "my surplus over P is always three times yours", whatever the opponent does. These **zero-determinant** strategies came out of a determinant identity hiding in exactly the Markov chain above. Are extortioners a real threat to cooperation, or do they eat themselves in a population? The adversarial side is in Ch. 46, and the evolutionary verdict in Ch. 45.

40.5 The experiment

Find the threshold. The graph shows average payoffs (per round) as functions of the discount factor $x = \delta$. The green line is steady cooperation, $R = 3$. The red curve is the best deviation against grim trigger, $(1-\delta)T + \delta P$. The blue curve is the alternating deviation against TFT, $T/(1+\delta)$ (with $S = 0$). Cooperation is safe wherever green lies above the others.



Grim trigger holds cooperation for $\delta \geq 1/2$ (red crossing); tit-for-tat needs $\delta \geq 2/3$ (blue crossing).

Change **5** (the temptation T) to 8 in both curves: how much longer must the shadow of the future be? Change the **1** in $1x$ (the punishment P) to 2: does harsher or milder punishment help grim trigger? Finally change the **0** in $0x$ (the sucker's payoff S) to 1 and watch the blue crossing move while the red one stays put.

Run your own tournament. This is the engine behind the bar chart, trimmed to fit.

```
import numpy as np

T, R, P, S = 5, 3, 1, 0                      # KNOB: payoffs (need T > R > P > S)
PAY = {('C', 'C'): (R, R), ('C', 'D'): (S, T), ('D', 'C'): (T, S), ('D', 'D'): (P, P)}
ROUNDS, NOISE = 200, 0.0                     # KNOB: game length, chance a move is flipped
rng = np.random.default_rng(1)

STRATS = {                                   # each sees (my history, their history)
    'ALL-C':  lambda me, op: 'C',
    'ALL-D':  lambda me, op: 'D',
    'TFT':    lambda me, op: op[-1] if op else 'C',
    'GRIM':   lambda me, op: 'D' if 'D' in op else 'C',
    'TF2T':   lambda me, op: 'D' if op[-2:] == ['D', 'D'] else 'C',
    'WSLS':   lambda me, op: 'C' if not me else (me[-1] if op[-1] == 'C' else ('D' if me[-1] == 'C' else 'C')),
    'RANDOM': lambda me, op: 'C' if rng.random() < 0.5 else 'D',
}

def play(f, g):
    a, b, sa, sb = [], [], 0, 0
    for _ in range(ROUNDS):
        x, y = f(a, b), g(b, a)
        if rng.random() < NOISE: x = 'D' if x == 'C' else 'C'
        if rng.random() < NOISE: y = 'D' if y == 'C' else 'C'
        pa, pb = PAY[(x, y)]
        a.append(x); b.append(y); sa += pa; sb += pb
    return sa / ROUNDS, sb / ROUNDS

names = list(STRATS)
score = {n: [] for n in names}
for i, n in enumerate(names):                # round robin, including a match against a twin
    for m in names[i:]:
        s1, s2 = play(STRATS[n], STRATS[m])
        score[n].append(s1)
        if m != n: score[m].append(s2)
for n in sorted(names, key=lambda n: -np.mean(score[n])):
    print(f"{n:7s} {np.mean(score[n]):.3f}")
```

Things to try:

- Set `NOISE = 0.05` and rerun with several seeds. How stable is the ranking?
- Remove `'RANDOM'`, or add three copies of `'ALL-D'`. Does TFT overtake GRIM?

- Write *generous TFT* (after the opponent defects, still cooperate with probability $1/3$) and *suspicious TFT* (defect first, then copy). Which of the two does noise hurt more?
- Make it **ecological**: after each tournament, give each strategy a population share proportional to its score and rerun with those shares. Which strategies go extinct first?

40.6 The challenge

1. **Intuition.** Two Wi-Fi stations repeatedly share a channel. One argues "I will always back off politely, whatever you do"; the other says "I will back off as long as you do, and jam you for ten seconds if you cheat". Which promise does more to keep the channel cooperative, and why does the *credibility* of the second promise matter?

2. **Derivation.** For the "k-period punishment" strategy (cooperate; after a defection, defect for exactly k rounds, then return to cooperation), find the smallest δ, as a function of k, T, R, P, at which mutual use of it is an equilibrium. Check that it tends to the grim-trigger threshold $\frac{T-R}{T-P}$ as $k \to \infty$.

3. **Implementation.** Using `long_run`, scan all memory-one strategies on a grid $p_s \in \{0, 0.25, 0.5, 0.75, 1\}$ (625 strategies). For each, find its payoff against itself and the best payoff any grid strategy can earn against it. Plot the strategies that are "nearly stable" (no invader gains more than 0.01) and describe what they have in common.

4. **Open investigation.** Run the ecological version of the tournament (strategies reproduce in proportion to score) with a mutation process that occasionally introduces random memory-one strategies. Over long runs, does the population settle, cycle between cooperation and defection, or wander? How does the answer change with the error rate? There is no known closed-form description of the long-run behaviour for general mutation processes.

40.7 Loose threads

This chapter turned the prisoner's dilemma from a paradox into a calculation: cooperation is a self-enforcing equilibrium once δ passes an exact threshold. It also left several doors ajar.

- **Infinitely many equilibria.** The folk theorem says repetition can sustain almost anything, including exploitation. Which equilibrium a society lands in is a question for history, learning and evolution, not for the definition of equilibrium (Ch. 45).
- **The proofs checked only a few deviations.** That was legitimate, but only because of the one-shot deviation principle, which is dynamic programming in disguise (Ch. 52).
- **We assumed everyone sees everything.** Every strategy here observed the opponent's actual move. Real Wi-Fi stations, firms and nations see only noisy signals: a collision might be bad luck or sabotage. With imperfect monitoring, punishment has to be triggered by *evidence*, and the analysis needs beliefs about what the other player is and did. That's the doorway into Ch. 41.
- **ESS is a static test.** It says which states resist invasion, not how a population moves between them, or whether it moves in circles. That's the replicator equation of Ch. 45.
- **Designing the game itself.** If the dilemma is the problem, why not change the payoffs? Protocol designers do exactly that: they add fines, reputations and verifiable commitments so that cooperation becomes the dominant strategy. Engineering the incentives instead of the players is Ch. 42.

Chapter 41 — Games with Incomplete Information

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 39, Ch. 19, Ch. 40 · **Leads to:** Ch. 42, Ch. 43 · **Related:** Ch. 35, Ch. 33, Ch. 96 **Reading time:** ~25 min

41.1 The hook

You want to buy a used car. There are good ones ("peaches") and bad ones ("lemons"), and on a test drive they look identical. The seller knows which one she has, because she has driven it for five years. You don't.

So you do the sensible thing and offer a price that reflects an *average* car. Now look at that offer from the sellers' side. The owner of a peach finds your average price insulting, because her car is worth more, and keeps it. The owner of a lemon is delighted to sell. The cars actually on offer at your price are therefore *worse than average*. Once you realize this, you lower your offer. More peach owners withdraw. The average falls again. In 1970, George Akerlof showed that this spiral can run all the way down: a market in which every buyer values every car more than its owner does, so that every trade would make both sides happier, can collapse to *no trade at all*. The paper was famously rejected by three journals as either trivial or wrong. It later earned a Nobel Prize.

The same spiral threatens health insurance (the sickest are keenest to buy), loans (the riskiest borrowers accept any rate), freelance marketplaces, and spectrum auctions. The problem isn't greed. It is **asymmetric information**: one side knows something the other doesn't, and everyone knows that.

Two escape routes suggest themselves, and they're opposites.

- The informed side can try to **signal**. A peach owner might offer a two-year warranty, something a lemon owner can't afford to promise. A job applicant may spend four years earning a degree that a weaker applicant would find too costly to get.
- The uninformed side can try to **screen**. The insurer offers a menu, a cheap policy with a big deductible and an expensive one with full cover, and lets customers sort *themselves* by what they choose.

Here's a puzzle to carry through the chapter. Why do so many scam emails announce, in the first line, that they come from a foreign prince with a fortune to share? Wouldn't a more plausible story catch more victims? Hold that thought. By the end you'll see the absurd opening line as a precisely tuned piece of strategy.

41.2 The big idea

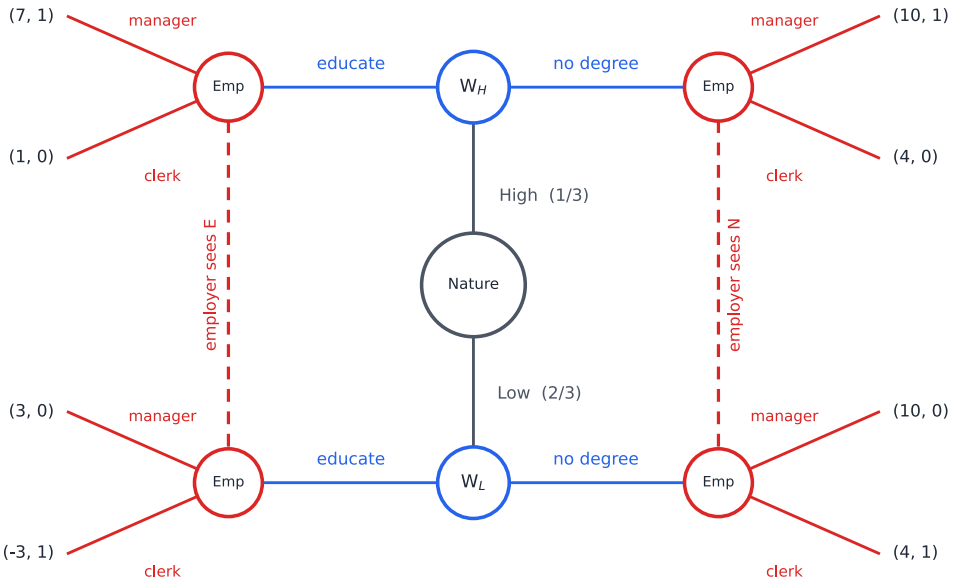
In Ch. 39 every player knew every payoff. Now some players have **private information**: their own cost, value, quality, or intention. The others can't see it, so they must form **beliefs** about it. And because beliefs drive choices, actions themselves become evidence. Whatever you do, others will read it.

The key move, due to John Harsanyi (1967), turns this mess into something we already know how to handle. Pretend that before the game starts, a neutral player called **Nature** rolls dice and deals each player a secret **type**: "peach" or "lemon", "able" or "weak", "high value" or "low value". The odds on the dice are common knowledge, even though each player sees only their own roll. Uncertainty about *who you're playing* becomes uncertainty about *what Nature did*, and probability theory (Ch. 19) knows how to deal with that.

From there, two ideas carry everything.

1. **A strategy is a plan for every type.** A seller's strategy isn't "sell" or "keep" but "if peach, keep; if lemon, sell". You must plan for all the types you could have been, because the *other* players' best responses depend on what you would have done in each case.
2. **Beliefs must be Bayesian where they can be.** When you see an action, update your beliefs about the actor's type by Bayes' rule. An analogy: a poker player who bets big is either strong or bluffing. A good opponent doesn't take the bet at face value; she asks how often a player of each type would make this bet, and updates.

Signaling is the art of choosing actions that are *too expensive to fake*. A signal works not because it is informative in itself (a degree in classics may teach nothing about software), but because it costs different types different amounts.



payoffs: (worker, employer). Manager job worth 10, clerk 4; degree costs 3 (High) or 7 (Low)

A job-market signaling game. Nature deals the worker a type; the worker chooses whether to get a degree; the employer, seeing only the degree (dashed information sets), assigns a job. Payoffs are (worker, employer).

41.3 The mathematics

The lemons spiral, exactly

Let car quality q be uniform on $[0, 1]$. An owner values her car at q; a buyer values it at kq with $k > 1$, so every trade would create value. Quality is private to the owner. Buyers are competitive, so the market price equals buyers' expected value of the cars actually on offer.

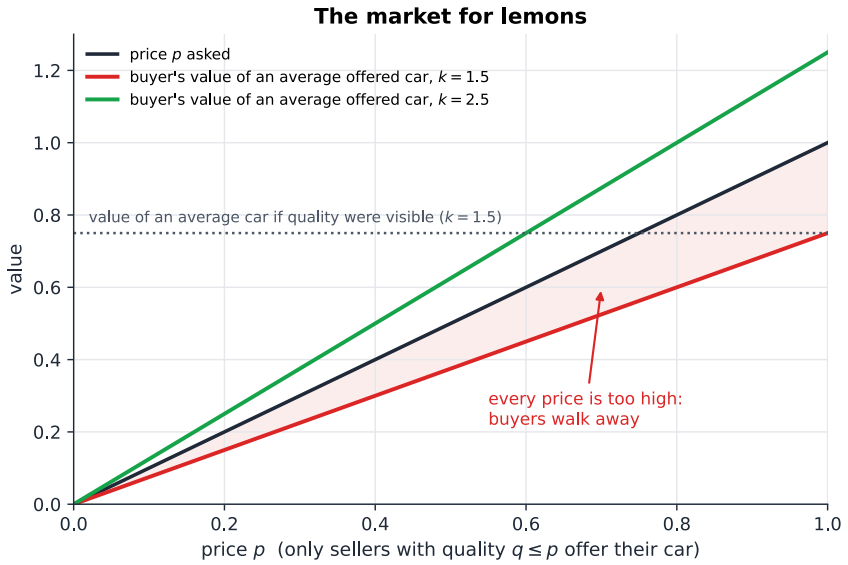
> **Market collapse (Akerlof)**
>
> If $1 < k < 2$, the only equilibrium price is $p = 0$: essentially no car is traded, even though every trade would benefit both sides.

Proof. At price $p \in (0, 1]$, exactly the owners with $q \le p$ sell. Conditional on $q \le p$, quality is uniform on $[0, p]$, so the expected quality on offer is $p/2$ and buyers value a random offered car at $kp/2$. An equilibrium needs buyers' value to equal the price:

$$\frac{kp}{2} = p \iff p\left(\frac{k}{2} - 1\right) = 0.$$

For $k < 2$ the bracket is negative, so the only solution is $p = 0$. At any positive price, $kp/2 < p$ and buyers refuse to pay it. (At $p > 1$ every car is offered, average quality is $1/2$, and $k/2 < 1 < p$, so no price above 1 works either.) ∎

Watch what makes the argument work: the price determines *who participates*, and who participates determines what the price should be. That feedback loop is the signature of **adverse selection**. For $k = 1.5$, a buyer who could see quality would pay 0.75 on average; without that information, the market pays nothing. Information is worth something to the market as a whole, a fact that Ch. 33 teaches you to measure in bits.



At price p only cars of quality at most p are offered, so buyers value the offered pool at $kp/2$. For $k = 1.5$ (red) that's always below the price and the market unravels; only $k \geq 2$ (green) keeps it alive.

Bayesian games

Bayesian game

A **Bayesian game** has

- players $i = 1, \dots, n$, each with an action set A_i;
- for each player a set of **types** Θ_i;
- a **common prior** π on $\Theta = \Theta_1 \times \cdots \times \Theta_n$;
- payoffs $u_i(a, \theta)$ that may depend on everyone's actions *and* types.

Player i learns only θ_i, and forms the posterior belief $\pi(\theta_{-i} \mid \theta_i)$ by Bayes' rule. A **strategy** is a function $s_i : \Theta_i \to A_i$, one action for every possible type.

Bayesian Nash equilibrium (BNE)

A strategy profile s^* is a **Bayesian Nash equilibrium** if every type of every player maximizes expected payoff given its beliefs:

$$s_i^*(\theta_i) \in \arg\max_{a_i \in A_i} \; \mathbb{E}_{\theta_{-i} \sim \pi(\cdot \mid \theta_i)} \left[u_i\big(a_i,\; s_{-i}^*(\theta_{-i}),\; \theta\big) \right] \quad \text{for all } i,\ \theta_i.$$

Harsanyi's insight is that a BNE is simply a Nash equilibrium of a bigger ordinary game in which the "players" are the type-contingent strategies, and Nature is just a chance move. Nash's existence theorem from Ch. 39 therefore applies, for finite type and action sets.

The cleanest worked example has a continuum of types.

A first-price sealed-bid auction

Two bidders each have a private value v_i, independent and uniform on $[0, 1]$. Each submits a sealed bid; the higher bid wins and **pays its own bid**. A winner with value v who bids b gets $v - b$; a loser gets 0.

Guess a symmetric equilibrium in which each bids a fixed fraction of value, $b(v) = \beta v$. **Check** that it is a best response. Bidder 1 with value v bidding b wins when $\beta v_2 < b$, which has probability $\min(b/\beta,\ 1)$. For $b \leq \beta$ the expected payoff is

$$\Pi(b) = (v - b)\,\frac{b}{\beta}.$$

Setting $\Pi'(b) = (v - 2b)/\beta = 0$ gives $b = v/2$, a maximum since $\Pi'' < 0$. (Bids above β win for sure but pay more than necessary.) The best response to "the other bids βv" is to bid $v/2$, *whatever* β is, as long as $\beta \geq 1/2$. Consistency requires $\beta = 1/2$.

So $b(v) = v/2$ is a BNE: **shade your bid to half your value.** The seller's expected revenue is the expected winning bid, $\mathbb{E}[\max(v_1, v_2)]/2 = \frac{2}{3} \cdot \frac{1}{2} = \frac{1}{3}$.

Bid shading is the defining feature of incomplete information. You'd never bid half your value if you knew the other bid; you'd bid a hair above it. Not knowing, you trade off the probability of winning against the profit when you win.

? The coincidence that isn't one

Change the rule: highest bid wins but pays the **second**-highest bid. Now bidding your true value is a dominant strategy (prove it in one line!), and the seller's expected revenue is $\mathbb{E}[\min(v_1, v_2)] = \frac{1}{3}$, *exactly* the same as in the first-price auction. Very different rules, very different bidding, identical revenue. That isn't luck. The **revenue equivalence theorem** in Ch. 43 says when and why it must happen.

Signaling games and perfect Bayesian equilibrium

In the tree above, the worker moves first and the employer second, after watching. Plain BNE is too weak a concept here: it allows the employer to make threats at information sets that are never reached, like "if you educate, I'll make you a clerk anyway". We need beliefs at *every* information set, and actions that are optimal given those beliefs.

Perfect Bayesian equilibrium (PBE)

In a signaling game, a **PBE** is a sender strategy $\sigma(\theta)$, a receiver strategy $\rho(m)$ for each message m, and beliefs $\mu(\theta \mid m)$, such that

1. each sender type's message maximizes its payoff given ρ;
2. after each message, $\rho(m)$ maximizes the receiver's expected payoff given $\mu(\cdot \mid m)$;
3. for messages sent with positive probability, μ is obtained by Bayes' rule (Ch. 19.3) from the prior and σ. For messages never sent, μ may be anything.

PBEs come in two broad kinds. In a **separating** equilibrium, different types send different messages, so the message reveals the type. In a **pooling** equilibrium, all types send the same message, and the receiver learns nothing.

Take the game in the figure: prior $P(H) = \frac{1}{3}$, a manager job worth 10 to the worker and a clerk job worth 4, a degree costing 3 for the high type and 7 for the low type, and an employer who scores 1 for putting each type in the right job.

Two very different equilibria

In the job-market game of the figure:

1. **Separating:** "High educates, Low doesn't; the employer makes graduates managers and the rest clerks" is a PBE.
2. **Pooling:** "Nobody educates; the employer makes everybody a clerk, and would also make a graduate a clerk" is a PBE, supported by the off-path belief $\mu(H \mid E) \le \frac{1}{2}$.

Proof. **Separating.** Bayes' rule gives $\mu(H \mid E) = 1$ and $\mu(H \mid N) = 0$, so the employer's replies (manager after E, clerk after N) are optimal. High's payoffs: educate $10 - 3 = 7$, don't 4, so High educates. Low's payoffs: educate $10 - 7 = 3$, don't 4, so Low doesn't. No one wants to deviate.

Pooling. On path, everyone sends N, so Bayes gives $\mu(H \mid N) = \frac{1}{3}$. The employer's expected score is $\frac{1}{3}$ for "manager" and $\frac{2}{3}$ for "clerk", so clerk is optimal. Message E is never sent, so condition 3 allows any belief there. With $\mu(H \mid E) \le \frac{1}{2}$, clerk is optimal after E as well. Then educating gives High $4 - 3 = 1 < 4$ and Low $4 - 7 < 4$, so neither deviates. ■

The two equilibria have exactly the same game, the same payoffs and the same rationality, and in one of them the able worker is recognized while in the other she is stuck as a clerk forever. The pooling equilibrium survives only because of an off-path belief: the employer "thinks" that a graduate is probably the low type, even though the low type would never want a degree. That belief is allowed but feels absurd.

The continuous version is Michael Spence's job-market model (1973). Let education level $e \ge 0$ cost e/θ for a worker of productivity $\theta \in \{1, 2\}$, with wage equal to expected productivity. Separation at a degree level e^* requires that Low doesn't mimic, $2 - e^* \le 1$, and that High is willing, $2 - e^*/2 \ge 1$. Together these give $1 \le e^* \le 2$: **a whole interval of separating equilibria**, each needing a different amount of costly, socially useless schooling.

? Which beliefs are reasonable?

PBE lets beliefs off the equilibrium path be anything, and so it supports pooling equilibria that rest on absurd suspicions, plus a continuum of separating ones. Game theorists responded with **refinements**, the most famous being the *Intuitive Criterion* of Cho and Kreps (1987), which says to ignore types that couldn't possibly gain from a deviation. Applied here, it kills the pooling equilibrium and selects the cheapest separating one, $e^* = 1$. Why that criterion, and whether any refinement is the "right" one, is a live debate you'll meet in Ch. 96.

Screening: let them sort themselves

In signaling the informed party moves first. In **screening**, the uninformed party moves first by designing a menu, and the informed party responds by choosing from it. An insurer can't see who is risky, so it offers two contracts: full cover at a high premium, and partial cover (a large deductible) at a low premium. Safe drivers, who expect few claims, find the deductible cheap and take the low premium. Risky drivers pay for full cover. The menu is built so that each type *prefers* the contract meant for it. That self-selection requirement is called **incentive compatibility**.

Two features of good screening menus are universal, and we'll only state them here.

- The "best" type (the one the designer most wants to identify) gets an efficient contract, but has to be left some surplus, an **information rent**, or it would pretend to be another type.
- The other types get *distorted* contracts (a deductible larger than efficient), deliberately made worse so that they're unattractive to mimic.

Now the scam email. The scammer's real cost isn't sending emails, which is nearly free. It's the time spent on each reply, the back-and-forth, before it turns out the target isn't going to pay. The absurd story is a **screen**. Anyone sceptical enough to eventually back out is filtered out by the first line, and the replies come mostly from people who will go all the way. As computer scientist Cormac Herley observed in 2012, a more believable email would generate more replies and *less* profit. The implausibility is the design.

? Is a menu always enough?

Screening, auctions, voting rules, and tax schedules all ask the same question: what outcomes can a designer achieve when everyone else holds private information? It looks hopeless, since the set of possible mechanisms is enormous. Yet one theorem lets you restrict attention to mechanisms that simply *ask* each player for their type and make honesty optimal. That theorem, the **revelation principle**, opens Ch. 42.

41.4 The algorithm

Finite Bayesian games → finite normal-form games. If player i has $|\Theta_i|$ types and $|A_i|$ actions, it has $|A_i|^{|\Theta_i|}$ pure strategies. List them, compute each profile's *ex ante* expected payoff by summing over the prior, and every tool from Ch. 39 applies. This is correct but expensive, since the strategy count is exponential in the number of types. In practice one checks best responses type by type instead, which costs only $|\Theta_i| \cdot |A_i|$ evaluations per player.

Pure PBE of a signaling game. The search has three nested loops:

1. Enumerate the sender's pure strategies $\sigma : \Theta \to M$ (here $2^2 = 4$ of them).
2. For each message, compute the receiver's belief: Bayes' rule if the message is used, otherwise scan a grid of off-path beliefs.
3. Compute the receiver's best reply to each belief, then check that no sender type wants to switch message.

```
import itertools
import numpy as np

prior = {"H": 1/3, "L": 2/3}                # Nature's odds of each worker type
cost = {"H": 3, "L": 7}                     # cost of education by type
wage = {"M": 10, "C": 4}                    # worker's value of each job
fit = {("H", "M"): 1, ("L", "C"): 1}        # employer gets 1 for a correct match, else 0

def worker(t, e, job): return wage[job] - (cost[t] if e == "E" else 0)
def best_job(mu_H):                         # employer's reply given belief P(H | signal)
    vM, vC = mu_H * fit.get(("H", "M"), 0), (1 - mu_H) * fit.get(("L", "C"), 0)
    return "M" if vM > vC else "C"

for sH, sL in itertools.product("EN", repeat=2):     # the sender's pure strategies
    sigma = {"H": sH, "L": sL}
    for off in np.linspace(0, 1, 11):                # belief at an unused signal
        beliefs, reply = {}, {}
        for e in "EN":
            senders = [t for t in "HL" if sigma[t] == e]
            if senders:                              # on path: Bayes' rule
                mass = sum(prior[t] for t in senders)
                beliefs[e] = prior["H"] / mass if "H" in senders else 0.0
            else:                                    # off path: any belief allowed
                beliefs[e] = off
            reply[e] = best_job(beliefs[e])
        ok = all(worker(t, sigma[t], reply[sigma[t]]) >= worker(t, d, reply[d])
                 for t in "HL" for d in "EN")
        if ok:
            print(f"H->{sH}, L->{sL}  beliefs P(H|E)={beliefs['E']:.1f}, P(H|N)={beliefs['N']:.1f}"
                  f"  employer: E->{reply['E']}, N->{reply['N']}")
        if sH != sL: break                           # separating: no off-path signal to scan
```

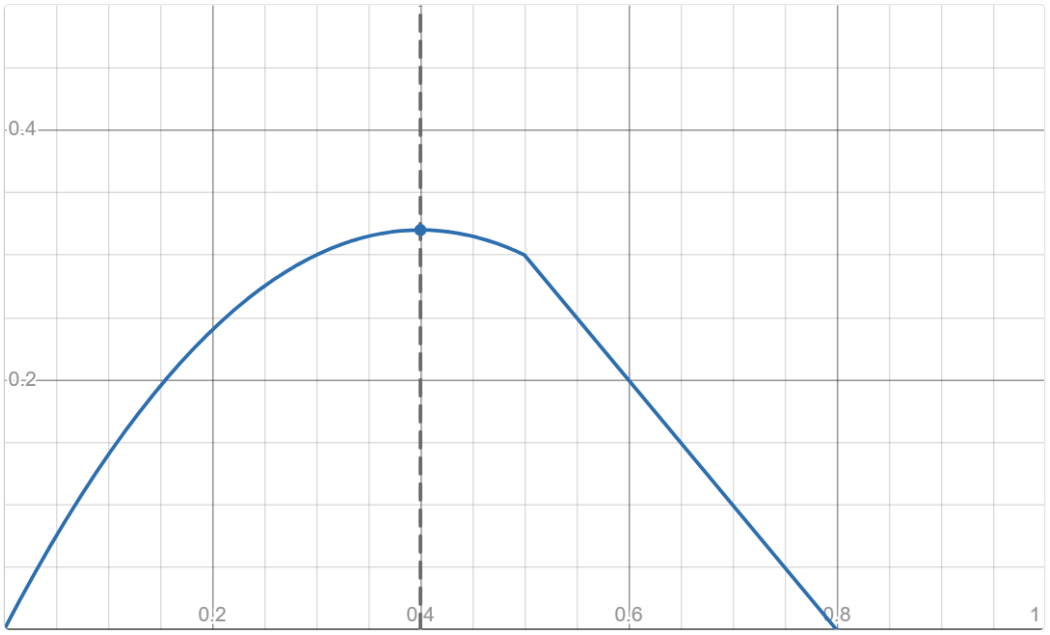
It prints the separating equilibrium once, and the pooling-on-N equilibrium for every grid belief $\mu(H \mid E) \in \{0, 0.1, \ldots, 0.5\}$ (at exactly 0.5 the employer is indifferent, and the code's tie-break picks clerk). Pooling on E and the "reverse" separation (Low educates, High doesn't) never appear.

Cost and failure cases.

- With $|\Theta|$ types and $|M|$ messages there are $|M|^{|\Theta|}$ sender strategies, each with a grid of off-path beliefs. That's fine for toy games and hopeless for realistic ones.
- *Mixed* (semi-separating) equilibria, where a type randomizes so that the receiver's posterior lands exactly on an indifference point, are invisible to a pure search. They need the indifference principle of Ch. 39 applied to posteriors.
- *Grids can lie.* The pooling equilibrium holds for $\mu(H \mid E) \le \frac{1}{2}$, a closed interval. A grid that skipped 0.5 would still find it, but a game whose equilibrium needs a belief in a tiny interval could slip between the grid points. Solve the receiver's indifference condition exactly when you can.
- *Ties.* Indifference is common at equilibrium, and the tie-breaking rule inside `best_job` silently selects among equilibria. Change `>` to `>=` and watch the output change.

41.5 The experiment

Shade your bid. In the first-price auction, a bidder with value $v = 0.8$ who bids x against an opponent bidding half her value wins with probability $\min(2x, 1)$, so her expected profit is $(0.8 - x)\min(2x, 1)$.



Expected profit of a bidder with value 0.8; the peak sits at exactly half her value.

Change **0.8** to other values in both places and confirm the peak always sits at $v/2$. Then change the **2** in $\min(2x, 1)$ to **3**: the opponent now bids a third of her value, so you win more easily. Does your best bid change? Try it with value 0.5 and with value 0.8, and explain why the two answers differ.

Watch a market die. This script runs the lemons spiral with real cars: each week, only owners whose car is worth less than the price sell, and buyers reset the price to what the offered cars are worth.

```
import numpy as np
import matplotlib.pyplot as plt

rng = np.random.default_rng(0)
cars = 10_000
quality = rng.uniform(0, 1, cars)     # KNOB: try rng.beta(2, 5, cars) or rng.uniform(0.5, 1, cars)
k = 1.5                               # KNOB: buyers value a car at k * quality (k > 1: trade is efficient)
price = k * quality.mean()            # buyers start by paying for the average car
history = [price]

for week in range(25):
    offered = quality[quality <= price]          # only owners of worse-than-price cars sell
    if offered.size == 0:
        break
    price = k * offered.mean()                   # buyers pay what the offered pool is worth
    history.append(price)
    share = offered.size / cars
    print(f"week {week:2d}: price {price:.3f}, cars on sale {share:6.1%}")

plt.plot(history, "o-")
plt.xlabel("week"); plt.ylabel("market price")
plt.title(f"Lemons market, k = {k}")
plt.show()
```

With $k = 1.5$ the price starts at 0.75 and loses a quarter of its value every week: 0.56, 0.42, 0.31, ..., with only about 6% of cars still on sale by week 9. Things to try:

- Set `k = 2.5`. Does the market survive, and at what price?
- Keep `k = 1.5` but use `rng.uniform(0.5, 1, cars)`, so no car is truly terrible. Does a *floor* on quality rescue the market?
- Add a **warranty**: suppose owners of cars with `quality > 0.7` can certify them at a cost of `0.05`, and certified cars sell in a separate market. Which owners certify, and what happens to the uncertified market?

41.6 The challenge

1. **Intuition.** A hospital adopts a policy that every applicant for a nursing position must complete an unpaid two-week trial shift. Explain how this could function as a signal, a screen, or neither, depending on who bears the cost. What would have to be true about applicants' outside options for it to separate types?

2. **Derivation.** Generalize the first-price auction to n bidders with independent values uniform on $[0, 1]$. Guess $b(v) = \beta v$, derive $\beta = \frac{n-1}{n}$, and compute the seller's expected revenue. Then show that a second-price auction with the same bidders gives the same revenue.

3. **Implementation.** Extend the PBE search to **three** worker types (low, medium, high, with education costs 7, 5, 3), three messages (no degree, bachelor's, master's), and three jobs. Report every pure PBE, classify each as separating, pooling, or partially pooling, and count how many depend on off-path beliefs.

4. **Open investigation.** In the lemons simulation, let a fraction ϕ of buyers be "experts" who can see quality and pay kq for exactly the cars they want, while the rest trade blind. How large must ϕ be to stop the unravelling at $k = 1.5$? Explore how the answer depends on the shape of the quality distribution. Is there a distribution for which no amount of expertise short of $\phi = 1$ saves the market?

41.7 Loose threads

This chapter added one ingredient to game theory, private information, and the world got stranger: markets that should exist can vanish, useless degrees can be rational, and absurd emails can be optimal. Several threads were left hanging on purpose.

- **Revenue equivalence.** Two auctions with completely different bidding behaviour raised exactly $\frac{1}{3}$. Whether that's a theorem or a coincidence, and what breaks it (risk aversion, correlated values, asymmetric bidders), is Ch. 43.
- **Too many equilibria, again.** Signaling games produce pooling and a continuum of separating equilibria, all of them PBE. The refinements that try to pick out the reasonable ones, and the arguments about whether they should, lead into Ch. 96.
- **Designing the menu.** We stated the shape of an optimal screening menu (rent at the top, distortion below) without deriving it. The derivation, and the revelation principle that makes it possible, is Ch. 42.
- **Where do common priors come from?** Harsanyi's trick assumes all players agree on Nature's dice. Drop that assumption and you face beliefs about beliefs about beliefs, an infinite hierarchy that ties into the Bayesian updating of Ch. 35.
- **Learning the type over time.** In Ch. 40 cooperation rested on repeated interaction. Combine repetition with private types and you get **reputation**: a player who might be a committed cooperator can sustain trust even in a finitely repeated dilemma, breaking the unravelling argument. How much a small doubt can achieve is one of the most surprising results in the theory of repeated games.

Chapter 42 — Mechanism Design: Engineering Incentives

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 23, Ch. 19, Ch. 39, Ch. 41 · **Leads to:** Ch. 43, Ch. 44, Ch. 96 · **Related:** Ch. 49, Ch. 30 **Reading time:** ~25 min

42.1 The hook

Two women stand before King Solomon. Each claims the same baby. Solomon cannot see into their hearts; he can only listen to what they say, and both say the same thing. So he announces a rule: the child will be cut in two and each woman given half. One woman says "do it". The other says "give her the child, only let it live". Solomon hands the baby to the second woman.

Strip away the drama and you have an engineering problem. The king holds **private information he does not have**: who the real mother is. The people who do have it will say whatever serves them. Solomon's trick was not to ask a better question but to design a **rule** under which the two women's *answers* would differ, because their *preferences* differ. That is the whole subject of this chapter in one story, and it is also a warning: Solomon's rule only works once. A second false mother who has heard the story simply says "let it live" too.

Here is a modern, less bloody version. Three households on a river want a footbridge. It costs 300. The town clerk proposes the obvious rule: "Tell me what the bridge is worth to you. If the total is at least 300, we build it and split the cost equally, 100 each." The true values are 250, 50 and 40. Honestly reported, the total is 340, the bridge goes up, and household 3, who values it at 40, pays 100 for the privilege. Household 3 is no fool. If negative reports are allowed, it reports -1000 and the bridge dies. If they are not, household 1 has the opposite temptation: in a slightly different world where the others valued it less, writing "1,000,000" costs nothing and guarantees the bridge. The clerk's rule asks for the truth and rewards lying.

And it gets worse before it gets better. Suppose the town abandons money and simply votes. Three council members rank three bridge designs X, Y, Z:

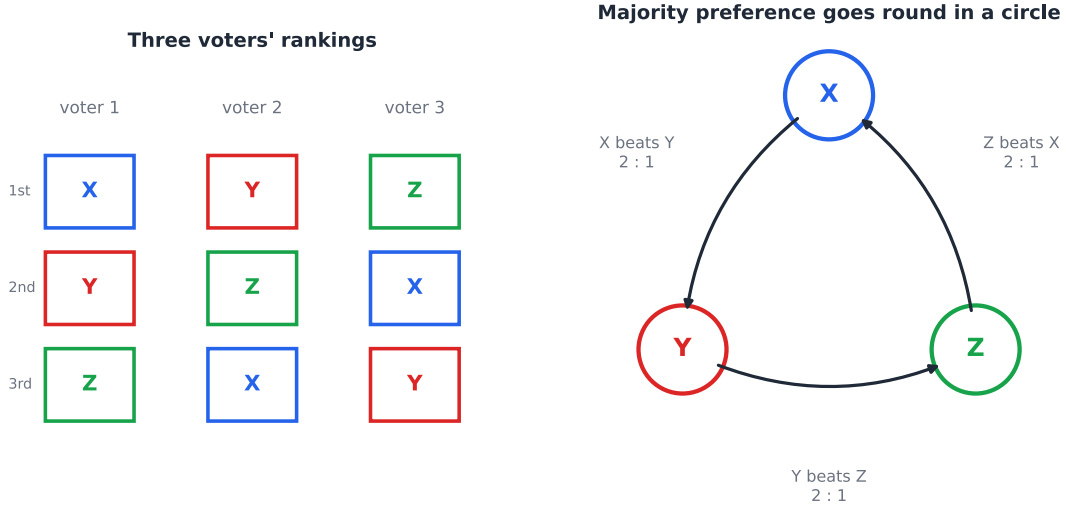

Figure 42.1 — The Condorcet cycle. Every voter is perfectly rational, yet "the majority prefers" is not a ranking at all.

Each member's ranking is perfectly sensible. Yet a majority prefers X to Y, a majority prefers Y to Z, and a majority prefers Z to X. Whoever controls the *order* of pairwise votes controls the winner: put Y against Z first, then the survivor against X, and X wins; reorder the agenda and Y or Z wins instead. The group has no "will" to discover.

So the question this chapter chases is simple to ask and surprisingly deep to answer:

> **Can we write down rules, for votes, for auctions, for bridges, under which telling the truth is every participant's selfish best move?**

We will find a remarkable "yes" when money can change hands, a precise reason why, and the first glimpse of a theorem that says "no" when it cannot.

42.2 The big idea

Ordinary game theory (Ch. 39) takes the game as given and asks what rational players will do. **Mechanism design runs game theory backwards.** You start from the outcome you *want*, say "build the bridge exactly when it is worth more than it costs", and you design the game whose equilibrium produces that outcome, even though every player is selfish and holds private information.

That is why it is sometimes called *reverse game theory*, and why engineers should feel at home in it. A control engineer designs a feedback law so that the closed loop does what she wants whatever the plant's internal state. A mechanism designer designs rules so that the "closed loop" of selfish agents does what she wants whatever their private preferences.

Picture a mechanism as a box:

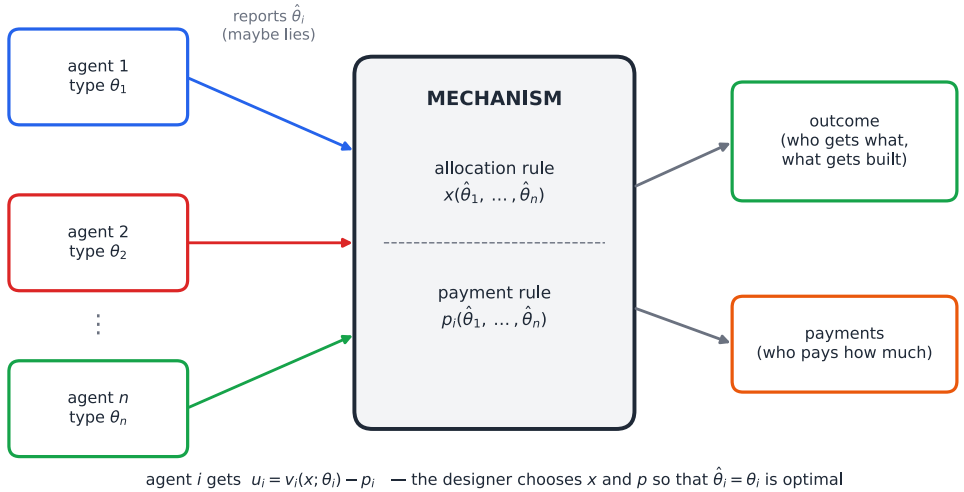

Figure 42.2 — A mechanism. Agents hold private types, send reports that may be lies, and the box turns reports into an outcome and a payment for each agent.

Three ingredients matter.

1. **Types.** Each agent i privately knows a type θ_i: how much the bridge is worth to her, how she ranks the designs, what a radio licence would earn her. This is exactly the setting of Bayesian games in Ch. 41.
2. **Reports.** The agents send messages. In the simplest mechanisms, the message *is* a claimed type $\hat{\theta}_i$.
3. **Rules.** The box applies an **allocation rule** (what happens) and a **payment rule** (who pays what).

The magic word is **incentive compatibility**: the rules are built so that reporting $\hat{\theta}_i = \theta_i$ is optimal for each agent. The analogy to hold on to is a well-designed tax form. A bad form invites you to shade the numbers; a good one is constructed so that shading cannot help you, and you stop bothering to think strategically at all. That last point is the real prize. A mechanism with a dominant truthful strategy is *robust*: it works without the designer knowing anyone's beliefs, and without participants needing to out-think each other.

The other big idea is a disappointment that turns into a design principle. Without money, the Condorcet cycle is not a curiosity but a symptom: as we will state below, essentially every voting rule over three or more options can be manipulated. With money, a single clever trick fixes the bridge problem. The trick is to **charge each agent for the harm her report does to everyone else.** Once you are billed for your externality, your private interest and society's interest line up, and lying stops paying.

42.3 The mathematics

Social choice functions

Let $N = \{1, \ldots, n\}$ be agents and O a set of possible outcomes (build or not; who gets which item). Agent i has a type $\theta_i \in \Theta_i$, and $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)$.

Social choice function and mechanism

A **social choice function** $f : \Theta_1 \times \cdots \times \Theta_n \to O$ says which outcome the designer *wants* for each profile of true types. A **mechanism** $(M_1, \ldots, M_n, g)$ gives each agent a message space M_i and an outcome rule $g : M_1 \times \cdots \times M_n \to O$. It is **direct** if $M_i = \Theta_i$: you simply announce a type.

The designer never observes $\boldsymbol{\theta}$. She observes messages, and the messages are chosen strategically.

When there is no money, agents only have preferences over O. Arrow's work in 1951 and the Gibbard–Satterthwaite theorem of the 1970s say how little you can then do:

Arrow's impossibility theorem (statement)

With at least three alternatives, no rule that turns every profile of individual rankings into a social ranking can satisfy all of: **unanimity** (if everyone prefers a to b, so does society), **independence of irrelevant alternatives** (society's verdict on a versus b depends only on individual verdicts on a versus b), and **non-dictatorship**.

Gibbard–Satterthwaite (statement)

With at least three possible winners and every ranking allowed, any voting rule that is **strategy-proof** (no voter ever gains by misreporting her ranking) and **onto** (every candidate can win) is a **dictatorship**.

The Condorcet cycle of Figure 42.1 is the smallest witness that majority rule breaks independence-plus-transitivity. The full proofs are combinatorial gems, and we are not going to give them here.

? Why must it be a dictator?

Gibbard–Satterthwaite does not merely say "manipulation is possible". It says that the *only* escape is to hand all power to one voter. How can two innocent-looking axioms force something as specific as a dictator? The proof hunts down a "pivotal voter" whose ranking flips society's choice, and shows that voter controls everything. The full argument, and its kinship with Arrow's theorem, are in Ch. 96.

Adding money: quasilinear utility

Now let money move. In the **quasilinear** model, an outcome is a pair (decision $x \in O$, payments $p_1, \dots, p_n$), and agent i's utility is

$$u_i = v_i(x; \theta_i) - p_i.$$

Money enters linearly and is worth the same to everyone. That assumption is strong (rich and poor do not value a euro equally) but it is what makes the theory tick.

Dominant-strategy incentive compatibility (DSIC)

A direct mechanism $(x(\cdot), p(\cdot))$ is **DSIC** (or **strategy-proof**) if for every agent i, every true type θ_i, every false report $\hat{\theta}_i$, and every report profile $\hat{\boldsymbol{\theta}}_{-i}$ of the others,

$$v_i\big(x(\theta_i, \hat{\boldsymbol{\theta}}_{-i}); \theta_i\big) - p_i(\theta_i, \hat{\boldsymbol{\theta}}_{-i}) \;\geq\; v_i\big(x(\hat{\theta}_i, \hat{\boldsymbol{\theta}}_{-i}); \theta_i\big) - p_i(\hat{\theta}_i, \hat{\boldsymbol{\theta}}_{-i}).$$

Truth is a dominant strategy: it is optimal *whatever the others do*, truthful or not.

A weaker notion, **Bayesian incentive compatibility** (BIC), asks only that truth be optimal *in expectation*, assuming the others are truthful and types are drawn from known distributions, i.e. that truth-telling is a Bayes–Nash equilibrium in the sense of Ch. 41. The expectations are the ordinary ones of Ch. 19.

Result 1: the revelation principle

Why study only direct mechanisms, where you just announce your type? Real mechanisms have rounds, clocks, bids and counter-bids. The first central result says you lose nothing.

Revelation principle (dominant-strategy version)

If some mechanism (M, g) has a dominant-strategy equilibrium $s_i^* : \Theta_i \to M_i$ that implements f, meaning $g(s_1^*(\theta_1), \dots, s_n^*(\theta_n)) = f(\boldsymbol{\theta})$ for all $\boldsymbol{\theta}$, then the direct mechanism $g^{\text{dir}}(\hat{\boldsymbol{\theta}}) = g(s_1^*(\hat{\theta}_1), \dots, s_n^*(\hat{\theta}_n))$ implements f and is DSIC.

Proof. Build a "proxy box": agent i tells the proxy her type $\hat{\theta}_i$, and the proxy plays $s_i^*(\hat{\theta}_i)$ on her behalf in the original mechanism. Suppose agent i with true type θ_i considers lying, reporting $\hat{\theta}_i$, when the others report $\hat{\boldsymbol{\theta}}_{-i}$. Her outcome is then $g(s_i^*(\hat{\theta}_i), \mathbf{s}^*_{-i}(\hat{\boldsymbol{\theta}}_{-i}))$. But $s_i^*(\hat{\theta}_i)$ is just *some* message $m_i \in M_i$, and since $s_i^*(\theta_i)$ is dominant in the original mechanism, it does at least as well as any m_i against *any* messages of the others, in particular against $\mathbf{s}^*_{-i}(\hat{\boldsymbol{\theta}}_{-i})$. So reporting θ_i is at least as good as reporting $\hat{\theta}_i$. Truth is dominant, and with truthful reports the outcome is $g(\mathbf{s}^*(\boldsymbol{\theta})) = f(\boldsymbol{\theta})$. ∎

The proof is almost insultingly short, and that is the point: anything clever an agent could do, the proxy already does for her. The same argument with "Bayes–Nash" in place of "dominant" gives the Bayesian revelation principle. The practical moral is double-edged. The principle lets theorists search only over truthful direct mechanisms. It does *not* tell engineers to build direct mechanisms: asking a bidder to report a value for every one of 2^{50} bundles of licences is hopeless, which is why real designs are indirect (Ch. 43).

Result 2: VCG makes truth dominant

Now the trick promised in 42.2. Let the designer's goal be **efficiency**: choose the decision maximising total value,

$$x^*(\hat{\boldsymbol{\theta}}) \in \arg\max_{x \in O} \sum_{j=1}^{n} v_j(x; \hat{\theta}_j).$$

Vickrey–Clarke–Groves (VCG) mechanism with the Clarke pivot

Given reports $\hat{\boldsymbol{\theta}}$: choose $x^*(\hat{\boldsymbol{\theta}})$ as above, and charge agent i

$$p_i(\hat{\boldsymbol{\theta}}) \;=\; \underbrace{\max_{x \in O} \sum_{j \neq i} v_j(x; \hat{\theta}_j)}_{\text{others' best welfare without } i} \;-\; \underbrace{\sum_{j \neq i} v_j\big(x^*(\hat{\boldsymbol{\theta}}); \hat{\theta}_j\big)}_{\text{others' welfare with } i}.$$

Agent i pays exactly the **externality** she imposes: how much worse off her presence makes everyone else.

VCG is DSIC

In the quasilinear model, the VCG mechanism is dominant-strategy incentive compatible.

Proof. Fix agent i, her true type θ_i, and arbitrary reports $\hat{\boldsymbol{\theta}}_{-i}$ of the others. Write $h_i = \max_x \sum_{j \neq i} v_j(x; \hat{\theta}_j)$; it does not depend on anything agent i says. If i reports $\hat{\theta}_i$, leading to decision $\hat{x} = x^*(\hat{\theta}_i, \hat{\boldsymbol{\theta}}_{-i})$, her utility is

$$u_i(\hat{\theta}_i) = v_i(\hat{x}; \theta_i) - h_i + \sum_{j \neq i} v_j(\hat{x}; \hat{\theta}_j) = \Big[v_i(\hat{x}; \theta_i) + \sum_{j \neq i} v_j(\hat{x}; \hat{\theta}_j)\Big] - h_i.$$

The bracket is the total welfare *as measured with her true value and the others' reports*, evaluated at $\hat{x}$. Agent i can influence only which $\hat{x}$ is chosen, and h_i is a constant to her. The bracket is maximised over all of O by choosing $\hat{x} = \arg\max_x [v_i(x;\theta_i) + \sum_{j\neq i} v_j(x;\hat{\theta}_j)]$, and that is precisely the decision the mechanism picks when she reports $\hat{\theta}_i = \theta_i$. So no report beats the truth, whatever the others report. ■

Notice what the proof did: VCG aligned each agent's objective with the designer's objective, *up to a constant she cannot affect*. This is the same move as a well-chosen Lagrangian or penalty term in optimization (Ch. 23): change the objective so that the local optimiser's best response is the global optimum.

Two side facts, easy to check. Payments are never negative, because the others' best welfare without i is at least their welfare at x^*. And truthful agents never regret participating (**individual rationality**) when values are non-negative and "nothing happens to you" is always available, because $u_i = \max_x \sum_j v_j - \max_x \sum_{j\neq i} v_j \geq 0$.

The footbridge, done right

Cost 300, split 100 each if built. Net values (value minus share) are $150,\ -50,\ -60$, summing to $+40$, so VCG builds. Write w_i for net value; "not build" gives everyone 0.

- Household 1: the others' net sum is -110. Without household 1 they would not build and get 0; with her they get -110. She pays $0 - (-110) = 110$ on top of her 100 share, so 210 in all. Her utility is $250 - 210 = 40$.
- Households 2 and 3: without household 2 the others' sum is $90 > 0$, so the bridge is built anyway and her presence changes nothing for them: she pays no extra. Same for household 3 (others' sum 100).

Now let household 2 exaggerate her dislike, reporting net -200. The total becomes -110, the bridge is cancelled, and she is now pivotal: the others lose 90, which she pays. Her utility drops from -50 to -90. Lying cost her 40.

Household 1's extra 110 is called the **Clarke tax**. Only **pivotal** agents, those whose report flips the decision, pay it.

? Where does the money go?

In the bridge example VCG collects 110 in Clarke tax that no one needs. If you hand it back to the households, you change their incentives and truth-telling can collapse. If you burn it, you waste welfare. Is there *any* rule that is efficient, truthful, voluntary, and exactly balances the budget? For two people trading a single good, the Myerson–Satterthwaite theorem says no, and the proof is a beautiful integration argument. It waits for you in Ch. 96.

Result 3: one-dimensional types and monotonicity

VCG targets efficiency. What can a DSIC mechanism do in general? For the most common case, **single-parameter** agents, the answer is clean. Each agent has one number $v_i \geq 0$ (value per unit of "stuff"), the mechanism gives her an amount $x_i(\mathbf{b}) \in [0,1]$ (a probability of winning, a share of bandwidth) based on bids $\mathbf{b}$, and her utility is $v_i x_i(\mathbf{b}) - p_i(\mathbf{b})$. Fix the others' bids and drop the subscript: write $x(b)$ and $p(b)$ as functions of her own bid.

Monotonicity is necessary

If (x,p) is DSIC, then $x(b)$ is non-decreasing in b, and for any $z < y$,

$$z\,[x(y) - x(z)] \;\leq\; p(y) - p(z) \;\leq\; y\,[x(y) - x(z)].$$

Proof. Truth for an agent of value z means she does not want to pretend to be y; truth for an agent of value y means she does not want to pretend to be z:

$$z\,x(z) - p(z) \geq z\,x(y) - p(y),$$
$$y\,x(y) - p(y) \geq y\,x(z) - p(z).$$

Rearranging the first gives the left inequality of the sandwich, the second gives the right one. The two ends of the sandwich can only be ordered if $(y-z)[x(y) - x(z)] \geq 0$, and since $y > z$ this forces $x(y) \geq x(z)$. ■

Divide the sandwich by $y - z$ and let $y \to z$: wherever x is differentiable, $p'(z) = z\,x'(z)$. Integrating, with $p(0) = 0$,

$$p(b) \;=\; b\,x(b) - \int_0^b x(z)\,dz.$$

This is **Myerson's lemma**: in single-parameter settings, *every* monotone allocation rule can be made truthful, and the payment is then *forced* (the converse, that this payment makes any monotone rule DSIC, follows from the same picture). Geometrically, the payment is the area to the *left* of the allocation curve, between it and the vertical axis, up to height $x(b)$.

Try it on one item and a "highest bid wins" allocation. If the best rival bid is B, then $x(b) = 0$ for $b < B$ and $x(b) = 1$ for $b > B$. The formula gives $p(b) = b - (b - B) = B$. **The winner pays the second-highest bid.** We have just *derived* the Vickrey second-price auction, rather than guessed it. It is also VCG for a single item, as you can check from the definition.

42.4 The algorithm

VCG is a recipe you can code for any finite outcome set. It needs one welfare maximisation with everyone, and one more without each agent: $n + 1$ optimisations in all.

```
def vcg(outcomes, values):
    """outcomes: list of decisions; values[i](x) = agent i's reported value for x."""
    n = len(values)
    welfare = lambda x, skip=None: sum(v(x) for j, v in enumerate(values) if j != skip)
    x_star = max(outcomes, key=welfare)                       # efficient decision
    pay = []
    for i in range(n):
        best_without_i = max(welfare(x, skip=i) for x in outcomes)
        pay.append(best_without_i - welfare(x_star, skip=i))    # externality of i
    return x_star, pay

# footbridge: outcome 1 = build, 0 = don't; values are net of the 100 share
net = [150, -50, -60]
print(vcg([0, 1], [lambda x, w=w: w * x for w in net]))       # (1, [110, 0, 0])
```

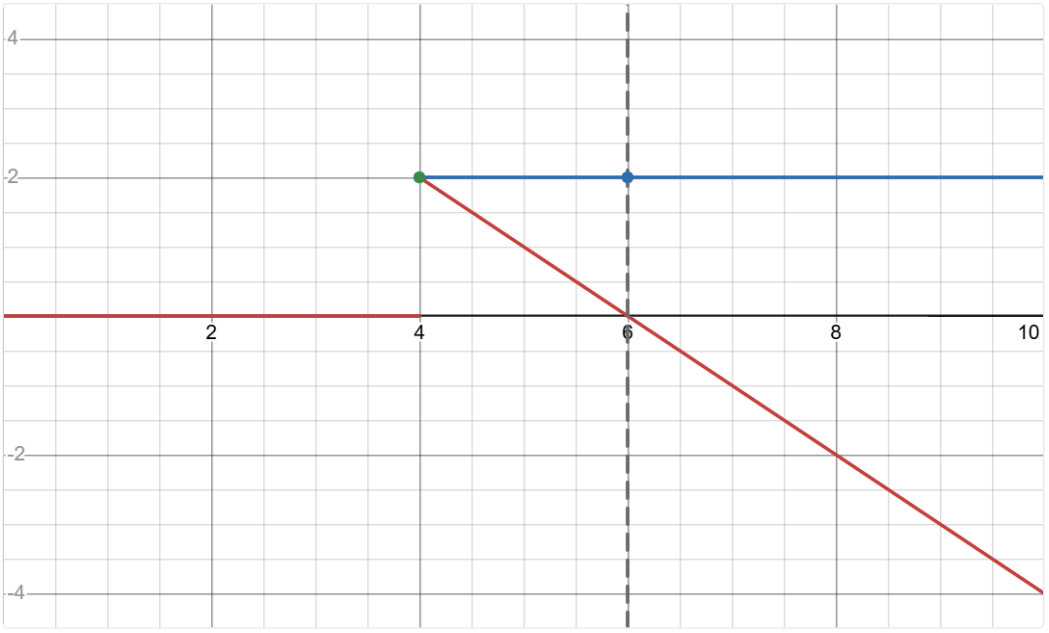
Complexity. The cost is $(n+1)$ times the cost of maximising welfare. For a yes/no decision that is trivial. For allocating m distinct items to bidders with values on *bundles*, the outcome set has up to $(n+1)^m$ elements, and welfare maximisation is the NP-hard **winner determination problem**, a weighted set-packing integer program (Ch. 49). That is a deep tension: truthfulness was proved assuming the mechanism finds the *exact* optimum.

Failure cases worth knowing:

- **Approximation breaks truth.** Replace the argmax by a heuristic and the VCG proof collapses: an agent may now gain by lying to steer the heuristic toward an outcome it would not find on its own. Designing mechanisms that are both truthful and computationally efficient is the field of *algorithmic mechanism design*, which leans on the limits in Ch. 30.
- **Collusion.** DSIC is about single agents. Two losing bidders can sometimes jointly lie and both win (you will meet a spectacular case in Ch. 43).
- **Numerics.** Payments are *differences* of large optima. With floating-point values of similar size, a pivotal agent's tax can be swamped by rounding; use exact arithmetic (integers, fractions) for money. The same catastrophic-cancellation warning appears in Ch. 22.
- **False-name bids.** VCG assumes each agent has one identity. On the internet, one person can bid as many, and VCG is not robust to that.

42.5 The experiment

A. Feel the incentives. The graph plots the utility of a bidder whose true value is 6 against a rival whose bid is 4, as a function of her own bid x. Blue is the second-price auction (win and pay 4 if $x > 4$). Red is a first-price auction (win and pay x if $x > 4$).



Blue never rises above its value at the truthful bid $x = 6$; red rewards shading down toward 4 and punishes bids above 6.

Change the rival's bid from 4 to 7: in the four domain restrictions replace 4 by 7, and replace the blue line $y = 2$ by $y = -1$ (value 6 minus price 7); the red line $y = 6 - x$ is unchanged. Now the truthful bid 6 loses, and the blue line shows that bidding above 7 would win at a loss. Truth is still optimal. Then try to find *any* rival bid for which a blue bid other than 6 does strictly better. You can't, and the proof in 42.3 says why.

B. Try to cheat VCG. This script runs the Clarke-pivot footbridge and lets household `i` try every report on a grid. Change `true_net`, the cost share inside it, and `i`.

```
import numpy as np

def clarke(reports):
    """Build iff total net report > 0. Returns (decision, Clarke taxes)."""
    reports = np.asarray(reports, dtype=float)
    build = reports.sum() > 0
    taxes = []
    for k in range(len(reports)):
        others = reports.sum() - reports[k]
        pivotal = (others > 0) != build
        taxes.append(abs(others) if pivotal else 0.0)
    return build, np.array(taxes)

true_net = np.array([150.0, -50.0, -60.0])   # value minus 100 cost share
i = 1                                        # the household trying to cheat

def utility(report):
    r = true_net.copy(); r[i] = report
    build, tax = clarke(r)
    return true_net[i] * build - tax[i]

grid = np.linspace(-500, 500, 2001)
u = np.array([utility(r) for r in grid])
print(f"truthful report {true_net[i]:+.0f}: utility {utility(true_net[i]):.1f}")
print(f"best report on grid: {grid[u.argmax()]:+.0f}, utility {u.max():.1f}")
print(f"best lie strictly better than truth? {u.max() > utility(true_net[i]) + 1e-9}")

# The naive clerk's rule: build iff sum > 0, no taxes. Lying pays here.
naive = lambda rep: true_net[i] * ((true_net.sum() - true_net[i] + rep) > 0) + 0.0
print("naive rule, truth:", naive(true_net[i]), " best lie:", max(naive(r) for r in grid))
```

With the numbers given, household 2 cannot beat its truthful utility of -50 under VCG, but under the naive rule a lie lifts it from -50 to 0. Now set `true_net = [30, -20, -5]` and look at the total tax collected. Then randomise `true_net` a thousand times and plot the histogram of total Clarke tax: that money is the price of truth.

42.6 The challenge

1. **Intuition.** Solomon's mechanism stops working once the false mother knows it. Explain, in the language of 42.3, which incentive constraint fails. Then propose a version of Solomon's test that uses *money* (each woman may pay to claim the child) and argue informally which woman would pay more, and what could still go wrong.
2. **Derivation.** For a single item, show directly from the VCG definition that the winner's payment equals the second-highest reported value and losers pay nothing. Then take an allocation rule that gives one unit to the highest bidder *only if* her bid exceeds a reserve r, and use Myerson's formula $p(b) = b\,x(b) - \int_0^b x(z)\,dz$ to find what she pays.
3. **Implementation.** Extend the `vcg` function to k identical items among n bidders who each want at most one. Verify numerically that the winners all pay the same price, identify that price, and check with random lies that no bidder ever gains.
4. **Open investigation.** For three voters and three candidates there are $6^3 = 216$ ranking profiles. Write a program that, for plurality with alphabetical tie-breaking, Borda, and instant-runoff voting (Ch. 44), counts the fraction of profiles in which some single voter can profitably misreport. How does the fraction grow with the number of voters and candidates, and does any non-dictatorial rule come close to zero? (No one has a clean formula for most rules.)

42.7 Loose threads

This chapter promised truthfulness, and with money it delivered: VCG makes honesty a dominant strategy whenever the designer's goal is total welfare and utilities are quasilinear. But look at what we swept aside.

- **We only maximised welfare.** A seller does not want efficiency; she wants revenue. The Clarke tax in the bridge example was an accident, not an objective. What mechanism extracts the *most* money from bidders whose values she can only guess at?

> **? The seller's mechanism**
>
> Myerson's lemma pins down payments for any monotone allocation. So the expected revenue of a truthful mechanism is a function of the allocation rule alone. Which allocation maximises it? The answer involves a strange quantity, the "virtual value" $v - \frac{1-F(v)}{f(v)}$, and sometimes tells the seller to refuse to sell to the only bidder present. That surprising rule, and why it beats every auction format you know, is the business of Ch. 43.

- **We never proved the impossibility theorems.** Arrow and Gibbard–Satterthwaite were stated, not proved; their proofs are in Ch. 96.
- **Budget balance** was left as a mystery above.
- **Groups were ignored.** DSIC protects against one liar, not coalitions; cooperative behaviour is the subject of Ch. 44.
- **Computation was waved at.** When the welfare optimum is NP-hard, can a truthful mechanism get close to it? For some problems, provably not without losing truthfulness; for others, this is open.

And one deeper unease. Every result here assumed agents are perfectly rational expected-utility maximisers who understand the rules. Real people in a second-price auction sometimes overbid anyway. A "strategy-proof" mechanism that people do not *believe* is strategy-proof may behave like a manipulable one. Designing for real minds, rather than ideal ones, is where much of the current research lives.

Chapter 43 — Auctions, Markets, and Strategic Bidding

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 19, Ch. 5, Ch. 41, Ch. 42 · **Leads to:** Ch. 46, Ch. 96 · **Related:** Ch. 48, Ch. 49, Ch. 38 **Reading time:** ~25 min

43.1 The hook

In the year 2000, several European governments sold licences for the third generation of mobile phone networks, the radio spectrum that every smartphone now lives on. The licences were broadly similar, the bidders were often the very same telecom giants, and the auctions happened within months of each other. The outcomes were not similar at all.

The United Kingdom raised about £22.5 billion, roughly 2.5% of national income, in an auction that ran for seven weeks and 150 rounds. The Netherlands, a few months later, raised about €2.7 billion, a small fraction of what had been forecast, with about the same number of licences as there were strong incumbent firms ready to bid. In Switzerland, bidders withdrew or merged before the auction began, four licences went to four bidders at close to the reserve price, and the government collected about CHF 205 million, a tiny fraction of the British take per head of population. The economist Paul Klemperer, who helped design the British auction, summed up the lesson: in auctions, *details matter*.

Go back ten years and the details bite harder. In 1990 New Zealand sold spectrum licences with a **second-price** sealed-bid auction: the highest bidder wins and pays the second-highest bid. Economists love this format; we derived it in Ch. 42 as the unique truthful way to sell one item. The public did not love it. As John McMillan later reported, in one licence the winning bid was NZ$100,000 and the price paid was NZ$6, because the only other bid was NZ$6. Headlines asked why the government was giving away the airwaves.

So which is it? Is the second-price auction a mathematical triumph (truthful, efficient, simple) or a revenue disaster? Why did "the same" auction raise, per head of population, more than 25 times as much in one country as in another? And what is a seller supposed to do when she does not even know what the bidders think the item is worth?

By the end of this chapter you will be able to compute, for a clean model, exactly what each format earns. And you will meet a theorem so strong it feels like a trick: in that clean model, a whole family of very different-looking auctions earns *exactly the same* expected revenue. The real-world disasters are all stories about where that model breaks.

43.2 The big idea

There are four classic formats for selling one item.

Format	How it runs	Winner pays
English (ascending)	Price rises; bidders drop out; last one standing wins	The price at which the second-to-last bidder quit
Dutch (descending)	Price falls from high; first to shout "mine" wins	The price at which she shouted
First-price sealed	Everyone submits one sealed bid; highest wins	Her own bid
Second-price sealed (Vickrey)	Same, but…	The second-highest bid

Two pairs collapse at once. A Dutch auction is **strategically identical** to a first-price sealed auction: in both, your only decision is the price at which you commit, and you pay that price if it is the highest. And when bidders know their own values (the **private values** setting), an English auction works like a second-price auction: you stay in until the price reaches your value, and the winner pays roughly where the runner-up dropped out.

So really there are two worlds, and they push bidders in opposite directions.

- In the **second-price** world, your bid controls only *whether* you win, not *what you pay*. So you should bid exactly your value: bidding higher only adds wins at a loss, bidding lower only loses wins you wanted (Ch. 42 has the picture).
- In the **first-price** world, your bid is your price. Bid your value and you win nothing (zero profit); bid lower and you keep a margin, at the risk of losing. So everyone **shades**: they bid below their values, trading off a fatter margin against a thinner chance of winning.

The analogy is the difference between a fixed-price menu and haggling. In the first, you only need to know what you want. In the second, you need a theory of everybody else.

Here is the surprise to keep in mind. In the second-price auction the seller collects the *second*-highest value. In the first-price auction she collects the highest *bid*, which is shaded. One number is a lower value, the other a shaded higher value. They could be ordered either way. Section 43.3 shows they are equal on average, and not by coincidence.

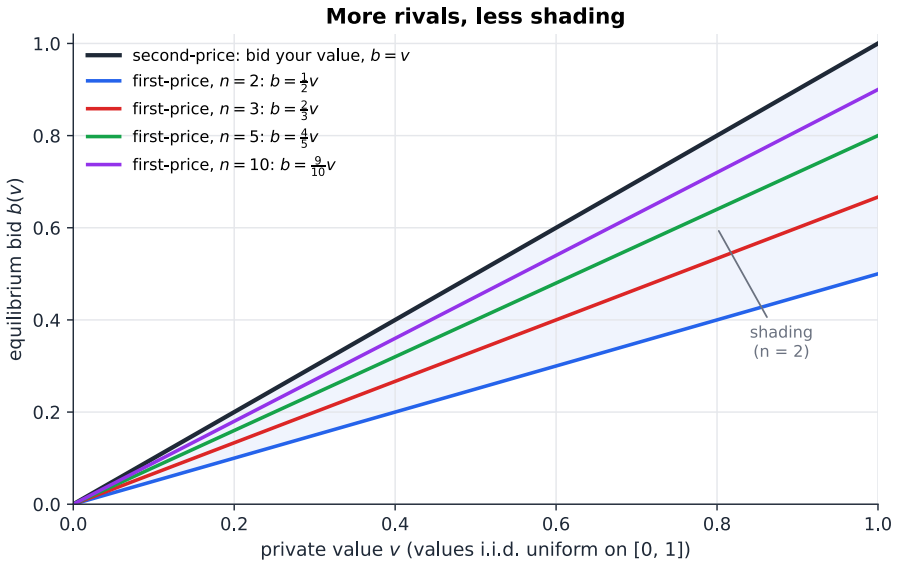

Figure 43.1 — Equilibrium bidding with values uniform on $[0,1]$. Second-price bidders bid their value; first-price bidders shade, and the shading shrinks as rivals multiply.

43.3 The mathematics

The model

There are n bidders. Bidder i has a private value v_i, and the values are **independent and identically distributed** with a continuous distribution function F and density f on $[0, \bar{v}]$ (the *independent private values*, or IPV, model). Each bidder knows her own value and only the distribution of the others', which makes this a Bayesian game in the sense of Ch. 41. Utility is quasilinear: win at price p and get $v_i - p$; lose and get 0. For concrete numbers we use the uniform case $F(v) = v$ on $[0,1]$.

One fact from probability (Ch. 19) does most of the work. The maximum of k independent uniforms has CDF $P(\max \le t) = t^k$, so its density is kt^{k-1} and its mean is $\int_0^1 t \cdot kt^{k-1}\,dt = \frac{k}{k+1}$. For the second-highest of n uniforms, the mean is $\frac{n-1}{n+1}$.

Result 1: equilibrium shading in the first-price auction

First-price equilibrium, uniform values

With n bidders and values i.i.d. uniform on $[0,1]$, the strategy $\beta(v) = \frac{n-1}{n}\,v$ played by everyone is a symmetric Bayes–Nash equilibrium of the first-price auction.

Proof. Guess that the other $n-1$ bidders use $\beta(v) = c\,v$ for some $c \in (0,1]$, and look for bidder 1's best bid b when her value is v. She wins if every rival bids below b, i.e. if every rival value is below b/c. For $b \le c$, independence gives

$$P(\text{win}) = \left(\frac{b}{c}\right)^{n-1}, \qquad \pi(b) = (v-b)\left(\frac{b}{c}\right)^{n-1}.$$

Differentiate and set to zero (the constant $c^{-(n-1)}$ drops out):

$$-b^{n-1} + (n-1)(v-b)\,b^{n-2} = 0 \quad\Longrightarrow\quad b = \frac{n-1}{n}\,v.$$

The second derivative is negative at this point, so it is a maximum, and bids above c win with certainty but cost more, so they are worse. Her best response is linear with slope $\frac{n-1}{n}$. For a *symmetric* equilibrium her best response must be the strategy we assumed for the others, so $c = \frac{n-1}{n}$. Since $\frac{n-1}{n}v \le c$ for every $v \le 1$, the condition $b \le c$ we used holds. ∎

With two bidders you bid half your value. With ten, you bid 90%. Competition squeezes out the shading, which is Figure 43.1.

There is a pretty interpretation. If Y is the highest of the other $n-1$ values, then $E[Y \mid Y < v] = \frac{n-1}{n}v$ for uniforms. You bid what you expect the strongest rival's value to be, *given that you beat it*. That formula, $\beta(v) = E[Y \mid Y < v]$, is the general first-price equilibrium for any distribution F.

Result 2: revenue equivalence

Expected revenue in the second-price auction is the expected second-highest value: $\frac{n-1}{n+1}$. In the first-price auction it is the expected highest bid, $\frac{n-1}{n} \cdot E[\max_i v_i] = \frac{n-1}{n} \cdot \frac{n}{n+1} = \frac{n-1}{n+1}$. **Identical.** For $n = 2$, both give $\frac{1}{3}$.

Coincidence? Ch. 42 already has the reason. Apply Myerson's lemma to the *expected* allocation and payment. Let $x(v)$ be the probability that a bidder of value v wins and $m(v)$ her expected payment, both in equilibrium. Truth-telling to the "direct" version of any equilibrium (the revelation principle) gives the same sandwich argument as in Ch. 42, now in expectation, and hence

$$m(v) = v\,x(v) - \int_0^v x(z)\,dz + m(0).$$

Revenue equivalence

In the IPV model, any two auctions in which, in equilibrium, (i) the bidder with the highest value always wins, and (ii) a bidder with value 0 pays nothing in expectation, give every bidder the same expected payment $m(v)$, and hence give the seller the same expected revenue.

Proof. Under (i), a bidder of value v wins exactly when all $n-1$ others have lower values, so $x(v) = F(v)^{n-1}$, the same in both auctions. Under (ii), $m(0) = 0$. The formula above then determines $m(v)$ completely from x, so it is the same in both auctions. Expected revenue is $n\,E[m(v_i)]$, which is therefore the same too. ∎

Check it in the uniform case: $x(v) = v^{n-1}$, so $m(v) = v^n - \frac{v^n}{n} = \frac{n-1}{n}v^n$, and $n\,E[m] = (n-1)\int_0^1 v^n\,dv = \frac{n-1}{n+1}$. It also covers stranger formats: an **all-pay auction**, where every bidder pays her bid win or lose (a model of lobbying, patent races, or the effort spent on a job application), earns the same expected revenue too.

What revenue equivalence does not say

It says *expected* revenue is equal. The distributions differ: the second-price price is more variable, which is exactly how New Zealand ended up selling a licence for NZ$6 when there was only one serious bidder. A risk-averse seller, or a government facing headlines, is not indifferent.

Result 3: the optimal auction

The mystery in Ch. 42 asked which mechanism earns the seller the most. Revenue equivalence says all "efficient" formats tie, so to do better the seller must sometimes **not** give the item to the highest bidder. The cleanest lever is a **reserve price** r: no sale unless someone bids at least r.

Start with one bidder. With a posted price r, she buys if $v \ge r$, so revenue is $r\,(1 - F(r)) = r(1-r)$ for uniform values. Maximising, $r^* = \frac{1}{2}$ and revenue is $\frac{1}{4}$. With no reserve, one bidder in a second-price auction pays 0. So the seller *should* risk not selling at all.

For n bidders the same calculation becomes a short identity. Take the expected payment $m(v)$ above, with $m(0) = 0$, average it over $v \sim F$, and swap the order of integration in the double integral:

$$\int_0^{\bar v}\!\!\int_0^{v} x(z)\,dz\,f(v)\,dv = \int_0^{\bar v} x(z)\,\big(1 - F(z)\big)\,dz.$$

That gives

$$E\big[m(v)\big] = \int_0^{\bar v} x(v)\left[v - \frac{1-F(v)}{f(v)}\right] f(v)\,dv = E\big[\varphi(v)\,x(v)\big], \qquad \varphi(v) = v - \frac{1-F(v)}{f(v)}.$$

Myerson's optimal auction (regular case)

Expected revenue of any truthful mechanism equals the expected **virtual value** of the winner, $E\big[\sum_i \varphi(v_i)\,x_i\big]$. If φ is increasing, revenue is maximised by giving the item to the bidder with the highest $\varphi(v_i)$, provided it is positive, and to no one otherwise. For i.i.d. bidders this is a second-price auction with reserve r^* solving $\varphi(r^*) = 0$.

Proof. Summing over bidders, expected revenue is $E[\sum_i \varphi(v_i)x_i(\mathbf{v})]$. For each value profile, the expression $\sum_i \varphi(v_i)x_i$ with $\sum_i x_i \le 1$ is largest when all weight goes to the largest $\varphi(v_i)$ if that is positive, and nothing is sold if all are negative. If φ is increasing, this allocation is monotone in each bid, so by Myerson's lemma it can be made truthful, and the payment it forces is "the larger of the reserve and the second-highest bid". Maximising pointwise maximises the expectation. ∎

For uniform values $\varphi(v) = v - (1-v) = 2v - 1$, so $r^* = \frac{1}{2}$, **whatever the number of bidders**. With two bidders, the reserve lifts expected revenue from $\frac{1}{3} \approx 0.333$ to $\frac{5}{12} \approx 0.417$, a 25% gain, at the cost of sometimes not selling to a bidder who valued the item. Optimal revenue and efficiency pull in different directions.

? When values are not private

Everything above assumed you know what the item is worth *to you*. Spectrum, oil leases and takeover targets are worth roughly the same to everyone, and nobody knows how much. Then winning is bad news: you win exactly when you were the most optimistic, and the naive bidder systematically overpays. This **winner's curse** breaks revenue equivalence, and the English auction, which lets you watch rivals quit, now beats the sealed formats by "linking" your price to their information. The *linkage principle* and the affiliated-values model that makes it precise are in Ch. 96.

Many items: packages and markets

The 3G auctions sold many licences at once, and values were **not additive**. A firm that wins one regional licence may need the neighbouring one to build a viable network: the pair is worth more than the sum of its parts (complements). Figure 43.2 shows a toy version.

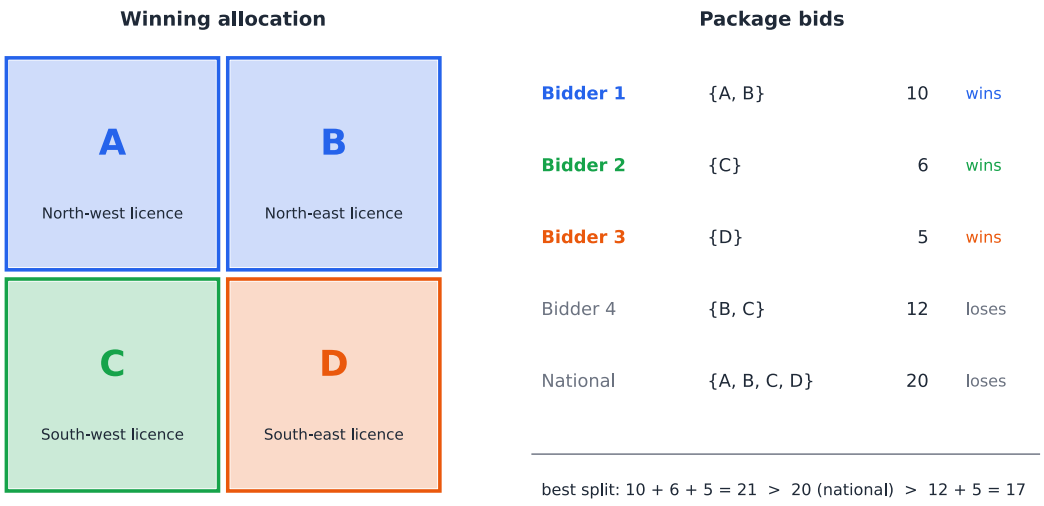

Figure 43.2 — A package auction. Bids are on bundles; the auctioneer picks the set of non-overlapping bids with the largest total.

Picking the winners is the **winner determination problem**: choose a set of pairwise disjoint packages with maximum total bid. Here the three local bidders together (21) beat the national bidder (20). Now compute VCG payments as in Ch. 42. Without bidder 1, the best allocation is the national bid, 20; with her, the others get $6 + 5 = 11$; so she pays 9. Similarly bidder 2 pays $20 - 15 = 5$ and bidder 3 pays $20 - 16 = 4$. **Total revenue: 18**, although a single bidder was offering 20 for the lot. Worse, if bidders 2 and 3 were one firm, the incentives would change again. Truthful does not mean sensible.

Two design ideas tame this. **Simultaneous ascending (clock) auctions** raise prices on all licences together round by round, so bidders discover which packages are affordable; the UK 3G sale was of this family. And the theory of **markets** says that when goods are substitutes, a set of item prices exists at which every bidder demands exactly what she is allocated, a **Walrasian equilibrium**, which an ascending clock can find.

Not all markets have prices. Doctors and hospitals, students and schools, kidney donors and patients: here money cannot or should not clear the market. Gale and Shapley showed in 1962 that in a two-sided matching market, a **stable matching** (no doctor and hospital who would both rather be with each other than with their assigned partners) always exists, and the next section gives the algorithm that finds it.

43.4 The algorithm

Deferred acceptance (Gale–Shapley). One side proposes; the other side holds its best offer so far and rejects the rest, until no one is left to propose.

```
def deferred_acceptance(prop_prefs, recv_prefs):
    """prop_prefs[p] = list of receivers, best first; recv_prefs[r] likewise.
    Returns dict receiver -> proposer for a proposer-optimal stable matching."""
    rank = {r: {p: k for k, p in enumerate(lst)} for r, lst in recv_prefs.items()}
    nxt = {p: 0 for p in prop_prefs}             # next receiver p will try
    held = {}                                    # receiver -> proposer held
    free = list(prop_prefs)
    while free:
        p = free.pop()
        if nxt[p] >= len(prop_prefs[p]):
            continue                             # p has been rejected everywhere
        r = prop_prefs[p][nxt[p]]; nxt[p] += 1
        if p not in rank[r]:
            free.append(p); continue             # r finds p unacceptable
        if r not in held:
            held[r] = p
        elif rank[r][p] < rank[r][held[r]]:
            free.append(held[r]); held[r] = p    # r trades up
        else:
            free.append(p)                       # r rejects p
    return held
```

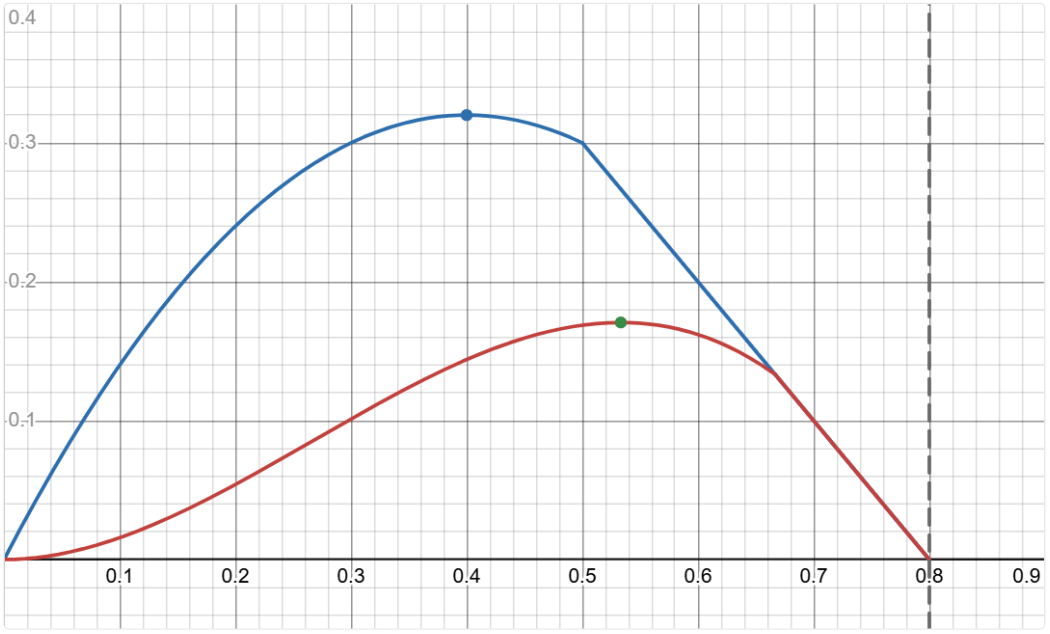
Why it stops, and why the result is stable. Each proposer proposes to each receiver at most once, so with n on each side there are at most n^2 proposals: $O(n^2)$ time. A receiver's held partner only ever improves. Now suppose p and r would both prefer each other to their final partners. Then p proposed to r before reaching her final partner (she ranks r higher), and r rejected her, at that time or later, for someone r prefers. Since r only trades up, r's final partner beats p, contradicting the assumption. So no blocking pair exists.

The auction side. Monte Carlo (Ch. 38) is the workhorse for comparing formats: draw values, apply the equilibrium strategies, average revenue. Its error falls like $1/\sqrt{\text{samples}}$, so to separate $\frac{1}{3}$ from $\frac{5}{12}$ reliably you need thousands of draws, and to see a 1% revenue difference you need hundreds of thousands. For package auctions, winner determination is a weighted set-packing integer program (Ch. 49); brute force over subsets of bids, as used to check the numbers of Figure 43.2, is exponential and fine only for toy cases.

Failure cases. Deferred acceptance is strategy-proof for the *proposing* side only; receivers can sometimes gain by misreporting. With couples who must be placed together (a real issue in medical residency matching), a stable matching may not exist at all. Clock auctions can suffer the **exposure problem**: a bidder who chases a complementary pair can end up holding only one licence at a price above its stand-alone value.

43.5 The experiment

A. Find your best first-price bid. Your value is 0.8. Blue: one rival who bids half her (uniform) value, so you win with probability $2x$. Red: two such rivals bidding two-thirds of their values, so you win with probability $(1.5x)^2$. The curves are your expected profit at bid x.



The peaks sit at $\frac{1}{2}\cdot 0.8 = 0.4$ and $\frac{2}{3}\cdot 0.8 \approx 0.533$: exactly the equilibrium bids of Result 1.

Change the value 0.8 to 0.5 (in all four curves) and confirm that the peaks move to 0.25 and 0.333. Then make the one rival more aggressive: replace $2x$ by $1.25x$ (she bids 80% of her value, for $x < 0.8$). Does your best bid rise or fall? Is it still a best response to bid half your value?

B. Race the formats. Draw values, play the equilibrium strategies, compare revenues. Change `n`, `reserve`, and the value distribution.

```
import numpy as np
import matplotlib.pyplot as plt

rng = np.random.default_rng(0)
n, trials, reserve = 2, 200_000, 0.5
v = rng.random((trials, n))                # i.i.d. uniform private values
s = np.sort(v, axis=1)
top, second = s[:, -1], s[:, -2]

first_price  = (n - 1) / n * top           # highest equilibrium bid
second_price = second                      # truthful bids: pay the runner-up
with_reserve = np.where(top < reserve, 0.0, np.maximum(second, reserve))

for name, rev in [("first-price", first_price), ("second-price", second_price),
                  (f"second-price, reserve {reserve}", with_reserve)]:
    se = rev.std() / np.sqrt(trials)
    print(f"{name:28s} mean {rev.mean():.4f} +/- {1.96*se:.4f}   std {rev.std():.3f}")
print("theory (no reserve):", (n - 1) / (n + 1))

plt.hist(first_price, bins=80, alpha=0.6, density=True, label="first-price revenue")
plt.hist(second_price, bins=80, alpha=0.6, density=True, label="second-price revenue")
plt.xlabel("seller revenue"); plt.legend(); plt.show()
```

Same mean, different spread: the histogram shows why a risk-averse seller cares about the format. Now replace `rng.random` with `rng.beta(2, 5, ...)` (values usually low) and note that the first-price line `(n-1)/n * top` is no longer the equilibrium. What breaks first, the code or the theorem?

43.6 The challenge

1. **Intuition.** Explain without equations why the optimal reserve price for uniform values is $\frac{1}{2}$ *no matter how many bidders there are*, even though with 100 bidders the reserve almost never binds. Then explain why governments are often told to set reserves well above what this theory suggests.
2. **Derivation.** Let two bidders have values on $[0, 1]$ with CDF $F(v) = v^2$ (strong bidders are common). Use revenue equivalence to find the first-price equilibrium bid $\beta(v)$, the seller's expected revenue, and the optimal reserve price from the virtual value $\varphi(v)$. Is φ increasing here?
3. **Implementation.** Write a brute-force winner-determination solver for package bids and a VCG payment routine. Reproduce the payments $9, 5, 4$ for Figure 43.2. Then find a package bid that bidders 2 and 3, acting together, could *add* (a fake shill bid) to lower their total payment.
4. **Open investigation.** Simulate a repeated first-price auction in which each of several bidders adapts her shading factor by a simple learning rule (for example, nudge the factor toward whatever would have earned more last round). Do the factors converge to $\frac{n-1}{n}$? Does the answer change with the learning rate, with noise, or with asymmetric bidders? Online ad exchanges, which moved from second-price to first-price auctions around 2019, face exactly this question.

43.7 Loose threads

We answered the questions of the hook in a clean world: independent private values, risk-neutral bidders, one item. In that world the second-price auction is truthful and the first-price auction is not, yet they earn the same, and the best a seller can do is a second-price auction with a well-chosen reserve. The real failures came from where that world ends: too few serious bidders (Switzerland, the Netherlands, the NZ$6 licence), common values, packages, and collusion.

? Prices are shadows of a linear program

In a market where buyers each want one item and sellers each have one, the efficient assignment is a linear program, and something odd happens: its **dual variables** are exactly a set of market-clearing prices, and the set of all such prices forms a lattice with a buyer-best and a seller-best corner. Why does the dual of an assignment problem know about competitive equilibrium? That bridge between optimisation and markets runs through LP duality in Ch. 48.

? Bidding against a machine that learns

A real bidder on an ad exchange does not know F, faces millions of auctions, and competes with algorithms that are themselves adapting. Is there a strategy whose total profit is guaranteed to be nearly as good as the best fixed shading factor in hindsight, whatever the opponents do? Strategies with vanishing **regret** do exactly that; how they work, and what equilibrium they converge to, is the subject of Ch. 46.

We also left untouched:

- **Asymmetric bidders.** When one bidder is known to be strong, the first-price equilibrium has no closed form and revenue equivalence fails. Handicapping the strong bidder can *raise* revenue.
- **Many-to-one matching with couples** and the strategic behaviour of receiving sides.
- **Why the VCG revenue in Figure 43.2 was "too low"**: the set of payments that no coalition can object to is called the *core*, and modern spectrum auctions use core-selecting payment rules. The theory of the core belongs to cooperative games, which is where Ch. 44 begins.

Chapter 44 — Coalitions, Voting, and Collective Decisions

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 23, Ch. 39, Ch. 42, Ch. 43 · **Leads to:** Ch. 45, Ch. 96 · **Related:** Ch. 28, Ch. 38, Ch. 48 **Reading time:** ~25 min

44.1 The hook

When the European Economic Community was founded in 1958, its six members wrote a voting rule for the Council of Ministers. On many questions each country cast a weighted vote: France, West Germany and Italy 4 each, Belgium and the Netherlands 2 each, Luxembourg 1. There were 17 votes in all, and a proposal passed with 12. Luxembourg, the smallest member, had one vote out of seventeen, about 6% of the total. A fair-looking rule.

Here is the strange part. List every possible coalition of countries voting "yes", and ask in how many of them Luxembourg's vote *made the difference* between passing and failing. The answer is **none**. Not one. Luxembourg's vote could never change the outcome of a weighted vote, in any configuration of the other five. The country had a vote, but it had **no power**.

That puzzle is about *voting* power, but the same question hides in every joint venture. Three energy firms build a shared microgrid. Alone, firm A could earn 10 (in millions per year), firm B 20, and firm C nothing: it owns storage but no generation. Any two together earn more (A and B 40, A and C 50, B and C 60) and all three together earn 90. Firm C is worthless on its own and essential in partnership. How should they split the 90? Equally? In proportion to what each could earn alone (which gives C nothing)? Something else?

And the question hides in elections too. A hundred voters rank three candidates:

Voters	1st	2nd	3rd
40	A	C	B
35	B	C	A
20	C	B	A
5	C	A	B

Under plurality (most first choices), A wins. Under ranked-choice instant runoff, B wins. Under the Borda count, and in every head-to-head contest, C wins. Same voters, same ballots, three different "winners".

So the chapter asks: **when a group acts together, who really holds power, who deserves what, and whose choice is "the group's choice"?** Mathematics cannot settle what is fair. What it can do, remarkably, is pin down exactly which fairness rules are even possible.

44.2 The big idea

The previous chapters were *non-cooperative*: each player chose a strategy alone, and we asked what equilibrium emerged. Now we zoom out. **Cooperative game theory** does not model how players negotiate. It assumes groups can sign binding agreements, and asks only: what can each coalition achieve, and how should the proceeds be split?

The central object is a single function. For each coalition S of players, $v(S)$ is the total value that S can guarantee on its own. Everything else, the alliances, the haggling, the threats to walk away, is compressed into those numbers.

The key intuition is **marginal contribution**. Imagine the players arrive at a room one at a time, in random order. Each, on arrival, adds something to the coalition already there. Firm C arriving first adds 0. Arriving after A, it adds $50 - 10 = 40$. Arriving last, it adds $90 - 40 = 50$. Your fair share, says Lloyd Shapley, is your **average marginal contribution over all arrival orders**. That turns out to be the only rule satisfying a handful of very mild fairness axioms.

The same idea measures **power**: in a voting game, a country's "contribution" is 1 if its arrival turns a losing coalition into a winning one, and 0 otherwise. Luxembourg's average contribution is zero because its single vote never tips any total across the line.

Voting rules are a different kind of aggregation: not dividing money but combining rankings. Here the big idea is negative, and you have already met it in Ch. 42: Arrow's theorem says no ranking rule is perfect. So the practical question becomes "which imperfection do we prefer?", and the ranked-choice example shows the choice has teeth.

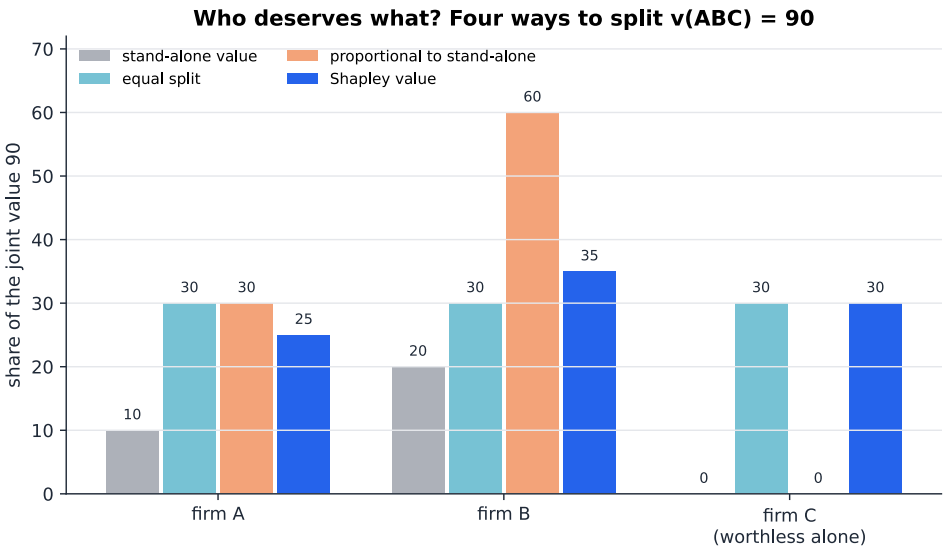

Figure 44.1 — Four ways to split the microgrid's 90. The Shapley value (25, 35, 30) rewards C for what it enables, not for what it earns alone.

44.3 The mathematics

Coalitional games and the core

Transferable-utility (TU) game

A set of players $N = \{1, \dots, n\}$ and a **characteristic function** $v : 2^N \to \mathbb{R}$ with $v(\varnothing) = 0$. The number $v(S)$ is the total payoff coalition S can secure and divide freely among its members. The game is **superadditive** if $v(S \cup T) \geq v(S) + v(T)$ for disjoint S, T.

An **allocation** is a vector $\mathbf{x} = (x_1, \dots, x_n)$ with $\sum_i x_i = v(N)$: the grand coalition's value is shared out completely.

The core

The **core** is the set of allocations that no coalition can object to:

$$\sum_{i \in S} x_i \;\geq\; v(S) \quad \text{for every } S \subseteq N.$$

If some S received less than $v(S)$, its members could walk away together and do better.

For the microgrid, the Shapley allocation $(25, 35, 30)$ is in the core: each firm gets more than it earns alone, and the pairs get $60 \geq 40$, $55 \geq 50$, $65 \geq 60$. But the core can be empty, and the smallest example is worth proving.

The three-player majority game has an empty core

Let $v(S) = 1$ if $|S| \geq 2$ and $v(S) = 0$ otherwise (any two of three can take the whole prize). No allocation lies in the core.

Proof. Suppose $\mathbf{x}$ were in the core. The three two-player constraints say $x_1 + x_2 \geq 1$, $x_1 + x_3 \geq 1$, $x_2 + x_3 \geq 1$. Adding them, $2(x_1 + x_2 + x_3) \geq 3$. But $x_1 + x_2 + x_3 = v(N) = 1$, so $2 \geq 3$, a contradiction. ∎

The proof is a hint of something bigger: it multiplies the coalition constraints by weights ($\frac{1}{2}$ each) that "cover" every player exactly once and finds them demanding more than exists.

? Exactly when is the core non-empty?

The majority game failed because a balanced family of coalitions, each weighted by $\frac{1}{2}$, together demanded $\frac{3}{2}$ of a prize of size 1. Is that the *only* way a core can be empty? The Bondareva–Shapley theorem says yes: the core is non-empty precisely when no balanced weighting of coalitions demands more than $v(N)$. The proof is a two-line consequence of a deeper fact about linear programs and their duals. Find that fact, and the theorem, in Ch. 48.

The Shapley value

Let π be an ordering of the players and P_i^π the set of players who come before i in π. Player i's marginal contribution in that order is $v(P_i^\pi \cup \{i\}) - v(P_i^\pi)$.

Shapley value

$$\phi_i(v) = \frac{1}{n!} \sum_{\pi} \Big[v\big(P_i^\pi \cup \{i\}\big) - v\big(P_i^\pi\big) \Big] \;=\; \sum_{S \subseteq N \setminus \{i\}} \frac{|S|!\,(n - |S| - 1)!}{n!} \Big[v(S \cup \{i\}) - v(S) \Big].$$

The two formulas agree, and the Shapley value is efficient

(a) The permutation average equals the subset sum above. (b) $\sum_i \phi_i(v) = v(N)$.

Proof. (a) Group the $n!$ orderings by the set S of players who precede i. An ordering has predecessors exactly S when it lists the $|S|$ members of S in any order, then i, then the remaining $n - |S| - 1$ players in any order. That is $|S|!\,(n - |S| - 1)!$ orderings, each contributing the same marginal term $v(S \cup \{i\}) - v(S)$. Dividing by $n!$ gives the subset formula. The counting is the standard one of Ch. 28.

(b) Fix one ordering $\pi = (i_1, i_2, \dots, i_n)$. The marginal contributions along it telescope:

$$\big[v(\{i_1\}) - v(\varnothing)\big] + \big[v(\{i_1, i_2\}) - v(\{i_1\})\big] + \cdots + \big[v(N) - v(N \setminus \{i_n\})\big] = v(N) - v(\varnothing) = v(N).$$

So the contributions of all players sum to $v(N)$ in *every* ordering. Averaging over orderings preserves this. ■

Here is the microgrid in full. Each row is an arrival order; entries are marginal contributions.

Order	A	B	C
A, B, C	10	30	50
A, C, B	10	40	40
B, A, C	20	20	50
B, C, A	30	20	40
C, A, B	50	40	0
C, B, A	30	60	0
Average	**25**	**35**	**30**

Each row sums to 90, as the proof promised. Shapley characterised his value by four axioms: **efficiency** (shares add to $v(N)$), **symmetry** (interchangeable players get equal shares), **null player** (a player who never adds anything gets nothing), and **additivity** (the value of the sum of two games is the sum of the values). He proved that **exactly one** rule satisfies all four.

Four innocent axioms, and no freedom left at all. Yet additivity is the axiom economists argue about most: why should fairness in a *sum* of two unrelated games be the sum of the fair shares? The uniqueness proof, and the values you get by dropping additivity, are in Ch. 96.

Power in weighted voting

A **weighted voting game** $[q;\ w_1, \dots, w_n]$ has $v(S) = 1$ if $\sum_{i \in S} w_i \geq q$ and 0 otherwise. The Shapley value of such a game is the **Shapley–Shubik power index**: the probability that player i is **pivotal**, the one whose arrival first pushes the total to q. A cousin, the **Banzhaf index**, counts the coalitions in which i is a **swing** (the coalition wins with i and loses without), instead of orderings.

For the 1958 Council, $[12;\ 4, 4, 4, 2, 2, 1]$, enumeration of all 720 orderings gives Shapley–Shubik indices $\frac{7}{30}$ for each large country, $\frac{3}{20}$ for Belgium and the Netherlands, and 0 for Luxembourg. Banzhaf counts are 10, 10, 10, 6, 6, 0 swings. Luxembourg's zero has a one-line proof.

Why Luxembourg never swings

Luxembourg is a swing in coalition $S \ni$ Lu exactly when the others in S have weight W with $W < 12$ but $W + 1 \geq 12$, i.e. $W = 11$. Every other country's weight is even ($4, 4, 4, 2, 2$), so W is always even and never 11. ■

Notice that the weights are a terrible guide to power: Luxembourg had $\frac{1}{17} \approx 5.9\%$ of the votes and 0% of the power, while Belgium had $\frac{2}{17} \approx 11.8\%$ of the votes and 15% of the (Shapley–Shubik) power.

Voting rules

With rankings instead of money, a **voting rule** maps a profile of rankings to a winner. Four common ones:

- **Plurality:** most first choices wins.
- **Borda count:** with m candidates, a candidate gets $m - 1$ points for each first place, $m - 2$ for each second, and so on.
- **Instant-runoff (ranked-choice):** repeatedly eliminate the candidate with fewest first choices, moving each of its ballots to its next surviving choice, until someone has a majority.
- **Condorcet:** the candidate who beats every other head to head, if one exists (Figure 42.1 shows it need not).

The hook's profile separates them all. Plurality: A 40, B 35, C 25, so A. Borda (2, 1, 0 points): $\text{A} = 2 \cdot 40 + 5 = 85$, $\text{B} = 2 \cdot 35 + 20 = 90$, $\text{C} = 40 + 35 + 2 \cdot 25 = 125$, so C. Head to head, C beats A by 60 to 40 and B by 65 to 35: C is the Condorcet winner. And instant runoff eliminates C first:

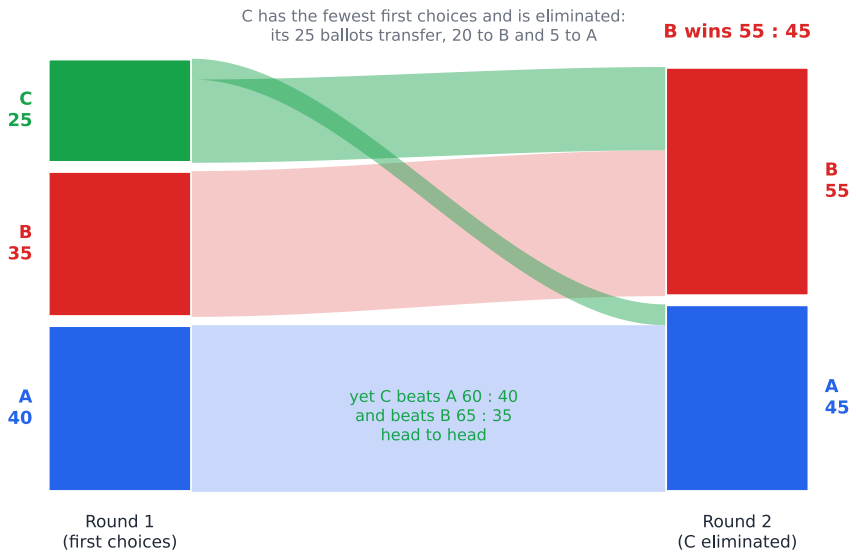

Figure 44.2 — Instant runoff on the hook's ballots. The candidate everyone would accept as a compromise is the first one thrown out.

This is the "squeezed centre" effect: a broadly acceptable candidate who is few voters' *first* choice can be eliminated before her broad support is ever counted. Arrow's theorem (Ch. 42) guarantees every rule has some such flaw. For **two** candidates, by contrast, May's theorem says simple majority is the only rule that treats voters equally, treats candidates equally, and responds positively to extra support. All the trouble starts at three.

Bargaining

Two players can split a surplus if they agree; if they don't, they get disagreement payoffs d_1, d_2. Nash (1950) proposed four axioms (efficiency, symmetry, invariance to rescaling each player's utility, and independence of irrelevant alternatives) and proved they single out the allocation that maximises the **Nash product**

$$(u_1 - d_1)(u_2 - d_2) \quad \text{over feasible agreements with } u_1 \ge d_1,\ u_2 \ge d_2.$$

Splitting a unit surplus

Feasible agreements are $u_1 = x$, $u_2 = 1 - x$. Maximise $g(x) = (x - d_1)(1 - x - d_2)$. Then $g'(x) = (1 - x - d_2) - (x - d_1) = 0$ gives

$$x^* = \frac{1 + d_1 - d_2}{2}, \qquad 1 - x^* = \frac{1 - d_1 + d_2}{2},$$

and $g'' = -2 < 0$ confirms a maximum. Each player gets her disagreement payoff plus **half the surplus** $1 - d_1 - d_2$. A better outside option is worth exactly half its value at the table.

Compare this with the two-player Shapley value: $\phi_1 = \tfrac{1}{2}v(\{1\}) + \tfrac{1}{2}\big[v(N) - v(\{2\})\big] = v(\{1\}) + \tfrac{1}{2}\big[v(N) - v(\{1\}) - v(\{2\})\big]$. With $d_i = v(\{i\})$ it is the *same* split. Two very different philosophies, averaging marginal contributions and maximising a product, agree whenever only two players are involved.

? Where does the Nash product come from?

Nash's solution falls out of axioms, not out of any model of people actually haggling. Yet if two players alternate offers, and each round of delay shrinks the pie a little, the unique equilibrium of that very non-cooperative game converges to the Nash bargaining solution as the delay shrinks to zero. Why should an axiom about fairness and a game about impatience give the same answer? Rubinstein's alternating-offers model is worked out in Ch. 96.

44.4 The algorithm

Exact Shapley values cost $n!$ orderings or, with the subset formula, 2^{n-1} coalitions per player: $O(n\,2^n)$ evaluations of v. That is fine for $n \le 20$ and hopeless beyond. Two escapes:

1. **Monte Carlo over orderings** (Ch. 38). Sample random permutations and average marginal contributions. Each sample is an unbiased estimate, so the error falls like $1/\sqrt{m}$ for m samples. This is how "SHAP" explanations of machine-learning models approximate the Shapley value of each input feature, with "players" being features and $v(S)$ the model's prediction using only the features in S.
2. **Dynamic programming for weighted voting.** Player i swings in S when the other members' weight W satisfies $q - w_i \le W \le q - 1$. So count the subsets of the *other* players by total weight, a subset-sum count:

```
def banzhaf_swings(weights, q):
    """Number of coalitions in which each player is a swing. O(n^2 * total weight)."""
    total = sum(weights)
    swings = []
    for i, wi in enumerate(weights):
        count = [1] + [0] * total            # count[W] = #subsets of others with weight W
        for j, wj in enumerate(weights):
            if j != i:
                for W in range(total, wj - 1, -1):
                    count[W] += count[W - wj]
        swings.append(sum(count[W] for W in range(max(q - wi, 0), q)))
    return swings

print(banzhaf_swings([4, 4, 4, 2, 2, 1], 12))   # [10, 10, 10, 6, 6, 0]
```

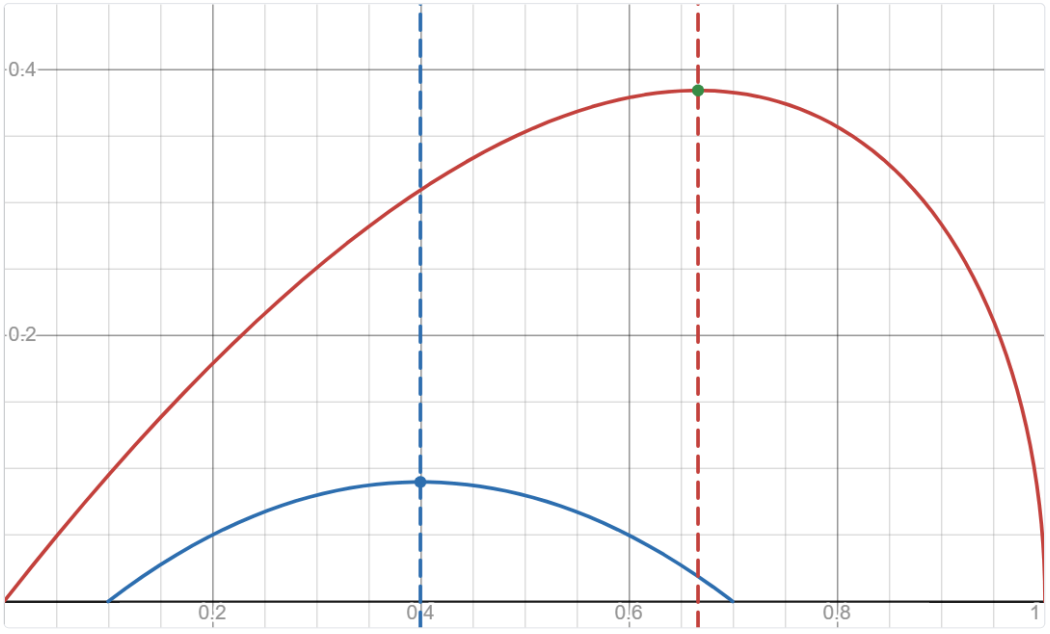
The running time is $O(n^2 \sum w)$: polynomial in the weights' *size*, exponential in their number of digits, so "pseudo-polynomial". With large integer weights (populations, say), computing exact power indices is NP-hard, a fact that connects this chapter to Ch. 30. A similar DP, also tracking coalition size, gives the Shapley–Shubik index.

Instant runoff is a loop: tally first surviving choices, stop if someone has a majority, else drop the lowest and repeat. It runs in $O(m \cdot B)$ for m candidates and B ballots, but it hides a numerical trap: **ties for last place**. Different tie-breaking rules can change the winner, and real election laws spend pages on them.

Failure cases. The core may be empty, so "find a core allocation" can have no answer; Shapley values always exist but may lie outside the core and then invite defection. Monte Carlo Shapley estimates for players with tiny values can be swamped by noise from large ones; stratify by position in the ordering to reduce variance.

44.5 The experiment

A. Bargain with a risk-averse partner. Blue is the Nash product for splitting 1 with disagreement points $d_1 = 0.1$, $d_2 = 0.3$. Red is player 1 bargaining with a *risk-averse* player 2 whose utility for money y is $\sqrt{y}$, and disagreement points 0.



Blue peaks at $x = \frac{1+0.1-0.3}{2} = 0.4$. Red peaks at $x = \frac{2}{3}$: the risk-averse partner, who fears disagreement more, concedes more.

Change $d_1 = 0.1$ to 0.3 in the blue curve (and its domain) and predict the new peak before you look. Then replace $\sqrt{1-x}$ by $(1-x)^{0.25}$ (even more risk-averse): how much more does player 1 get?

B. Measure power, split value, count votes. Change `v`, the voting weights and quota, and the ballots.

```
import itertools
import numpy as np

def shapley(players, v):
    phi = dict.fromkeys(players, 0.0)
    orders = list(itertools.permutations(players))
    for order in orders:
        seen = frozenset()
        for p in order:
            phi[p] += (v(seen | {p}) - v(seen)) / len(orders)
            seen = seen | {p}
    return {p: round(x, 4) for p, x in phi.items()}

grid = {"": 0, "A": 10, "B": 20, "C": 0, "AB": 40, "AC": 50, "BC": 60, "ABC": 90}
print("microgrid:", shapley("ABC", lambda S: grid["".join(sorted(S))]))

w = {"Fr": 4, "De": 4, "It": 4, "Be": 2, "Nl": 2, "Lu": 1}; q = 12
print("1958 power:", shapley(list(w), lambda S: float(sum(w[p] for p in S) >= q)))

ballots = [(40, "ACB"), (35, "BCA"), (20, "CBA"), (5, "CAB")]
def irv(ballots, alive):
    while True:
        tally = {c: sum(n for n, r in ballots if [x for x in r if x in alive][0] == c) for c in alive}
        top = max(tally, key=tally.get)
        if 2 * tally[top] > sum(tally.values()): return top, tally
        alive = alive - {min(tally, key=tally.get)}
borda = {c: sum(n * (2 - r.index(c)) for n, r in ballots) for c in "ABC"}
print("IRV:", irv(ballots, set("ABC")), " Borda:", borda)
```

Now try to give Luxembourg power. What is the smallest change to one weight, or to the quota, that makes its index positive? Then replace the microgrid's $v(\{A,B\}) = 40$ by 70 and check whether the Shapley value is still in the core.

44.6 The challenge

1. **Intuition.** In the "glove game", player L owns a left glove and players R1 and R2 each own a right glove; a pair is worth 1, a single glove nothing. Before computing anything, guess how the Shapley value splits the 1, and what the core contains. Explain why the two answers disagree so strongly, and which one you find fairer.
2. **Derivation.** Prove that for any weighted voting game, a player whose weight is 0 has Shapley–Shubik index 0, and that two players with equal weights have equal indices. Then find weights and a quota for three players in which the player with the *largest* weight has the *same* power as the smallest.
3. **Implementation.** Write a Monte Carlo Shapley estimator that samples m random orderings. For a 15-player weighted voting game with random weights, plot the error against the exact (DP) index as a function of m on log–log axes, and check the slope is $-\tfrac{1}{2}$.
4. **Open investigation.** Draw 10,001 voters whose rankings of 3 candidates are independent and uniformly random over the 6 orders ("impartial culture"). Estimate by simulation how often there is no Condorcet winner, and how often plurality, Borda and instant runoff each fail to elect the Condorcet winner when one exists. How do these frequencies change with 4, 5, 6 candidates, and with voters whose preferences are correlated along a left–right axis? Which rule would you recommend, and on what evidence?

44.7 Loose threads

We found three ways a group can "decide": dividing value (the core, the Shapley value), measuring power (Shapley–Shubik and Banzhaf), and aggregating rankings (plurality, Borda, runoff, Condorcet). Each gave crisp mathematics and an uncomfortable surprise: an empty core, a member with no power, a compromise candidate eliminated first.

What we did not tell you:

- **Why the Shapley value is unique**, and what changes if you drop additivity, is in Ch. 96; so is **Rubinstein's bargaining game**, which turns Nash's axioms into a story about impatience.
- **When the core exists** is a linear-programming duality fact, held over for Ch. 48.
- **How coalitions are actually formed**, who approaches whom and why some alliances are stable, was compressed into the single function v. Non-cooperative models of coalition formation are an active research area.

And one thread runs forward. Throughout this chapter we assumed players are *rational*: they calculate shares, compare outside options, and vote strategically or sincerely by choice. Yet in laboratory bargaining games, people reject "unfair" offers that would leave them better off, and they offer close to 50–50 when they could keep far more.

> **? Fairness from nowhere**
>
> If a rational responder should accept any positive offer, why do human beings across many cultures reject offers below about a quarter of the pie, and why do proposers rarely make them? One answer is that fairness norms are *strategies that survived*: in a population that plays bargaining games over and over, the rules people follow are shaped by which ones prosper. How a population can evolve toward fair splits without anyone choosing them is the story of Ch. 45.

45.1 The hook

On the grassy hillsides of California's Coast Range lives a small lizard, *Uta stansburiana*, the side-blotched lizard. The males come in three throat colours, and each colour is a way of life.

- **Orange** males are big, aggressive and territorial. They hold large patches of ground with many females.
- **Blue** males are smaller. Each guards a single female closely and cooperates with blue neighbours.
- **Yellow** males look like females. They hold no territory at all; they sneak into other males' patches and mate on the sly.

Here is the trouble. Orange beats blue: a single blue mate-guarder cannot hold out against a bully with a large territory. Yellow beats orange: the bully's territory is too large to watch, and the sneakers slip in. Blue beats yellow: a male who never takes his eyes off his one female cannot be cuckolded.

That is rock, paper, scissors, played not by people but by genes. Field studies in the 1990s found that the three morphs do not settle down. The common colour of one breeding season becomes rarer later, its nemesis rises, and the cycle turns over the course of a few years. Nobody in this game is thinking. No lizard has a strategy in the sense of Ch. 39; each simply *is* a strategy, fixed at birth. And yet the population behaves as if it were solving a game.

There is an older puzzle too. Why do so many animals fight by ritual? Stags roar and walk side by side before they ever lock antlers. Snakes wrestle without biting. If victory brings a female or a territory, why doesn't every individual fight all-out? A population of polite ritual fighters looks like an open invitation to one ruthless mutant.

Both puzzles have the same mathematical shape. We drop the idea of a rational player and replace it with a **population**: a crowd of individuals, each hard-wired to one strategy, meeting at random, with payoff measured as reproductive success. Strategies that score above the average spread. Strategies that score below it fade. The question is no longer "what should I do?" but "what survives?"

The answers are surprisingly sharp. Selection can find a Nash equilibrium without anyone computing one. It can also cycle forever, or shatter the population against the edges of the simplex, depending on one inequality between two numbers. By the end of this chapter you will know which inequality.

45.2 The big idea

Picture a large population as a bag of coloured marbles: a fraction x_1 play strategy 1, a fraction x_2 play strategy 2, and so on. The vector $\mathbf{x} = (x_1, \dots, x_n)$ has non-negative entries summing to 1. It lives on the **simplex**, a line segment for two strategies, a triangle for three.

Every generation, individuals pair off at random. An individual of type i meets type k with probability x_k, so its expected payoff is

$$f_i(\mathbf{x}) = \sum_k a_{ik}\, x_k = (\mathbf{A}\mathbf{x})_i,$$

where $\mathbf{A}$ is the payoff matrix. The average payoff in the population is $\bar{f} = \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}$.

Now the one idea the chapter turns on. Payoff is fitness: the number of offspring. A type that does better than average grows *as a share of the population*. A type that does worse shrinks. Its growth rate is proportional to how far it is above the average:

$$\frac{\dot{x}_i}{x_i} = f_i(\mathbf{x}) - \bar{f}(\mathbf{x}).$$

That is the **replicator equation**. It is the "rich get richer, relative to the average" rule, and it has three features worth noticing before any algebra.

1. **Nobody optimises.** There is no argmax anywhere. Selection is a blind ratchet that only compares each type to the current average.
2. **The environment is the population.** Your fitness depends on who else is around, so the target moves as you climb towards it. That is what makes this a *game* and not ordinary optimisation.
3. **Extinct types stay extinct.** If $x_i = 0$ then $\dot{x}_i = 0$. Replicator dynamics cannot invent a strategy; only mutation can. So we will have to ask what happens when a rare mutant appears: can it invade?

That last question gives the second idea of the chapter, due to John Maynard Smith and George Price (1973). A strategy is **evolutionarily stable** if, once the whole population uses it, no small band of mutants playing anything else can invade. Think of an immune system rather than a chess player: the question is not whether the strategy is clever, but whether it can repel every intruder.

The analogy to hold on to is a thermostat. Hawks do well when hawks are rare (they bully the doves). Hawks do badly when hawks are common (they keep meeting each other and getting injured). So the hawk share is pushed up when it is low and down when it is high. Like a thermostat, the population settles at the share where the push is zero. That share turns out to be a mixed Nash equilibrium, discovered by a process that knows nothing about Nash.

45.3 The mathematics

The replicator equation and the simplex

Replicator dynamics

For a symmetric game with $n \times n$ payoff matrix $\mathbf{A}$, the replicator dynamics on the simplex $\Delta_n = \{\mathbf{x} \in \mathbb{R}^n : x_i \geq 0,\ \sum_i x_i = 1\}$ are

$$\dot{x}_i = x_i\big[(\mathbf{A}\mathbf{x})_i - \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}\big], \qquad i = 1, \dots, n.$$

Two quick checks show the definition makes sense. Summing over i gives $\sum_i \dot{x}_i = \bar{f} - \bar{f}\sum_i x_i = 0$ on the simplex, so shares keep summing to 1. And each face $x_i = 0$ is invariant, so the simplex is never left. This is a system of nonlinear ODEs of the kind studied in Section 11.9; we only need its rest points and their stability.

Adding a constant c to a column of $\mathbf{A}$ adds $c\,x_k$ to every f_i and to $\bar{f}$ alike, so it leaves the dynamics unchanged. Only payoff *differences* within a column matter. Keep this in mind: it will tell us which numbers in the rock–paper–scissors matrix actually drive the outcome.

Rest points are (almost) Nash equilibria

Folk theorem of evolutionary game theory (first part)

If $\mathbf{p}$ is a symmetric Nash equilibrium of the game, then $\mathbf{p}$ is a rest point of the replicator dynamics. Conversely, an interior rest point is a Nash equilibrium, and any rest point that is the limit of an interior trajectory is a Nash equilibrium.

Proof of the first two claims. $\mathbf{p}$ is a Nash equilibrium when every strategy in its support earns the same payoff and no strategy earns more (Ch. 39 gives this as the indifference principle). So for each i, either $p_i = 0$ or $(\mathbf{A}\mathbf{p})_i = \bar{f}$, and in both cases $\dot{x}_i = 0$. Conversely, at an interior rest point every $x_i > 0$, so $(\mathbf{A}\mathbf{x})_i = \bar{f}$ for all i. All pure strategies earn the same, so none is a profitable deviation. ■

The word "almost" in the heading matters. Every pure strategy is a rest point (a population of all-hawks stays all-hawks, because nothing else exists to grow), even when it is a terrible strategy. Rest points are cheap. *Stable* rest points are what we want.

Hawk and dove

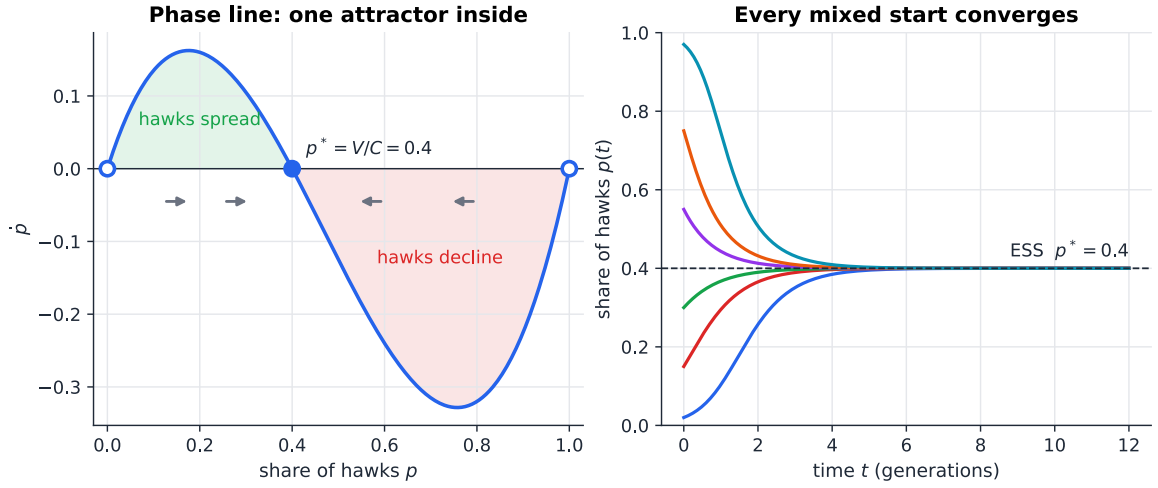
Two animals contest a resource worth V. A hawk escalates until injured or the opponent retreats; an injury costs C. A dove displays and retreats if the other escalates. Two doves share. With $C > V > 0$:

$$\mathbf{A} = \begin{pmatrix} \dfrac{V - C}{2} & V \\[2mm] 0 & \dfrac{V}{2} \end{pmatrix} \qquad \begin{matrix} \text{row 1: hawk} \\ \text{row 2: dove} \end{matrix}$$

Let p be the hawk share. Then $f_H = p\frac{V-C}{2} + (1-p)V$ and $f_D = (1-p)\frac{V}{2}$, so $f_H - f_D = \frac{V - Cp}{2}$. With two strategies, $f_H - \bar{f} = (1-p)(f_H - f_D)$, and the replicator equation collapses to a single ODE:

$$\dot{p} = \frac{p(1-p)(V - Cp)}{2}.$$

The rest points are $p = 0$, $p = 1$ and $p^* = V/C$. The derivative of the right-hand side at p^* is $-\frac{1}{2}p^*(1-p^*)C < 0$, so p^* is a stable node; at $p = 0$ the derivative is $V/2 > 0$ and at $p = 1$ it is $(C - V)/2 > 0$, so both pure states are unstable. For $V = 4$, $C = 10$ the attractor is $p^* = 0.4$ and the local rate is -1.2 per generation: a disturbance decays like $e^{-1.2t}$.



Left: the phase line $\dot{p}$ against the hawk share p for $V = 4$, $C = 10$; hawks grow below $p^* = 0.4$ and shrink above it. Right: six populations started anywhere strictly between 0 and 1 all converge to 40% hawks.

This answers the ritual-fighting puzzle in one line. All-dove is not stable: a hawk among doves earns $V = 4$ against the doves' $V/2 = 2$. All-hawk is not stable either: when injuries are costly ($C > V$), a dove among hawks earns 0 while hawks earn $(V - C)/2 = -3$. The population settles at a mixture, with the hawk share rising as the prize grows and falling as injuries get worse. Restraint is not kindness. It is what is left when escalation becomes too expensive.

Notice something unsettling. At $p^* = 0.4$ every individual earns 1.2. In an all-dove population every individual would earn 2. Selection drove the population to a state that is *worse for everyone* than one it cannot stay in. Evolution maximises nothing; this is the prisoner's dilemma of Ch. 40 wearing fur.

Evolutionary stability

Evolutionarily stable strategy (ESS)

A (possibly mixed) strategy $\mathbf{p}$ is an ESS if for every other strategy $\mathbf{q} \neq \mathbf{p}$:

1. $\mathbf{q}^{\mathsf{T}}\mathbf{A}\mathbf{p} \leq \mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{p}$ (a Nash equilibrium: mutants do no better against the residents), and
2. if $\mathbf{q}^{\mathsf{T}}\mathbf{A}\mathbf{p} = \mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{p}$, then $\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{q} > \mathbf{q}^{\mathsf{T}}\mathbf{A}\mathbf{q}$ (residents beat mutants in the rare mutant–mutant encounters).

Condition 2 is the tie-breaker: if a mutant is as good as the resident against residents, the resident must win against the mutant. An equivalent form (a standard result we quote rather than prove) is **local superiority**: $\mathbf{p}$ is an ESS if and only if

$$\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{x} > \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} \quad \text{for all } \mathbf{x} \neq \mathbf{p} \text{ in a neighbourhood of } \mathbf{p} \text{ in } \Delta_n.$$

In words: near $\mathbf{p}$, the strategy $\mathbf{p}$ does better against the current population than the population does against itself.

For hawk–dove with $\mathbf{p} = (p^*, 1-p^*)$ and $\mathbf{x} = (p, 1-p)$, a short computation gives $\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{x} - \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \frac{C}{2}(p - p^*)^2 > 0$, so V/C hawks is an ESS. (Check it yourself: the difference is $(p^* - p)(f_H - f_D)$ evaluated at $\mathbf{x}$.)

The central theorem: an ESS is an attractor

Why should a static "can't be invaded" condition say anything about the dynamics? Because of a clever Lyapunov function borrowed from information theory.

ESS implies asymptotic stability (Taylor and Jonker; Hofbauer, Schuster and Sigmund)

If $\mathbf{p}$ is an ESS, then $\mathbf{p}$ is an asymptotically stable rest point of the replicator dynamics.

Proof. Let S be the support of $\mathbf{p}$ (the strategies it uses) and consider, for $\mathbf{x}$ with $x_i > 0$ on S, the relative entropy

$$H(\mathbf{x}) = \sum_{i \in S} p_i \ln \frac{p_i}{x_i}.$$

This is the Kullback–Leibler divergence of Ch. 33: $H \geq 0$ with equality only at $\mathbf{x} = \mathbf{p}$ (Gibbs' inequality), so H is a candidate Lyapunov function. Differentiate along a trajectory, using $\dot{x}_i/x_i = (\mathbf{A}\mathbf{x})_i - \bar{f}$:

$$\begin{aligned} \dot{H} &= -\sum_{i \in S} p_i \frac{\dot{x}_i}{x_i} = -\sum_{i \in S} p_i \big[(\mathbf{A}\mathbf{x})_i - \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}\big] \\ &= -\big[\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{x} - \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x}\big]. \end{aligned}$$

The last step uses $\sum_{i \in S} p_i = 1$. By local superiority, the bracket is strictly positive for $\mathbf{x} \neq \mathbf{p}$ near $\mathbf{p}$, so $\dot{H} < 0$ there. A function that is zero at $\mathbf{p}$, positive nearby, and strictly decreasing along trajectories forces nearby trajectories into $\mathbf{p}$: that is Lyapunov's theorem, the nonlinear cousin of the eigenvalue test in Section 10.9. ∎

The proof is worth rereading for its meaning. Selection steadily reduces the information-theoretic "surprise" between the population and the ESS. The population is, in a precise sense, *learning* $\mathbf{p}$. The converse fails: there are asymptotically stable rest points that are not ESSs, so the static notion and the dynamic one are not the same thing.

? Selection as learning

The relative entropy H decreasing along selection looks exactly like a Bayesian posterior concentrating on the truth, and the replicator equation looks exactly like the multiplicative-weights update you will meet in Ch. 46. Is natural selection literally an inference algorithm? The formal bridge between replicator dynamics and Bayesian updating, and its limits, is a thread picked up in Ch. 35 and Ch. 53.

Rock, paper, scissors: one inequality decides everything

Back to the lizards. Use a generalised rock–paper–scissors matrix in which a win pays $a > 0$ and a loss costs $b > 0$:

$$\mathbf{A} = \begin{pmatrix} 0 & -b & a \\ a & 0 & -b \\ -b & a & 0 \end{pmatrix} \qquad \text{(rows: Rock, Paper, Scissors)}.$$

By symmetry the unique interior rest point is the centre $\mathbf{p} = (\tfrac{1}{3}, \tfrac{1}{3}, \tfrac{1}{3})$. Every row and column sums to $a - b$. Write $\mathbf{x} = \mathbf{p} + \mathbf{d}$ with $\sum_i d_i = 0$. Then:

- $\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \frac{1}{3}\sum_k x_k (\text{column sum}) = \frac{a-b}{3}$;
- $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = (a-b)(x_1x_2 + x_2x_3 + x_3x_1)$, because each pair $\{i,k\}$ contributes a one way and $-b$ the other;
- $x_1x_2 + x_2x_3 + x_3x_1 = \frac{1}{2}\big(1 - \|\mathbf{x}\|^2\big) = \frac{1}{3} - \frac{1}{2}\|\mathbf{d}\|^2$.

Putting these together gives an exact identity, valid on the whole simplex, not only near the centre:

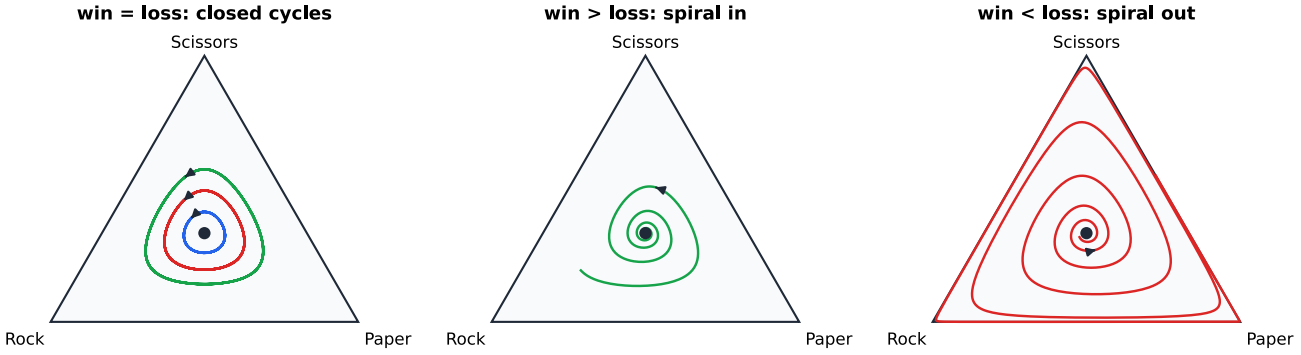
$$\mathbf{p}^{\mathsf{T}}\mathbf{A}\mathbf{x} - \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{x} = \frac{a-b}{2}\,\|\mathbf{x}-\mathbf{p}\|^2.$$

Feed it into the Lyapunov computation, where now $H = -\ln 3 - \frac{1}{3}\ln(x_1x_2x_3)$:

$$\dot{H} = -\frac{a-b}{2}\,\|\mathbf{x}-\mathbf{p}\|^2.$$

Three regimes follow at once.

Case	Sign of $\dot{H}$	What happens	ESS?
$a > b$ (wins pay more than losses cost)	negative	every interior orbit spirals into the centre	yes
$a = b$ (zero-sum)	zero	$x_1x_2x_3$ is conserved; closed cycles forever	no
$a < b$ (losses hurt more)	positive	orbits spiral out towards the boundary	no



Replicator orbits on the strategy triangle. Left, $a = b = 1$: each orbit is a level curve of $x_1x_2x_3$ and cycles forever. Centre, $a = 1.5$, $b = 1$: the centre is an ESS and attracts. Right, $a = 1$, $b = 1.5$: the orbit winds outwards and hugs the edges, so each strategy in turn nearly goes extinct.

In the zero-sum case the cycle period near the centre follows from linearisation. The Jacobian at $\mathbf{p}$ restricted to the simplex has eigenvalues $\pm j/\sqrt{3}$ (check it with the eigenvalue tools of Ch. 10), so small cycles have period $2\pi\sqrt{3} \approx 10.9$ generations. Purely imaginary eigenvalues usually mean linearisation tells you nothing about stability; here the conserved quantity rescues us and proves the orbits really are closed.

The right-hand panel is the dramatic one. In a population where losing is worse than winning is good, the orbit approaches the boundary of the triangle: long stretches in which almost everyone plays one strategy, then a sudden takeover by its nemesis. In a finite population, one of those near-extinctions will eventually become a real one, and the cycle ends with a single survivor. Which survivor? That depends on luck, and luck is not in the replicator equation at all.

> **? When the deterministic model lies**
>
> The replicator equation treats the population as infinite, so a share of 10^{-30} still counts as alive. Real populations have N individuals, and a share below $1/N$ is extinction. How the deterministic cycles of the right-hand panel turn into a random walk that is absorbed at a corner, and how long that takes, is a question about Markov chains with absorbing states: see Ch. 34 and Ch. 36.

Population games beyond pairs

Nothing above required pairwise encounters. In a **population game** each strategy i has a fitness $f_i(\mathbf{x})$ that is any smooth function of the population state: drivers choosing routes, where your travel time depends on how many others chose the same road, or packets choosing paths in a network. The replicator equation $\dot{x}_i = x_i(f_i - \bar{f})$ still makes sense, and the folk theorem still holds. When the fitnesses come from a **potential**, $f_i = \partial\Phi/\partial x_i$, the dynamics climb Φ like a gradient flow (Section 23.5) and cannot cycle. Hawk–dove has a potential; rock–paper–scissors does not, which is exactly why it can cycle.

45.4 The algorithm

Simulating replicator dynamics takes a few lines of code, and it is easy to get wrong in a way that looks like biology.

```
REPLICATOR(A, x0, h, steps):
    x ← x0                                  # a point on the simplex
    for k = 1 .. steps:
        fit  ← A x                          # payoff of each pure strategy
        avg  ← xᵀ fit                       # population average
        x    ← x + h · x ⊙ (fit − avg)      # forward Euler step
        x    ← max(x, 0); x ← x / sum(x)    # guard against round-off
    return x
```

Each step costs one matrix–vector product, $O(n^2)$ for n strategies. The simplex is preserved exactly in exact arithmetic (the update sums to zero), and the clipping line only cleans up floating-point dust.

The failure case. Run this on zero-sum rock–paper–scissors ($a = b$), where the true orbits are closed. Forward Euler spirals *outwards*. The reason is the stability analysis of ODE solvers from Ch. 22 in miniature: near the centre the system behaves like $\dot{\mathbf{z}} = \mathbf{J}\mathbf{z}$ with eigenvalues $\pm j\omega$, $\omega = 1/\sqrt{3}$. One Euler step multiplies a mode by $1 + jh\omega$, whose magnitude is $\sqrt{1 + h^2\omega^2} > 1$. Over one unit of time the amplitude grows by roughly $e^{h\omega^2/2} = e^{h/6}$. With $h = 0.1$ and 200

generations that is a factor of about $e^{3.3} \approx 28$ in amplitude near the centre, and the orbit is flung against the edges of the triangle. A student who sees this plot and concludes "rock–paper–scissors populations are unstable" has discovered a property of Euler's method, not of lizards.

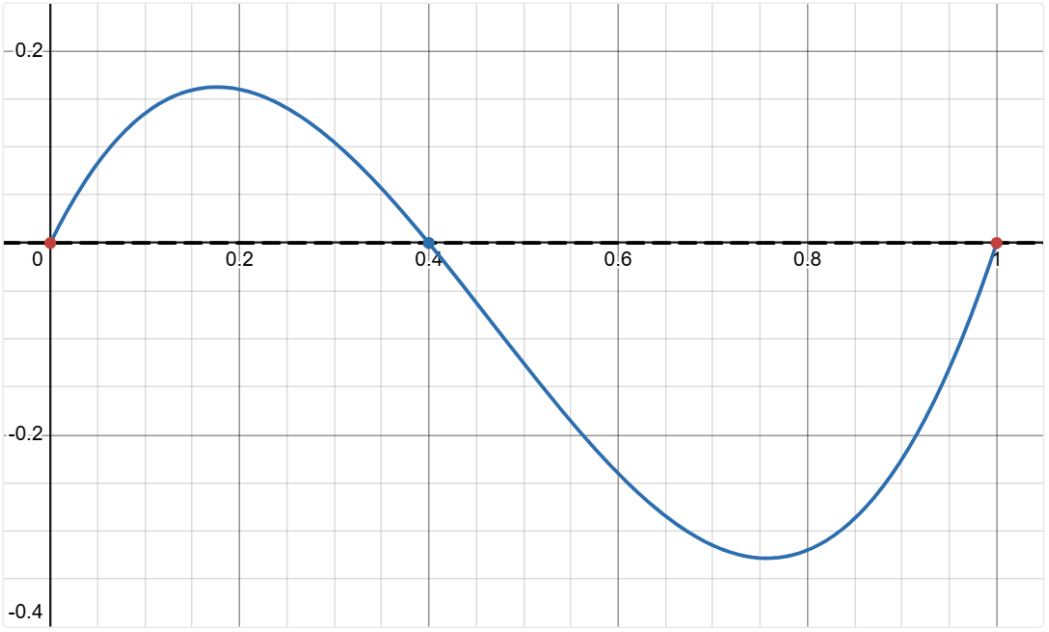
The fixes are standard:

- Use a higher-order integrator (RK4, or an adaptive solver). The drift does not vanish, but it drops from $O(h)$ to $O(h^4)$ per unit time.
- Monitor a conserved quantity. In the zero-sum case $x_1 x_2 x_3$ must stay constant; its drift is a free error meter.
- Beware the popular **discrete-time replicator** $x_i' = x_i \, \dfrac{c + f_i}{c + \bar{f}}$ with a background fitness $c > 0$. It is a perfectly good model of non-overlapping generations, but it is a *different* dynamical system. For zero-sum rock–paper–scissors it spirals outwards to the boundary, so its long-run behaviour disagrees with the continuous model.

Finding ESSs. For small games, enumerate supports. For each subset S of strategies, solve the linear indifference system $(\mathbf{A}\mathbf{p})_i = (\mathbf{A}\mathbf{p})_k$ for $i, k \in S$ with $\sum_{i \in S} p_i = 1$ (Ch. 8), keep solutions with $\mathbf{p} \geq 0$ that satisfy the Nash condition, then test the second ESS condition. That is 2^n subsets, fine for $n \leq 15$ and hopeless beyond. Deciding whether a game has an ESS at all is known to be computationally hard in general, so there is no shortcut hiding in the background.

45.5 The experiment

First, the hawk–dove phase line. The curve is $\dot{p} = p(1 - p)(V - Cp)/2$ with $V = 4$ and $C = 10$; the filled point is the ESS.



The phase line for hawk–dove. Change the 4 (the prize V) and both 10s (the injury cost C) and watch the ESS slide to V/C; set V above C and the interior root leaves the interval, so all-hawk wins.

Now the cycle. The script below integrates generalised rock–paper–scissors and plots the three shares and the product $x_1 x_2 x_3$ on a log scale.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
a, b = 1.0, 1.0             # win payoff and loss cost: try a=1.5 or b=1.5
h = 0.01                    # time step: try 0.1 and watch the cycle break
T = 200.0                   # total time in generations
x = np.array([0.5, 0.3, 0.2])   # starting shares of Rock, Paper, Scissors
method = "rk4"              # "euler" or "rk4"
# -------------------------------------------------------------------------

A = np.array([[0, -b, a], [a, 0, -b], [-b, a, 0]])

def f(x):
    fit = A @ x
    return x * (fit - x @ fit)

steps = int(T / h)
xs = np.empty((steps, 3))
for k in range(steps):
    xs[k] = x
    if method == "euler":
        x = x + h * f(x)
    else:
        k1 = f(x); k2 = f(x + h/2*k1); k3 = f(x + h/2*k2); k4 = f(x + h*k3)
        x = x + h/6 * (k1 + 2*k2 + 2*k3 + k4)

t = np.arange(steps) * h
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(10, 4))
for i, name in enumerate(["Rock", "Paper", "Scissors"]):
    ax1.plot(t, xs[:, i], label=name)
ax1.set_xlabel("generations"); ax1.set_ylabel("share"); ax1.legend()
ax2.semilogy(t, xs.prod(axis=1))
ax2.set_xlabel("generations"); ax2.set_ylabel("x1*x2*x3 (conserved if a=b)")
print("final shares:", xs[-1].round(4), " product:", xs[-1].prod())
plt.tight_layout(); plt.show()
```

Things to try, in order:

1. Run it as is. The product starts at $0.5 \times 0.3 \times 0.2 = 0.03$ and RK4 keeps it at 0.03 to about ten decimal places. The shares cycle forever.
2. Switch `method = "euler"`. With `h = 0.01` the product drifts down to about 0.025 in 200 generations; with `h = 0.1` it collapses to a few times 10^{-6} and Paper ends with over 99% of the population. Same model, different integrator, opposite conclusion.
3. Back on RK4, set `a = 1.5`. The product climbs towards its maximum $1/27 \approx 0.037$: the centre is an ESS. Then try `b = 1.5`: the product plunges towards zero and the population lives on the edges.
4. Starting share of `1e-12` for Scissors: how long until Scissors "comes back"? What would a real population of a million lizards do in that time?

45.6 The challenge

1. **Intuition.** In hawk–dove, the ESS hawk share V/C does not depend on how many individuals there are or how often they meet. Explain in words why a larger prize leads to *more* fighting at equilibrium, and why everyone at the ESS earns less than in an all-dove world, yet all-dove cannot last.
2. **Derivation.** For the two-strategy coordination game $\mathbf{A} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$ find all rest points of the replicator dynamics, classify their stability, and determine which are ESSs. Then show directly from the definition that the interior Nash equilibrium is *not* an ESS.
3. **Implementation.** Write the support-enumeration ESS finder sketched in 45.4 for $n \times n$ matrices. Test it on hawk–dove, on the three regimes of rock–paper–scissors, and on a 4×4 random matrix. Then compare: for 1,000 random 3×3 games, what fraction have an ESS, and in what fraction does a random interior start converge to one under RK4?
4. **Open investigation.** Add a fourth strategy to rock–paper–scissors, for example a "Loner" who opts out of contests for a fixed payoff σ. Explore numerically how the long-run behaviour changes as σ varies: do you see rest points, cycles, or something irregular? Is there a value of σ at which the qualitative behaviour changes abruptly? (There is no single right answer; the shape of what you find is the point.)

45.7 Loose threads

This chapter took a deliberately narrow view: infinite populations, random pairing, payoffs that never change, and no mutation beyond the occasional invader. Every one of those assumptions hides a story.

We showed that the centre of rock–paper–scissors either attracts, repels, or is ringed by closed orbits. With three strategies that is the whole menu, because a flow on a two-dimensional triangle cannot do anything wilder than settle or cycle (the Poincaré–Bendixson theorem). With four strategies, the triangle becomes a tetrahedron, and that safety net disappears.

> **? Can selection be chaotic?**
>
> With four or more strategies the replicator equation is a three-dimensional flow, and nothing forbids a strange attractor. There are explicit four-strategy games whose replicator orbits never settle and never repeat, with sensitive dependence on the initial mix of strategies. What makes a flow chaotic, and how you would recognise it in one of these population games, is the subject of Ch. 84; the change of variables that turns any replicator system into a Lotka–Volterra predator–prey model, and lets you import its theory wholesale, waits in Ch. 83.

The second loose thread is the mystery of finite populations already raised in 45.3: drift, absorption and fixation probabilities. The third is the word "learning". The replicator update multiplies each share by a factor that grows with its payoff. Keep that picture in mind as you turn the page: in Ch. 46 the same multiplicative rule reappears, run not by genes but by an algorithm facing an adversary, and there it comes with a guarantee that no amount of bad luck can break.

We have also said nothing about where the payoff matrix comes from. In the lizards, the matrix is not fixed: it depends on density, on the season, on the mix of females. Allowing the game itself to evolve in response to the population is one of the active frontiers where evolutionary game theory meets ecology.

Chapter 46 — Adversarial Decision-Making

> **Level 2 · Track C — Game Theory and Strategic Intelligence Builds on:** Ch. 23, Ch. 19, Ch. 39 · **Leads to:** Ch. 48, Ch. 52, Ch. 53, Ch. 54 · **Related:** Ch. 45, Ch. 77, Ch. 30 **Reading time:** ~25 min

46.1 The hook

A penalty kick takes less time than the goalkeeper needs to react. The keeper must commit to a side before the ball is struck, and the kicker must choose a side knowing the keeper is guessing. Suppose a kicker scores with these probabilities:

	keeper dives left	keeper dives right
kick left	0.60	0.95
kick right	0.90	0.70

Shooting to the left is strong if the keeper goes the wrong way, but this keeper is very good at saving left-side kicks. What should the kicker do?

Here is a strange offer. The keeper's coach has hacked the kicker's phone and read the kicker's game plan. Before the kick, the keeper will know exactly how the kicker intends to decide. Should the kicker panic?

If the plan is "always kick right", yes: the keeper dives right and the scoring chance drops to 0.70. If the plan is "always kick left", the chance drops to 0.60. Any fixed choice can be punished. But suppose the plan is: *roll a die-like device and kick left with probability exactly* $4/11$. The keeper reads it, thinks hard, and discovers that it does not matter which way they dive. The scoring chance is 0.7909 either way. The leak has cost the kicker nothing.

That is the miracle of this chapter, and it is not a trick of this particular table. In any two-player game where one side's gain is the other's loss, there is a randomised strategy you can publish to the world and still guarantee the best result you could ever have hoped for against a perfect opponent. John von Neumann proved it in 1928, and he later said that until it was proved he saw nothing worth publishing in game theory.

The same idea runs a long way past football. A chess program assumes the opponent always finds the best reply. A spam filter assumes the spammer adapts to every rule. A portfolio manager follows a panel of expert advisers, some of whom are wrong in ways designed to fool them. A robust controller is tuned for the worst disturbance, not the average one. In each case the question is the same:

Can you make decisions that are guaranteed good, against an opponent who knows exactly how you make them?

The answer is yes, in a precise and surprising sense. And the guarantee comes from an algorithm so simple it fits on two lines.

46.2 The big idea

Ordinary optimisation (Ch. 23) treats the world as fixed: the objective function sits still while you climb it. Probability (Ch. 19) treats the world as random but indifferent: the dice do not care what you chose. Adversarial thinking takes the third view. Whatever you do, assume the world responds in the way that hurts you most.

That sounds paranoid, and sometimes it is. But it buys something priceless: a **guarantee**. If your plan is good against the worst case, it is good against every case. You never need a model of your opponent.

Three ideas make the guarantee useful rather than hopeless.

Pessimism has a value. For each plan, imagine the opponent's best reply and record what you get. Pick the plan whose worst case is best. That number, the **maxmin** value, is what you can secure no matter what. The opponent can do the same from their side, and secure the **minmax**. The gap between the two numbers is the territory the players are actually fighting over.

Randomness is armour. If you are predictable, an adversary who knows your plan exploits it. A coin flip the adversary can *read* but cannot *predict* closes the gap. The opponent knows the probabilities but not the outcome, and against the right probabilities every reply is equally bad for them.

Regret replaces the impossible benchmark. In repeated play you usually cannot beat an adaptive adversary in absolute terms, because they can make every round costly. But you can compare yourself to a humbler target: the best *single* fixed action you could have chosen with hindsight. The shortfall against that target is your **regret**. A remarkable family of algorithms guarantees that regret grows more slowly than the number of rounds, against *any* sequence of losses, chosen by *anyone*. Average regret per round goes to zero. Nobody can stop it.

The surprise at the end of 46.3 is that the third idea proves the first two. Two players who each just try to keep their regret small end up, on average, playing von Neumann's equilibrium. Learning finds the minimax solution without ever being told it exists.

46.3 The mathematics

Zero-sum games and their two values

> **Two-player zero-sum game**
>
> Player 1 (rows) chooses $i \in \{1, \dots, m\}$, player 2 (columns) chooses $k \in \{1, \dots, n\}$, and player 1 receives a_{ik} while player 2 receives $-a_{ik}$. Mixed strategies are probability vectors $\mathbf{x} \in \Delta_m$, $\mathbf{y} \in \Delta_n$, and the expected payoff to player 1 is $\mathbf{x}^{\mathsf{T}} \mathbf{A} \mathbf{y}$.

Player 1 can guarantee

$$\underline{v} = \max_{\mathbf{x} \in \Delta_m} \min_{\mathbf{y} \in \Delta_n} \mathbf{x}^{\mathsf{T}} \mathbf{A} \mathbf{y}$$

(choose $\mathbf{x}$ first, then let the opponent react), and player 2 can hold player 1 down to

$$\overline{v} = \min_{\mathbf{y} \in \Delta_n} \max_{\mathbf{x} \in \Delta_m} \mathbf{x}^{\mathsf{T}} \mathbf{A} \mathbf{y}.$$

For fixed $\mathbf{x}$ the inner minimum of a linear function of $\mathbf{y}$ is attained at a pure strategy, so $\min_{\mathbf{y}} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} = \min_k (\mathbf{x}^{\mathsf{T}}\mathbf{A})_k$. The opponent never needs to randomise in *reply*. Randomisation matters only for whoever moves first.

Weak minimax inequality

For every matrix, $\underline{v} \le \overline{v}$. Moving second never hurts.

Proof. Fix any $\mathbf{x}$ and $\mathbf{y}$. Then

$$\min_{\mathbf{y}'} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y}' \;\le\; \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} \;\le\; \max_{\mathbf{x}'} \mathbf{x}'^{\mathsf{T}}\mathbf{A}\mathbf{y}.$$

The left side depends only on $\mathbf{x}$ and the right side only on $\mathbf{y}$, and the inequality holds for every pair. So the largest possible left side is at most the smallest possible right side: $\max_{\mathbf{x}} \min_{\mathbf{y}'} \le \min_{\mathbf{y}} \max_{\mathbf{x}'}$. $\blacksquare$

With **pure** strategies only, the inequality is often strict. In matching pennies ($a_{ik} = +1$ if the choices match, -1 otherwise) the pure maxmin is -1 and the pure minmax is $+1$: whoever must reveal a pure choice first loses. Mixing at $\tfrac{1}{2}$ each brings both values to 0.

The penalty kick, solved

Let the kicker kick left with probability q. Against a keeper diving left the kicker scores $0.60q + 0.90(1-q) = 0.90 - 0.30q$; against a keeper diving right, $0.95q + 0.70(1-q) = 0.70 + 0.25q$. The keeper picks the smaller of the two, so the kicker maximises the lower envelope of two lines. One line falls and one rises, so the maximum sits where they cross:

$$0.90 - 0.30q = 0.70 + 0.25q \quad\Longrightarrow\quad q^{*} = \frac{0.20}{0.55} = \frac{4}{11} \approx 0.364, \qquad v = 0.90 - 0.30 \cdot \tfrac{4}{11} \approx 0.7909.$$

The same calculation from the keeper's side, diving left with probability r, gives $0.95 - 0.35r = 0.70 + 0.20r$, so $r^{*} = 5/11 \approx 0.455$ and again $v \approx 0.7909$. Both pessimists arrive at the same number. The kicker can guarantee at least 0.7909; the keeper can guarantee at most 0.7909. Here $\underline{v} = \overline{v}$, and neither side benefits from knowing the other's plan.

Notice the counter-intuitive detail: the kicker's left side is the *weaker* option against a correct guess, yet the kicker still uses it about a third of the time. The point of kicking left is not to score on the left. It is to stop the keeper from leaning right.

Von Neumann's theorem and its linear program

Minimax theorem (von Neumann, 1928)

For every finite matrix $\mathbf{A}$,

$$\max_{\mathbf{x} \in \Delta_m} \min_{\mathbf{y} \in \Delta_n} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} \;=\; \min_{\mathbf{y} \in \Delta_n} \max_{\mathbf{x} \in \Delta_m} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} \;=\; v.$$

The common value v is the **value of the game**; any pair of optimisers $(\mathbf{x}^{*}, \mathbf{y}^{*})$ is a Nash equilibrium, and every Nash equilibrium is such a pair.

The row player's problem is a linear program of the kind solved in Section 23.3:

$$\begin{aligned} \text{maximise} \quad & t \\ \text{subject to} \quad & (\mathbf{x}^{\mathsf{T}}\mathbf{A})_k \ge t \quad (k = 1, \dots, n), \\ & \textstyle\sum_i x_i = 1, \quad \mathbf{x} \ge \mathbf{0}. \end{aligned}$$

The column player's problem is another LP, and the two are *dual* to each other. Strong duality, the deep theorem of Ch. 48, says their optimal values coincide, which is the minimax theorem. That route is short but leans on machinery we have not built. Instead we will prove the theorem with nothing more than an inequality about exponentials, and the proof will hand us an algorithm as a bonus.

Regret and the Hedge algorithm

The setting is **online learning with experts**. There are n actions ("experts"). In each round $t = 1, \dots, T$:

1. you choose a probability vector $\mathbf{p}_t \in \Delta_n$;
2. an adversary, who may know everything about your algorithm and the past, chooses a loss vector $\boldsymbol{\ell}_t \in [0,1]^n$;
3. you suffer expected loss $\mathbf{p}_t^{\mathsf{T}}\boldsymbol{\ell}_t$ and see the whole vector $\boldsymbol{\ell}_t$.

Regret

$$R_T = \sum_{t=1}^{T} \mathbf{p}_t^{\mathsf{T}}\boldsymbol{\ell}_t \;-\; \min_{i} \sum_{t=1}^{T} \ell_{t,i}.$$

Your total loss, minus the total loss of the best single action in hindsight.

The obvious algorithm, **Follow the Leader** (put all your weight on the action with the smallest loss so far), is a disaster. With two actions, let the first losses be $(\frac{1}{2}, 0)$ and then alternate $(0,1), (1,0), (0,1), \ldots$. The leader always switches to the action about to lose. FTL loses 1 almost every round, while each fixed action loses only about half the time, so $R_T \approx T/2$: linear regret, the worst possible order. The flaw is that FTL is deterministic and jumps; the adversary reads it and punishes each jump.

Hedge (also called multiplicative weights or exponential weights) softens the jump. Keep a weight per action, start at $w_{1,i} = 1$, and after each round multiply:

$$w_{t+1,i} = w_{t,i}\, e^{-\eta\, \ell_{t,i}}, \qquad \mathbf{p}_t = \frac{\mathbf{w}_t}{\sum_i w_{t,i}}.$$

Actions that lose are penalised exponentially but never killed. Compare the replicator equation of Ch. 45: shares multiplied by a factor depending on payoff. The resemblance is not a coincidence.

Regret bound for Hedge

For any adversary and any $\eta > 0$,

$$R_T \le \frac{\ln n}{\eta} + \frac{\eta T}{2}.$$

With $\eta = \sqrt{2 \ln n / T}$ this gives $R_T \le \sqrt{2T \ln n}$, so the average regret $R_T/T \le \sqrt{2 \ln n / T} \to 0$.

Proof. Track the total weight $W_t = \sum_i w_{t,i}$, with $W_1 = n$. Two estimates squeeze $\ln W_{T+1}$.

Upper bound. For $z \ge 0$, $e^{-z} \le 1 - z + z^2/2$. With $z = \eta \ell_{t,i} \in [0, \eta]$:

$$\frac{W_{t+1}}{W_t} = \sum_i p_{t,i}\, e^{-\eta \ell_{t,i}} \le 1 - \eta\, \mathbf{p}_t^{\mathsf{T}} \boldsymbol{\ell}_t + \frac{\eta^2}{2} \sum_i p_{t,i} \ell_{t,i}^2 \le 1 - \eta\, \mathbf{p}_t^{\mathsf{T}} \boldsymbol{\ell}_t + \frac{\eta^2}{2}.$$

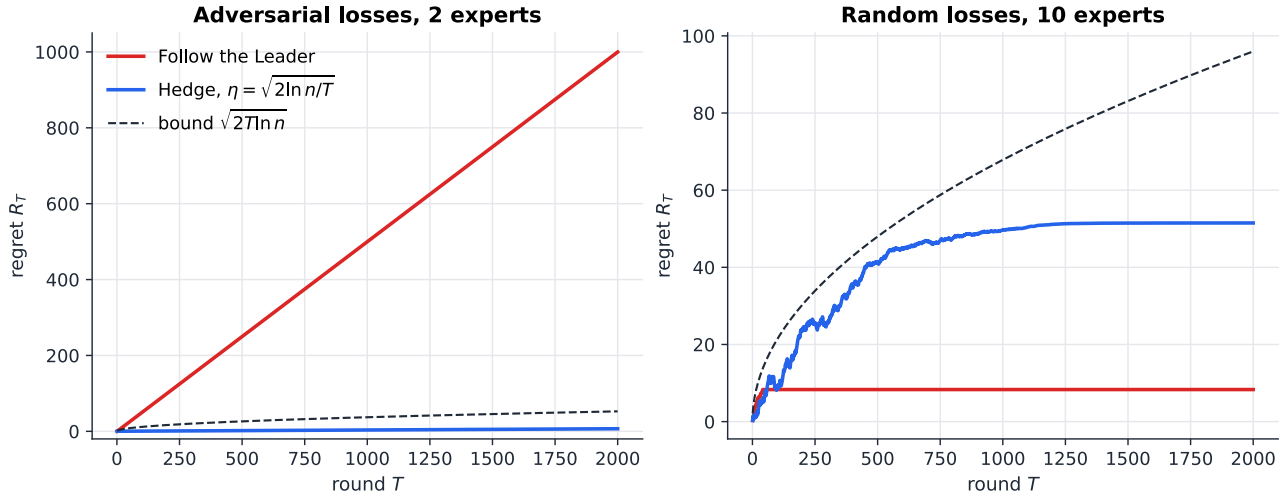
Since $\ln(1+u) \le u$, taking logs and summing over t:

$$\ln \frac{W_{T+1}}{W_1} \le -\eta \sum_{t=1}^{T} \mathbf{p}_t^{\mathsf{T}} \boldsymbol{\ell}_t + \frac{\eta^2 T}{2}.$$

Lower bound. The total weight is at least the weight of the best action i^*: $W_{T+1} \ge w_{T+1,i^*} = e^{-\eta L^*}$, where $L^* = \min_i \sum_t \ell_{t,i}$. So $\ln(W_{T+1}/W_1) \ge -\eta L^* - \ln n$.

Combine. $-\eta L^* - \ln n \le -\eta \sum_t \mathbf{p}_t^{\mathsf{T}} \boldsymbol{\ell}_t + \eta^2 T/2$. Divide by η and rearrange: $\sum_t \mathbf{p}_t^{\mathsf{T}} \boldsymbol{\ell}_t - L^* \le \ln n / \eta + \eta T/2$. Minimising the right side over η gives $\eta = \sqrt{2 \ln n / T}$ and the bound $\sqrt{2T \ln n}$. ∎

Read the proof again and notice what it never assumed. Nothing about where the losses come from. Nothing about randomness, stationarity, or the adversary's computing power. The only facts used are that losses lie in $[0,1]$ and that the adversary must commit to $\boldsymbol{\ell}_t$ without seeing your coin flip. The number of actions enters only through $\ln n$: a million experts cost you about $\sqrt{2 \cdot 13.8\, T} \approx 5.3\sqrt{T}$, against $2.1\sqrt{T}$ for ten. A hundred thousand times more advisers, two and a half times the regret.



Left: on the adversarial sequence that alternates losses between two actions, Follow the Leader's regret grows linearly (about 1000 after 2000 rounds) while Hedge stays near 7, well under its guarantee $\sqrt{2T \ln 2} \approx 53$. Right: on random losses with ten actions, one slightly better, FTL actually beats Hedge (regret about 8 against about 51); Hedge pays an insurance premium for its worst-case guarantee.

The right-hand panel is a warning against reading guarantees as predictions. When the world is benign, a greedy algorithm can win; Hedge, tuned for the worst case, explores more than it needs to. Insurance always costs something on a sunny day.

? Is $\sqrt{T \ln n}$ the end of the road?

The bound grows like $\sqrt{T}$. Could a smarter algorithm guarantee regret growing like $\ln T$, or even a constant, against every adversary? The answer is no, and the proof is a probabilistic surprise: let the adversary choose losses by *fair coin flips*, so no algorithm can do better than $T/2$ on average, while the best of n independent random walks beats $T/2$ by about $\sqrt{(T/2) \ln n}$. Why the maximum of n random walks behaves like that is a question about fluctuations of random walks, answered in Ch. 34.

The minimax theorem from regret

Now the payoff. Rescale $\mathbf{A}$ so its entries lie in $[0, 1]$ (adding a constant and scaling changes nothing essential). Let both players run a no-regret algorithm such as Hedge against each other for T rounds:

- the row player, who wants a large $\mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y}$, feeds Hedge the losses $\boldsymbol{\ell}_t = \mathbf{1} - \mathbf{A}\mathbf{y}_t$;
- the column player, who wants it small, feeds Hedge the losses $\boldsymbol{\ell}_t = \mathbf{A}^{\mathsf{T}}\mathbf{x}_t$.

Write ε_T for the larger of the two average regrets, $\bar{v} = \frac{1}{T}\sum_t \mathbf{x}_t^{\mathsf{T}}\mathbf{A}\mathbf{y}_t$ for the average payoff, and $\bar{\mathbf{x}}, \bar{\mathbf{y}}$ for the average strategies.

> **No regret implies minimax**
>
> $\overline{v} \le \underline{v} + 2\varepsilon_T$. Since $\varepsilon_T \to 0$ for Hedge, $\overline{v} = \underline{v}$, and $(\bar{\mathbf{x}}, \bar{\mathbf{y}})$ is a $2\varepsilon_T$-approximate equilibrium.

Proof. The row player's regret bound says that no fixed row does much better than what was actually earned: $\max_i \frac{1}{T}\sum_t (\mathbf{A}\mathbf{y}_t)_i \le \bar{v} + \varepsilon_T$. The left side is $\max_{\mathbf{x}} \mathbf{x}^{\mathsf{T}}\mathbf{A}\bar{\mathbf{y}}$. Symmetrically, the column player's bound gives $\min_{\mathbf{y}} \bar{\mathbf{x}}^{\mathsf{T}}\mathbf{A}\mathbf{y} \ge \bar{v} - \varepsilon_T$. Chain them:

$$\overline{v} = \min_{\mathbf{y}} \max_{\mathbf{x}} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} \le \max_{\mathbf{x}} \mathbf{x}^{\mathsf{T}}\mathbf{A}\bar{\mathbf{y}} \le \bar{v} + \varepsilon_T \le \min_{\mathbf{y}} \bar{\mathbf{x}}^{\mathsf{T}}\mathbf{A}\mathbf{y} + 2\varepsilon_T \le \max_{\mathbf{x}} \min_{\mathbf{y}} \mathbf{x}^{\mathsf{T}}\mathbf{A}\mathbf{y} + 2\varepsilon_T = \underline{v} + 2\varepsilon_T.$$

Let $T \to \infty$ and combine with the weak inequality $\underline{v} \le \overline{v}$. $\blacksquare$

Pause on how strange this is. Neither player knows the game is zero-sum, or that an equilibrium exists, or what the other is doing. Each merely refuses to have regrets. The theorem of the existence of a value falls out of an exponential inequality.

> **? What happens when the game is not zero-sum?**
>
> Run the same two Hedge players on a general-sum game, the prisoner's dilemma of Ch. 40 or a 3×3 coordination game, and the averages no longer need to approach a Nash equilibrium. They converge to a weaker object, a *coarse correlated equilibrium*. Is there any fast learning rule that finds a Nash equilibrium of a general game? The evidence says no: computing one is complete for a complexity class called PPAD, believed intractable. Where that hardness comes from is a story from Ch. 30.

Robust decisions: when the adversary is Nature

Sometimes the "opponent" is not a mind but uncertainty itself: an unknown demand, an unmodelled disturbance, a parameter you could not measure. Abraham Wald proposed in 1945 to treat Nature as an adversary and choose the action with the best worst case, the **maxmin** rule. Leonard Savage objected that this is too timid and proposed **minimax regret**: for each scenario compute how much you lose relative to the best action for that scenario, and minimise the largest such regret.

> **Sizing a plant**
>
> Profit (in millions) for three capacities under three demand scenarios:
>
> | capacity | low | medium | high | worst case | worst regret |
> |---|---|---|---|---|---|
> | small | 4 | 5 | 5 | **4** | 7 |
> | medium | 2 | 7 | 8 | 2 | **4** |
> | large | −2 | 5 | 12 | −2 | 6 |
>
> The best profits per scenario are $4, 7, 12$, so the regret of *medium* in the three scenarios is $2, 0, 4$. Wald's maxmin chooses *small*, guaranteeing 4. Savage's minimax regret chooses *medium*, never more than 4 below the best possible outcome. Two worst-case philosophies, two different plants.

Neither rule is "right". Maxmin protects the level of the outcome; minimax regret protects against looking foolish in hindsight, the same benchmark Hedge uses. Robust optimisation (Ch. 54) turns these ideas into tractable programs where the scenarios form a continuous uncertainty set, and robust control does the same for a disturbance signal of bounded energy.

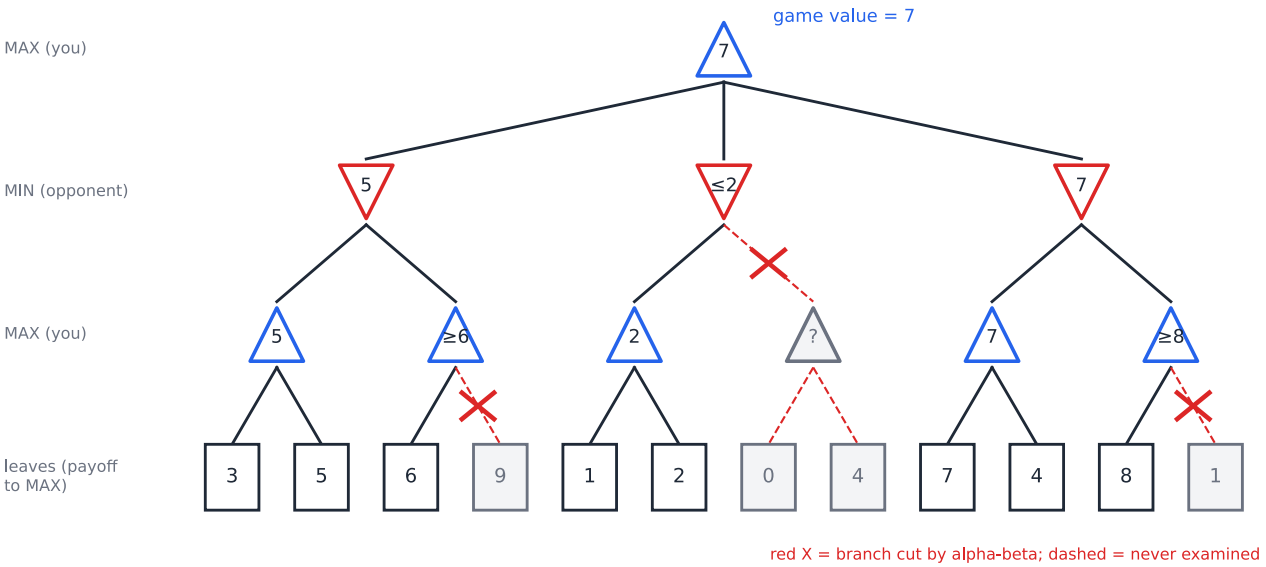
46.4 The algorithm

Minimax search with alpha–beta pruning

In a game of perfect information such as chess or Go, there is no need to randomise: the players alternate, every move is visible, and the value of a position is defined by backing up values from the leaves of the game tree. MAX nodes take the maximum of their children, MIN nodes the minimum. This backward recursion is dynamic programming on a tree (Ch. 52), and it proves a fact von Neumann and Zermelo knew early on: every finite two-player game of perfect information has a value achieved by pure strategies.

The trouble is size. A tree with branching factor b and depth d has b^d leaves. **Alpha–beta pruning** computes exactly the same root value while skipping branches that provably cannot matter. It carries two numbers down the tree: α, the best value MAX is already guaranteed somewhere above, and β, the best value MIN is already guaranteed.

```
ALPHABETA(node, α, β, maximizing):
    if node is a leaf (or depth limit reached):
        return EVAL(node)
    if maximizing:
        v ← −∞
        for each child c:
            v ← max(v, ALPHABETA(c, α, β, false))
            α ← max(α, v)
            if α ≥ β: break          # MIN above will never let play reach here
        return v
    else:
        v ← +∞
        for each child c:
            v ← min(v, ALPHABETA(c, α, β, true))
            β ← min(β, v)
            if α ≥ β: break          # MAX above already has something better
        return v
```



A three-ply game tree. Alpha–beta examines 8 of the 12 leaves and still returns the exact value 7. In the left subtree, once MAX sees a 6, the MIN node above (which already holds 5) will never allow it, so the 9 is never read. In the middle subtree, MIN finds a reply worth only 2, below the 5 MAX already has at the root, so the whole second branch is skipped. Values marked $\geq$ or $\leq$ are bounds, not exact values.

The correctness argument is a short induction: a pruned branch could only change a node's value in a direction that some ancestor would reject anyway. The efficiency depends entirely on **move ordering**. If the best move is always searched first, Knuth and Moore (1975) showed that alpha–beta examines about $b^{\lceil d/2 \rceil} + b^{\lfloor d/2 \rfloor} - 1$ leaves instead of b^d. For chess-like numbers, $b = 35$ and $d = 10$, that is roughly 1.05×10^8 positions instead of 2.76×10^{15}, a saving of a factor of about 26 million. In effect the search can go twice as deep for the same effort. With the worst ordering, alpha–beta prunes nothing.

Failure cases. Real programs cannot reach the leaves, so they stop at a depth limit and call a heuristic `EVAL`. Two famous pathologies follow.

- *The horizon effect.* A program facing an unavoidable loss can make delaying moves that push the loss just past its search depth, and so believe it has escaped.
- *Error amplification.* Minimax trusts its evaluation function absolutely. If `EVAL` is slightly wrong in a consistent direction, the search actively steers towards the positions where it is most wrong, because those look best.

Hedge in practice

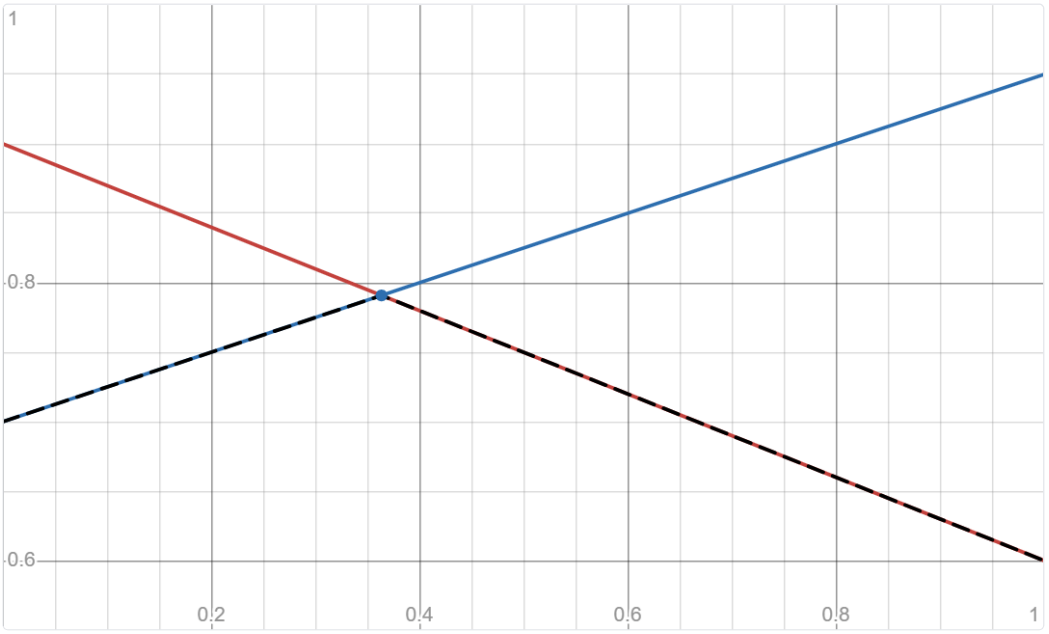
```
def hedge(losses, eta):
    """losses: T x n array in [0, 1]. Returns the T x n array of strategies played."""
    T, n = losses.shape
    cum = np.zeros(n)
    P = np.empty((T, n))
    for t in range(T):
        w = np.exp(-eta * (cum - cum.min()))   # shift: avoids underflow
        P[t] = w / w.sum()
        cum += losses[t]
    return P
```

Each round costs $O(n)$. Two numerical details matter. Subtracting the minimum cumulative loss before exponentiating changes nothing mathematically (it cancels in the normalisation) but prevents every weight from underflowing to zero after a few thousand rounds. And the tuned rate $\eta = \sqrt{2 \ln n / T}$ needs T in advance; if you do not know the horizon, the *doubling trick* (restart with $T = 1, 2, 4, 8, \ldots$) or a decreasing rate $\eta_t \propto \sqrt{\ln n / t}$ keeps the $O(\sqrt{T \ln n})$ guarantee at the price of a constant factor.

Solving a matrix game. For an exact answer, solve the LP of 46.3 with any LP solver: polynomial time in m and n. For huge games where even writing down $\mathbf{A}$ is costly, self-play Hedge finds an ε-equilibrium in $O(\ln n/\varepsilon^2)$ rounds, and it only needs to evaluate $\mathbf{A}\mathbf{y}$ and $\mathbf{A}^{\mathsf{T}}\mathbf{x}$. This is the engine behind modern poker programs, which run regret-minimising algorithms on games far too large to tabulate.

46.5 The experiment

First, the kicker's view of the penalty. The two lines are the scoring probabilities against each dive, as functions of the probability q (on the x-axis) of kicking left; the keeper always picks the lower line.



The kicker maximises the lower envelope (dashed). Change the four scoring probabilities 0.9, 0.3, 0.7, 0.25 (they come from the table in 46.1) and watch the optimal mix move; make one line lie entirely above the other and the optimum jumps to a pure strategy.

Next, let two Hedge learners play the penalty game against each other and watch them discover von Neumann's solution.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
A = np.array([[0.60, 0.95],     # P(goal): rows = kicker L/R,
              [0.90, 0.70]])    #          cols = keeper dives L/R
T = 5000                        # rounds of play
eta = np.sqrt(2 * np.log(2) / T)  # learning rate: try 10x larger or smaller
# -------------------------------------------------------------------------

Lk, Lg = np.zeros(2), np.zeros(2)   # cumulative losses: kicker, goalkeeper
avg_k, avg_g, gap = np.zeros(2), np.zeros(2), []
for t in range(1, T + 1):
    p = np.exp(-eta * (Lk - Lk.min())); p /= p.sum()   # kicker's mix
    q = np.exp(-eta * (Lg - Lg.min())); q /= q.sum()   # keeper's mix
    Lk += 1 - A @ q          # kicker loses when no goal
    Lg += A.T @ p            # keeper loses when goal
    avg_k += (p - avg_k) / t
    avg_g += (q - avg_g) / t
    # duality gap of the averages: best reply value minus worst case value
    gap.append((A @ avg_g).max() - (avg_k @ A).min())

print("kicker avg P(left) :", avg_k[0].round(4), " theory 4/11 =", round(4/11, 4))
print("keeper avg P(left) :", avg_g[0].round(4), " theory 5/11 =", round(5/11, 4))
print("value bracket      :", (avg_k @ A).min().round(4), (A @ avg_g).max().round(4))
plt.loglog(np.arange(1, T + 1), gap, label="duality gap of average play")
plt.loglog(np.arange(1, T + 1), 2*np.sqrt(2*np.log(2)*T)/np.arange(1, T + 1), "--",
           label="2 x regret bound / t (tuned for t = T)")
plt.xlabel("round t"); plt.legend(); plt.show()
```

With the default knobs the averages come out near 0.347 and 0.467 (theory: 0.364 and 0.455), and the value is bracketed between about 0.787 and 0.793, enclosing the true 0.7909. The final duality gap, about 0.007, sits well below the guaranteed $2\varepsilon_T \approx 0.033$. Things to try:

1. Multiply `eta` by 10. The averages still converge, but look at the *current* strategies `p` and `q` (print them every 500 rounds): they swing around the equilibrium like the rock–paper–scissors orbits of Ch. 45 and never settle. Only the averages converge.
2. Divide `eta` by 10. The learners are now too timid; after 5000 rounds they have barely left the uniform mix.
3. Replace `A` by rock–paper–scissors rescaled to $[0,1]$, for example $\frac{1}{2}(\mathbf{A}_{\text{RPS}}+1)$, and check the averages approach $(\frac{1}{3},\frac{1}{3},\frac{1}{3})$.
4. Make the keeper play Follow the Leader instead of Hedge. Who now exploits whom?

46.6 The challenge

1. **Intuition.** In the penalty table, suppose the kicker becomes *better* at scoring left when the keeper guesses wrong (raise 0.95 to 0.99). Does the kicker now kick left more often or less often at equilibrium? Predict before computing, and explain the answer in terms of what each player is trying to prevent.
2. **Derivation.** Prove that for any 2×2 zero-sum game without a pure saddle point, the row player's optimal probability on the first row is $q^* = \dfrac{a_{22} - a_{21}}{a_{11} - a_{12} - a_{21} + a_{22}}$, and derive the value. Then show that Follow the Leader has regret at least $T/2 - 1$ on the alternating sequence of 46.3.
3. **Implementation.** Implement tic-tac-toe with plain minimax and with alpha–beta. Count the leaves each examines from the empty board, then try three move orderings (fixed, random, centre-and-corners first) and compare the counts with the Knuth–Moore estimate.
4. **Open investigation.** Hedge with a fixed η has $O(\sqrt{T})$ regret against adversaries but, as the right panel of the regret figure shows, can be beaten by Follow the Leader when losses are random. Design an algorithm that does about as well as FTL on benign data and as well as Hedge on adversarial data, and test it on both sequences of the figure. How much must it give up on each side? (Algorithms of this "best of both worlds" type exist; how close you can get with a simple design is for you to find out.)

46.7 Loose threads

This chapter gave you a guarantee and an algorithm, and it hid how far both reach.

We solved perfect-information games by searching a tree with a hand-made evaluation function, and we solved matrix games by letting regret minimisers play each other. Modern game-playing systems merge the two ideas: they search a tree, but the evaluation and the move ordering are learned, and the learning happens by playing against copies of themselves.

> **? Learning to evaluate by playing yourself**
>
> A Go board has more legal positions than there are atoms in the observable universe, so no evaluation function can be written by hand and no tree can be searched to the end. Programs trained purely by self-play nevertheless surpassed every human player. What exactly is being learned, why self-play does not simply cycle like the over-eager Hedge learners of 46.5, and what replaces alpha–beta in those systems are questions taken up in Ch. 53, building on the Bellman recursion of Ch. 52.

We also leaned on one hidden assumption throughout: that you see the whole loss vector after each round. A slot machine, an advertising slot or a network route shows you only the loss of the action you took. That is the *bandit* problem, where you must pay to explore, and the regret guarantee changes shape in an interesting way.

Finally, minimax thinking has a cousin that is far older than game theory: the cryptographer's assumption that the enemy knows the system. Kerckhoffs' principle says a cipher must stay secure even when everything except the key is public, which is exactly the spirit of publishing your mixed strategy. In Ch. 77 the adversary returns, with unlimited patience and bounded computing power, and the guarantees take yet another form.

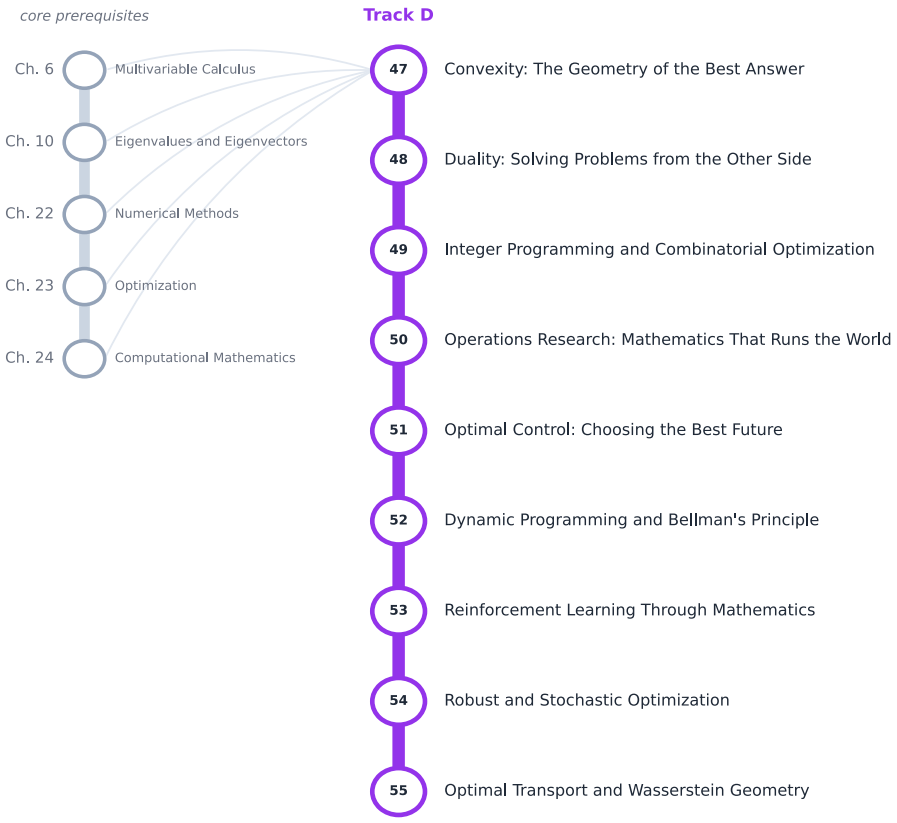
Track D — Optimization and Operations Research

> **Level 2 — Specializations.** From introductory engineering tools to the advanced frameworks that schedule, route and control the world.



Suggested reading order for Track D. The grey stations on the left are the core chapters it leans on.

Before you start

This track assumes you are comfortable with these core chapters:

- Ch. 6 — Multivariable Calculus
- Ch. 10 — Eigenvalues and Eigenvectors
- Ch. 22 — Numerical Methods
- Ch. 23 — Optimization
- Ch. 24 — Computational Mathematics

Chapters

Ch.	Chapter	What it explores
47	Convexity: The Geometry of the Best Answer	Convex sets/functions, separation theorems, convex optimization.
48	Duality: Solving Problems from the Other Side	Lagrangian duality, KKT conditions, sensitivity analysis.
49	Integer Programming and Combinatorial Optimization	Integer models, branch-and-bound, cutting planes, relaxations.
50	Operations Research: Mathematics That Runs the World	Scheduling, inventory, logistics, resource allocation.
51	Optimal Control: Choosing the Best Future	Dynamic optimization, Pontryagin's principle, control constraints.
52	Dynamic Programming and Bellman's Principle	Bellman equations, optimal policies, state-space methods.
53	Reinforcement Learning Through Mathematics	Markov decision processes, value functions, policy optimization.
54	Robust and Stochastic Optimization	Uncertain parameters, chance constraints, worst-case optimization.
55	Optimal Transport and Wasserstein Geometry	Transport plans, Wasserstein distances, distribution matching.

Every chapter follows the same arc: **the hook** (a puzzle or a failure), **the big idea**, **the mathematics**, **the algorithm**, **the experiment** you can run, **the challenge**, and **loose threads**: the questions the chapter deliberately leaves open.

Chapter 47 — Convexity: The Geometry of the Best Answer

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 6, Ch. 10, Ch. 23 · **Leads to:** Ch. 48, Ch. 49, Ch. 54 · **Related:** Ch. 39, Ch. 61, Ch. 75 **Reading time:** ~30 min

47.1 The hook

In 1958 Frank Rosenblatt built a machine that learned. The Mark I Perceptron looked at a grid of photocells, took a weighted sum of their outputs, and fired if the sum crossed a threshold. Each time it guessed wrong, it nudged its weights toward the right answer. Newspapers predicted thinking machines within a decade.

Eleven years later Marvin Minsky and Seymour Papert pointed out something the machine could never learn. Put four points on a square:

point	$(0,0)$	$(1,1)$	$(1,0)$	$(0,1)$
label	A	A	B	B

This is the exclusive-or pattern: label B when exactly one coordinate is 1. A perceptron draws one straight line and puts A on one side and B on the other. Try it. Every line you draw through that square leaves at least one point on the wrong side. Run the perceptron's learning rule on these four points and the weights never settle: they cycle forever.

That raises a question that matters well beyond 1969:

> **How do you *prove* that no line works?**

There are infinitely many lines, so you can't try them all. "I tried for an hour and failed" doesn't count as a proof. What you want is a **certificate**: a short piece of evidence that anyone can check in ten seconds and that settles the matter for good.

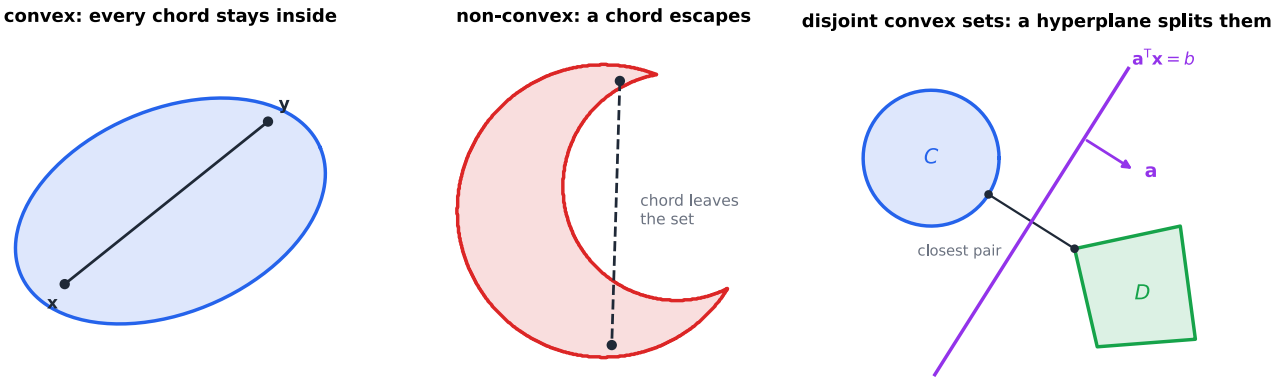
The same question turns up all over engineering. A filter specification asks for passband ripple under 0.1 dB, stopband attenuation over 80 dB and only 20 taps; is that achievable at all? A power network must carry a set of flows without overloading any line; is there any feasible dispatch? An optimizer reports a cost of 41.7; is that the best possible, or did it stop in a ditch? In every case "yes" is easy to certify: show the design. "No" and "this is optimal" are much harder. They are claims about *every* possible design.

This chapter shows that for one family of shapes, the **convex** ones, the hard claims have short proofs. A wall is the proof: a single hyperplane. By the end you will be able to write down the ten-second certificate for XOR. You will also see why the same geometry makes "local" answers into "global" ones.

47.2 The big idea

The core chapter defined convex sets and functions and proved the payoff: for a convex problem every local minimum is global (§23.7). Here is the intuition behind that result, and the idea this whole track grows from.

A convex set has no hidden corners. Stand anywhere inside it and you can see every other point along a straight line of sight that never leaves the set. A crescent moon fails this test: from one horn you can't see the other.



Left: in a convex set every chord stays inside. Centre: in a crescent a chord escapes. Right: two disjoint convex sets can always be split by a hyperplane, and the shortest segment between them points along its normal $\mathbf{a}$.

A convex set has two descriptions. You can describe it from the *inside*, as all the mixtures (convex combinations) of its points. Or you can describe it from the *outside*, as the intersection of all the half-spaces that contain it, like a gemstone defined by the flat cuts of its facets. For a closed convex set the two descriptions agree. Most of optimization theory is a conversation between them:

- an inside description lets you *exhibit* things: here is a feasible design, here is a point in both sets;
- an outside description lets you *rule things out*: here is a wall, and everything you want lies on the far side of it.

The certificate the hook asked for is an outside description. If two point clouds can't be separated, it's because their convex "shadows" overlap, and a single shared point proves it. If they can be separated, the line itself is the proof.

An analogy: walking downhill in fog. You are on a mountainside in thick fog and can only feel the slope under your feet. On a general mountain, reaching a spot where every direction goes up proves nothing. There may be a deeper valley over the ridge. On a convex bowl that spot *is* the bottom, because the ground under your feet already tells you about the whole bowl. The tangent plane you feel is a global floor (Figure 47.2). Local information is global information. That one sentence is why convex optimization is reliable and fast, and why so much of applied mathematics is spent turning problems into convex ones.

47.3 The mathematics

We work in $\mathbb{R}^n$ with the Euclidean inner product. Convex sets, convex functions, the first- and second-order tests, and "local implies global" are in §23.7 and are not repeated here. We need one more definition.

Convex combination and convex hull

A **convex combination** of points $\mathbf{x}_1, \dots, \mathbf{x}_k$ is $\sum_i \theta_i \mathbf{x}_i$ with $\theta_i \ge 0$ and $\sum_i \theta_i = 1$. The **convex hull** $\operatorname{conv} S$ of a set S is the set of all convex combinations of points of S. It is the smallest convex set containing S.

For a finite set of points in the plane, the convex hull is the shape a rubber band makes when you stretch it around them (computing it fast is a classic of Ch. 75). **Carathéodory's theorem** says that in $\mathbb{R}^n$ every point of $\operatorname{conv} S$ is a convex combination of at most $n+1$ points of S: in the plane, every point of the hull lies in some triangle with corners in S.

The closest point

Everything in this chapter flows from one elementary fact.

Theorem 47.1 — Projection onto a closed convex set

Let $C \subseteq \mathbb{R}^n$ be nonempty, closed and convex, and let $\mathbf{z} \in \mathbb{R}^n$. There is exactly one point $\mathbf{p} = P_C(\mathbf{z}) \in C$ closest to $\mathbf{z}$. It is characterised by the **obtuse-angle condition**

$$(\mathbf{z} - \mathbf{p})^{\mathsf{T}} (\mathbf{y} - \mathbf{p}) \le 0 \qquad \text{for all } \mathbf{y} \in C.$$

Proof. **Existence.** Pick any $\mathbf{y}_0 \in C$ and let $r = \|\mathbf{z} - \mathbf{y}_0\|$. Any closer point lies in $C \cap \{\mathbf{y} : \|\mathbf{y} - \mathbf{z}\| \le r\}$, which is closed and bounded, hence compact. The continuous function $\mathbf{y} \mapsto \|\mathbf{y} - \mathbf{z}\|$ attains its minimum there.

Characterisation. Let $\mathbf{p}$ be a closest point and $\mathbf{y} \in C$. By convexity $\mathbf{p} + t(\mathbf{y} - \mathbf{p}) \in C$ for $t \in [0,1]$, so

$$\varphi(t) = \|\mathbf{z} - \mathbf{p} - t(\mathbf{y} - \mathbf{p})\|^2 = \|\mathbf{z} - \mathbf{p}\|^2 - 2t(\mathbf{z} - \mathbf{p})^{\mathsf{T}}(\mathbf{y} - \mathbf{p}) + t^2 \|\mathbf{y} - \mathbf{p}\|^2$$

has its minimum on $[0,1]$ at $t = 0$. Then $\varphi'(0) = -2(\mathbf{z} - \mathbf{p})^{\mathsf{T}}(\mathbf{y} - \mathbf{p}) \ge 0$, which is the stated inequality. Conversely, if $\mathbf{p} \in C$ satisfies the inequality, then for any $\mathbf{y} \in C$, $\varphi(1) = \|\mathbf{z} - \mathbf{y}\|^2 \ge \|\mathbf{z} - \mathbf{p}\|^2 + \|\mathbf{y} - \mathbf{p}\|^2$, so $\mathbf{p}$ is closest.

Uniqueness. If $\mathbf{p}_1, \mathbf{p}_2$ are both closest, apply the inequality at $\mathbf{p}_1$ with $\mathbf{y} = \mathbf{p}_2$ and at $\mathbf{p}_2$ with $\mathbf{y} = \mathbf{p}_1$, then add: $(\mathbf{p}_2 - \mathbf{p}_1)^{\mathsf{T}}(\mathbf{p}_2 - \mathbf{p}_1) \le 0$. Hence $\mathbf{p}_1 = \mathbf{p}_2$. $\square$

In words: the line from $\mathbf{z}$ to its projection makes an obtuse (or right) angle with every direction that stays in C. For the unit disc and $\mathbf{z} = (2, 2)$, $P_C(\mathbf{z}) = (1/\sqrt{2}, 1/\sqrt{2}) \approx (0.707, 0.707)$. Every chord of the disc starting at that point heads away from $\mathbf{z}$. Convexity was essential. For the crescent of Figure 47.1, a point in the "bite" has *two* equally close points on the inner arc, and the obtuse-angle condition fails.

Separation

Theorem 47.2 — Separating a point from a convex set

Let C be nonempty, closed and convex, and $\mathbf{z} \notin C$. Then there are $\mathbf{a} \neq \mathbf{0}$ and b with

$$\mathbf{a}^{\mathsf{T}}\mathbf{y} \le b < \mathbf{a}^{\mathsf{T}}\mathbf{z} \qquad \text{for all } \mathbf{y} \in C.$$

Proof. Let $\mathbf{p} = P_C(\mathbf{z})$ and $\mathbf{a} = \mathbf{z} - \mathbf{p} \neq \mathbf{0}$ (since $\mathbf{z} \notin C$). The obtuse-angle condition reads $\mathbf{a}^{\mathsf{T}}\mathbf{y} \le \mathbf{a}^{\mathsf{T}}\mathbf{p}$ for all $\mathbf{y} \in C$. Put $b = \mathbf{a}^{\mathsf{T}}\mathbf{p}$. Then $\mathbf{a}^{\mathsf{T}}\mathbf{z} - b = \mathbf{a}^{\mathsf{T}}(\mathbf{z} - \mathbf{p}) = \|\mathbf{a}\|^2 > 0$. $\square$

The proof is constructive: the normal of the wall is the vector from the closest point to the outsider. One immediate corollary is the "outside description" promised in §47.2. **A closed convex set equals the intersection of all closed half-spaces containing it**, because any point outside is cut off by one of them.

Theorem 47.3 — Separating two convex sets

Let C and D be disjoint nonempty convex sets with C closed and D compact. Then some hyperplane strictly separates them: there are $\mathbf{a} \neq \mathbf{0}$, b with $\mathbf{a}^{\mathsf{T}}\mathbf{x} < b < \mathbf{a}^{\mathsf{T}}\mathbf{y}$ for all $\mathbf{x} \in C$, $\mathbf{y} \in D$.

Proof. The difference set $E = D - C = \{\mathbf{y} - \mathbf{x}\}$ is convex (it is the image of the convex set $D \times C$ under a linear map). It is closed because a compact set plus a closed set is closed, and it doesn't contain $\mathbf{0}$ because the sets are disjoint. Theorem 47.2 separates $\mathbf{0}$ from E. With $\mathbf{w} = -P_E(\mathbf{0})$ it gives $\mathbf{w}^{\mathsf{T}}(\mathbf{y} - \mathbf{x}) \ge \|\mathbf{w}\|^2 > 0$ for all pairs. Hence $\inf_D \mathbf{w}^{\mathsf{T}}\mathbf{y} \ge \sup_C \mathbf{w}^{\mathsf{T}}\mathbf{x} + \|\mathbf{w}\|^2$, and any b strictly between the two numbers works with $\mathbf{a} = \mathbf{w}$. $\square$

The vector $\mathbf{w}$ is exactly the shortest segment from C to D, the one drawn in the right panel of Figure 47.1. Two relatives are worth stating without proof:

- **Separation without compactness.** Any two disjoint convex sets can be separated *weakly* ($\mathbf{a}^\mathsf{T}\mathbf{x} \le b \le \mathbf{a}^\mathsf{T}\mathbf{y}$). Strictness can fail: the region above $y = e^x$ and the region below $y = 0$ are disjoint, but the gap between them shrinks to zero.
- **Supporting hyperplanes.** At every boundary point $\mathbf{x}_0$ of a convex set C there is a hyperplane through $\mathbf{x}_0$ with all of C on one side. A convex set can be "touched" from outside at every point of its surface. A crescent cannot: no line touches the inner arc while keeping the whole moon on one side.

The certificate for XOR

Now we can answer the hook.

Theorem 47.4 — Linear separability

Two finite point sets $A, B \subset \mathbb{R}^n$ can be strictly separated by a hyperplane if and only if $\operatorname{conv} A \cap \operatorname{conv} B = \varnothing$.

Proof. ($\Leftarrow$) Convex hulls of finite sets are compact and convex, so Theorem 47.3 applies. ($\Rightarrow$) Suppose $\mathbf{a}^\mathsf{T}\mathbf{x} < b$ on A and $\mathbf{a}^\mathsf{T}\mathbf{y} > b$ on B, and some point $\mathbf{m}$ lies in both hulls. Writing $\mathbf{m} = \sum \theta_i \mathbf{x}_i$ with $\mathbf{x}_i \in A$ gives $\mathbf{a}^\mathsf{T}\mathbf{m} = \sum \theta_i \mathbf{a}^\mathsf{T}\mathbf{x}_i < b$. Writing it as a combination of points of B gives $\mathbf{a}^\mathsf{T}\mathbf{m} > b$. Contradiction. $\square$

For XOR the certificate is one point, $\mathbf{m} = (\tfrac12, \tfrac12)$:

$$\tfrac12(0,0) + \tfrac12(1,1) = (\tfrac12, \tfrac12) = \tfrac12(1,0) + \tfrac12(0,1).$$

The two diagonals of the square cross. Any line that put both A points strictly on one side would have to put their midpoint there too. The B points would force that same midpoint onto the other side. That is the ten-second proof, and it rules out all infinitely many lines at once. The "yes" answers have short proofs too: for $A = \{(0,0),(1,0)\}$ and $B = \{(0,1),(1,1)\}$ the line $y = \tfrac12$ is its own certificate.

Engineering Note: support vector machines

When two classes are separable, there are many separating hyperplanes. The proof of Theorem 47.3 picks a special one: the perpendicular bisector of the shortest segment between the two hulls. That hyperplane has the widest possible margin, and finding it is exactly the **hard-margin support vector machine**, a convex quadratic program. The few points that touch the margin are the "support vectors".

Farkas' lemma: infeasibility has a certificate

The same idea certifies that a system of linear equations has **no nonnegative solution**. This is the version that powers linear programming. The core chapter uses it to justify the KKT conditions (§23.4) and the strong duality of LP (§23.3) without proving it. Here is the proof.

Theorem 47.5 — Farkas' lemma

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^m$. Exactly one of the following holds:

1. there is $\mathbf{x} \ge \mathbf{0}$ with $\mathbf{A}\mathbf{x} = \mathbf{b}$;
2. there is $\mathbf{y}$ with $\mathbf{A}^\mathsf{T}\mathbf{y} \ge \mathbf{0}$ and $\mathbf{b}^\mathsf{T}\mathbf{y} < 0$.

Proof. Both cannot hold: otherwise $0 \le (\mathbf{A}^\mathsf{T}\mathbf{y})^\mathsf{T}\mathbf{x} = \mathbf{y}^\mathsf{T}\mathbf{A}\mathbf{x} = \mathbf{y}^\mathsf{T}\mathbf{b} < 0$. Now suppose (1) fails. The cone $K = \{\mathbf{A}\mathbf{x} : \mathbf{x} \ge \mathbf{0}\}$, all nonnegative combinations of the columns of $\mathbf{A}$, is convex, and as a finitely generated cone it is closed (a standard fact we take on trust). Since $\mathbf{b} \notin K$, Theorem 47.2 gives $\mathbf{a}$ and β with $\mathbf{a}^\mathsf{T}\mathbf{k} \le \beta < \mathbf{a}^\mathsf{T}\mathbf{b}$ for all $\mathbf{k} \in K$. Because $\mathbf{0} \in K$, $\beta \ge 0$. Because K is a cone, $t\,\mathbf{k} \in K$ for every $t > 0$, so $\mathbf{a}^\mathsf{T}\mathbf{k} \le 0$ for all $\mathbf{k} \in K$; otherwise scaling would push it past β. Applying this to each column $\mathbf{A}\mathbf{e}_j$ gives $\mathbf{A}^\mathsf{T}\mathbf{a} \le \mathbf{0}$. Put $\mathbf{y} = -\mathbf{a}$: then $\mathbf{A}^\mathsf{T}\mathbf{y} \ge \mathbf{0}$ and $\mathbf{b}^\mathsf{T}\mathbf{y} = -\mathbf{a}^\mathsf{T}\mathbf{b} < -\beta \le 0$. $\square$

Worked Example 47.1: reading an infeasibility certificate

Is there $\mathbf{x} \ge \mathbf{0}$ with

$$x_1 + x_2 + x_3 = 1, \qquad x_1 - x_2 + 3x_3 = 4\ ?$$

Geometry. The columns $(1,1)$, $(1,-1)$, $(1,3)$ point at angles $45°$, $-45°$ and $71.6°$. The target $\mathbf{b} = (1,4)$ points at $76.0°$, just outside the cone the columns sweep out.

Certificate. Take $\mathbf{y} = (3,-1)$. Then $\mathbf{A}^\mathsf{T}\mathbf{y} = (3-1,\ 3+1,\ 3-3) = (2,4,0) \ge \mathbf{0}$ and $\mathbf{b}^\mathsf{T}\mathbf{y} = 3 - 4 = -1 < 0$.

What it means. Three times the first equation minus the second gives $2x_1 + 4x_2 + 0x_3 = -1$. The left side is nonnegative for every $\mathbf{x} \ge \mathbf{0}$, and the right side is negative. No solution exists. You don't have to trust any solver: one subtraction settles it.

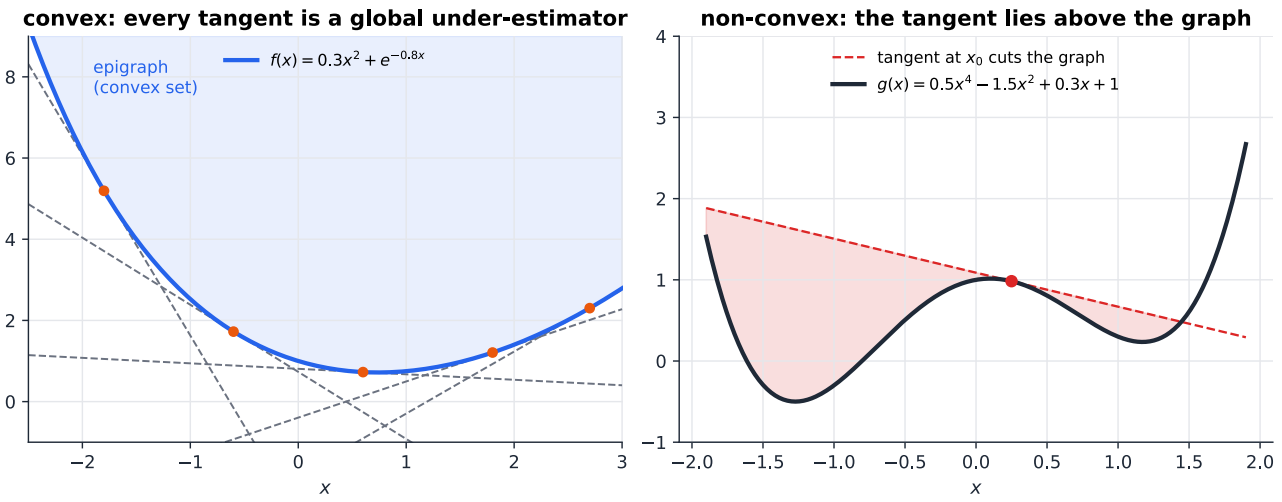
The hook's two questions now have one answer. **For convex problems, "no" always has a short certificate, and the certificate is a hyperplane.** In linear programming the hyperplane's coefficients $\mathbf{y}$ will turn out to be *prices*, but that story belongs to the next chapter.

Convex functions from the outside

Separation also explains the geometry of convex functions. The core chapter proved that a differentiable convex f lies above each of its tangents, $f(\mathbf{y}) \ge f(\mathbf{x}) + \nabla f(\mathbf{x})^\mathsf{T}(\mathbf{y} - \mathbf{x})$. Equality holds at $\mathbf{y} = \mathbf{x}$, so

$$f(\mathbf{y}) = \max_{\mathbf{x}} \Big[f(\mathbf{x}) + \nabla f(\mathbf{x})^\mathsf{T}(\mathbf{y} - \mathbf{x}) \Big].$$

A convex function is the upper envelope of its tangent planes. This is the outside description of its epigraph: the region above the graph is cut out by the half-spaces above the tangents.



Left: every tangent of $f(x) = 0.3x^2 + e^{-0.8x}$ is a global floor, and f is their upper envelope. Right: for a non-convex function the tangent at a hump overestimates the function on both sides (shaded), so local slope information says nothing reliable about distant points.

For non-smooth functions the tangent is replaced by any supporting line, which exists by the supporting-hyperplane theorem applied to the epigraph.

Subgradient

$\mathbf{g}$ is a **subgradient** of a convex f at $\mathbf{x}$ if $f(\mathbf{y}) \geq f(\mathbf{x}) + \mathbf{g}^{\mathsf{T}}(\mathbf{y} - \mathbf{x})$ for all $\mathbf{y}$. The set of all of them is the **subdifferential** $\partial f(\mathbf{x})$.

For $f(x) = |x|$, $\partial f(0) = [-1, 1]$: every line through the origin with slope between -1 and 1 stays under the V. The optimality condition becomes $\mathbf{0} \in \partial f(\mathbf{x}^*)$, and its proof is one line: if $\mathbf{0}$ is a subgradient, then $f(\mathbf{y}) \geq f(\mathbf{x}^*) + \mathbf{0}$ for all $\mathbf{y}$. This is how one handles the L^1 penalties of sparse signal recovery, the hinge loss of SVMs and the max-functions of minimax design, none of which are differentiable at their optimum.

Constraints: the normal cone

For a convex problem $\min_{\mathbf{x} \in C} f(\mathbf{x})$ the core chapter's optimality test (§23.7, "local equals global", item 4) says that no feasible direction goes downhill. In the language of this chapter:

Normal cone

$N_C(\mathbf{x}) = \{\mathbf{g} : \mathbf{g}^{\mathsf{T}}(\mathbf{y} - \mathbf{x}) \leq 0 \text{ for all } \mathbf{y} \in C\}$, the outward normals of all supporting hyperplanes of C at $\mathbf{x}$.

The optimality condition is then $-\nabla f(\mathbf{x}^*) \in N_C(\mathbf{x}^*)$: the downhill direction must point straight out through a supporting wall. Compare Theorem 47.1. The projection of $\mathbf{z}$ is the point $\mathbf{p}$ with $\mathbf{z} - \mathbf{p} \in N_C(\mathbf{p})$. In the interior the normal cone is $\{\mathbf{0}\}$ and we recover $\nabla f = \mathbf{0}$. At a corner of a polyhedron, Farkas' lemma says the normal cone is spanned by the normals of the active constraints, and the condition becomes the KKT equations of §23.4 with nonnegative multipliers. KKT is the normal-cone condition with the cone written out in coordinates.

Common Pitfall: convex objective, non-convex set

All of this needs *both* a convex function and a convex feasible set. Minimising the convex $\|\mathbf{x} - \mathbf{z}\|$ over a non-convex set (integer points, a circle, "at most k nonzero entries") can have many local minima, and the obtuse-angle condition no longer identifies the answer. Ch. 49 is about exactly this kind of trouble.

? The wall is a price tag

In Farkas' lemma the separating vector $\mathbf{y}$ combined the constraints into a contradiction. For a feasible LP, a similar vector combines them into a *bound* on the objective, and at the optimum the bound is tight. The coefficients of that wall turn out to be the marginal value of each resource, the shadow prices of §23.3. Why must the best bound equal the best design, with no gap? And why does this stop being true for non-convex problems? Separation is the hidden engine, and Ch. 48 shows how.

47.4 The algorithm

Separation theorems prove that certificates exist. Algorithms have to find them. Two simple algorithms do most of the work, and both are built from the projection of Theorem 47.1.

Projected gradient descent

To minimise a smooth convex f over a closed convex set C, take an ordinary gradient step (§23.5) and then snap back to the nearest feasible point:

```
input: f, its gradient, projection P_C, start x0 in C, step alpha
for k = 0, 1, 2, ...
    y      = x_k − alpha * grad f(x_k)        # unconstrained step
    x_{k+1} = P_C(y)                          # back to the feasible set
    stop when ||x_{k+1} − x_k|| is tiny
```

The fixed points are exactly the optimal points. $\mathbf{x} = P_C(\mathbf{x} - \alpha\nabla f(\mathbf{x}))$ says, by Theorem 47.1, that $-\alpha\nabla f(\mathbf{x}) \in N_C(\mathbf{x})$, which is the normal-cone condition. Two facts make the iteration trustworthy.

- **Projection never stretches distances:** $\|P_C(\mathbf{u}) - P_C(\mathbf{v})\| \le \|\mathbf{u} - \mathbf{v}\|$. To see it, add the obtuse-angle inequalities at the two projections and apply Cauchy–Schwarz. The snap-back step can never undo the progress of the gradient step.
- **Rates.** If ∇f is L-Lipschitz and $\alpha = 1/L$, then $f(\mathbf{x}_k) - f^* \le L\|\mathbf{x}_0 - \mathbf{x}^*\|^2/(2k)$: error $O(1/k)$, the same as unconstrained gradient descent. If f is also m-strongly convex, the distance to $\mathbf{x}^*$ shrinks by a factor of at least $1 - m/L$ per step. That is linear convergence, with the condition number $\kappa = L/m$ of §23.5 setting the speed.

Cost per step is one gradient plus one projection. Projections are cheap for boxes (clip each coordinate), balls (rescale), half-spaces (one formula) and the probability simplex (a sort, $O(n \log n)$). For a general polyhedron the projection is itself a quadratic program, and other methods (interior-point, §23.2) take over.

Alternating projections: finding a point, or a wall

To find a point in $C \cap D$, bounce between the two sets:

```
x = any starting point
repeat:  p = P_C(x);  x = P_D(p)
```

This is von Neumann's method of **alternating projections** (called POCS, projection onto convex sets, in signal processing). If the sets intersect, the iterates converge to a point in the intersection. If they are disjoint and one is compact, they converge to a **closest pair** $(\mathbf{p}, \mathbf{x})$. The vector $\mathbf{x} - \mathbf{p}$ is then the normal of a separating hyperplane through the midpoint (proof of Theorem 47.3). The same loop answers "feasible?" either way: it either exhibits a common point or hands you the certificate wall.

The perceptron, revisited

Rosenblatt's rule is a cousin of these methods. With labels $s_i = \pm 1$ and augmented points $\tilde{\mathbf{x}}_i = (\mathbf{x}_i, 1)$:

```
w = 0
repeat: pick any i with s_i * w.x_i <= 0  (a misclassified point)
        w = w + s_i * x_i
until no point is misclassified
```

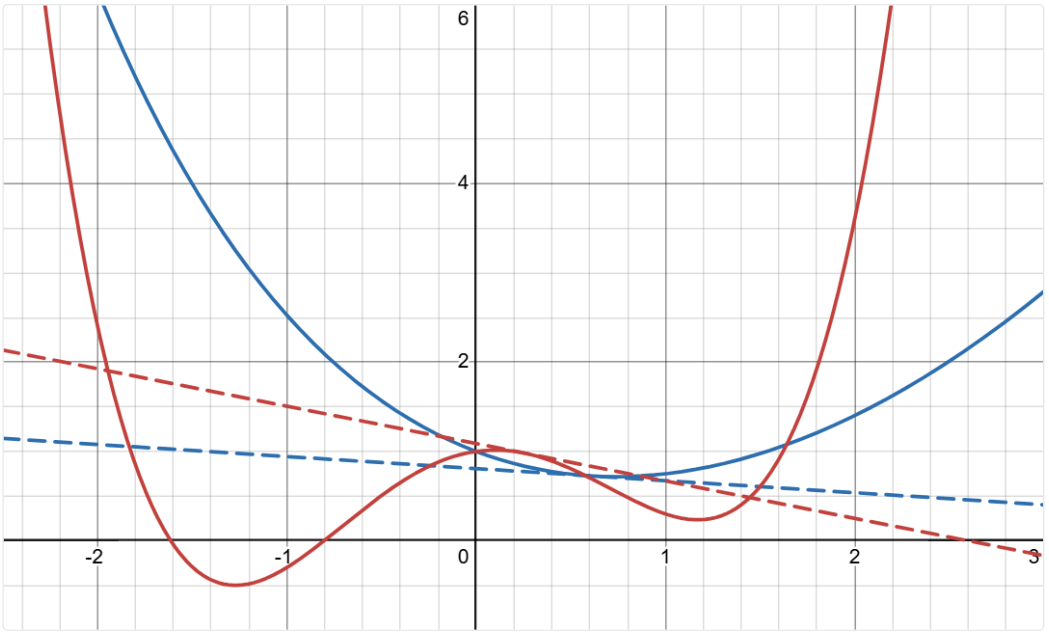
Novikoff's theorem (1962): if some unit vector separates the data with margin $\gamma > 0$ and every $\|\tilde{\mathbf{x}}_i\| \le R$, the rule stops after at most $(R/\gamma)^2$ updates. The margin γ is a quantitative version of "the convex hulls are disjoint": the further apart the hulls, the faster the learning. On XOR the hulls meet at $(\tfrac{1}{2}, \tfrac{1}{2})$, $\gamma = 0$, and the loop never ends.

Failure cases

- **Non-convex sets** (sparse vectors, integer points, rank constraints). Projection may not be unique, alternating projections can get stuck in cycles, and none of the guarantees above hold.
- **Sets that meet at a sliver.** If C and D touch at a very small angle, alternating projections creep toward the intersection, with each step shrinking the error only by about the cosine of that angle.
- **Expensive projections.** If P_C costs as much as the original problem, these methods offer nothing. For that case, ellipsoid and cutting-plane methods need only a *separation oracle*: a routine that, given a point outside C, returns one wall that cuts it off.

47.5 The experiment

Drag a tangent. The first two lines are $f(x) = 0.3x^2 + e^{-0.8x}$ and its tangent at $x_0 = 0.6$. Replace every `0.6` in the second line with another value (try -1.5, 0, 2.5): the tangent always stays under the graph. Then do the same with the tangent to the double-well g at $x_0 = 0.25$ (fourth line; try 1.2 and -1.3). For some x_0 the tangent pokes above the graph.



Blue: a convex function and one tangent, always below. Red: a non-convex function whose tangents can cross the graph. Change the x_0 values and watch which family keeps its promise.

Find a point or a wall. The script below runs alternating projections between the unit disc C and the half-plane $D = \{x + 2y \geq b\}$. With $b = 3$ the sets are disjoint. It prints the distance $3/\sqrt{5} - 1 \approx 0.341641$ and a separator, which after scaling is $x + 2y \approx 2.618$, halfway between the disc's tangent line $x + 2y = \sqrt{5}$ and D's edge $x + 2y = 3$. With $b = 1.5$ the distance drops to 0 and the last iterate is a common point.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
c, r = np.array([0.0, 0.0]), 1.0          # disc C: ||x - c|| <= r
a, b = np.array([1.0, 2.0]), 3.0          # half-plane D: a.x >= b  (try b = 1.5)
x = np.array([-2.0, 2.5])                 # starting point
iters = 30

def proj_disc(z):                         # closest point of C to z
    d = z - c; n = np.linalg.norm(d)
    return z if n <= r else c + r * d / n

def proj_half(z):                         # closest point of D to z
    s = a @ z - b
    return z if s >= 0 else z - s * a / (a @ a)

path = [x]
for k in range(iters):
    p = proj_disc(x); x = proj_half(p)
    path += [p, x]
path = np.array(path)
gap = np.linalg.norm(x - p)
print(f"distance between the sets ~ {gap:.6f}")
if gap > 1e-6:                            # build the separating hyperplane
    w = x - p; beta = w @ (x + p) / 2
    print(f"separator: {w[0]:.4f} x + {w[1]:.4f} y = {beta:.4f}")

t = np.linspace(0, 2 * np.pi, 200)
plt.fill(c[0] + r * np.cos(t), c[1] + r * np.sin(t), alpha=0.2)
xs = np.linspace(-3, 3, 2)
plt.plot(xs, (b - a[0] * xs) / a[1], "g", label="boundary of D")
plt.plot(path[:, 0], path[:, 1], "o-", ms=3, color="k", label="alternating projections")
plt.axis("equal"); plt.legend(); plt.show()
```

Things to try: move the disc centre `c` toward the line and watch the number of useful iterations grow as the sets begin to touch. Replace `proj_disc` with a projection onto a *ring* $\{0.5 \leq \|\mathbf{x}\| \leq 1\}$ (non-convex) and look for starting points where the method stalls far from the true closest pair.

47.6 The challenge

1. **Intuition.** Sketch two non-convex sets in the plane that are disjoint but cannot be separated by any line. Then explain in one sentence which step of the proof of Theorem 47.3 fails for them.
2. **Derivation.** Prove that projection onto a closed convex set is non-expansive, $\|P_C(\mathbf{u}) - P_C(\mathbf{v})\| \leq \|\mathbf{u} - \mathbf{v}\|$, using only the obtuse-angle condition of Theorem 47.1. Then derive the explicit projection onto the box $\{\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}\}$ and check that it satisfies the condition.

3. **Implementation.** Write a function that takes two finite point sets in $\mathbb{R}^2$ and returns either a separating line or a *certificate of inseparability*: weights $\boldsymbol{\theta} \geq 0$, $\boldsymbol{\phi} \geq 0$, each summing to 1, with $\sum \theta_i \mathbf{a}_i = \sum \phi_j \mathbf{b}_j$. (Hint: Farkas' lemma tells you which linear feasibility problem to pose.) Test it on XOR and on two well-separated clusters.
4. **Open investigation.** Alternating projections between two convex sets that touch at a single point can converge very slowly. Build families of such pairs (two tangent discs, a disc and a tangent line, a parabola's epigraph and a line) and measure how the error after k steps decays: $1/k$, $1/\sqrt{k}$, or something else? Is there a geometric quantity at the touching point that predicts the rate?

47.7 Loose threads

This chapter built the geometry and left three doors closed.

? A hyperplane in a space of signals

Everything here lived in $\mathbb{R}^n$. Engineers constantly optimise over *functions*: pulse shapes, filter responses, control signals. Those live in infinite-dimensional spaces, where closed bounded sets need not be compact and the existence step of Theorem 47.1 can fail. Does every convex set of signals still have a separating wall? The answer is the Hahn–Banach theorem, one of the pillars of Ch. 61, and it changes what "a hyperplane" means.

? Why do non-convex problems so often behave?

Training a neural network is wildly non-convex: millions of variables, symmetries, saddle points everywhere. Yet plain gradient descent, with no certificate of anything, routinely finds solutions that generalise well. Nobody has a complete explanation of why these landscapes are so benign. It remains an open problem at the meeting point of optimization and learning theory, and Ch. 53 meets the same puzzle in policy optimization.

The third thread is the price-tag mystery of §47.3: the certificate vector $\mathbf{y}$ is about to become the dual variable, and the whole of Ch. 48 is about what it measures. Two further pointers: von Neumann's minimax theorem for zero-sum games (Ch. 39) is a separation theorem in disguise, and when the data of a convex problem are uncertain, the feasible set itself becomes an intersection of infinitely many half-spaces (Ch. 54).

Chapter 48 — Duality: Solving Problems from the Other Side

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 6, Ch. 23, Ch. 47 · **Leads to:** Ch. 49, Ch. 51, Ch. 55 · **Related:** Ch. 39, Ch. 43, Ch. 50 **Reading time:** ~30 min

48.1 The hook

Every five minutes, somewhere in a control room, an operator has to decide how much electricity each of several hundred power stations should generate. Demand must be met exactly. No transmission line may overheat. The total cost must be as low as possible. Each station has its own fuel curve, ramp limits and quirks, and most of those details are private. A coal plant does not want to publish its true costs. A wind farm doesn't know its output until the wind blows.

One way to run this is central planning: collect every detail, solve one enormous problem, and send each station an order. Modern electricity markets mostly do something stranger. They broadcast **a price**, one number per location. Each station looks at the price, decides on its own how much it wants to produce, and offers that. If the total is too low, the price goes up; if it's too high, the price goes down. When the market clears, the stations' selfish choices add up to the minimum-cost dispatch, exactly what the central planner would have ordered.

That should seem too good to be true. Why should prices, which carry so much less information than the full problem, be enough to coordinate the optimum? And there's a second, sharper puzzle hidden in it. In some markets, after the price is set, the operator has to make extra side payments called "uplift" to certain stations. Without those payments, the stations would lose money by following the "optimal" schedule. So prices sometimes *fail*. What is the mathematical difference between a world where prices work and one where they don't?

This chapter answers both questions with a single construction, the **Lagrangian dual**. It turns every minimisation problem into a maximisation over prices. The two problems look at the same truth from opposite sides. For convex problems they meet exactly. For non-convex ones a gap opens, and the uplift payment is that gap, measured in money.

48.2 The big idea

Picture two people working on the same problem.

The **designer** stands inside the feasible region. Every feasible design she tries has some cost, and that cost is an *upper bound* on the best possible cost: the optimum can't be worse than something she has already built. Her bounds come down as she finds better designs.

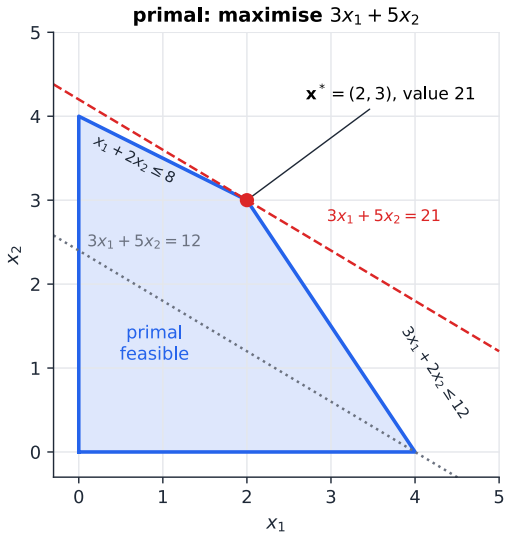
The **price-setter** never builds anything. She attaches a price to each constraint, which you can think of as a fine for each unit of violation. Then she asks: if constraints could be broken freely at these prices, what is the cheapest total of cost plus fines? Because any truly feasible design pays no fines, and at nonnegative prices can only collect credits for unused slack, that relaxed minimum is a *lower bound* on the true optimum. Her bounds go up as she tunes the prices.

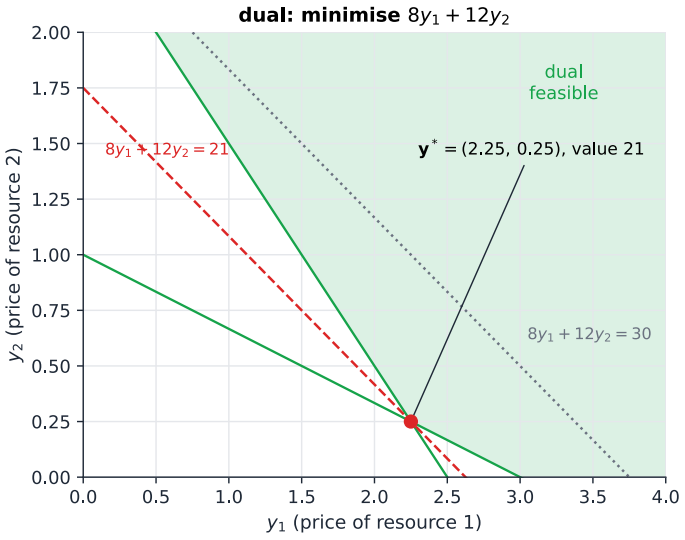
The designer's numbers come down from above and the price-setter's come up from below. **Weak duality** says the floor can never pass through the ceiling. **Strong duality** says that, for convex problems, the two meet. When they meet you hold two numbers that agree, and the agreement is the certificate of optimality that Ch. 47 promised. Nobody has to search further.

Here is the smallest example. A workshop makes two products with profits 3 and 5 per unit. It has 8 hours of machine time (product 1 needs 1 hour per unit, product 2 needs 2) and 12 kg of material (3 kg and 2 kg). The primal problem is

$$\max\ 3x_1 + 5x_2 \quad \text{s.t.} \quad x_1 + 2x_2 \le 8, \quad 3x_1 + 2x_2 \le 12, \quad x_1, x_2 \ge 0.$$

Suppose a buyer offers to rent the whole workshop, paying y_1 per machine hour and y_2 per kilogram. You'll accept only if the rent for the resources in each product is at least that product's profit: $y_1 + 3y_2 \ge 3$ and $2y_1 + 2y_2 \ge 5$. The buyer wants to pay as little as possible, $\min 8y_1 + 12y_2$. That is the **dual** problem, and it is the same "combine the constraints into a bound" trick as Farkas' lemma in §47.3, now aimed at the objective instead of at a contradiction.





Two problems, one number. The best production plan $(2, 3)$ earns 21 (left). The cheapest fair rent $(2.25, 0.25)$ also costs 21 (right). Every other feasible plan earns less than 21 and every other fair rent costs more: the dotted lines show a plan worth 12 and a rent worth 30.

The two answers are both 21. A machine hour is worth 2.25 at the margin and a kilogram 0.25. Those are the **shadow prices** of §23.3, now read as the price-setter's whole strategy. Give the workshop one more machine hour and its best profit rises to 23.25; one more kilogram, and it rises to 21.25. The prices tell you the value of resources you don't yet have.

48.3 The mathematics

The Lagrangian, dual function and the statements of weak and strong duality are in §23.7, and the KKT conditions are in §23.4 (with their equality-only ancestor, Lagrange multipliers, in §6.11). Here we prove the results and see *why* they hold.

Setup

The primal problem is

$$p^* = \min_{\mathbf{x}} \; f(\mathbf{x}) \quad \text{s.t.} \quad g_i(\mathbf{x}) \le 0, \; i = 1, \dots, m.$$

(Equality constraints add free-sign multipliers and change nothing essential. We leave them out to keep the notation light.) The **Lagrangian** is $\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) = f(\mathbf{x}) + \boldsymbol{\lambda}^{\mathsf{T}} \mathbf{g}(\mathbf{x})$, the **dual function** is $q(\boldsymbol{\lambda}) = \inf_{\mathbf{x}} \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda})$, and the **dual problem** is $d^* = \max_{\boldsymbol{\lambda} \ge 0} q(\boldsymbol{\lambda})$. Note that the infimum is over *all* $\mathbf{x}$, feasible or not. That freedom is what lets the dual decompose.

Theorem 48.1 — Weak duality

q is concave, and $q(\boldsymbol{\lambda}) \le f(\mathbf{x})$ for every $\boldsymbol{\lambda} \ge \mathbf{0}$ and every feasible $\mathbf{x}$. Hence $d^* \le p^*$, whatever f and g_i are.

Proof. For fixed $\mathbf{x}$, $\boldsymbol{\lambda} \mapsto \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda})$ is affine. An infimum of affine functions is concave, because its hypograph is an intersection of half-spaces, which is the outside description of Ch. 47. For feasible $\mathbf{x}$ and $\boldsymbol{\lambda} \ge \mathbf{0}$ each term $\lambda_i g_i(\mathbf{x}) \le 0$, so $q(\boldsymbol{\lambda}) \le \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) \le f(\mathbf{x})$. $\square$

The dual is *always* a concave maximisation, even when the primal is a nightmare. That is the first reason duality is useful. You can always get a bound by solving an easy problem.

The picture: supporting lines

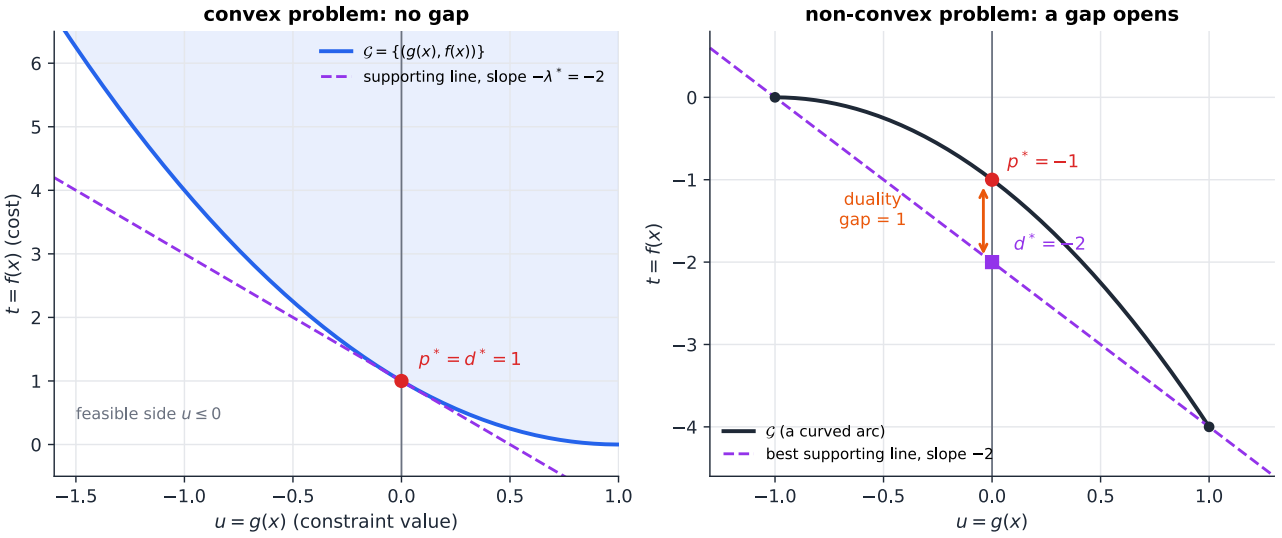
Take a single constraint and collect every pair of (constraint value, cost) that any $\mathbf{x}$ can achieve:

$$\mathcal{G} = \{(u, t) : \; u = g(\mathbf{x}), \; t = f(\mathbf{x}) \text{ for some } \mathbf{x}\} \subset \mathbb{R}^2.$$

The primal optimum is the lowest point of $\mathcal{G}$ to the left of the vertical axis: $p^* = \inf\{t : (u, t) \in \mathcal{G}, \; u \le 0\}$. The dual function is

$$q(\lambda) = \inf_{(u,t) \in \mathcal{G}} (t + \lambda u).$$

The lines $t + \lambda u = c$ have slope $-\lambda$. Push such a line up from below until it touches $\mathcal{G}$: its intercept with the axis $u = 0$ is exactly $q(\lambda)$. **The dual problem tilts a supporting line to make its intercept as high as possible.** Weak duality is now visible. A line lying under all of $\mathcal{G}$ with nonpositive slope must pass under the lowest feasible point too.



The geometry of duality. Left: $\min x^2$ s.t. $1 - x \le 0$. The set $\mathcal{G}$ is convex from below, a tilted line touches it at $(0, 1)$, and $p^* = d^* = 1$. Right: $\min -x^2$ s.t. $x - 1 \le 0$, $0 \le x \le 2$. The arc bends the wrong way, no line can reach $(0, -1)$ without cutting the arc, and the best intercept is -2. The vertical distance is the duality gap.

Worked Example 48.1: a duality gap, computed

Primal: $\min_{0\le x\le 2} -x^2$ subject to $x \le 1$. Feasible $x \in [0,1]$, so $p^* = -1$ at $x = 1$.

Dual function. $q(\lambda) = \min_{0\le x\le 2} \big(-x^2 + \lambda(x-1)\big)$. For fixed λ the bracket is concave in x, so its minimum over the interval is at an endpoint: $x = 0$ gives $-\lambda$, and $x = 2$ gives $\lambda - 4$. Hence $q(\lambda) = \min(-\lambda,\ \lambda - 4)$.

Dual problem. The two pieces cross at $\lambda^* = 2$, so $d^* = q(2) = -2$.

Gap. $p^* - d^* = -1 - (-2) = 1 > 0$. The Lagrangian minimiser at $\lambda = 2$ is $x = 0$ or $x = 2$, and neither is the primal optimum $x = 1$. The price can't "talk" the problem into choosing the middle point, because the middle point is never the cheapest at any price.

This is the electricity-market puzzle in miniature. When a generator has a start-up cost or a minimum stable output, its cost curve is non-convex. The price that clears the market makes the planner's schedule unprofitable for that generator, which on its own would rather sit at an "endpoint" (off, or full). The uplift payment covers the gap.

? Where else does the gap open?

Integer constraints such as "build the plant or don't" and "route the truck or don't" make $\mathcal{G}$ a scattered cloud of points, and the gap of Worked Example 48.1 becomes the normal state of affairs. Yet the dual bound is still the most valuable number an integer solver has, and clever relaxations can shrink the gap to zero. How the bound is used to prune billions of possibilities, and how cuts close the gap, is the story of Ch. 49.

Strong duality: separation does the work

Theorem 48.2 — Strong duality under Slater's condition

Suppose f and every g_i are convex, p^* is finite, and there is a strictly feasible point $\mathbf{x}_0$ with $g_i(\mathbf{x}_0) < 0$ for all i (**Slater's condition**). Then $d^* = p^*$, and the dual optimum is attained.

Proof. Use the "upper-right shadow" of $\mathcal{G}$ instead of $\mathcal{G}$ itself:

$$\mathcal{A} = \{(\mathbf{u}, t) \in \mathbb{R}^m \times \mathbb{R} :\ \exists\, \mathbf{x} \text{ with } \mathbf{g}(\mathbf{x}) \le \mathbf{u},\ f(\mathbf{x}) \le t\}.$$

Step 1: $\mathcal{A}$ is convex. If $(\mathbf{u}_1, t_1)$ and $(\mathbf{u}_2, t_2)$ are witnessed by $\mathbf{x}_1$ and $\mathbf{x}_2$, then for $\theta \in [0,1]$ the point $\theta\mathbf{x}_1 + (1-\theta)\mathbf{x}_2$ witnesses the mixture, because convexity gives $g_i(\theta\mathbf{x}_1 + (1-\theta)\mathbf{x}_2) \le \theta g_i(\mathbf{x}_1) + (1-\theta) g_i(\mathbf{x}_2) \le \theta u_{1i} + (1-\theta)u_{2i}$, and the same for f. This is the one place convexity is used.

Step 2: separate. The set $\mathcal{B} = \{(\mathbf{0}, t) : t < p^*\}$ is convex and disjoint from $\mathcal{A}$, since a point in both would be a feasible $\mathbf{x}$ with $f(\mathbf{x}) < p^*$. By the separation theorem for disjoint convex sets (§47.3, the non-strict version) there is $(\boldsymbol{\lambda}, \mu) \neq (\mathbf{0}, 0)$ with

$$\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{u} + \mu t \ \ge\ \mu s \qquad \text{for all } (\mathbf{u}, t) \in \mathcal{A},\ s < p^*.$$

Step 3: signs. $\mathcal{A}$ is closed under increasing any coordinate. If some λ_i or μ were negative, sending that coordinate to $+\infty$ would push the left side to $-\infty$ and break the inequality. So $\boldsymbol{\lambda} \ge \mathbf{0}$ and $\mu \ge 0$. Letting $s \uparrow p^*$ gives $\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{u} + \mu t \ge \mu p^*$ on $\mathcal{A}$.

Step 4: the line is not vertical. If $\mu = 0$, then $\boldsymbol{\lambda} \neq \mathbf{0}$, $\boldsymbol{\lambda} \ge \mathbf{0}$, and $\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{u} \ge 0$ on $\mathcal{A}$. But Slater's point gives $(\mathbf{g}(\mathbf{x}_0), f(\mathbf{x}_0)) \in \mathcal{A}$ with $\boldsymbol{\lambda}^{\mathsf{T}}\mathbf{g}(\mathbf{x}_0) < 0$. Contradiction. So $\mu > 0$.

Step 5: read off the bound. Divide by μ and put $\boldsymbol{\lambda}^* = \boldsymbol{\lambda}/\mu \ge \mathbf{0}$. Each $\mathbf{x}$ gives the point $(\mathbf{g}(\mathbf{x}), f(\mathbf{x})) \in \mathcal{A}$, so $f(\mathbf{x}) + \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{g}(\mathbf{x}) \ge p^*$ for every $\mathbf{x}$, i.e. $q(\boldsymbol{\lambda}^*) \ge p^*$. With weak duality, $q(\boldsymbol{\lambda}^*) = d^* = p^*$. $\square$

The proof is a picture. Convexity makes $\mathcal{A}$ a convex blob, separation gives a supporting line at the optimum, and Slater's condition keeps that line from standing vertical, where it would have no slope to read a price from. The optimal multipliers *are* the slope of the separating hyperplane of Ch. 47, as that chapter's first mystery promised.

Common Pitfall: Slater is sufficient, not necessary

Without a strictly feasible point strong duality *can* fail even for convex problems. A classic is $\min e^{-x_2}$ subject to $x_1^2/x_2 \le 0$ with $x_2 > 0$: the feasible set is $x_1 = 0$, $p^* = 1$, yet $d^* = 0$. For linear constraints the condition relaxes to plain feasibility, which is why LP strong duality (§23.3) needs no Slater point.

KKT falls out

Theorem 48.3 — Zero gap forces the KKT conditions

If $\mathbf{x}^*$ is primal optimal, $\boldsymbol{\lambda}^*$ is dual optimal and $p^* = d^*$, then

1. $\mathbf{x}^*$ minimises $\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}^*)$ over all $\mathbf{x}$ (so $\nabla f(\mathbf{x}^*) + \sum \lambda_i^* \nabla g_i(\mathbf{x}^*) = \mathbf{0}$ when everything is differentiable);
2. $\lambda_i^* g_i(\mathbf{x}^*) = 0$ for every i (**complementary slackness**).

Proof. Chain the definitions:

$$f(\mathbf{x}^*) = q(\boldsymbol{\lambda}^*) = \inf_{\mathbf{x}} \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}^*) \le \mathcal{L}(\mathbf{x}^*, \boldsymbol{\lambda}^*) = f(\mathbf{x}^*) + \sum_i \lambda_i^* g_i(\mathbf{x}^*) \le f(\mathbf{x}^*).$$

The two ends are equal, so both inequalities are equalities. The first equality says $\mathbf{x}^*$ attains the infimum: claim 1, and stationarity follows because an unconstrained minimiser of a differentiable function has zero gradient. The second says $\sum_i \lambda_i^* g_i(\mathbf{x}^*) = 0$. Every term is ≤ 0, so every term is 0: claim 2. $\square$

Read complementary slackness as an economist would. **A resource that isn't used up has price zero; a resource with a positive price is used up exactly.** In the workshop both resources are exhausted at $(2, 3)$ ($2+6=8$, $6+6=12$), and both have positive prices.

The chain also shows that $(\mathbf{x}^*, \boldsymbol{\lambda}^*)$ is a **saddle point**: $\mathcal{L}(\mathbf{x}^*, \boldsymbol{\lambda}) \le \mathcal{L}(\mathbf{x}^*, \boldsymbol{\lambda}^*) \le \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}^*)$. Strong duality says $\min_{\mathbf{x}} \max_{\boldsymbol{\lambda}\ge 0} \mathcal{L} = \max_{\boldsymbol{\lambda}\ge 0} \min_{\mathbf{x}} \mathcal{L}$. It's a two-player game between designer and price-setter, and it doesn't matter who moves first. That is the same exchange of min and max as von Neumann's minimax theorem for zero-sum games (Ch. 39, Ch. 46).

Sensitivity: what a price predicts

Perturb the constraints to $\mathbf{g}(\mathbf{x}) \le \mathbf{u}$ and call the new optimal value $p(\mathbf{u})$. Then $p(\mathbf{0}) = p^*$. Loosening ($\mathbf{u} > \mathbf{0}$) can only help, and tightening can only hurt.

Theorem 48.4 — Global sensitivity inequality

If strong duality holds with dual optimum $\boldsymbol{\lambda}^*$, then for **every** $\mathbf{u}$

$$p(\mathbf{u}) \;\ge\; p^* - \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{u}.$$

If p is differentiable at $\mathbf{0}$, then $\nabla p(\mathbf{0}) = -\boldsymbol{\lambda}^*$.

Proof. Let $\mathbf{x}$ satisfy $\mathbf{g}(\mathbf{x}) \le \mathbf{u}$. Since $\boldsymbol{\lambda}^* \ge \mathbf{0}$,

$$f(\mathbf{x}) = \mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}^*) - \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{g}(\mathbf{x}) \;\ge\; q(\boldsymbol{\lambda}^*) - \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{u} = p^* - \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{u}.$$

Take the infimum over such $\mathbf{x}$. For the derivative, the inequality says the affine function $p^* - \boldsymbol{\lambda}^{*\mathsf{T}}\mathbf{u}$ touches p at $\mathbf{0}$ from below, so $-\boldsymbol{\lambda}^*$ is a subgradient of p there. A differentiable function's only subgradient is its gradient. $\square$

The inequality is one-sided, and that is the practical lesson:

- **Large λ_i^*, tighten constraint i:** the optimal cost is *guaranteed* to rise steeply, at least by λ_i^* per unit. Never tighten an expensive constraint casually.
- **Large λ_i^*, loosen constraint i:** the theorem promises nothing beyond a first-order estimate. The gain could be smaller than λ_i^* per unit, because another constraint may become active.
- **$\lambda_i^* = 0$:** small changes in either direction don't matter to first order. That doesn't make the constraint useless at large changes.

Check on the workshop, a *maximisation*, so the signs flip. One extra machine hour raises the profit from 21 to 23.25, exactly $y_1^* = 2.25$. One extra kilogram raises it to 21.25, exactly $y_2^* = 0.25$. LP values are piecewise linear in $\mathbf{u}$, so the prediction is exact until the optimal vertex changes. For the convex example $\min x^2$ s.t. $x \ge b$, the value $p(b) = b^2$ has slope $2b$, and the multiplier at $b = 1$ is $\lambda^* = 2$.

Engineering Note: locational marginal prices

In a power-market dispatch problem, the multiplier of the power-balance constraint at bus k is the cost of serving one more megawatt there, the **locational marginal price**. Theorem 48.4 is why it is a fair price, and complementary slackness is why prices differ across a congested line but agree across an uncongested one. Planners use these multipliers to decide where a new line or a battery is worth most.

48.4 The algorithm

The hook's market isn't just an analogy. It is an algorithm called **dual decomposition** (or **dual ascent**), and it is how very large problems that share a few constraints get solved in practice.

Why prices decompose problems

Suppose n agents each choose $\mathbf{x}_k$ with private cost f_k, and they share one resource: $\sum_k \mathbf{a}_k^{\mathsf{T}}\mathbf{x}_k \le c$. The Lagrangian

$$\mathcal{L} = \sum_k f_k(\mathbf{x}_k) + \lambda\Big(\sum_k \mathbf{a}_k^{\mathsf{T}}\mathbf{x}_k - c\Big) = \sum_k \Big[f_k(\mathbf{x}_k) + \lambda\,\mathbf{a}_k^{\mathsf{T}}\mathbf{x}_k\Big] - \lambda c$$

is a **sum of separate problems**: once λ is fixed, agent k minimises its own bracket and nobody needs to know anyone else's f_k. The only shared information is the price. That is why markets, network congestion control and distributed machine learning can all be organised around prices.

The price update is a gradient step

How should the price move? There's a one-line answer.

Proposition: the constraint violation is a supergradient of the dual

If $\mathbf{x}(\boldsymbol{\lambda})$ minimises $\mathcal{L}(\cdot, \boldsymbol{\lambda})$, then for every $\boldsymbol{\lambda}'$, $q(\boldsymbol{\lambda}') \le q(\boldsymbol{\lambda}) + (\boldsymbol{\lambda}' - \boldsymbol{\lambda})^{\mathsf{T}}\mathbf{g}(\mathbf{x}(\boldsymbol{\lambda}))$.

Proof. $q(\boldsymbol{\lambda}') \le \mathcal{L}(\mathbf{x}(\boldsymbol{\lambda}), \boldsymbol{\lambda}') = \mathcal{L}(\mathbf{x}(\boldsymbol{\lambda}), \boldsymbol{\lambda}) + (\boldsymbol{\lambda}' - \boldsymbol{\lambda})^{\mathsf{T}}\mathbf{g}(\mathbf{x}(\boldsymbol{\lambda}))$, and the first term is $q(\boldsymbol{\lambda})$. $\square$

So to climb the concave dual, move the price in the direction of the constraint violation, and never let it go negative:

```
lambda = initial prices (>= 0)
repeat:
    each agent k:   x_k = argmin  f_k(x_k) + lambda . (a_k x_k)      # in parallel, privately
    violation       = sum_k a_k x_k - c
    lambda          = max(0, lambda + alpha * violation)              # raise price if over-demanded
until violation is small and the bounds agree
```

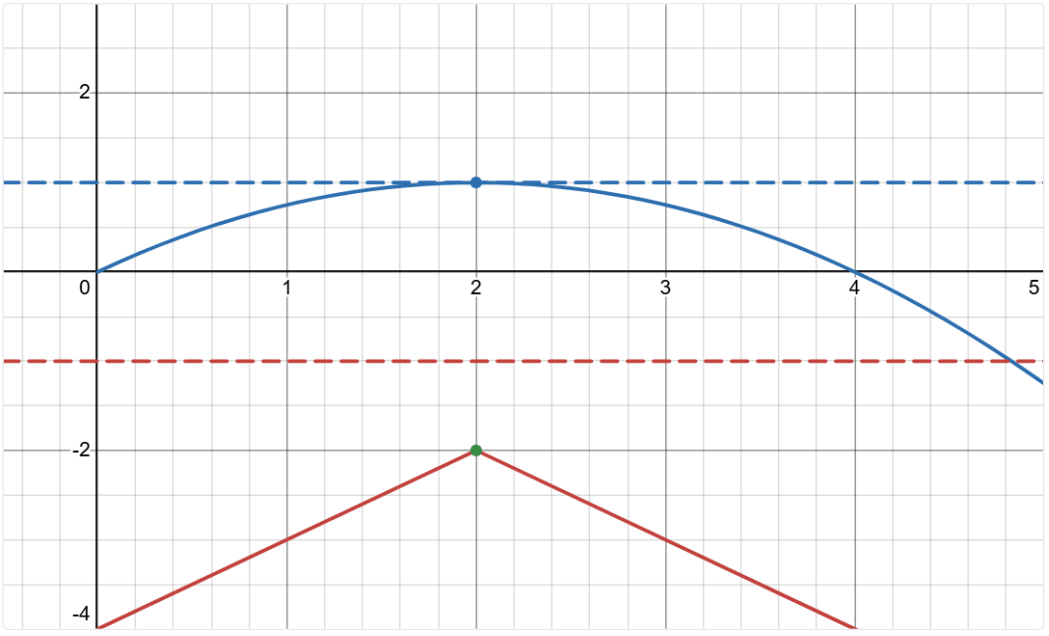
Convergence. If every f_k is strictly convex, q is differentiable and a small fixed step α converges. If the f_k are merely convex (linear costs, for example), q has kinks, and you need diminishing steps such as $\alpha_k \propto 1/\sqrt{k}$. Even then the error falls only like $O(1/\sqrt{k})$, which is slow. Each iteration hands you a certificate for free: the dual value $q(\boldsymbol{\lambda}_k)$ bounds the optimum from one side, and any feasible repair of $\mathbf{x}(\boldsymbol{\lambda}_k)$ bounds it from the other.

Failure cases.

- **Linear costs make agents jumpy.** If f_k is linear, the minimiser $\mathbf{x}(\lambda)$ leaps from one extreme to the other as λ crosses a threshold, and the total demand oscillates around c without settling. The standard cure is to add a quadratic penalty $\frac{\rho}{2}\|\text{violation}\|^2$ to the Lagrangian (the **augmented Lagrangian**, and its distributed form **ADMM**). That buys smoothness at the price of coupling.
- **Primal infeasibility.** The dual can converge while $\mathbf{x}(\boldsymbol{\lambda}_k)$ remains slightly infeasible. Engineers report averaged iterates or project the final answer onto the feasible set.
- **Non-convexity.** Worked Example 48.1 shows the limit. With a gap, no price makes the agents' selfish choices add up to the optimum, and the loop can cycle between "endpoints" forever.

48.5 The experiment

Tilt the dual. The blue curve is the dual function $q(\lambda) = b\lambda - \lambda^2/4$ of $\min x^2$ s.t. $x \geq b$ with $b = 1$. The blue dashed line is the primal value $p^\star = b^2 = 1$. Change both `1` s in the first line and the dashed level to a new b (try $b = 1.5$: the peak moves to $\lambda^\star = 2b = 3$ and the level to 2.25). The peak always touches the primal value. That is strong duality, and its location is the sensitivity $dp^\star/db = 2b$. The red curve is the dual $\min(-\lambda, \lambda - 4)$ of Worked Example 48.1, and the red dashed line is its primal value -1. The peak at -2 never reaches the line.



Dual functions plotted against the price λ (horizontal axis). The convex problem's dual (blue) rises to meet its primal value; the non-convex one (red) stops a full unit short.

Run a market for power. The script allocates a total power P across channels with noise levels N_k to maximise capacity $\sum_k \ln(1 + p_k/N_k)$, the water-filling problem of §23.4. It never solves the problem directly. It announces a price λ, lets each channel buy $p_k = \max(0, 1/\lambda - N_k)$, and adjusts the price. Each round it records two bounds: the dual value (an upper bound, since this is a maximisation) and the capacity of a rescaled feasible design (a lower bound).

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
N = np.array([0.2, 0.5, 1.0, 1.6])   # noise level of each channel
P = 2.0                              # total power budget
lam, alpha, iters = 2.0, 0.3, 40     # starting price, price step, rounds

def best_response(lam):              # each channel maximises log(1+p/N) - lam*p
    return np.maximum(0.0, 1.0 / lam - N)

def utility(p):
    return np.sum(np.log(1 + p / N))

upper, lower, prices = [], [], []
for k in range(iters):
    p = best_response(lam)
    upper.append(utility(p) - lam * p.sum() + lam * P)    # dual value g(lam)
    feas = p * P / p.sum() if p.sum() > 0 else np.full_like(N, P / len(N))
    lower.append(utility(feas))                           # a feasible design
    prices.append(lam)
    lam = max(1e-6, lam + alpha * (p.sum() - P))          # raise price if over budget

print("final price  :", round(lam, 4), " water level 1/price:", round(1 / lam, 4))
print("final powers :", np.round(best_response(lam), 4))
print("bounds       :", round(lower[-1], 5), "<= optimum <=", round(upper[-1], 5))

fig, ax = plt.subplots(1, 2, figsize=(10, 3.5))
ax[0].plot(upper, label="dual bound g(lambda)"); ax[0].plot(lower, label="feasible design")
ax[0].set_xlabel("round"); ax[0].set_ylabel("capacity (nats)"); ax[0].legend()
ax[1].plot(prices); ax[1].set_xlabel("round"); ax[1].set_ylabel("price lambda")
plt.tight_layout(); plt.show()
```

With the default knobs the price settles at $\lambda^* \approx 0.8108$ (water level $1/\lambda^* = 1.2333$). The powers come out as $(1.0333,\ 0.7333,\ 0.2333,\ 0)$: the noisiest channel gets nothing, its nonnegativity constraint is active. Both bounds agree at 2.93175 nats. Things to try: raise `alpha` to 0.6 and the price keeps oscillating without settling (at 1.5 it runs away entirely); set `P = 0.2` so only one channel is worth buying; replace the utility with a non-concave one, say $\sqrt{p}$ capped at a threshold, and see whether the two bounds still meet.

48.6 The challenge

1. **Intuition.** A constraint in your design has multiplier $\lambda^* = 0$. A colleague proposes deleting it "because it doesn't matter". Describe, with a sketch of $\mathcal{G}$ or of $p(u)$, a situation in which deleting it changes the optimum completely.
2. **Derivation.** Derive the dual of the minimum-norm problem $\min \tfrac{1}{2}\|\mathbf{x}\|^2$ s.t. $\mathbf{A}\mathbf{x} = \mathbf{b}$, solve the dual in closed form, and show that strong duality recovers $\mathbf{x}^* = \mathbf{A}^{\mathsf{T}}(\mathbf{A}\mathbf{A}^{\mathsf{T}})^{-1}\mathbf{b}$. Then do the same with $\mathbf{x} \geq \mathbf{0}$ added, and explain why the closed form disappears.
3. **Implementation.** Extend the water-filling script to two shared budgets, a total power limit and a per-group limit on channels 1–2. Use two prices updated simultaneously. Plot both prices and verify complementary slackness numerically by printing each price next to the slack of its constraint.
4. **Open investigation.** Take a market with a few non-convex agents, each of which either produces nothing or at least a minimum output $m_k > 0$, and run price adjustment. Measure the duality gap as you add more and more small agents. Does the gap per agent shrink? Find, by experiment, how the gap scales with the number of agents and with the size of the non-convexity (this is related to the Shapley–Folkman lemma, but the rate in your model is for you to discover).

48.7 Loose threads

Duality was presented here for a handful of variables. Each generalisation opens a new door.

> **? A price for every instant**
>
> In optimal control the decision is a whole trajectory $\mathbf{u}(t)$ and the constraint is a differential equation $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$ that must hold at *every* instant. Attach a multiplier to each instant and you get a multiplier *function* $\mathbf{p}(t)$, which itself obeys a differential equation running backward in time. Why backward? And what does this "costate" price? Pontryagin's principle in Ch. 51 answers both.

> **? The dual of moving dirt**
>
> Moving a pile of sand into a hole of the same shape at least total cost is a linear program with infinitely many variables, one for each pair of source and destination points. Its dual looks for a *price field* $\varphi(\mathbf{x})$ that a hauling company could charge. The Kantorovich duality that links them, and the strange "conjugate" operation that turns one price field into another, wait in Ch. 55.

The third thread is §48.3's mystery: the gap of non-convex problems, and how integer programming exploits the dual bound anyway (Ch. 49). When the constraints themselves are uncertain, the dual of a worst-case problem becomes a problem about probability distributions (Ch. 54). For the economics of prices that fail, see auctions and markets in Ch. 43.

49.1 The hook

A data-centre team is filling a hall with server racks. There are two designs. A type-X rack delivers 5 units of compute and draws 5 kW; a type-Y rack delivers 8 units and draws 9 kW. The hall has 6 rack positions and a 45 kW power feed. How many of each should they install?

An engineer who knows linear programming (§23.3) writes it down in a minute:

$$\max\ 5x + 8y \quad \text{s.t.} \quad x + y \le 6, \quad 5x + 9y \le 45, \quad x, y \ge 0,$$

and the solver replies at once: $x = 2.25$, $y = 3.75$, compute 41.25.

You can't install a quarter of a rack. The obvious fix is to round. Rounding to the nearest integers gives $(2, 4)$, which draws $10 + 36 = 46$ kW and trips the breaker. Rounding down to $(2, 3)$ is safe but gives only 34, 18% below the LP's promise. Hunting around nearby, $(3, 3)$ gives 39. The true optimum turns out to be $(0, 5)$: five type-Y racks, compute 40, and *zero* of the type the LP wanted 2.25 of. The best integer answer isn't a rounding of the LP answer at all. It sits on the far side of the feasible region.

With two variables you can list all 25 feasible integer points and check. Real problems aren't like that. An airline assigning crews to flights, a chip designer placing logic cells, a utility deciding which power stations to switch on tomorrow: each has thousands or millions of yes/no decisions. One hundred binary choices already give $2^{100} \approx 1.27 \times 10^{30}$ combinations. At a billion checks per second that would take about 4×10^{13} years, thousands of times the age of the universe.

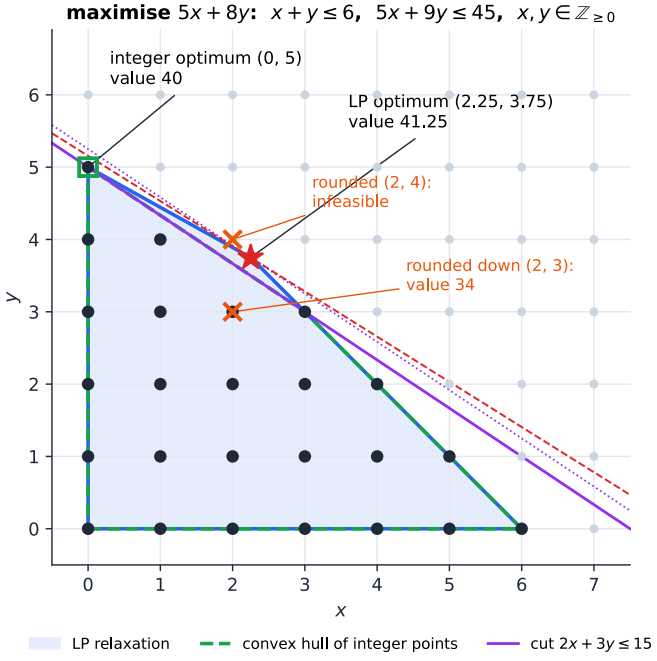
Yet commercial solvers settle problems like these to proven optimality every day, often in minutes. They don't round, and they don't enumerate. This chapter is about the trick: **use the easy continuous problem as a bound, and cut the hopeless search tree down with it.**

49.2 The big idea

The integer points sit inside the LP's polygon like seeds in a fruit. The LP relaxation, which drops the integrality requirement, is a *convex* problem (Ch. 47): easy to solve, and it always over-promises. Its value is an upper bound on what any integer design can achieve. Integer programming runs on two ideas built on that bound.

Idea 1: divide and bound. Split the problem into pieces, "$x \le 2$" and "$x \ge 3$", which together contain every integer point and remove the fractional LP solution in between. Solve each piece's LP. If a piece's bound is already worse than a design you hold in hand, the whole piece, with every integer point inside it, can be thrown away without being looked at. That is **branch-and-bound**. Its power comes entirely from how much the bounds let you skip.

Idea 2: tighten the fruit. Between the integer points and the LP polygon there's wasted space. If you could shrink the polygon to the **convex hull** of the integer points, the tightest convex shape containing them, its corners would *be* integer points, and a single LP would solve the integer problem. You can't compute the hull directly; it may have astronomically many facets. But you can add a few of its walls, **cutting planes**, exactly where the LP solution is cheating.



The rack problem. The LP relaxation (blue) has a fractional corner worth 41.25. The convex hull of the integer points (green dashed) is smaller. One extra wall, the cut $2x + 3y \le 15$ (purple), slices off the fractional corner, and on the trimmed polygon the LP optimum is the integer point $(0, 5)$.

A useful analogy is detective work. Branching is splitting the suspects into groups and interrogating each group's alibi. A bound is an alibi so strong that the whole group goes home at once. A cut is a new fact that rules out an impossible story ("nobody was in two rooms at the same time") without naming a suspect. Real solvers do both, constantly. That is **branch-and-cut**.

49.3 The mathematics

Modelling with integers

The step from "continuous" to "integer" is mostly about what you can *say*. Binary variables $z \in \{0,1\}$ turn logic into linear inequalities.

Requirement	Constraint
choose at most one of items 1–4	$z_1 + z_2 + z_3 + z_4 \le 1$
if you build A you must build B	$z_A \le z_B$
power p only if the station is on, $0 \le p \le P_{\max}$	$0 \le p \le P_{\max} z$
fixed start-up cost F plus running cost c	cost $Fz + cp$ with $p \le P_{\max} z$
either $\mathbf{a}^{\mathsf T}\mathbf{x} \le b_1$ or $\mathbf{c}^{\mathsf T}\mathbf{x} \le b_2$	$\mathbf{a}^{\mathsf T}\mathbf{x} \le b_1 + Mz$, $\mathbf{c}^{\mathsf T}\mathbf{x} \le b_2 + M(1-z)$

The last row uses a **big-M**, a constant large enough that the constraint switches off when its binary says so. The fixed-charge row is exactly the start-up cost that broke the electricity market's prices in §48.3. Non-convexity that defeats prices can often be *modelled* exactly with a few binaries.

The classic test problem is the **0–1 knapsack**: $\max \sum v_i z_i$ s.t. $\sum w_i z_i \le W$, $z_i \in \{0,1\}$. Pack items of value v_i and weight w_i into a bag of capacity W. It looks innocent. It is NP-hard.

> **Common Pitfall: big-M too big**
>
> Any M large enough gives a *correct* model, but not an equally good one. In the relaxation, z may take the value $p/P_{\max}$, so a huge M lets z be tiny and almost cancels the fixed cost. The LP bound becomes weak, and branch-and-bound must work far harder. Choose the smallest M that is valid. Physical limits ($P_{\max}$ itself) are usually the right choice.

Relaxations bound, and hulls are exact

Write the integer program as $z_{\mathrm{IP}} = \max\{\mathbf{c}^{\mathsf T}\mathbf{x} : \mathbf{x} \in S\}$ with $S = P \cap \mathbb{Z}^n$, where $P = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b}\}$ is the LP polyhedron, and let $z_{\mathrm{LP}} = \max\{\mathbf{c}^{\mathsf T}\mathbf{x} : \mathbf{x} \in P\}$.

> **Theorem 49.1 — The relaxation bound and the convex hull**
>
> 1. $z_{\mathrm{IP}} \le z_{\mathrm{LP}}$.
> 2. If S is finite and nonempty, $z_{\mathrm{IP}} = \max\{\mathbf{c}^{\mathsf T}\mathbf{x} : \mathbf{x} \in \operatorname{conv} S\}$, and the maximum is attained at a point of S.

Proof. (1) $S \subseteq P$, and maximising over a larger set can't give less. (2) Every $\mathbf{x} \in \operatorname{conv} S$ is a convex combination $\sum \theta_k \mathbf{s}_k$ of points of S (§47.3), so $\mathbf{c}^{\mathsf T}\mathbf{x} = \sum \theta_k \mathbf{c}^{\mathsf T}\mathbf{s}_k \le \max_k \mathbf{c}^{\mathsf T}\mathbf{s}_k \le z_{\mathrm{IP}}$. A linear function can't do better on a mixture than on the best ingredient. The reverse inequality holds because $S \subseteq \operatorname{conv} S$. □

So integer programming *is* linear programming over the right polygon, $\operatorname{conv} S$. The difficulty is entirely in describing that polygon. For the racks, $\operatorname{conv} S$ has corners $(0,0)$, $(6,0)$, $(3,3)$, $(0,5)$ and the inequality description

$$x \ge 0, \qquad y \ge 0, \qquad x + y \le 6, \qquad 2x + 3y \le 15.$$

The **integrality gap** $z_{\mathrm{LP}} - z_{\mathrm{IP}} = 41.25 - 40 = 1.25$ measures how much the relaxation over-promises. It's the integer-programming cousin of the duality gap in Ch. 48.

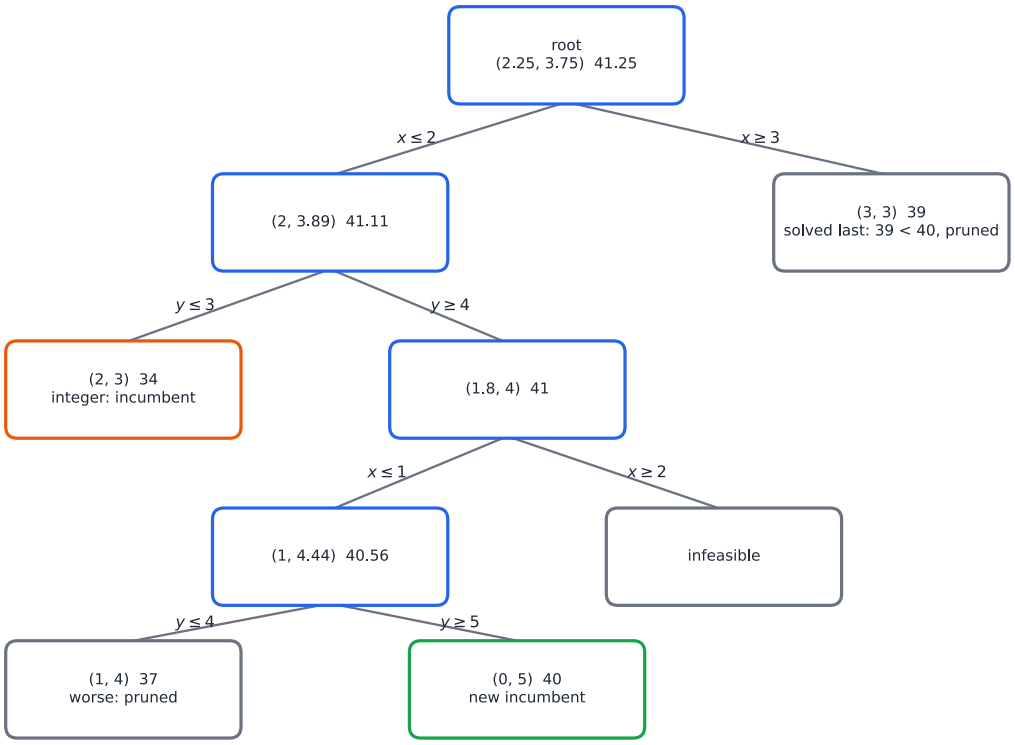
Branch-and-bound

Branch-and-bound explores a tree. Each node is the original problem plus some extra bounds on variables, and its LP value $\bar z$ is an upper bound for every integer point in that node. The best integer solution found so far, the **incumbent**, has value z°.

> **Theorem 49.2 — Pruning never loses the optimum**
>
> Suppose the integer points of a node are split into two children by $x_j \le \lfloor \bar x_j \rfloor$ and $x_j \ge \lfloor \bar x_j \rfloor + 1$, and a node is discarded only if (a) its LP is infeasible, (b) its LP solution is integer (it then updates the incumbent), or (c) $\bar z \le z^\circ$. Then when no open nodes remain, the incumbent is optimal.

Proof. Every integer point of a node lies in exactly one child, because no integer lies strictly between $\lfloor \bar x_j \rfloor$ and $\lfloor \bar x_j \rfloor + 1$. So the leaves of the tree always partition S. Take an optimal $\mathbf{x}^\star$ and follow it down the tree to the leaf that contains it. That leaf was closed for one of three reasons. (a) is impossible, since $\mathbf{x}^\star$ is feasible for it. Under (b), the leaf's LP optimum is an integer point of value at least $\mathbf{c}^{\mathsf T}\mathbf{x}^\star$, and it entered the incumbent. Under (c), $\mathbf{c}^{\mathsf T}\mathbf{x}^\star \le \bar z \le z^\circ$. In each case the final incumbent is at least as good as $\mathbf{x}^\star$. The tree is finite when the variables are bounded, because each branch shrinks an integer range. □

Here is the whole search for the racks, branching on the more fractional variable and exploring the "$\le$" child first.



Branch-and-bound on the rack problem. Each box shows the node's LP solution and its value, an upper bound for that branch. Depth-first search finds the incumbent 34, improves it to 40 at $(0, 5)$, and then closes the right branch without branching on it: that branch's integer optimum is only 39.

Nine LPs settle the problem, and the final one is closed by its bound. In larger problems the bound does far more work: whole subtrees with billions of leaves vanish in a single comparison.

Cutting planes

Theorem 49.3 — Chvátal–Gomory cuts are valid

Let $\mathbf{A}\mathbf{x} \le \mathbf{b}$, $\mathbf{x} \ge \mathbf{0}$ define P and let $\mathbf{u} \ge \mathbf{0}$. Then every integer point of P satisfies

$$\sum_j \lfloor (\mathbf{u}^{\mathsf{T}}\mathbf{A})_j \rfloor x_j \;\le\; \lfloor \mathbf{u}^{\mathsf{T}}\mathbf{b} \rfloor.$$

Proof. Combining the rows with weights $\mathbf{u} \ge \mathbf{0}$ gives the valid inequality $\sum_j (\mathbf{u}^{\mathsf{T}}\mathbf{A})_j x_j \le \mathbf{u}^{\mathsf{T}}\mathbf{b}$, the same "combine constraints" move as in Farkas' lemma and LP duality. Because $\mathbf{x} \ge \mathbf{0}$, rounding the coefficients *down* can only shrink the left side, so $\sum_j \lfloor (\mathbf{u}^{\mathsf{T}}\mathbf{A})_j \rfloor x_j \le \mathbf{u}^{\mathsf{T}}\mathbf{b}$ still holds. For integer $\mathbf{x}$ the left side is now an integer, and an integer at most $\mathbf{u}^{\mathsf{T}}\mathbf{b}$ is at most $\lfloor \mathbf{u}^{\mathsf{T}}\mathbf{b} \rfloor$. $\square$

The last step is the only place integrality enters, and it's where fractional points get cut off. For the racks take $\mathbf{u} = (\tfrac{3}{4}, \tfrac{1}{4})$:

$$\tfrac{3}{4}(x+y) + \tfrac{1}{4}(5x+9y) \le \tfrac{3}{4}\cdot 6 + \tfrac{1}{4}\cdot 45 \quad\Longrightarrow\quad 2x + 3y \le 15.75 \quad\Longrightarrow\quad 2x + 3y \le 15.$$

The LP optimum has $2(2.25) + 3(3.75) = 15.75$, so it violates the cut by 0.75. Re-solving with the cut added gives $(0, 5)$, value 40, the integer optimum, in a single round. The cut is exactly the missing facet of the hull.

That was lucky. In general Gomory (1958) showed how to read a violated cut directly from the final simplex tableau. Chvátal (1973) proved that repeating the round-down operation finitely many times always reaches $\operatorname{conv} S$, but the number of rounds can be enormous. In practice cuts and branching work together: cut until progress stalls, then branch.

When the LP is already integral

Some integer programs need no integer machinery at all.

Total unimodularity

A matrix $\mathbf{A}$ is **totally unimodular** (TU) if every square submatrix has determinant 0, $+1$ or -1.

Theorem 49.4 — TU matrices give integer vertices

If $\mathbf{A}$ is TU and $\mathbf{b}$ is an integer vector, every vertex of $P = \{\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b},\ \mathbf{x} \ge \mathbf{0}\}$ is integer. Hence the LP relaxation solves the integer program.

Proof. Stacking $\mathbf{A}$ on $-\mathbf{I}$ (for $\mathbf{x} \geq \mathbf{0}$) keeps the matrix TU, because expanding a determinant along the rows coming from $-\mathbf{I}$ leaves a $\pm$ determinant of a submatrix of $\mathbf{A}$. A vertex is the unique solution of $\mathbf{B}\mathbf{x} = \mathbf{b}'$ for some nonsingular square submatrix $\mathbf{B}$ of the stacked matrix and the matching integer entries $\mathbf{b}'$. By Cramer's rule (Ch. 8), $x_i = \det \mathbf{B}_i / \det \mathbf{B}$, where $\mathbf{B}_i$ is $\mathbf{B}$ with column i replaced by $\mathbf{b}'$. The numerator is an integer, and the denominator is ± 1. $\square$

Incidence matrices of directed graphs, and of bipartite graphs, are TU. That's why shortest paths, maximum flows and the assignment problem (n workers, n jobs) are "integer programs" that a plain LP, or a specialised network algorithm (Ch. 27), solves exactly in polynomial time. Recognising hidden network structure in an integer model is one of the most profitable skills in operations research.

Lagrangian relaxation

Duality (Ch. 48) gives a second kind of bound. Move the awkward constraints into the objective with prices $\boldsymbol{\lambda} \geq \mathbf{0}$ and keep the easy ones, integrality included. The dual function is then an upper bound on z_{IP} (for a maximisation), and a classical result of Geoffrion (1974) says the best such bound is *never worse* than the LP bound, and often strictly better. The gap of Worked Example 48.1 doesn't go away, but it can be pushed below the integrality gap. For the crew-scheduling and unit-commitment problems of Ch. 50, that is often the difference between a bound you can use and one you can't.

How hard is this, really?

Deciding whether a 0–1 knapsack can reach value V is NP-complete, and general integer programming is NP-hard. Unless P = NP, no algorithm solves every instance in time polynomial in the input size. Branch-and-bound offers no guarantee either: there are tiny-looking families on which it must explore exponentially many nodes (§49.4 and §49.5 below show one).

> **? Hard in theory, easy in practice?**
>
> Solvers routinely close industrial integer programs with millions of variables, yet the theory says the worst case is hopeless. Is that because real instances have hidden structure, or because P = NP after all? Nobody knows. The P versus NP question is open, and Ch. 30 explains what a proof either way would have to overcome. Even the practical success of branch-and-cut has no satisfying theoretical explanation.

49.4 The algorithm

Branch-and-bound, as code

```
input: max c.x  s.t.  A x <= b,  x >= 0,  x_j integer for j in J
incumbent = None, z_best = -infinity
open = [ root problem ]
while open is not empty:
    node = select(open)                    # depth-first, best-bound, or a mix
    solve the LP relaxation of node -> (x_bar, z_bar)
    if infeasible or z_bar <= z_best:  continue          # prune
    if x_bar_j is integer for all j in J:
        incumbent, z_best = x_bar, z_bar;  continue      # new incumbent
    j = choose a fractional variable       # branching rule
    open += [ node + {x_j <= floor(x_bar_j)},  node + {x_j >= floor(x_bar_j) + 1} ]
report incumbent, and the gap  (max bound over open nodes) - z_best
```

Three choices decide whether this finishes in a second or in a century.

- **Node selection.** *Depth-first* dives quickly to integer leaves, so it finds incumbents early and uses little memory. *Best-bound* always expands the node with the highest $\bar{z}$, so it proves optimality with the fewest nodes but can keep a huge open list. Modern solvers dive first and switch later.
- **Branching variable.** "Most fractional" is the textbook rule and is often poor. *Strong branching* tentatively solves both children's LPs for several candidates and picks the variable whose children improve the bound most. It's expensive per node, but it often cuts the tree by orders of magnitude.
- **Warm starts.** A child differs from its parent by one bound, so the parent's optimal basis is still dual-feasible. A few **dual simplex** pivots (§23.3) re-solve it, far cheaper than starting from scratch.

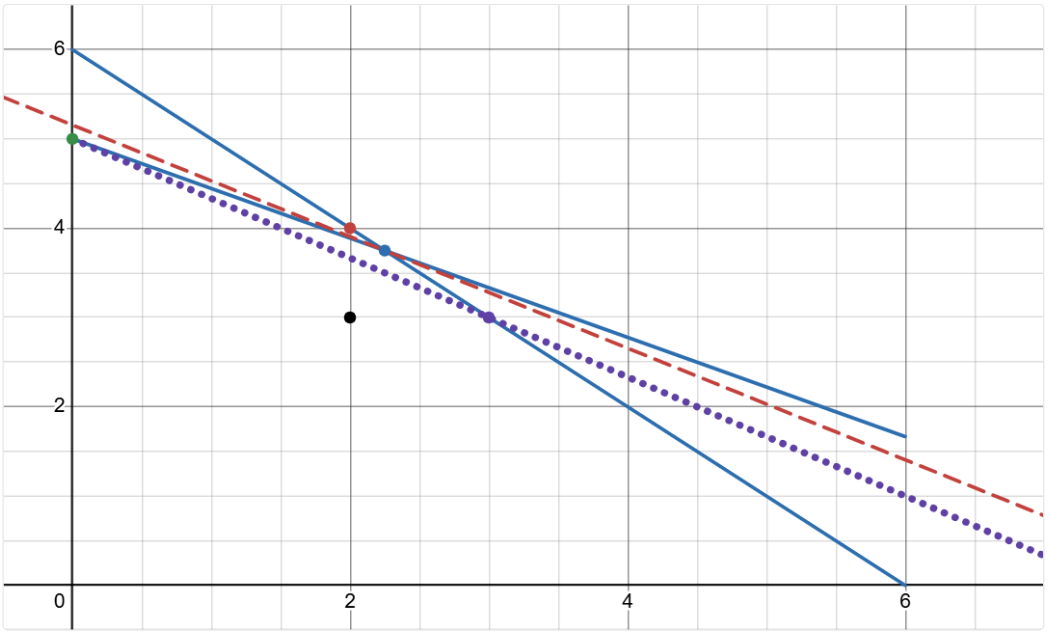
Anytime answers. At every moment the solver holds an incumbent (a lower bound) and the best open-node bound (an upper bound). The **optimality gap** $(\bar{z}_{\max} - z^{\circ})/|z^{\circ}|$ tells you how far from optimal the current design could be. Industrial users often stop at 1%: a guarantee that rounding never gave them.

Branch-and-cut inserts a cut-separation loop at each node: solve the LP, look for violated cuts (Gomory, knapsack covers, clique inequalities…), add them, re-solve, and branch only when the cuts stop helping. Add primal heuristics that try to round or repair LP solutions into good incumbents, and you have the skeleton of every commercial MIP solver.

Failure cases. The worst case is exponential, and it isn't exotic. Take $2z_1 + 2z_2 + \cdots + 2z_n = n$ with n odd and $z_i \in \{0, 1\}$. No solution exists (the left side is even), but setting every free variable to $\frac{1}{2}$-ish keeps the LP feasible until about half the variables are fixed. So plain branch-and-bound must explore at least about $2^{n/2}$ nodes before proving infeasibility. A single cut ($\sum z_i \leq \lfloor n/2 \rfloor$ from rounding) or a parity argument ends it at once, which shows why cuts matter. Other trouble spots are weak big-M formulations (§49.3), symmetry (identical machines make many branches equivalent copies of each other) and numerical tolerance ("integer" means within 10^{-6} or so, which can mislead with huge coefficients).

49.5 The experiment

Slide the objective. The graph draws the rack constraints and the integer points that matter. The dashed objective line $5x + 8y = 41.25$ touches the LP corner. Change `41.25` to `40`: the line drops to the integer optimum $(0, 5)$, and no integer point lies between the two lines. Now change the objective to $5x + 7y$ (edit both `8`s and recompute the level). Does the integer optimum stay at $(0, 5)$?



The rack problem in Desmos. Blue: the LP constraints. Purple dotted: the Chvátal–Gomory cut. Red dashed: an objective level line to slide.

Watch the tree explode. The script solves a 0–1 knapsack by depth-first branch-and-bound. The bound at each node is the knapsack's LP relaxation, which has a closed form: sort items by value per weight, take them greedily, and take a fraction of the first item that doesn't fit (Dantzig's bound). The script needs only numpy.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
n, seed = 30, 1                       # number of items, random instance
rng = np.random.default_rng(seed)
w = rng.integers(10, 100, n)          # weights   (try: v = w + 10 for a hard instance)
v = rng.integers(10, 100, n)          # values
cap = int(0.5 * w.sum())              # capacity

order = np.argsort(-v / w); v, w = v[order], w[order]   # best value per weight first

def lp_bound(k, room, val):           # LP relaxation of items k..n-1: greedy + one fraction
    for i in range(k, n):
        if w[i] <= room: room -= w[i]; val += v[i]
        else: return val + v[i] * room / w[i]
    return val

best, nodes, trace = 0, 0, []
stack = [(0, cap, 0)]                 # (next item, remaining room, value so far)
while stack:
    k, room, val = stack.pop(); nodes += 1
    best = max(best, val)
    if k == n or lp_bound(k, room, val) <= best:
        continue                      # leaf, or pruned: this branch cannot beat 'best'
    stack.append((k + 1, room, val))                    # skip item k
    if w[k] <= room:
        stack.append((k + 1, room - w[k], val + v[k]))   # take item k (explored first)
    trace.append(best)

print(f"optimum {best},  root LP bound {lp_bound(0, cap, 0):.2f},  nodes {nodes}"
      f"  (full tree would have {2**(n+1)-1:.3g})")
plt.plot(trace); plt.xlabel("nodes branched"); plt.ylabel("best value found")
plt.title("incumbent over the search"); plt.show()
```

With the default random instance ($n = 30$) the optimum is 1275 (checked against an exact dynamic program), the root bound is 1282.85, and the search visits only **59 nodes** out of a full tree of about 2.15×10^9. The bound is so tight that almost everything is pruned. Doubling to $n = 50$ still needs only 169 nodes.

Now make the instance nasty. Replace the three instance lines with `w = 2 * rng.integers(5, 50, n)`, `v = w.copy()` and `cap = int(0.5 * w.sum()) | 1`. Every weight is even and the capacity is odd, so the bag can never be filled exactly, and the LP bound always sits one unit above anything achievable. Nothing gets pruned early. The node counts become:

n	16	20	24
nodes visited	28,543	222,024	8,475,918

That's roughly an eight- to forty-fold increase for every four extra items: exponential growth, live on your laptop. (The $n = 24$ run can take a few minutes.) Things to try: switch the stack to a best-bound priority queue and compare node counts; add the parity cut "total weight $\leq$ cap -1" to `lp_bound` and watch the nasty instance collapse.

49.6 The challenge

1. **Intuition.** Draw a two-variable integer program whose LP relaxation is feasible and bounded but which has **no** integer feasible point at all. Then draw one where the LP optimum is far from *every* integer optimum, at least 10 units away.
2. **Derivation.** For the rack problem, derive the cut $2x + 3y \le 15$ as a Gomory fractional cut from the optimal simplex tableau of the LP relaxation (introduce slacks, find the row of a fractional basic variable, and take fractional parts). Check that you obtain the same inequality as the Chvátal–Gomory weights $\mathbf{u} = (\tfrac{3}{4}, \tfrac{1}{4})$.
3. **Implementation.** Write a general branch-and-bound for small integer programs in $\max\{\mathbf{c}^{\mathsf T}\mathbf{x} : \mathbf{A}\mathbf{x} \le \mathbf{b},\ \mathbf{x} \in \mathbb{Z}^n_{\ge 0}\}$ form, using `scipy.optimize.linprog` for the node LPs. Reproduce the tree of Figure 49.2. Then compare depth-first and best-bound node counts on random instances with $n = 10$ to 20.
4. **Open investigation.** For random knapsack instances (values and weights uniform on $[1, R]$), how does the expected number of branch-and-bound nodes grow with n? Polynomially? Does the answer change if values and weights are correlated, as in the `v = w + 10` variant? Plot node counts on log–log and log–linear axes and argue from your data which growth law fits.

49.7 Loose threads

Integer programming is where convexity ends and cleverness begins. Three of the deepest questions it raises are answered elsewhere.

> **? A different way to slice the knapsack**
>
> Branch-and-bound split the knapsack by *items*. There's another way to organise the same search, by *remaining capacity*: "what is the best value achievable with capacity c using the first k items?" That table has only nW entries, so it solves the knapsack in time proportional to n times the *number* W, which can be fast or hopeless depending on how big W is. Why doesn't this contradict NP-hardness, and what principle makes the table correct? Bellman's principle of optimality in Ch. 52.

> **? Models too big to write down**
>
> An airline's crew-scheduling model has one binary variable for every *legal pairing*, a sequence of flights a crew can fly in one trip. There are billions of them, far too many to list, let alone branch on. Yet such models are solved routinely by generating variables only when the dual prices of Ch. 48 say a new one would help. How does an LP solver "price out" a column it has never seen? That is column generation, in Ch. 50.

The third thread is the P versus NP mystery of §49.3 (Ch. 30). For counting how many integer points a polytope holds, and why that number grows like a polynomial when the polytope is scaled up, see the combinatorics of Ch. 28.

Chapter 50 — Operations Research: Mathematics That Runs the World

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 6, Ch. 23, Ch. 25 · **Leads to:** Ch. 51, Ch. 52, Ch. 54 · **Related:** Ch. 27, Ch. 30, Ch. 36, Ch. 48, Ch. 49 **Reading time:** ~30 min

50.1 The hook

A small print shop takes five orders on a Monday morning. Every order goes through the same two machines: first the press prints it, then the binder folds, stitches and trims it. The binder cannot start a job until the press has finished that job, and each machine handles one job at a time. The times, in hours, are:

job	A	B	C	D	E
press a_j	4	7	2	6	3
binder b_j	5	2	6	3	7

The press has 22 hours of work and the binder 23. The only decision is the *order* in which the jobs go through. The manager does the obvious thing and runs them alphabetically. The last book leaves the binder at hour 29.

Is that good? There are $5! = 120$ possible orders. Try them all and the worst takes 35 hours and the best takes 25. The alphabetical order sits in between, and it wastes four hours of binder time. Over a year of Mondays that is a lot of overtime.

Now scale up. A real shop with 20 jobs has $20! \approx 2.4 \times 10^{18}$ orders. A computer checking a billion orders a second would need about 77 years. Yet in 1954 Selmer Johnson, working at the RAND Corporation, published a rule that finds a best order for *any* number of jobs on two machines with nothing more than a sort. It takes milliseconds.

> **How can a rule beat a search over 10^{18} possibilities without looking at them?**

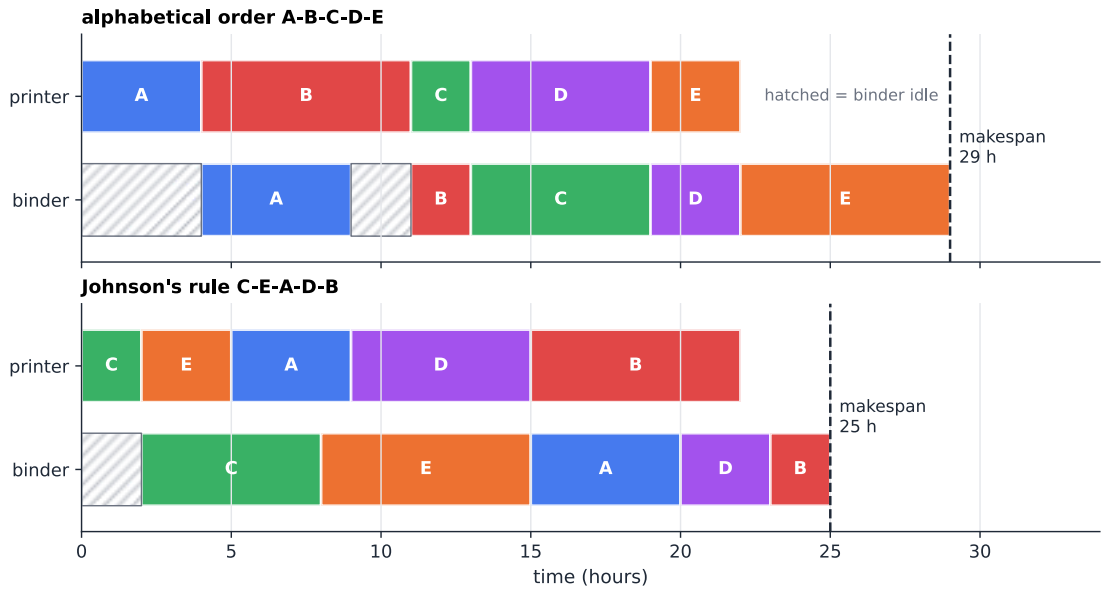
That question is the soul of operations research (OR). The field was born in the Second World War, when mathematicians were asked where to put radar stations, how big to make convoys, and how to pattern anti-submarine patrols. It now decides when your parcel leaves the depot, how many spare parts a power utility keeps, which aircraft flies which route, and how a mobile phone shares its transmit power across frequencies. This chapter shows you three of its classic results, each a small piece of mathematics with an enormous footprint: a scheduling rule, an inventory formula, and an allocation principle. Each one replaces a search with a *structural insight*.

50.2 The big idea

OR models have a common shape. You choose **decisions** (an order, a quantity, an allocation), subject to **constraints** (one job per machine, a budget, demand must be met), to minimise a **cost** or maximise a **benefit**. That is the optimization template of §23.1. What makes OR its own subject is the kind of structure the real world hands you:

- **Scheduling.** Decisions are orders or start times. The feasible set is a set of permutations: finite, huge, with no gradient. The trick is to find an *exchange argument*: show that swapping two neighbours in the wrong order never hurts. Then a sort is enough.
- **Inventory.** Decisions are how much and when to order. Two costs pull in opposite directions: ordering often is expensive in paperwork and trucks; ordering rarely means paying to store goods. The optimum sits where the two pulls balance, and the cost curve is surprisingly *flat* around it.
- **Logistics.** Decisions are flows on a network: so many tonnes from this factory to that warehouse. These are linear programs (§23.3), and their dual variables are prices (Ch. 48). When the decisions become yes/no (open this depot? send this truck along that road?), they turn into the integer programs of Ch. 49.
- **Resource allocation.** Decisions are how much of a scarce resource each activity gets. If returns diminish, the rule is *equalise the marginal returns*: the last dollar (or milliwatt) should buy the same benefit everywhere it goes.

Here is the analogy to keep in mind. A good OR model is like a well-cut key. The lock (the real system) is messy, but if you cut the key to match only the few pins that matter, it turns. Johnson's rule ignores almost everything about the shop and keeps one fact: which machine is the bottleneck for each job. That single fact is enough.



The same five jobs in two orders. Hatched blocks are hours the binder sits idle waiting for the press. Johnson's order starts with the job that frees the binder fastest and ends with the job that keeps it busy longest after the press stops.

Look at the picture. The binder can never start before the press has finished its first job, and it can never stop before it has done all 23 hours of its own work. So no schedule can finish before $\min_j a_j + \sum_j b_j = 2 + 23 = 25$ hours. Johnson's order hits that bound exactly, so it is optimal, and we have a *certificate*: a short argument anyone can check. The alphabetical order loses because it opens with job A (four hours on the press while the binder waits) and then job B, which is slow on the press and quick on the binder, starving the binder again.

50.3 The mathematics

Result 1: the makespan of a two-machine flow shop

Fix an order $\sigma = (\sigma_1, \dots, \sigma_n)$ of the jobs. Write $A_k = \sum_{i=1}^{k} a_{\sigma_i}$ for the time the press finishes the k-th job (the press never idles), and C_k for the time the binder finishes it. The binder can start job k only when both it is free and the press is done:

$$C_k = \max\left(C_{k-1},\ A_k\right) + b_{\sigma_k}, \qquad C_0 = 0.$$

Makespan formula

For the order σ, the time the last job leaves the binder is

$$C_{\max}(\sigma) = \max_{1 \le k \le n} \left(\sum_{i=1}^{k} a_{\sigma_i} + \sum_{i=k}^{n} b_{\sigma_i} \right).$$

Proof. Unroll the recursion. Since $\max(x, y) + c = \max(x + c, y + c)$,

$$\begin{aligned} C_n &= \max\left(C_{n-1} + b_{\sigma_n},\ A_n + b_{\sigma_n}\right) \\ &= \max\left(C_{n-2} + b_{\sigma_{n-1}} + b_{\sigma_n},\ A_{n-1} + b_{\sigma_{n-1}} + b_{\sigma_n},\ A_n + b_{\sigma_n}\right) \\ &= \cdots = \max_{1 \le k \le n} \left(A_k + \sum_{i=k}^{n} b_{\sigma_i} \right), \end{aligned}$$

where the final step uses $C_0 = 0$, so the last leftover term $C_0 + \sum_{i \ge 1} b_{\sigma_i}$ is dominated by the $k = 1$ term. ∎

The formula has a vivid reading. Term k is the length of a path through the Gantt chart: run along the press up to job k, drop down to the binder, then run along the binder to the end. The makespan is the longest such path, a **critical path**. Each job k is a candidate "hand-over point".

Result 2: the exchange argument and Johnson's rule

Now compare two orders that differ only by swapping neighbours: job i immediately before job j, or j before i. Every term of the makespan formula with the hand-over point elsewhere is unchanged, because it contains both jobs on the same machine or neither. Let P be the press time before the pair and S the binder time after it. The two terms that change are, for i first,

$$P + a_i + b_i + b_j + S \quad \text{and} \quad P + a_i + a_j + b_j + S,$$

whose maximum is $P + S + a_i + b_j + \max(b_i, a_j)$. For j first it is $P + S + a_j + b_i + \max(b_j, a_i)$. Subtract $P + S + a_i + a_j + b_i + b_j$ from both and use $\max(x, y) - x - y = -\min(x, y)$:

$$i \text{ before } j \text{ is no worse} \iff -\min(a_j, b_i) \le -\min(a_i, b_j) \iff \min(a_i, b_j) \le \min(a_j, b_i).$$

Johnson's rule (1954)

Put first the jobs with $a_j \le b_j$, in increasing order of a_j. Put after them the jobs with $a_j > b_j$, in decreasing order of b_j. The resulting order minimises the makespan on two machines.

Why does the rule satisfy the exchange condition for every neighbouring pair? Take two jobs from the first group with $a_i \le a_j$. Then $\min(a_i, b_j) \le a_i$, and $a_i \le \min(a_j, b_i)$ because $a_i \le a_j$ and $a_i \le b_i$. The second group is the mirror image, and for a first-group job i before a second-group job j, $\min(a_i, b_j)$ is at most $a_i \le b_i$ and at most $b_j < a_j$, so it is at most $\min(a_j, b_i)$. Starting from any optimal order, you can bubble-sort it into Johnson's order one neighbour swap at a time, and no swap ever increases the makespan. Ties need a little care; the challenge asks you to supply it.

For the print shop, the first group is $\{C, E, A\}$ ($a = 2, 3, 4$) and the second is $\{D, B\}$ ($b = 3, 2$), giving C-E-A-D-B with makespan 25. Eight of the 120 orders achieve 25; Johnson's rule finds one with a single sort, $O(n \log n)$ work.

? Add a third machine

Put a packing station after the binder and the exchange argument collapses: there are orders where no swap of neighbours helps, yet the order is far from optimal. In 1976 Garey, Johnson and Sethi proved that the three-machine flow shop is NP-hard, so no sort, and probably no polynomial algorithm of any kind, can solve it. What "NP-hard" really means, and why one extra machine crosses that line, is the subject of Ch. 30.

Result 3: the economic order quantity

A shop sells D units per year at a steady rate. Each order costs a fixed K (paperwork, delivery, set-up) no matter its size, and keeping one unit on the shelf for a year costs h (capital, space, spoilage). If you order Q units each time and the next delivery arrives just as the shelf empties, the stock follows a sawtooth from Q down to 0. The average stock is $Q/2$ and you place D/Q orders per year, so the annual cost is

$$C(Q) = \underbrace{\frac{KD}{Q}}_{\text{ordering}} + \underbrace{\frac{hQ}{2}}_{\text{holding}}.$$

Dimensions check: K is dollars per order, D/Q is orders per year, h is dollars per unit-year and $Q/2$ is units, so both terms are dollars per year.

EOQ and its flatness (Harris, 1913)

C is minimised at

$$Q^{*} = \sqrt{\frac{2KD}{h}}, \qquad C(Q^{*}) = \sqrt{2KDh},$$

and for any other order size $Q = rQ^{*}$,

$$\frac{C(rQ^{*})}{C(Q^{*})} = \frac{1}{2}\left(r + \frac{1}{r}\right).$$

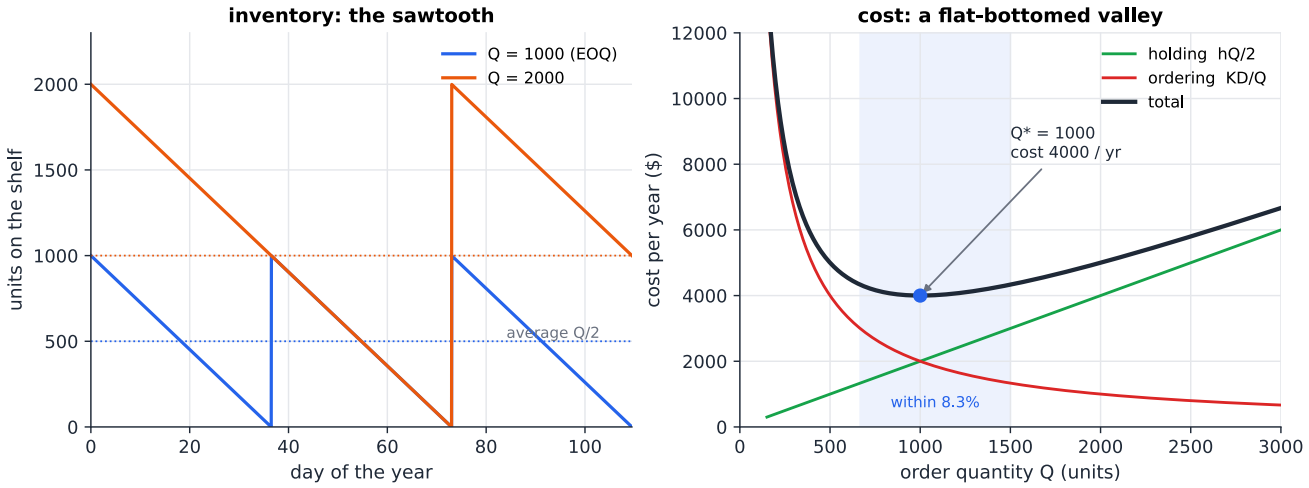
Proof. $C'(Q) = -KD/Q^2 + h/2$ vanishes at $Q^{*} = \sqrt{2KD/h}$, and $C''(Q) = 2KD/Q^3 > 0$, so this is the global minimum on $Q > 0$. Substituting, each term equals $\tfrac{1}{2}\sqrt{2KDh}$: at the optimum the two costs are *equal*. Writing $C^{*} = \sqrt{2KDh}$, we have $hQ^{*}/2 = KD/Q^{*} = C^{*}/2$, so

$$C(rQ^{*}) = \frac{KD}{rQ^{*}} + \frac{h\,rQ^{*}}{2} = \frac{1}{r}\cdot\frac{C^{*}}{2} + r\cdot\frac{C^{*}}{2}.$$

∎

The square root is a famous OR surprise. If demand doubles, you should *not* double the order size; it grows by only $\sqrt{2} \approx 1.41$. Big shops therefore carry relatively less stock than small ones, which is one quiet reason that scale pays.

The ratio formula is the real engineering gift. With $D = 10{,}000$ units/yr, $K = \$200$ and $h = \$4$/unit/yr, $Q^{*} = 1000$ units and $C^{*} = \$4000/yr$, $tenordersayear.Order1500atatimeinstead(r = 1.5\$)$ and the cost rises to $\$4333$, $only8.3r = 2\$)$ costs 25% more. A 50% mistake in Q costs single-digit percent. Because the error enters as $r + 1/r$, which is flat at $r = 1$, rough estimates of K and h are good enough. Estimate K as twice its true value and Q^{*} rises by only $\sqrt{2}$, costing 6%.



Left: stock on the shelf for two order sizes; doubling Q doubles the average stock. Right: the total cost is a flat-bottomed valley. Anywhere in the shaded band ($667 \le Q \le 1500$) you pay at most 8.3% over the optimum.

> **? What if customers don't behave?**
>
> The EOQ assumes demand flows at a perfectly known rate. Real demand is random, deliveries take time, and running out has a price. Then you must also choose a **safety stock**, and in the one-shot version (a newspaper seller who must decide this morning how many papers to buy) the optimal order is a *quantile* of the demand distribution, not its mean. Which quantile, and why a cost ratio picks it, is worked out in Ch. 54.

Resource allocation: equalise the margins

Suppose a transmitter has total power P to share among n frequency channels with noise levels $N_1, \dots, N_n$. Channel i given power p_i carries $\log(1 + p_i/N_i)$ units of data (Shannon's formula, Ch. 33). We want

$$\max_{p_i \ge 0} \sum_{i=1}^{n} \log\left(1 + \frac{p_i}{N_i}\right) \quad \text{subject to} \quad \sum_{i=1}^{n} p_i = P.$$

The returns are concave (each extra milliwatt buys less), so the KKT conditions of §23.4 are necessary and sufficient. Attach a multiplier ν to the budget (§6.11). At the optimum, every channel that gets power has the same marginal return, and channels left off would return less:

$$\frac{1}{N_i + p_i} = \nu \ \text{ if } p_i > 0, \qquad \frac{1}{N_i} \le \nu \ \text{ if } p_i = 0.$$

Writing $\mu = 1/\nu$, this is $p_i = \max(0,\ \mu - N_i)$: pour water of total volume P into a vessel whose floor has height N_i over channel i, and the water depth is the power. This is **water-filling**. With noise levels $1, 3, 6$ and $P = 6$, trying all three channels gives $\mu = 16/3 < 6$, so channel 3 is dry; the two others give $\mu = 5$ and powers $(4, 2, 0)$. Total rate: $\log_2 5 + \log_2(5/3) \approx 3.06$ bits per use, against 2.74 for an equal split.

The same principle runs budgets, crews and computing time: give the next unit of a resource to whichever activity values it most, and stop when the margins are level. The multiplier ν is the **shadow price** of the resource, the benefit of one more unit. That reading of multipliers as prices is the theme of Ch. 48.

Logistics and queues, in brief

Two more pillars deserve a sentence each. **Transportation problems** ship goods from supplies s_i to demands d_j at unit costs c_{ij}: minimise $\sum c_{ij} x_{ij}$ with $\sum_j x_{ij} \le s_i$, $\sum_i x_{ij} \ge d_j$, $x_{ij} \ge 0$. This is a linear program whose constraint matrix is so special that integer supplies and demands always admit an optimal flow in whole units, with no integer programming needed. **Queues** obey a law with almost no assumptions. If λ is the arrival rate, W the average time a customer spends in the system and L the average number present, then

$$L = \lambda W \qquad \text{(Little's law)}.$$

A wafer fab that starts 50 wafers a day and holds 1500 in progress has an average cycle time of $1500/50 = 30$ days. To cut that time you must cut work in progress, which is the mathematical core of "lean" manufacturing.

50.4 The algorithm

Johnson's rule is four lines. The makespan recursion is a few more:

```
def johnson(a, b):
    """Optimal two-machine flow-shop order. a, b: lists of times on machines 1, 2."""
    first = sorted([j for j in range(len(a)) if a[j] <= b[j]], key=lambda j: a[j])
    last  = sorted([j for j in range(len(a)) if a[j] >  b[j]], key=lambda j: -b[j])
    return first + last

def makespan2(seq, a, b):
    t1 = t2 = 0
    for j in seq:
        t1 += a[j]                  # press finishes job j
        t2 = max(t2, t1) + b[j]     # binder starts when free AND job is printed
    return t2
```

Complexity. Sorting costs $O(n \log n)$ and the makespan $O(n)$. The brute force it replaces costs $O(n \cdot n!)$.

EOQ is a closed form, but in practice you compute it with care. Real price lists give quantity discounts, so $C(Q)$ becomes piecewise; evaluate the EOQ on each price band, clip it to the band, and compare the few candidates. Production with a finite rate $R > D$ changes the average stock to $\frac{Q}{2}(1 - D/R)$, which replaces h by $h(1 - D/R)$ in the formula.

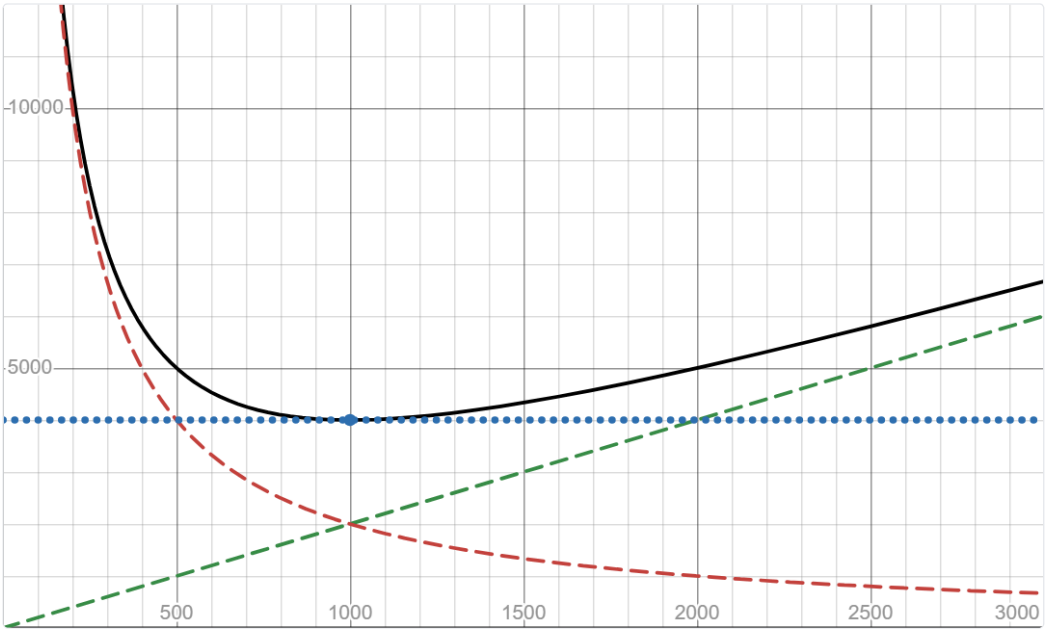
Water-filling needs the level μ. Sort the noise levels; for $m = n, n-1, \ldots$ try using the m quietest channels, set $\mu = (P + \sum_{i \le m} N_i)/m$, and stop at the first m with $\mu > N_m$. That is $O(n \log n)$. Bisection on μ also works and generalises to returns that have no closed form.

Failure cases. Each of these algorithms is exact *only for its model*. Johnson's rule says nothing about set-up times that depend on the previous job, about due dates, or about a third machine. EOQ breaks when demand is lumpy or random. Water-filling assumes the channel states are known; if they are estimated, the "optimal" allocation can pour power into a channel that is actually bad. The professional skill in OR is knowing which assumption is about to fail.

> **Engineering note**
>
> In practice, OR problems are rarely solved with a single elegant rule. They are written as integer or linear programs and handed to a solver. The elegant rules still matter. They give warm starts, lower bounds that certify a solver's answer, and a sanity check on its output.

50.5 The experiment

Part 1: feel the flat bottom. The graph shows the EOQ cost $C(Q) = KD/Q + hQ/2$ with $KD = 2{,}000{,}000$ and $h/2 = 2$. Change $h/2$ from 2 to 8 (storage becomes four times dearer). The minimum moves left, but by a factor of only 2, and the valley stays flat.



Total annual cost (black) as the sum of holding (green) and ordering (red). The minimum is where the two dashed curves cross.

Part 2: break Johnson's rule. The script below draws random 6-job instances, schedules them with Johnson's rule, and compares the result with the best of all 720 orders. Run it with `MACHINES = 2`: the rule is optimal every time. Then set `MACHINES = 3`. The script squashes the three machines into two virtual ones (machines 1+2 and 2+3) and applies Johnson's rule. With the seed given it is optimal in only 54% of trials, averages 2.6% above the best, and is 16.3% worse in the worst case. Try `N_JOBS = 8` (40,320 orders; slow but feasible) and other heuristics: sort by total time, or by the ratio a_j/c_j.

```
import itertools
import numpy as np

rng = np.random.default_rng(1)
N_JOBS, MACHINES, TRIALS = 6, 2, 200        # try MACHINES = 3

def makespan(seq, P):
    """P[j, m] = processing time of job j on machine m; jobs visit machines in order."""
    done = np.zeros(P.shape[1])
    for j in seq:
        done[0] += P[j, 0]
        for m in range(1, P.shape[1]):
            done[m] = max(done[m], done[m - 1]) + P[j, m]
    return done[-1]

def johnson(a, b):
    first = sorted([j for j in range(len(a)) if a[j] <= b[j]], key=lambda j: a[j])
    last = sorted([j for j in range(len(a)) if a[j] > b[j]], key=lambda j: -b[j])
    return first + last

gaps = []
for _ in range(TRIALS):
    P = rng.integers(1, 10, size=(N_JOBS, MACHINES))
    if MACHINES == 2:
        seq = johnson(P[:, 0], P[:, 1])
    else:   # squash three machines into two "virtual" ones and hope
        seq = johnson(P[:, 0] + P[:, 1], P[:, 1] + P[:, 2])
    best = min(makespan(s, P) for s in itertools.permutations(range(N_JOBS)))
    gaps.append(makespan(seq, P) / best - 1)

gaps = np.array(gaps)
print(f"Johnson-style order optimal in {np.mean(gaps == 0):.0%} of {TRIALS} trials")
print(f"average gap {gaps.mean():.1%}, worst gap {gaps.max():.1%}")
```

Watch what the numbers say. On two machines, structure beats search completely. On three, structure gives a good guess but no guarantee, and the only way to be sure is to search, exactly what the 1954 rule let us avoid.

50.6 The challenge

1. **Intuition.** A job takes 1 hour on the press and 9 on the binder. Explain in words, without formulas, why Johnson's rule wants it *first*, and why a job with 9 hours on the press and 1 on the binder belongs *last*. Then explain why the lower bound $\min_j a_j + \sum_j b_j$ is not always achievable.
2. **Derivation.** Finish the proof of Johnson's rule. Show that when several jobs tie (for example $a_i = b_i$, or two jobs with equal a), every tie-break produces the same makespan, and turn the "bubble-sort an optimal order" sketch into a careful induction. Then derive the EOQ with a finite production rate $R > D$ and show the optimal batch is $\sqrt{2KD/(h(1 - D/R))}$.
3. **Implementation.** Write a water-filling routine for n channels by bisection on μ. Test it on noise levels $1, 3, 6$ and power $P = 6$, and then plot total rate against P from 0 to 30. Mark the values of P at which each new channel switches on. What shape does the curve have between switch-on points?
4. **Open investigation.** For the three-machine flow shop, design the best polynomial-time heuristic you can, and measure its worst gap on random instances of 8–10 jobs against brute force. Can you find a family of instances on which your heuristic's ratio to the optimum keeps growing? No clean answer is known for what the best achievable guarantee is in practice; the literature (NEH, Taillard's benchmarks) is a good place to compare yourself.

50.7 Loose threads

This chapter solved three problems by *structure*: an exchange argument, a square-root balance, and level margins. Each worked because the model was static and certain. The threads that pull hardest are the ones that relax those two words.

> **? Why does Little's law need no assumptions?**
>
> $L = \lambda W$ holds for a supermarket queue, a router buffer, a hospital ward and a wafer fab, whatever the distributions of arrivals and service times, whatever the order in which customers are served. That universality looks too good to be true. The proof is a beautiful sample-path argument that compares two ways of measuring the same area under a curve, and it belongs to the theory of stochastic processes in Ch. 36.

Two more pointers. First, *time*. The inventory problem here was a single static choice of Q. If demand changes month by month, the decision becomes a sequence where each choice shapes the next state: that is optimal control in continuous time (Ch. 51) and dynamic programming in discrete stages (Ch. 52). The Wagner–Whitin algorithm for lot sizing with time-varying demand is a dynamic program. Second, *feedback*. Supply chains in which each stage orders from the next amplify small swings in demand into wild oscillations upstream, the "bullwhip effect". It is a stability phenomenon of a feedback loop, and the tools for taming it come from control (Ch. 51). When routes and depots become yes/no decisions, return to the branch-and-bound machinery of Ch. 49; and shortest-route ideas behind every parcel are in Ch. 27.

Chapter 51 — Optimal Control: Choosing the Best Future

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 6, Ch. 11, Ch. 12, Ch. 23 · **Leads to:** Ch. 52, Ch. 53, Ch. 54 · **Related:** Ch. 50, Ch. 61, Ch. 83, Ch. 92 **Reading time:** ~30 min

51.1 The hook

A robotic cart sits at rest on a straight rail. It must stop, exactly, at a mark 100 m away, in the shortest possible time. Its motor can push it forward or backward with any acceleration up to 1 $\mathrm{m/s^2}$ in size, and you choose the acceleration at every instant. What should you do?

Ask a room of engineers and most will sketch something smooth: ease in, build speed, ease off, glide to a stop. It feels right. Sudden changes look crude, and smooth curves look like good engineering.

Here is the smoothest sensible plan. Let the acceleration fall linearly from $+a$ to $-a$ over the trip. Among all plans of a given duration, this is the one that uses the least control effort $\int u^2\,dt$ (you'll derive it in §51.3). To keep $|u| \le 1$ $\mathrm{m/s^2}$, the trip must last $\sqrt{600} \approx 24.5$ s.

Now the crude plan: floor it for 10 s, then brake as hard as possible for 10 s. The cart reaches 10 m/s at the midpoint and stops at exactly 100 m after **20 s**. The smooth plan is 22% slower, and no amount of polishing fixes that, because the problem's best answer is not smooth at all.

Two questions follow, and they are much deeper than the cart:

> **How do you prove that nothing beats 20 seconds?** And when the system is a satellite, a chemical reactor or an epidemic, where intuition fails, **how do you find the best plan at all?**

The set of possible plans is a set of *functions*: an infinite-dimensional space. You cannot list them, and you cannot set a gradient to zero in the usual way, because the best plan sits on the boundary of the allowed set, with $|u| = 1$ almost all the time.

In the mid-1950s Lev Pontryagin, a topologist who had been blind since the age of fourteen, turned to problems of fastest manoeuvres posed by engineers. With his students Boltyanskii, Gamkrelidze and Mishchenko he found the answer: a **maximum principle** that turns the search over functions into a pointwise choice at each instant, guided by a hidden companion trajectory called the **costate**. This chapter builds that principle from the Lagrange multipliers you already know.

51.2 The big idea

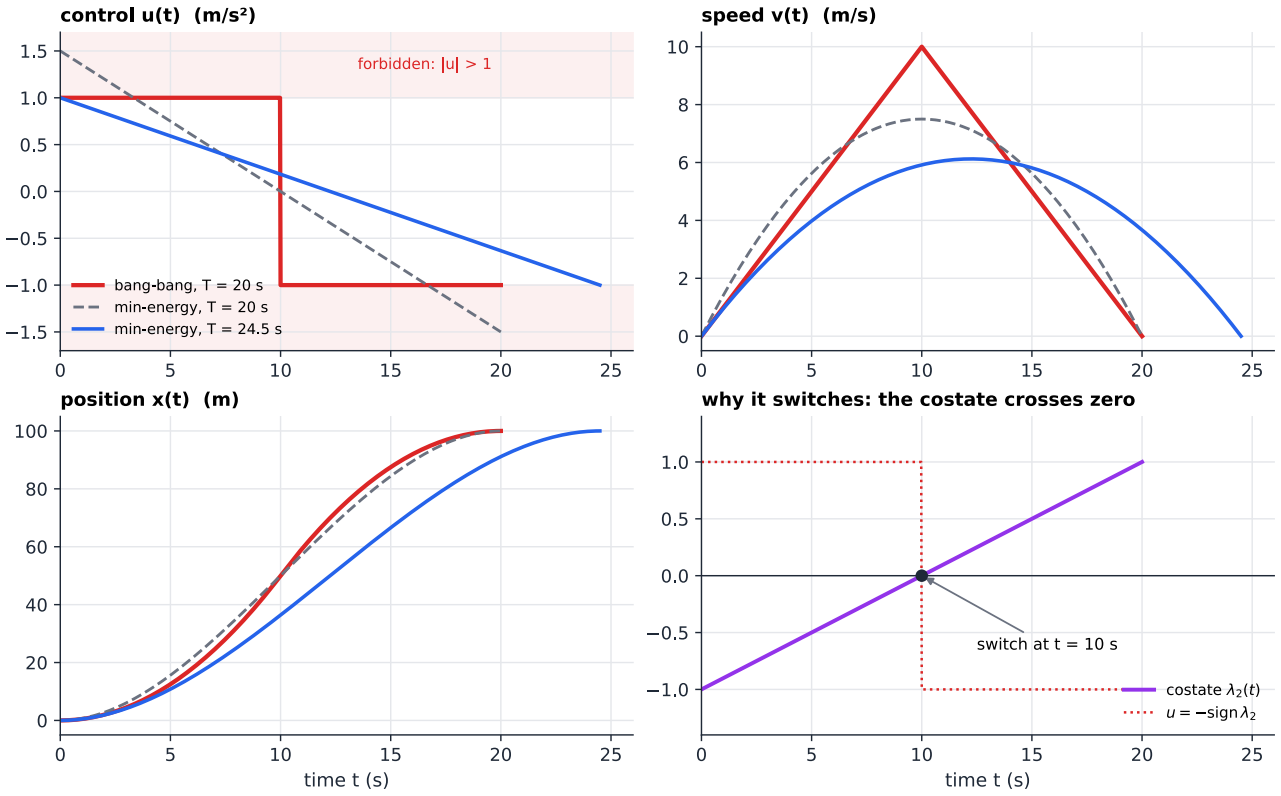
An optimal-control problem has three ingredients.

1. A **state** $\mathbf{x}(t)$ that summarises the system now (position and velocity; charge and current; susceptible and infected).
2. **Dynamics** $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, t)$, driven by a **control** $\mathbf{u}(t)$ that you choose from an allowed set U. This is the state-variable form of §12.7.
3. A **cost** to minimise, such as total time, fuel used, or tracking error, usually $J = \varphi(\mathbf{x}(T)) + \int_0^T L(\mathbf{x}, \mathbf{u}, t)\,dt$.

The obstacle is that each choice of $\mathbf{u}$ at time t affects every later state. A good move now must account for its whole future. Here is the trick. Attach to each state variable a **price**, $\lambda_i(t)$: the marginal value, at time t, of having a little more of x_i. If you knew those prices you could judge each instant on its own. You would pick the $\mathbf{u}$ that minimises "running cost now plus the value of the state change it causes", and the future would be taken care of by the prices.

That is the whole idea of Pontryagin's principle. The prices are the costate. They are found by running a second differential equation *backwards* from the final time, because the value of the state at time t depends on what happens after t.

An economic analogy helps. A factory manager doesn't need to plan every future year to decide today's production; she needs today's price of the factory's stock of capital. Prices summarise the future. In the cart problem, the costate turns out to say "speed is valuable" early in the trip and "speed is a liability" late in the trip. The moment the price of speed crosses zero, the right action flips from full throttle to full brake.



Top left: the bang-bang control (red) stays on the limits; the minimum-energy plan for the same 20 s (dashed) needs 1.5 m/s², breaking the limit, and the feasible smooth plan (blue) takes 24.5 s. Bottom right: the costate λ_2 is a straight line, and the control is the negative of its sign.

Look at the speed panel. Distance is the area under the speed curve, so every plan must enclose exactly 100 m of area. The speed can rise no faster than slope 1 and must fall back to zero at the same rate. The tallest triangle you can fit under those two constraints is the bang-bang one. Every other plan wastes area by rising or falling more slowly than it could.

51.3 The mathematics

The necessary conditions, derived

Take the problem with a free final state and no constraint on $\mathbf{u}$:

$$\min_{\mathbf{u}(\cdot)} J = \varphi(\mathbf{x}(T)) + \int_0^T L(\mathbf{x},\mathbf{u},t)\,dt \quad \text{subject to} \quad \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x},\mathbf{u},t),\ \ \mathbf{x}(0) = \mathbf{x}_0.$$

Treat the dynamics as a constraint at every instant, and give it a Lagrange multiplier function $\boldsymbol{\lambda}(t)$, exactly as in §6.11 but with one multiplier per time. Define the **Hamiltonian**

$$H(\mathbf{x},\mathbf{u},\boldsymbol{\lambda},t) = L(\mathbf{x},\mathbf{u},t) + \boldsymbol{\lambda}^{\mathsf{T}}\mathbf{f}(\mathbf{x},\mathbf{u},t).$$

Along any trajectory that obeys the dynamics, adding $\int \boldsymbol{\lambda}^{\mathsf{T}}(\mathbf{f} - \dot{\mathbf{x}})\,dt = 0$ changes nothing, so

$$J = \varphi(\mathbf{x}(T)) + \int_0^T \left(H - \boldsymbol{\lambda}^{\mathsf{T}}\dot{\mathbf{x}}\right) dt.$$

Integrate the last term by parts: $-\int_0^T \boldsymbol{\lambda}^{\mathsf{T}}\dot{\mathbf{x}}\,dt = -\boldsymbol{\lambda}(T)^{\mathsf{T}}\mathbf{x}(T) + \boldsymbol{\lambda}(0)^{\mathsf{T}}\mathbf{x}(0) + \int_0^T \dot{\boldsymbol{\lambda}}^{\mathsf{T}}\mathbf{x}\,dt$. Now perturb the control by $\delta\mathbf{u}(t)$. The state changes by $\delta\mathbf{x}(t)$, with $\delta\mathbf{x}(0) = \mathbf{0}$ because the start is fixed. To first order,

$$\delta J = \left(\nabla\varphi - \boldsymbol{\lambda}(T)\right)^{\mathsf{T}}\delta\mathbf{x}(T) + \int_0^T \left[\left(\frac{\partial H}{\partial \mathbf{x}} + \dot{\boldsymbol{\lambda}}\right)^{\mathsf{T}}\delta\mathbf{x} + \left(\frac{\partial H}{\partial \mathbf{u}}\right)^{\mathsf{T}}\delta\mathbf{u}\right] dt.$$

The state perturbation $\delta\mathbf{x}$ depends on $\delta\mathbf{u}$ in a complicated way, through the whole history. The multiplier lets us avoid computing it: *choose* $\boldsymbol{\lambda}$ so that its coefficients vanish.

First-order conditions for optimal control

If $\mathbf{u}^*$ is optimal (and $L, \mathbf{f}, \varphi$ are smooth), there is a costate $\boldsymbol{\lambda}(t)$ with

$$\dot{\mathbf{x}} = \frac{\partial H}{\partial \boldsymbol{\lambda}}, \qquad \dot{\boldsymbol{\lambda}} = -\frac{\partial H}{\partial \mathbf{x}}, \qquad \boldsymbol{\lambda}(T) = \nabla\varphi(\mathbf{x}(T)), \qquad \frac{\partial H}{\partial \mathbf{u}} = \mathbf{0}.$$

Proof. With $\boldsymbol{\lambda}$ defined by the backward equation $\dot{\boldsymbol{\lambda}} = -\partial H/\partial \mathbf{x}$ and the end condition $\boldsymbol{\lambda}(T) = \nabla\varphi$ (a linear ODE, so a solution exists), the first two pieces of δJ vanish, leaving $\delta J = \int_0^T (\partial H/\partial \mathbf{u})^{\mathsf{T}} \delta\mathbf{u}\, dt$. At a minimum this first variation must be zero for every perturbation $\delta\mathbf{u}$. Choosing $\delta\mathbf{u} = -\epsilon\, \partial H/\partial \mathbf{u}$ gives $\delta J = -\epsilon \int_0^T \|\partial H/\partial \mathbf{u}\|^2 dt$, which is negative unless $\partial H/\partial \mathbf{u} \equiv \mathbf{0}$. ∎

If the final state is fixed instead, $\delta\mathbf{x}(T) = \mathbf{0}$ and the end condition on $\boldsymbol{\lambda}$ disappears; the two boundary conditions on $\mathbf{x}$ take its place. Notice the structure: state forward from $t = 0$, costate backward from $t = T$, coupled through the control. This is a **two-point boundary-value problem** (§11.8), and that coupling is what makes optimal control hard to compute.

The minimum-energy cart

State x (position) and v (speed), dynamics $\dot{x} = v$, $\dot{v} = u$, cost $\int_0^T \tfrac{1}{2}u^2\, dt$, boundary conditions $x(0) = v(0) = v(T) = 0$, $x(T) = d$. The Hamiltonian is $H = \tfrac{1}{2}u^2 + \lambda_1 v + \lambda_2 u$, so

$$\dot{\lambda}_1 = -\frac{\partial H}{\partial x} = 0, \qquad \dot{\lambda}_2 = -\frac{\partial H}{\partial v} = -\lambda_1, \qquad \frac{\partial H}{\partial u} = u + \lambda_2 = 0.$$

So λ_1 is constant, λ_2 is linear in t, and $u = -\lambda_2$ is linear. Fitting the four boundary conditions gives $u(t) = \dfrac{6d}{T^2}\left(1 - \dfrac{2t}{T}\right)$, a cubic position profile and peak acceleration $6d/T^2$. With $d = 100$ m and $T = 20$ s the peak is $1.5\ \mathrm{m/s^2}$, over the limit. Keeping the peak at 1 needs $T = \sqrt{6d} \approx 24.5$ s.

Constraints: Pontryagin's principle

When the control is limited, $\mathbf{u}(t) \in U$, the optimum usually sits on the boundary of U, where $\partial H/\partial \mathbf{u}$ need not vanish. The fix is to replace "stationary" with "best":

Pontryagin's minimum principle (statement)

If $\mathbf{u}^*$ is optimal, there exist a constant $\lambda_0 \in \{0, 1\}$ and a costate $\boldsymbol{\lambda}(t)$, not both zero, such that with $H = \lambda_0 L + \boldsymbol{\lambda}^{\mathsf{T}}\mathbf{f}$ the state and costate equations above hold, and at almost every time

$$H\left(\mathbf{x}^*(t), \mathbf{u}^*(t), \boldsymbol{\lambda}(t), t\right) = \min_{\mathbf{u} \in U} H\left(\mathbf{x}^*(t), \mathbf{u}, \boldsymbol{\lambda}(t), t\right).$$

If the final time is free and the problem does not depend explicitly on t, then $H \equiv 0$ along the optimal trajectory.

(Pontryagin's group wrote it with the opposite sign as a *maximum* principle; it is the same statement.) The proof uses "needle" variations: change $\mathbf{u}$ to some other value in U on a tiny interval, and show that the cost cannot drop. It is not hard, but it is long; the first-order derivation above is the special case where the minimum over U is an interior stationary point. The constant λ_0 handles rare "abnormal" problems where the constraints alone pin down the answer; for the problems here $\lambda_0 = 1$.

Result: the minimum-time cart is bang-bang

Now minimise $T = \int_0^T 1\, dt$ with $\dot{x} = v$, $\dot{v} = u$, $|u| \le a$. The Hamiltonian is

$$H = 1 + \lambda_1 v + \lambda_2 u.$$

H is *linear* in u, so its minimum over $[-a, a]$ is at an end: $u = -a\ \operatorname{sign}(\lambda_2)$. The costate equations are the same as before: λ_1 constant, $\lambda_2(t) = c - \lambda_1 t$, a straight line. A straight line changes sign at most once. If λ_2 were identically zero, λ_1 would be too, and $H = 1 \neq 0$, which contradicts $H \equiv 0$. So:

Bang-bang structure

Every time-optimal control for the double integrator takes only the values $\pm a$ and switches at most once.

For the trip from rest at 0 to rest at d, the only such plan that works is "accelerate for t_s, brake for t_s", and $x(2t_s) = a t_s^2 = d$ gives $T = 2\sqrt{d/a}$. With $d = 100$ m and $a = 1\ \mathrm{m/s^2}$, $T = 20$ s. Using $H \equiv 0$ at $t = 0$, where $v = 0$ and $u = +a$, fixes $\lambda_2(0) = -1/a$, and the switch at $t_s = 10$ s makes $\lambda_2(t) = -1 + t/10$ for $a = 1$: the purple line in the figure.

Pontryagin's principle is only *necessary*. For the cart there is also a two-line proof of optimality that needs no costate, and it is worth seeing because it gives a certificate:

Proof that no plan beats $2\sqrt{d/a}$. Let any admissible plan reach rest at d at time T. Since $|\dot{v}| \le a$ and $v(0) = 0$, we have $v(t) \le at$. Since $v(T) = 0$, also $v(t) \le a(T - t)$. Then

$$d = \int_0^T v(t)\, dt \le \int_0^T a \min(t,\ T - t)\, dt = \frac{aT^2}{4},$$

so $T \ge 2\sqrt{d/a}$, with equality only when v follows the tent $a\min(t, T - t)$, the bang-bang plan. ∎

That is the speed panel's triangle argument made exact.

? What *is* the costate, really?

We introduced $\boldsymbol{\lambda}(t)$ as a bookkeeping device to make δJ simple, then called it a "price". Is it really one? Here is the claim: if $V(\mathbf{x}, t)$ is the best achievable cost starting from state $\mathbf{x}$ at time t, then along an optimal trajectory $\boldsymbol{\lambda}(t) = \nabla_{\mathbf{x}} V(\mathbf{x}^*(t), t)$, the sensitivity of the optimal future to the present state. Proving it requires a partial differential equation for V, the Hamilton–Jacobi–Bellman equation, which grows out of a completely different idea: Ch. 52.

From open loop to feedback: the switching curve

The plan above is **open loop**: a schedule $u(t)$ computed in advance. If a gust pushes the cart, the schedule is wrong. Better is a **feedback law** $u = k(x, v)$ that gives the optimal action from wherever you are. For the double integrator with target $(0, 0)$ we can find it by geometry.

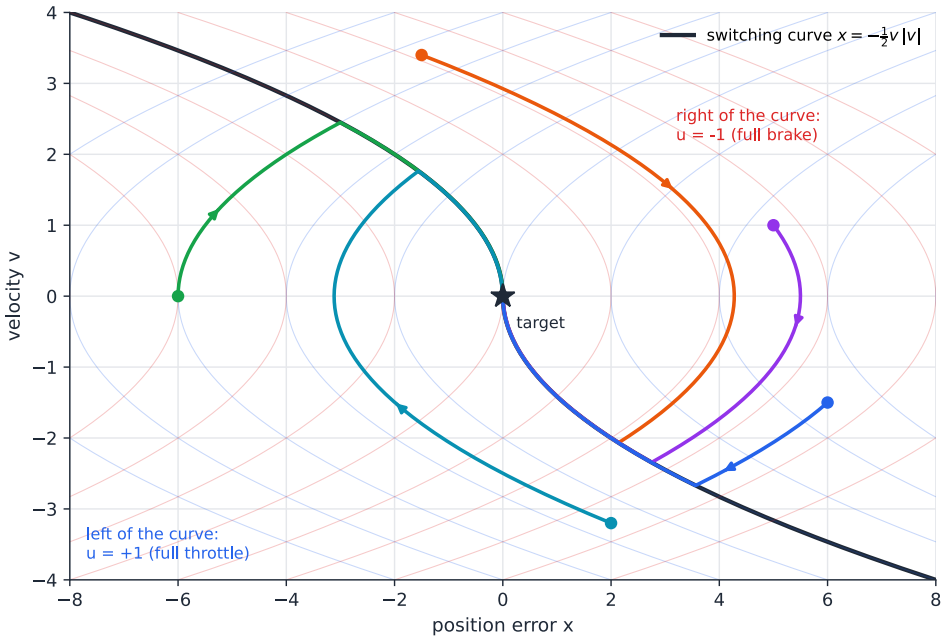
Under $u = +a$, the trajectories in the (x, v) plane are parabolas $x = v^2/(2a) + c$; under $u = -a$, they are $x = -v^2/(2a) + c$. Exactly one parabola of each family passes through the origin, and the halves that arrive there form the **switching curve**

$$x = -\frac{v|v|}{2a}.$$

From any point you ride a parabola to the curve, switch, and slide down the curve into the origin. With $s = x + v|v|/(2a)$, the optimal feedback is

$$u = -a\ \operatorname{sign}(s),$$

and the minimum time from (x_0, v_0) is $T^* = \left(\sigma v_0 + 2\sqrt{\sigma a x_0 + v_0^2/2}\right)/a$ with $\sigma = \operatorname{sign}(s_0)$.



Every optimal trajectory has at most one corner: a parabola of one family until it meets the black switching curve, then the curve itself into the origin. To the left of the curve the motor pushes forward at full power; to the right it brakes at full power.

Smooth costs, linear feedback

Bang-bang control comes from costs that are linear in u. When effort is penalised quadratically and the dynamics are linear, everything is smooth and the answer is a linear feedback. For $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ and $J = \int_0^\infty (\mathbf{x}^\mathsf{T}\mathbf{Q}\mathbf{x} + \mathbf{u}^\mathsf{T}\mathbf{R}\mathbf{u})\,dt$, the **linear–quadratic regulator** (LQR) is

$$\mathbf{u} = -\mathbf{R}^{-1}\mathbf{B}^\mathsf{T}\mathbf{P}\mathbf{x}, \qquad \mathbf{A}^\mathsf{T}\mathbf{P} + \mathbf{P}\mathbf{A} - \mathbf{P}\mathbf{B}\mathbf{R}^{-1}\mathbf{B}^\mathsf{T}\mathbf{P} + \mathbf{Q} = \mathbf{0},$$

where the second equation, the **algebraic Riccati equation**, has a unique positive-definite solution under mild conditions. For the scalar system $\dot{x} = u$ with $J = \int (x^2 + u^2)\,dt$ it reads $P^2 = 1$, so $u = -x$. The costate is $\lambda = 2Px$: linear in the state, which is why the feedback is linear. The LQR is the workhorse of aerospace and process control, and its stability guarantees come from the eigenvalue analysis of §10.9.

51.4 The algorithm

Real problems rarely have closed forms. There are three families of numerical methods.

Indirect (shooting) methods solve Pontryagin's two-point boundary-value problem. Guess the unknown initial costate $\boldsymbol{\lambda}(0)$, integrate state and costate forward with the control from the minimum condition, and measure the miss at time T. Then adjust the guess with Newton's method (§22.4):

```
guess lam0
repeat
    integrate x' = H_lam, lam' = -H_x, with u = argmin_u H, from (x0, lam0) to T
    miss = boundary_conditions(x(T), lam(T))
    lam0 = lam0 - J_miss^{-1} * miss        # Jacobian by finite differences
until |miss| < tol
```

Shooting is very accurate when it converges. But it is fragile: the costate equations are often unstable forward in time, so small errors in $\boldsymbol{\lambda}(0)$ blow up, and bang-bang controls make the miss function discontinuous.

Direct methods ("discretise, then optimise") chop $[0, T]$ into N steps, treat $\mathbf{u}_0, \dots, \mathbf{u}_{N-1}$ as ordinary variables, impose the discretised dynamics as constraints, and give the whole thing to a nonlinear-programming solver (Ch. 23). Control bounds become simple box constraints. The solver's Lagrange multipliers for the dynamics constraints approximate the costate, which is the discrete echo of our derivation. This is what most practical software does, from rocket-landing

guidance to robot motion planning.

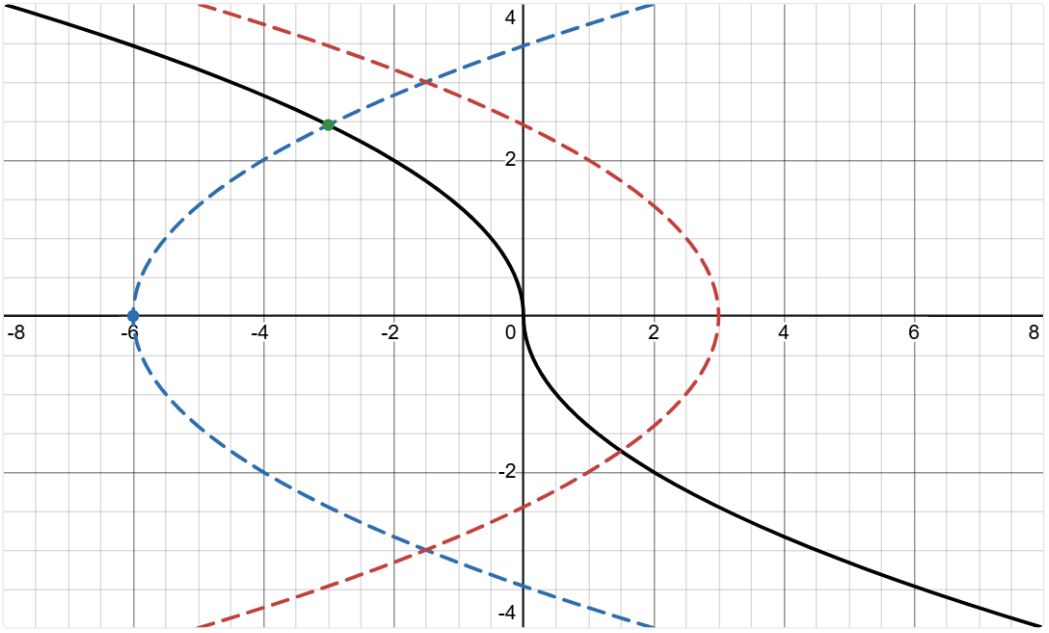
Dynamic programming computes the feedback law over a grid of states. It is robust and global, but its cost grows exponentially with the state dimension. That is the next chapter.

Failure cases. Bang-bang feedback implemented with a finite sampling time **chatters**: near the switching curve the sign of s flips back and forth every sample, wearing out relays and exciting unmodelled dynamics. Engineers soften it with a boundary layer, replacing $\operatorname{sign}(s)$ by a saturated linear function near $s = 0$. A second failure: *singular arcs*. If $\lambda_2 \equiv 0$ on an interval, the minimum condition says nothing about u, and you must differentiate the switching function repeatedly to recover it.

> **Engineering note**
>
> Model predictive control (MPC), standard in chemical plants and increasingly in power electronics and cars, solves a direct-method optimal-control problem over a short horizon *at every sampling instant*, applies only the first control move, measures the state again, and repeats. It turns open-loop optimisation into feedback by brute repetition.

51.5 The experiment

Part 1: the parabolas. In the phase plane (horizontal x, vertical y for velocity), the black curve is the switching curve for $a = 1$. The blue parabola is a full-throttle arc $x = y^2/2 + c$ with $c = -6$, starting from rest 6 m behind the target. Change c (try -2 and -10) and find where each arc meets the switching curve. That intersection is the switching point.



The full-throttle arc from $(-6, 0)$ meets the switching curve at $x = -3$, $v = \sqrt{6}$. The red dashed arc is a full-brake arc for comparison.

Part 2: fly the feedback. The script runs the optimal feedback $u = -a\ \operatorname{sign}(s)$ with a simple Euler integrator and compares the arrival time with the formula T^*. Things to change:

- `X0, V0`: try `5.0, 1.0` (theory 5.69 s) and `2.0, -3.2` (theory 6.73 s). In the second case the simulation reports **3 switches**, though the theory says one. Plot u against t and find where the extra switches happen.
- `DT = 0.1`: arrival slips from about 4.9 s to 6.0 s, with an extra switch. The controller overshoots the curve between samples.
- `U_MAX = 0.5`: the minimum time scales as $1/\sqrt{a}$ (here 6.93 s), not $1/a$.

```
import numpy as np
import matplotlib.pyplot as plt

X0, V0 = -6.0, 0.0      # start: 6 m behind the target, at rest
DT = 0.01               # time step (s); try 0.1 and 0.001
U_MAX = 1.0             # thrust limit (m/s^2); try 0.5
TOL = 0.05              # "arrived" when |x| and |v| are both below this

def feedback(x, v):
    s = x + v * abs(v) / (2 * U_MAX)        # signed distance to the switching curve
    return -U_MAX * np.sign(s) if s != 0 else -U_MAX * np.sign(v)

x, v, t, switches, u_old = X0, V0, 0.0, 0, None
xs, vs, us = [x], [v], []
while not (abs(x) < TOL and abs(v) < TOL) and t < 30:
    u = feedback(x, v)
    switches += (u_old is not None and u != u_old)
    u_old = u
    v += u * DT; x += v * DT; t += DT
    xs.append(x); vs.append(v); us.append(u)

s0 = X0 + V0 * abs(V0) / (2 * U_MAX)
T_star = (np.sign(s0) * V0 + 2 * np.sqrt(np.sign(s0) * U_MAX * X0 + V0**2 / 2)) / U_MAX
print(f"arrived at t = {t:.2f} s (theory {T_star:.2f} s) after {switches} switches")

fig, ax = plt.subplots(1, 2, figsize=(10, 4))
ax[0].plot(xs, vs); vv = np.linspace(-4, 4, 200)
ax[0].plot(-vv * np.abs(vv) / (2 * U_MAX), vv, "k--", label="switching curve")
ax[0].set_xlabel("x"); ax[0].set_ylabel("v"); ax[0].legend()
ax[1].step(np.arange(len(us)) * DT, us); ax[1].set_xlabel("t (s)"); ax[1].set_ylabel("u")
plt.show()
```

The default run prints an arrival at 4.85 s against the theoretical 4.90 s; the difference is the tolerance `TOL`, since the simulation stops just before the exact target.

51.6 The challenge

1. **Intuition.** For a cost $\int_0^T |u|\,dt$ (fuel, for a thruster whose consumption is proportional to thrust) with $|u| \le 1$ and a *fixed* trip time longer than the minimum, guess the shape of the optimal control. Explain why it should contain a phase where the motor is off, and why neither bang-bang nor smooth is the answer.
2. **Derivation.** Use the first-order conditions to solve the minimum-energy cart in full: find λ_1, $\lambda_2(0)$, $u(t)$, $v(t)$ and $x(t)$, and verify the cost $\int_0^T u^2\,dt = 12d^2/T^3$. Then derive the minimum-time formula $T^*(x_0, v_0)$ from the switching-curve construction.
3. **Implementation.** Write a direct method for the cart: $N = 50$ time steps, variables $u_0, \dots, u_{49}$, bounds $|u_k| \le 1$, and the end conditions as equality constraints. Minimise the trip time by bisection on T (is it feasible within T?). Feasibility for fixed T is a linear program. Compare your discrete answer with $T = 20$ s, and see what the LP's dual variables look like next to $\lambda_2(t)$.
4. **Open investigation.** Fuller's problem: minimise $\int_0^\infty x^2\,dt$ for $\dot{x} = v$, $\dot{v} = u$, $|u| \le 1$, from $(x_0, v_0) = (1, 0)$. Simulate candidate bang-bang feedbacks $u = -\operatorname{sign}(x + k\,v|v|)$ for a range of k, find the best k numerically, and count the switches. You should find something strange happening as the trajectory nears the origin. Which nonlinear systems show this behaviour, and why, is still an active research topic.

51.7 Loose threads

We found the best future by attaching a price to the state at every instant and then choosing greedily against those prices. Three things were left unsaid.

> **? Does a best plan even exist?**
>
> Everything in this chapter assumed an optimal control exists and then described it. In infinite-dimensional spaces that is not automatic: a sequence of ever-better controls can oscillate faster and faster and converge to nothing that is itself a control. Guaranteeing existence needs compactness of the right kind, usually convexity of the set of achievable velocities plus a weak form of convergence. The tools are those of Ch. 61, and Filippov's theorem is the classical answer.

> **? Steering through fog**
>
> Our cart knew its exact position and the exact dynamics. Real controllers see noisy measurements and face random disturbances. Remarkably, for linear systems with Gaussian noise and quadratic cost, the best you can do splits cleanly into two separate problems: estimate the state as well as possible, then apply the LQR as if the estimate were the truth. Why this "separation" holds there and fails almost everywhere else is a question for stochastic and robust optimization in Ch. 54, and for learning controllers that don't know the model at all in Ch. 53.

The costate mystery from §51.3 is resolved in the next chapter, which starts from a seemingly unrelated idea, that *the tail of an optimal path is optimal*, and arrives at the same Hamiltonian from the other side (Ch. 52). The pair of equations $\dot{\mathbf{x}} = \partial H/\partial \boldsymbol{\lambda}$, $\dot{\boldsymbol{\lambda}} = -\partial H/\partial \mathbf{x}$ is no accident either: they are Hamilton's equations of classical mechanics, and the principle of least action is an optimal-control problem posed by nature (Ch. 92). For the phase-plane geometry of the switching curve, and what happens to feedback systems near their equilibria, see Ch. 83.

Chapter 52 — Dynamic Programming and Bellman's Principle

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 19, Ch. 23, Ch. 27, Ch. 34 · **Leads to:** Ch. 53, Ch. 54 · **Related:** Ch. 40, Ch. 46, Ch. 50, Ch. 51, Ch. 89 **Reading time:** ~30 min

52.1 The hook

In 1950 Richard Bellman arrived at the RAND Corporation to work on multistage decision problems: how to schedule, stock, steer and fight when each decision changes the situation for the next. RAND was funded by the Air Force, and the Secretary of Defense of the day was said to turn red at the word *research*. So Bellman, by his own account, chose a name for his method that no congressman could object to. "Programming" meant planning, as in a military programme. "Dynamic" sounded impressive and, he joked, was impossible to use in a bad sense. The name was camouflage. The idea underneath it has since become one of the most widely used in all of applied mathematics.

Here is a problem of the kind he had in mind. A courier must get from depot S to customer T through three stages of relay points, choosing one point at each stage. Each leg has a cost (minutes, litres, risk). The legs are drawn in the figure in §52.2. A tempting strategy is **greedy**: at each point, take the cheapest leg out. From S the cheapest leg costs 2, to A1, then 6 to B2, 3 to C2 and 4 to T, for 15 in total. Not bad?

The best route costs 11. Greedy lost 36% by grabbing a cheap first step that led into an expensive neighbourhood.

You could list every route: $3 \times 3 \times 2 = 18$ of them. But a real network might have 20 stages with 10 points each, and then there are 10^{20} routes. Bellman's method solves that larger network with under 2000 additions, and it never looks at a single complete route.

> **How can you find the best path without ever comparing paths?**

The same question, in disguise, sits under other chapters of this book. Ch. 27 promised that the Bellman–Ford algorithm needs exactly $|V| - 1$ rounds to find shortest paths with negative edges. Ch. 40 claimed that to check a strategy in an infinitely repeated game you only need to test deviations *one period at a time*. Ch. 51 introduced a mysterious costate and called it a price. All three debts are paid in this chapter, by one principle.

52.2 The big idea

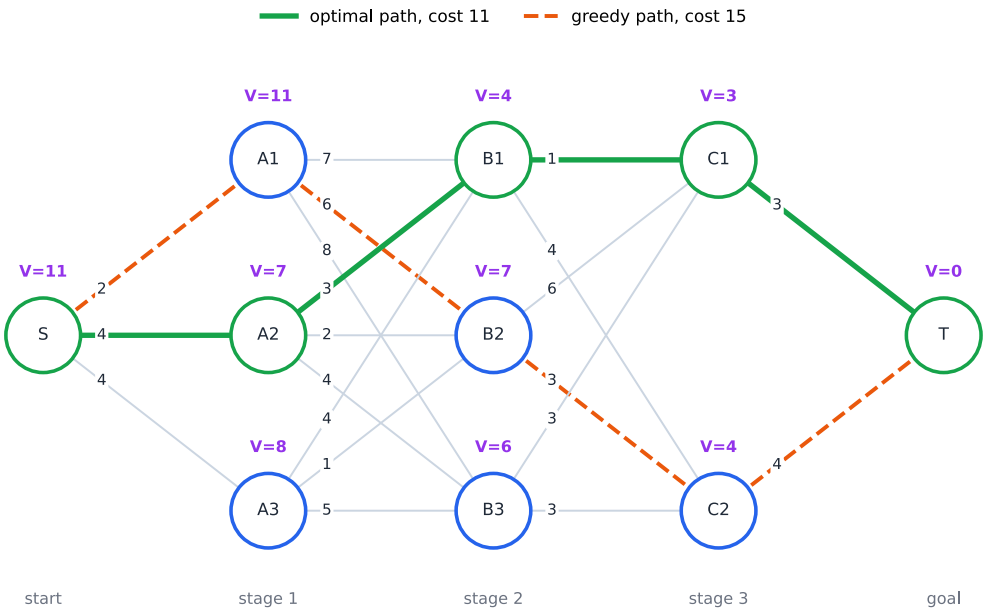
> **Bellman's principle of optimality**
>
> An optimal policy has the property that, whatever the initial state and first decision, the remaining decisions form an optimal policy for the state that results from the first decision.

In plain words: **every tail of an optimal path is itself optimal.** If the best route from S to T passes through B1, then its part from B1 to T must be the best route from B1 to T. If there were a better way from B1, you could splice it in and beat the "best" route.

That sounds almost too obvious to be useful. Its power comes from turning it around. Instead of asking "what is the best route from here?" for one starting point, ask it for *every* point, and start at the end. Write $V(\text{point})$ for the cheapest cost from that point to T, the **value** or **cost-to-go**. Then:

- $V(T) = 0$.
- For each point one stage back, $V(\text{point}) =$ min over legs of (leg cost $+ V$ of where the leg lands).
- Repeat, stage by stage, back to S.

Each point is processed once, and each leg is looked at once. The work grows with the number of *legs*, not the number of *routes*.



Solving backwards. Each purple number is the cheapest cost from that node to T, computed from the numbers one stage to its right. Greedy grabs the cheap first leg into A1, whose cost-to-go is 11; the green route pays 4 to reach A2, whose cost-to-go is only 7.

An analogy: imagine hiking in fog with signposts at every junction, each showing the distance to the valley along the best trail. At each junction, add each trail's length to the next signpost's number, and walk toward the smallest total. Dynamic programming is the art of writing those signposts. Once they exist, acting optimally is greedy, but greedy with respect to the *value*, not the immediate cost.

That last sentence is the deep lesson. Greedy failed because the immediate cost is a bad guide. Greedy with respect to V is perfect, because V has already folded the entire future into one number per state.

52.3 The mathematics

Finite-horizon dynamic programming

A **finite-horizon decision problem** has stages $k = 0, 1, \dots, N$, a set of states, an action set $A(s)$ in each state, a transition $s' = g_k(s, a)$ and a stage cost $c_k(s, a)$, with a terminal cost $c_N(s)$. A policy picks an action in every state at every stage.

Backward recursion

Define $V_N(s) = c_N(s)$ and, for $k = N-1, \dots, 0$,

$$V_k(s) = \min_{a \in A(s)} \left[c_k(s, a) + V_{k+1}\left(g_k(s, a)\right) \right].$$

Then $V_k(s)$ is the minimum total cost from state s at stage k, and choosing at each stage an action that attains the minimum is optimal.

Proof. By backward induction on k. At $k = N$ it is the definition. Suppose V_{k+1} is the true optimal cost-to-go. Any plan from (s, k) takes some first action a, paying $c_k(s, a)$, and then follows some plan from $s' = g_k(s, a)$ whose cost is at least $V_{k+1}(s')$. So every plan costs at least $c_k(s, a) + V_{k+1}(s') \geq V_k(s)$. Conversely, taking the minimising a and then an optimal plan from s' costs exactly $V_k(s)$. Hence $V_k(s)$ is the optimum, and it is attained by the greedy-in-V choice. ∎

With uncertainty, the next state is random with probabilities $P(s' \mid s, a)$, and the same proof goes through with an expectation (§19.9):

$$V_k(s) = \min_a \left[c_k(s, a) + \sum_{s'} P(s' \mid s, a)\, V_{k+1}(s') \right].$$

The key point is that **the state carries everything about the past that matters for the future**. That is the Markov property of Ch. 34. If the cost depended on the whole history, the recursion would fail unless you enlarged the state to hold that history.

The cost. With S states, A actions and N stages, the recursion takes $O(NSA)$ work (deterministic) or $O(NS^2A)$ (stochastic), against A^N plans for brute force. For the 20-stage, 10-point courier network that is $10 + 19 \times 100 + 10 = 1920$ leg evaluations instead of 10^{20} routes.

Result 1: why Bellman–Ford needs $|V| - 1$ rounds

Shortest paths on a general directed graph have no stages, but you can manufacture them by counting edges. For a source s, let $d_k(v)$ be the minimum weight of a walk from s to v that uses *at most* k edges ($d_0(s) = 0$, and $d_0(v) = \infty$ otherwise). The last edge of such a walk enters v from some u, and by the principle of optimality the rest must be a best walk to u with at most $k-1$ edges. So

$$d_k(v) = \min\left(d_{k-1}(v),\ \min_{(u,v) \in E} \left[d_{k-1}(u) + w(u, v) \right] \right).$$

One "round" of Bellman–Ford, relaxing every edge once, computes d_k from d_{k-1} in $O(|E|)$ time.

Bellman–Ford

If no cycle of negative total weight is reachable from s, then $d_{|V|-1}(v)$ is the shortest-path distance from s to every v. If $d_{|V|}(v) < d_{|V|-1}(v)$ for some v, a negative cycle is reachable.

Proof. Take any shortest walk from s to v. If it visits some vertex twice, it contains a cycle. That cycle has weight ≥ 0 by assumption, so cutting it out gives a walk that is no heavier and has fewer edges. Repeat until no vertex repeats. The result is a simple path, which visits at most $|V|$ vertices and so uses at most $|V|-1$ edges. Hence the minimum over walks with at most $|V|-1$ edges already equals the true distance, and further rounds cannot change anything. Conversely, if round $|V|$ still improves some $d(v)$, there is a cheapest walk with exactly $|V|$ edges, which must repeat a vertex; the cycle it contains must be negative, or removing it would contradict the improvement. ■

So the factor $|V|$ that Ch. 27 warned about is the **horizon** of a dynamic program: the longest a useful path can be. Dijkstra's algorithm avoids it by exploiting non-negative weights to settle vertices in order, which a negative edge can wreck.

The infinite horizon: Bellman's equation

Many problems have no natural end: a thermostat, an inventory system (Ch. 50), a robot that keeps working. Then we use a **Markov decision process** (MDP): states s, actions a, rewards $r(s,a)$, transition probabilities $P(s' \mid s,a)$, and a **discount factor** $0 \leq \gamma < 1$ that makes a reward k steps away worth γ^k of one now. (Rewards to be maximised are the same as costs to be minimised with a sign flip; this section uses rewards, as reinforcement learning does.) A stationary policy π picks action $\pi(s)$ in state s, and its value is

$$V^{\pi}(s) = E\left[\sum_{t=0}^{\infty} \gamma^t \, r(s_t, \pi(s_t)) \,\middle|\, s_0 = s\right].$$

The optimal value $V^*(s) = \sup_{\pi} V^{\pi}(s)$ satisfies **Bellman's optimality equation**, the stationary version of the backward recursion:

$$V^*(s) = \max_{a} \left[r(s,a) + \gamma \sum_{s'} P(s' \mid s,a)\, V^*(s') \right].$$

Call the right-hand side $(\mathcal{T}V)(s)$. The **Bellman operator** $\mathcal{T}$ maps a value table V to a new one. Bellman's equation says V^* is a fixed point, $V^* = \mathcal{T}V^*$. Two questions arise immediately. Is the fixed point unique? And can we find it?

The Bellman operator is a contraction

For any two value tables V, W,

$$\|\mathcal{T}V - \mathcal{T}W\|_\infty \leq \gamma \, \|V - W\|_\infty,$$

where $\|V\|_\infty = \max_s |V(s)|$. Consequently $\mathcal{T}$ has exactly one fixed point V^*, and **value iteration** $V_{k+1} = \mathcal{T}V_k$ converges to it from any start, with $\|V_k - V^*\|_\infty \leq \gamma^k \|V_0 - V^*\|_\infty$.

Proof. First a small fact: for any two functions f, g of a, $|\max_a f(a) - \max_a g(a)| \leq \max_a |f(a) - g(a)|$. (If $\max f \geq \max g$ and a^* maximises f, then $\max f - \max g \leq f(a^*) - g(a^*)$.) Apply it with $f(a) = r(s,a) + \gamma \sum_{s'} P(s' \mid s,a) V(s')$ and g the same with W:

$$|(\mathcal{T}V)(s) - (\mathcal{T}W)(s)| \leq \max_a \, \gamma \sum_{s'} P(s' \mid s,a)\, |V(s') - W(s')| \leq \gamma \|V - W\|_\infty,$$

because the probabilities sum to 1. Take the maximum over s. If V^* and W^* were two fixed points, $\|V^* - W^*\|_\infty \leq \gamma \|V^* - W^*\|_\infty$ would force them equal. For convergence, $\|V_k - V^*\|_\infty = \|\mathcal{T}V_{k-1} - \mathcal{T}V^*\|_\infty \leq \gamma \|V_{k-1} - V^*\|_\infty$, and induction finishes it. Existence follows because the iterates form a Cauchy sequence in a complete space, the Banach fixed-point theorem. ■

The discount factor is the *rate* of convergence. With $\gamma = 0.9$ the error shrinks a thousandfold in about 66 sweeps; with $\gamma = 0.99$ it takes about 687. Far-sighted problems are slow to solve.

Result 2: one-step deviations are enough

Here is the debt to Ch. 40. A policy can be beaten, in principle, by an elaborate alternative that deviates differently at every step forever. Do you have to check all of those?

One-step deviation principle (single decision-maker)

Let π be a stationary policy. If no **single** deviation improves it, that is, if for every state s and action a

$$V^{\pi}(s) \;\geq\; r(s,a) + \gamma \sum_{s'} P(s' \mid s,a)\, V^{\pi}(s'),$$

(deviate once to a, then return to π), then π is optimal: $V^{\pi} = V^*$.

Proof. The value of a policy satisfies its own Bellman equation, $V^{\pi}(s) = r(s,\pi(s)) + \gamma \sum_{s'} P(s' \mid s,\pi(s)) V^{\pi}(s')$: condition on the first step. So the right-hand side of the hypothesis *equals* $V^{\pi}(s)$ when $a = \pi(s)$, and it is at most $V^{\pi}(s)$ for every other a. The maximum over a is therefore $V^{\pi}(s)$, which says $\mathcal{T}V^{\pi} = V^{\pi}$. By the contraction theorem, $\mathcal{T}$ has only one fixed point, V^*. Hence $V^{\pi} = V^*$. ■

Discounting does the work. Any infinitely long, cunning deviation is worth only finitely many steps of deviation, up to an error of order γ^n, and a finite deviation can be undone one step at a time from its last step backwards, each step being a one-shot deviation that does not help. In a repeated game, each player faces exactly such an MDP once the other players' strategies are fixed, and this is the one-shot deviation principle that Ch. 40 used.

The same idea gives an algorithm. If π *can* be improved by a one-step deviation, switch to the improving action everywhere at once. The **policy improvement theorem** says the new greedy policy $\pi'(s) = \arg\max_a [r(s,a) + \gamma \sum_{s'} P V^{\pi}(s')]$ satisfies $V^{\pi'} \geq V^{\pi}$ in every state, with strict improvement somewhere unless π was already optimal. (Sketch: $\mathcal{T}_{\pi'} V^{\pi} = \mathcal{T} V^{\pi} \geq V^{\pi}$, and applying the monotone map $\mathcal{T}_{\pi'}$ repeatedly only increases the left side, which converges to $V^{\pi'}$.)

> **? How many improvements does it take?**
>
> Policy iteration, alternating "evaluate V^{π}" and "improve greedily", stops after finitely many steps, since there are finitely many policies and each step strictly improves. In practice it almost always finishes in a handful of iterations, even for millions of states. For a fixed discount factor, Ye proved in 2011 that it is strongly polynomial. Without that restriction, cleverly built examples force related variants to take exponentially many steps. An MDP is also a linear program, and whether linear programs can be solved in *strongly* polynomial time is one of Smale's problems for the twenty-first century, still open. The LP view of MDPs and its dual are in the spirit of Ch. 48.

Result 3 (sketch): where the costate came from

Return to continuous time, with dynamics $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$ and cost $\int L\, dt$ as in Ch. 51. Let $V(\mathbf{x}, t)$ be the optimal cost-to-go. Apply the principle of optimality over a tiny step dt: pay $L\, dt$, move to $\mathbf{x} + \mathbf{f}\, dt$, and continue optimally:

$$V(\mathbf{x}, t) = \min_{\mathbf{u}} \left[L(\mathbf{x}, \mathbf{u})\, dt + V(\mathbf{x} + \mathbf{f}\, dt,\ t + dt) \right].$$

Expand V to first order, cancel $V(\mathbf{x}, t)$ and divide by dt. This gives the **Hamilton–Jacobi–Bellman equation**

$$-\frac{\partial V}{\partial t} = \min_{\mathbf{u}} \left[L(\mathbf{x}, \mathbf{u}) + \nabla_{\mathbf{x}} V^{\mathsf{T}} \mathbf{f}(\mathbf{x}, \mathbf{u}) \right] = \min_{\mathbf{u}} H\left(\mathbf{x}, \mathbf{u}, \nabla_{\mathbf{x}} V\right).$$

The bracket is exactly Pontryagin's Hamiltonian with $\boldsymbol{\lambda}$ replaced by $\nabla_{\mathbf{x}} V$. Differentiate the HJB equation with respect to $\mathbf{x}$ along the optimal trajectory (the minimising $\mathbf{u}$ drops out by the envelope theorem), and you find that $\boldsymbol{\lambda}(t) = \nabla_{\mathbf{x}} V(\mathbf{x}^*(t), t)$ obeys $\dot{\boldsymbol{\lambda}} = -\partial H / \partial \mathbf{x}$, Ch. 51's costate equation. So the costate *is* a price. It is the marginal cost-to-go, the amount the optimal future changes per unit nudge of the present state.

This derivation quietly assumed V is differentiable. For the minimum-time cart of Ch. 51 it is not: V has a crease along the switching curve.

> **? A PDE whose solutions have corners**
>
> If the value function has kinks, in what sense does it "solve" the HJB equation? Classical derivatives don't exist on the crease, and many non-smooth functions satisfy the equation almost everywhere. Which one is the true value? The answer, found by Crandall and Lions in the 1980s, is the theory of **viscosity solutions**, one of the great ideas in modern PDE theory: Ch. 89.

State-space methods: the linear–quadratic case

Usually V must be stored as a table, one number per state. One famous exception is linear dynamics with quadratic costs, where V stays quadratic forever and the "table" is a matrix. Take the scalar system $x_{k+1} = x_k + u_k$ with stage cost $x_k^2 + u_k^2$. Guess $V_{k+1}(x) = P_{k+1} x^2$. Then

$$V_k(x) = \min_u \left[x^2 + u^2 + P_{k+1}(x + u)^2 \right],$$

minimised at $u = -\dfrac{P_{k+1}}{1 + P_{k+1}}\, x$, which gives $V_k(x) = P_k x^2$ with

$$P_k = 1 + \frac{P_{k+1}}{1 + P_{k+1}}.$$

This is a **Riccati recursion**, the discrete twin of the LQR equation in Ch. 51. Starting from $P_N = 0$, it produces $1, \tfrac{3}{2}, \tfrac{8}{5}, \tfrac{21}{13}, \ldots$, ratios of Fibonacci numbers, converging to the fixed point $P^2 - P - 1 = 0$, that is $P = \varphi = (1 + \sqrt{5})/2 \approx 1.618$. The optimal long-run feedback is $u = -x/\varphi \approx -0.618\, x$. The golden ratio, hiding in a regulator. For vector states, P_k becomes a matrix and the recursion costs $O(n^3)$ per step, even though the state space is a continuum.

Without such structure, a table over a d-dimensional state space with m grid points per axis has m^d entries. Bellman called this the **curse of dimensionality**. A modest robot arm with 12 state variables and 20 grid points each needs $20^{12} \approx 4 \times 10^{15}$ values.

52.4 The algorithm

Value iteration applies $\mathcal{T}$ until the table stops moving:

```
V = 0 for every state
repeat
    for each state s:
        V_new(s) = max over a of [ r(s,a) + gamma * sum_{s'} P(s'|s,a) V(s') ]
    delta = max_s |V_new(s) - V(s)|;   V = V_new
until delta < eps * (1 - gamma) / gamma
policy(s) = argmax over a of the same bracket
```

The stopping rule is not arbitrary. The contraction property implies $\|V_{k+1} - V^*\|_\infty \leq \frac{\gamma}{1-\gamma} \|V_{k+1} - V_k\|_\infty$, so the test guarantees the final table is within ε of V^*. Each sweep costs $O(S^2 A)$ in general, and $O(SA)$ when each action leads to only a few successor states.

Policy iteration alternates two steps: *evaluate* the current policy by solving the linear system $(\mathbf{I} - \gamma \mathbf{P}_\pi)\mathbf{v} = \mathbf{r}_\pi$ (Ch. 8), then *improve* greedily. Each iteration is expensive, $O(S^3)$ for a dense solve, but there are few of them.

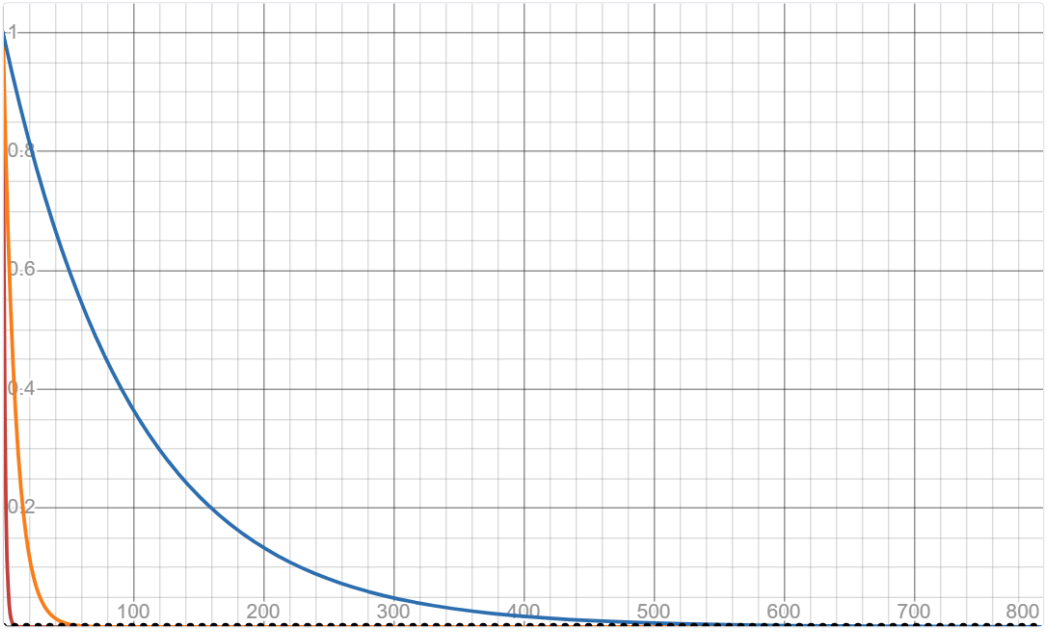
Numerical notes. $\mathbf{I} - \gamma \mathbf{P}_\pi$ is always invertible for $\gamma < 1$, because the eigenvalues of a stochastic matrix have magnitude at most 1 (Ch. 34). As $\gamma \to 1$, however, it becomes ill-conditioned, and value iteration slows to a crawl.

Failure cases. Dynamic programming needs (1) a *known model*, the probabilities and rewards; (2) a *small state space*, or special structure like LQR; and (3) the *Markov property*, a state that summarises the past. Break (3) and the recursion gives wrong answers with full confidence. A common fix is to enlarge the state, for example by adding the last few observations, which feeds the curse of dimensionality in (2).

> **Engineering note**
>
> Dynamic programming hides inside familiar engineering tools. The **Viterbi decoder** in every mobile phone and hard-disk read channel is a shortest-path DP over the states of a convolutional code (Ch. 79). Sequence alignment in genomics, speech recognition, and the dynamic time warping used to match signals are all DP over a grid.

52.5 The experiment

Part 1: the price of patience. Value iteration's error shrinks like γ^k. The three curves are $\gamma = 0.5$, 0.9 and 0.99; the dotted line is a factor of 1000. Read off where each curve crosses it (about 10, 66 and 687 sweeps). Then change 0.99 to 0.999 and see how far right the crossing moves.



Error bound after x sweeps of value iteration, as a fraction of the starting error.

Part 2: a grid world. A robot lives on a small grid with walls (`#`), a goal worth $+1$ (`G`) and a pit worth -1 (`P`). Each move costs `STEP`. With probability `SLIP` the robot slides sideways instead of going where it intends. The script runs value iteration and prints the values and the greedy policy.

```
import numpy as np

GAMMA, SLIP, STEP = 0.95, 0.2, -0.04      # knobs: try STEP = -0.5, SLIP = 0.0, GAMMA = 0.5
GRID = ["....G",
        ".#.#P",
        "....."]                          # G = goal (+1), P = pit (-1), # = wall
R, C = len(GRID), len(GRID[0])
MOVES = {"^": (-1, 0), "v": (1, 0), "<": (0, -1), ">": (0, 1)}
SIDE = {"^": "<>", "v": "<>", "<": "^v", ">": "^v"}

def go(r, c, a):
    r2, c2 = r + MOVES[a][0], c + MOVES[a][1]
    ok = 0 <= r2 < R and 0 <= c2 < C and GRID[r2][c2] != "#"
    return (r2, c2) if ok else (r, c)

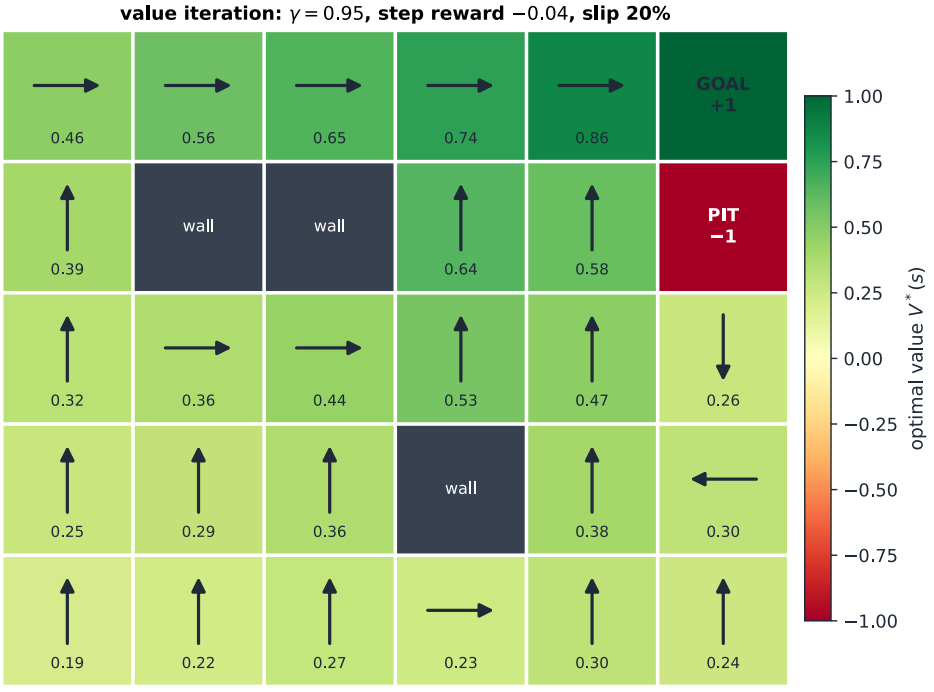
def q(V, r, c, a):                        # expected return of action a, then acting optimally
    nxt = [(1 - SLIP, a)] + [(SLIP / 2, b) for b in SIDE[a]]
    return STEP + GAMMA * sum(p * V[go(r, c, b)] for p, b in nxt)

V = np.zeros((R, C))
for k in range(1000):
    V_new = V.copy()
    for r in range(R):
        for c in range(C):
            cell = GRID[r][c]
            if cell in "GP#":
                V_new[r, c] = {"G": 1.0, "P": -1.0, "#": 0.0}[cell]
            else:
                V_new[r, c] = max(q(V, r, c, a) for a in MOVES)
    change = np.abs(V_new - V).max()
    V = V_new
    if change < 1e-8:
        break

print(f"converged after {k + 1} sweeps\n", np.round(V, 2))
for r in range(R):
    print(" ".join(GRID[r][c] if GRID[r][c] in "GP#" else
                   max(MOVES, key=lambda a: q(V, r, c, a)) for c in range(C)))
```

With the defaults it converges in 33 sweeps. Look at the bottom-right cell, directly below the pit: its policy is `<`, walking *away* from the goal to avoid sliding into the pit. Now try the knobs:

- `SLIP = 0.0`: convergence drops to 8 sweeps (the world is deterministic, and values settle as soon as the goal's information has travelled across the grid).
- `STEP = -0.5`: life is so painful that the bottom-right cell now chooses `^`, straight into the pit. A quick -1 beats a long walk at -0.5 a step. The robot has rationally chosen to end it.
- `GAMMA = 0.5`: the robot is so short-sighted that the goal is barely visible; most values are near zero, and the bottom-right cell bumps into the wall (`v`) rather than risk anything.



A larger grid world solved by value iteration with the default knobs. Values fall smoothly with distance from the goal. In the cell below the pit the arrow points away from the goal: with a 20% chance of slipping sideways, the safe detour is worth more than the short cut.

52.6 The challenge

1. **Intuition.** In the staged network, the cost-to-go of A1 is 11 and that of A3 is 8. Without recomputing anything, explain how the optimal route from S would change if the leg S→A3 dropped from 4 to 2. Then explain why changing a leg in stage 3 can change the optimal *first* decision, but changing a leg leaving S cannot change the cost-to-go of any node other than S.
2. **Derivation.** Prove the stopping rule: if $\|V_{k+1} - V_k\|_\infty \le \delta$, then $\|V_{k+1} - V^*\|_\infty \le \frac{\gamma}{1-\gamma}\delta$. Then complete the proof of the policy improvement theorem, using that $\mathcal{T}_{\pi'}$ is monotone (if $V \le W$ everywhere, then $\mathcal{T}_{\pi'}V \le \mathcal{T}_{\pi'}W$).
3. **Implementation.** Add policy iteration to the grid-world script: evaluate V^π by solving the linear system with `np.linalg.solve`, then improve greedily, until the policy stops changing. Count iterations for $\gamma = 0.5, 0.9, 0.99$ and compare with the number of value-iteration sweeps. Then implement Bellman–Ford with negative-cycle detection and test it on a graph with one negative edge.
4. **Open investigation.** Make the grid world big (say 50×50) with random walls and random pits. How does the number of policy-iteration steps grow with grid size and with γ? Can you construct a small MDP that forces policy iteration (with greedy switching in every state) to take many steps? Exponential lower bounds are known for some variants and not for others; see how close you can get.

52.7 Loose threads

Dynamic programming replaced a search over paths with a table of values, one number per state, filled in from the future backwards. It paid three debts: the $|V| - 1$ horizon of Bellman–Ford, the one-step deviation principle of repeated games, and the meaning of Ch. 51's costate. But everything rested on two quiet assumptions: we knew the model, and the table was small enough to write down.

> **? What if nobody tells you the probabilities?**
>
> Every Bellman update above needed $P(s' \mid s, a)$ and $r(s, a)$. A robot in a new building, a trading agent in a market, or a program learning to play Go knows neither. It only experiences one transition at a time. Can you still converge to V^* by averaging experience into the Bellman equation as you go? Remarkably, yes, under conditions on how you explore and how fast you average. That is Q-learning and the whole of Ch. 53.

The curse of dimensionality is the other loose thread, and it has no complete answer. Linear–quadratic structure defeats it exactly. Monte Carlo sampling (Ch. 38) defeats it for some problems. Neural networks that approximate V appear to defeat it in practice (Ch. 53), with few guarantees. When the transition probabilities themselves are uncertain, a robust version of the Bellman equation takes a worst case over a set of models (Ch. 54). When an opponent picks some of the transitions, the max becomes a max–min, and you are back in the game trees of Ch. 46.

Chapter 53 — Reinforcement Learning Through Mathematics

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 19, Ch. 23, Ch. 34, Ch. 52 · **Leads to:** Ch. 54, Ch. 61 · **Related:** Ch. 37, Ch. 38, Ch. 45, Ch. 46 **Reading time:** ~30 min

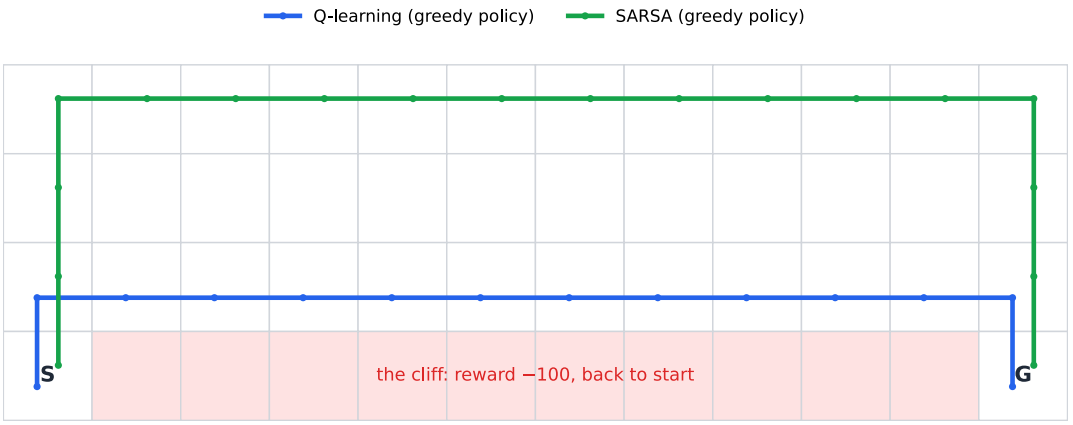
53.1 The hook

Picture a grid four squares tall and twelve wide. A walker starts in the bottom-left corner and wants to reach the bottom-right corner. Every step costs one point. Between the two corners, along the whole bottom row, runs a cliff. Step onto it and you lose a hundred points and are carried back to the start.

The walker has no map. Nobody tells it where the cliff is, or that there is a cliff at all. All it sees is the square it stands on and, after each step, a number: -1, or occasionally a shocking -100. From those numbers alone it must learn how to walk.

Now let two learning programs loose on this grid. Both try a random direction one time in ten and otherwise take the move that currently looks best. Both get the same 500 attempts. The first, **Q-learning**, ends up knowing the truly optimal route, the 13-step path that hugs the cliff edge. The second, **SARSA**, learns a timid detour up to the top row and back down, 17 steps long.

Then you look at the scores they actually earned during the last hundred attempts. The program that knows the best path averaged about -49 points per attempt. The timid one averaged about -26. The student who learned the right answer did almost twice as badly as the one who learned the wrong answer.



The same world, the same experience, two different conclusions. Q-learning's greedy policy (blue) takes the shortest route, one square from the edge. SARSA's (green) keeps three squares of safety margin. With 10% random moves, the shortest route sends the walker off the cliff about once every three attempts.

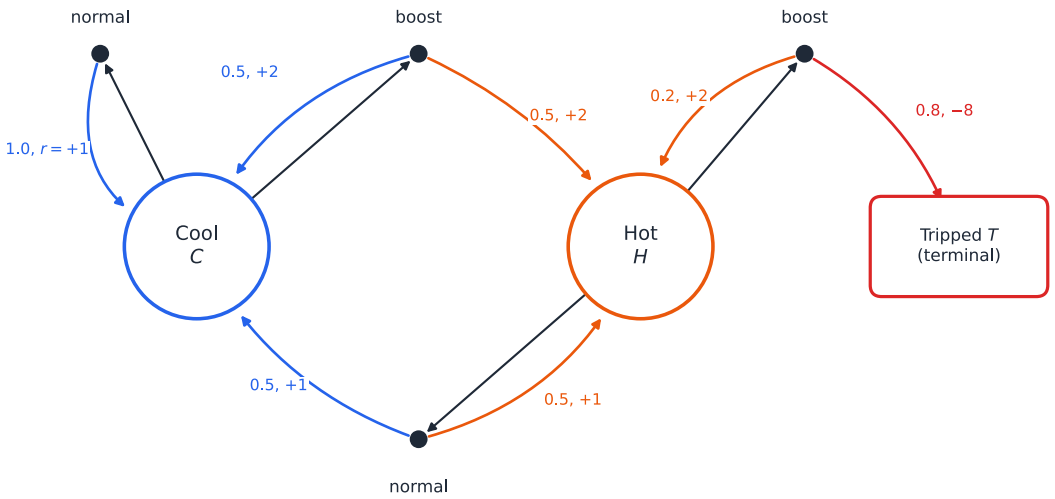
Q-learning has learned the value of walking the edge *if you never stumble*. But it does stumble, one step in ten, and on the edge a stumble is a fall. SARSA learned the value of its own clumsy behaviour, stumbles included, and concluded the edge is not worth it. Each program answered a different question correctly.

So which question should a learner be answering? And how can anything learn the value of a path at all from a stream of -1s and -100s, without ever seeing the map? The answer is a small amount of probability, one fixed-point theorem, and an idea so simple it is almost embarrassing: *guess, then correct your guess using your next guess.*

53.2 The big idea

Ch. 52 solved sequential decision problems when you know the rules: the transition probabilities and the rewards. Bellman's principle turned "plan the whole future" into "plan one step, then trust the value of where you land", and value iteration computed those values by sweeping over every state. Reinforcement learning asks what is left of that machinery when the rules are hidden and you can only *act and observe*.

Here is a small world we will use all chapter. An electric motor can run **cool** or **hot**. In each state the controller chooses **normal** or **boost**. Boost earns more (2 units of work per step against 1), but it heats the motor. A cool motor under boost becomes hot half the time. A hot motor under boost trips its thermal protection with probability 0.8, which costs a penalty and ends the run. Future rewards are discounted by $\gamma = 0.9$ per step.



The motor-drive decision process. Each black dot is a choice; the arrows leaving it are what Nature does next, with probability and reward. From Hot, boost pays $+2$ and then trips the motor 80% of the time, for a net reward of -8.

If you know this diagram, Ch. 52's value iteration gives the answer in a few lines: boost when cool, run normally when hot. The interesting case is when you don't know the diagram. You can only run the motor and watch.

Three ideas carry the whole subject.

1. Value is an average of the future. The value of "boost while cool" is the expected discounted sum of all rewards that follow. You cannot compute that expectation without the model, but you can *sample* it: try the action, see what happens. Averages of samples converge to expectations (Ch. 19).

2. Bootstrapping. Waiting for the end of a run is slow. Instead, after a single step you already have a better guess than before: the reward you just got plus your current estimate of where you landed. Move your old guess a little toward that one-step target. This is **temporal-difference learning**, and it is Bellman's equation turned into a correction rule. You are learning a guess from a guess. That such a thing converges at all is the mathematical heart of this chapter.

3. Exploration versus exploitation. If the motor controller always takes the action that currently looks best, it may never try the action that is actually best. A controller that starts with all estimates at zero, runs normal once and sees $+1$, will prefer normal forever and never discover that boost is better. It has to spend some of its time doing things that look worse, *to find out*. That cost is the -49 of the cliff walker.

An analogy: you move to a new city and want the best restaurant. Each meal is a noisy sample of a restaurant's quality (idea 1). You judge a neighbourhood partly by the restaurants you have already rated nearby (idea 2). And every night you must decide between your current favourite and a place you have never tried (idea 3).

53.3 The mathematics

Markov decision processes

Markov decision process (MDP)

An MDP is a tuple $(\mathcal{S}, \mathcal{A}, P, r, \gamma)$: a set of states $\mathcal{S}$, a set of actions $\mathcal{A}$, transition probabilities $P(s' \mid s, a)$, an expected reward $r(s, a)$ for taking action a in state s, and a discount factor $0 \le \gamma < 1$. A **policy** $\pi(a \mid s)$ is a probability distribution over actions in each state. The agent's **return** from time t is

$$G_t = R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \cdots = \sum_{k=0}^{\infty} \gamma^k R_{t+k+1}.$$

The next state depends on the past only through the current state and action, as in the chains of Ch. 34. Fix a policy and the MDP *becomes* a Markov chain with transition matrix $P_\pi(s' \mid s) = \sum_a \pi(a \mid s) P(s' \mid s, a)$. A policy is a way of choosing which Markov chain you live in.

The discount has two readings. Economically, a reward now is worth more than a reward later. Probabilistically, γ is the chance the world continues for another step, so $1/(1-\gamma)$ is the **effective horizon**: 10 steps for $\gamma = 0.9$, 100 for $\gamma = 0.99$. Since $|R| \le R_{\max}$ implies $|G_t| \le R_{\max}/(1-\gamma)$, returns are always finite.

Value functions

The **state value** and the **action value** of a policy π are

$$V^\pi(s) = E_\pi\left[G_t \mid S_t = s\right], \qquad Q^\pi(s, a) = E_\pi\left[G_t \mid S_t = s,\ A_t = a\right].$$

The optimal action value is $Q^*(s, a) = \max_\pi Q^\pi(s, a)$.

Ch. 52 derives the Bellman equations and proves that the Bellman operator on state values is a contraction; the same argument, word for word, shows that the **Bellman optimality operator** on action values

$$(\mathcal{T}Q)(s,a) = r(s,a) + \gamma \sum_{s'} P(s' \mid s,a) \max_{a'} Q(s',a')$$

is a γ-contraction in the max-norm, $\|\mathcal{T}Q - \mathcal{T}Q'\|_\infty \le \gamma \|Q - Q'\|_\infty$. So Q^* is its unique fixed point, value iteration $Q_{k+1} = \mathcal{T}Q_k$ converges to it geometrically, and any policy that is greedy with respect to Q^* is optimal. The new problem is that $\mathcal{T}$ contains P, and P is exactly what we don't have.

The motor drive, solved with the model

Write C, H for cool and hot, n, b for normal and boost. Running value iteration from $Q = 0$ with $\gamma = 0.9$ converges to

$$Q^* = \begin{pmatrix} Q^*(C,n) & Q^*(C,b) \\ Q^*(H,n) & Q^*(H,b) \end{pmatrix} = \begin{pmatrix} 14.95 & 15.50 \\ 14.50 & -3.39 \end{pmatrix}.$$

Check one entry against the fixed-point equation: $Q^*(H,b) = 0.2\,(2 + 0.9 \times 14.50) + 0.8 \times (-8) = 0.4 + 2.61 - 6.4 = -3.39$. The optimal policy boosts when cool and runs normally when hot, with $V^*(C) = 15.5$. Always running normal gives only $V(C) = 10$, and always boosting gives $V(C) = -2.35$. Notice how close the two actions in state C are: 15.50 against 14.95. A learner estimating these from noisy samples has to resolve a gap of 0.55 in numbers around 15.

Learning a fixed point from samples

Look at $\mathcal{T}Q$ again. It is an expectation over the next state s'. If we take action a in state s and observe a reward r and a next state s', then the single number

$$y = r + \gamma \max_{a'} Q(s',a')$$

is an unbiased sample of $(\mathcal{T}Q)(s,a)$: its expected value, over the randomness of the environment, is exactly $(\mathcal{T}Q)(s,a)$. We cannot apply $\mathcal{T}$, but we can draw noisy samples of it, one transition at a time. **Q-learning** nudges the estimate toward each sample:

$$Q(s,a) \leftarrow Q(s,a) + \alpha \underbrace{\big[\, r + \gamma \max_{a'} Q(s',a') - Q(s,a) \,\big]}_{\text{temporal-difference error } \delta}.$$

The bracket δ is the surprise: how much better or worse the step went than the current estimate predicted. When $Q = Q^*$ the surprise is zero *on average*, which is all Bellman's equation says.

Why should such a rule converge? Strip away the noise first and look at what the update does on average.

Theorem 53.1 — The averaged Q-learning step is a contraction

Let $\mathcal{T}$ be a γ-contraction in $\|\cdot\|_\infty$ with fixed point Q^*, and let $0 < \alpha \le 1$. The averaged update $\mathcal{U}Q = (1-\alpha)Q + \alpha\,\mathcal{T}Q$ satisfies

$$\|\mathcal{U}Q - Q^*\|_\infty \le \big(1 - \alpha(1-\gamma)\big)\,\|Q - Q^*\|_\infty.$$

Hence iterating $\mathcal{U}$ converges to Q^* geometrically, at rate $1 - \alpha(1-\gamma) < 1$.

Proof. Because $Q^* = \mathcal{T}Q^*$, we can write $Q^* = (1-\alpha)Q^* + \alpha\,\mathcal{T}Q^*$. Subtract this from $\mathcal{U}Q$:

$$\mathcal{U}Q - Q^* = (1-\alpha)(Q - Q^*) + \alpha(\mathcal{T}Q - \mathcal{T}Q^*).$$

Take max-norms, use the triangle inequality, and then the contraction property:

$$\|\mathcal{U}Q - Q^*\|_\infty \le (1-\alpha)\|Q - Q^*\|_\infty + \alpha\gamma\|Q - Q^*\|_\infty = \big(1 - \alpha(1-\gamma)\big)\|Q - Q^*\|_\infty.$$

Since $\alpha > 0$ and $\gamma < 1$, the factor is strictly less than 1, and the Banach fixed-point argument of Ch. 52 applies. $\square$

Two practical lessons follow. Small α slows convergence: with $\alpha = 0.1$ and $\gamma = 0.9$ the factor is 0.99, so the error shrinks by only 1% per sweep. Long horizons hurt too: as $\gamma \to 1$ the factor approaches 1 for any fixed α.

Real Q-learning does not apply $\mathcal{U}$. It replaces $\mathcal{T}Q$ by one noisy sample and updates one entry at a time. The noise forces a compromise in the step size. A constant α keeps reacting to every new sample, so the estimate jitters forever around Q^*. A step size that shrinks too fast stops learning before it arrives. The classical result of stochastic approximation (Robbins and Monro, 1951), applied to Q-learning by Watkins and Dayan (1992) and Tsitsiklis (1994), says the right compromise is

$$\sum_t \alpha_t(s,a) = \infty, \qquad \sum_t \alpha_t(s,a)^2 < \infty$$

for every pair (s,a), for example $\alpha = 1/N(s,a)$ or $1/N(s,a)^{0.7}$, where N counts visits. The first sum lets the estimate travel any distance; the second makes the accumulated noise finite.

Convergence of tabular Q-learning (stated)

In a finite MDP, if every state–action pair is updated infinitely often and the step sizes satisfy the two conditions above, then $Q_t \to Q^*$ with probability 1, *whatever policy generated the data.*

The last clause is the cliff walker's secret. Because the target uses $\max_{a'}$, Q-learning learns the value of the *greedy* policy even while behaving with ε-random moves. It is **off-policy**: it learns about one policy while following another. SARSA replaces $\max_{a'} Q(s',a')$ by $Q(s',a')$ for the action a' it actually takes next, so it learns Q^π for its own exploring policy. It is **on-policy**.

Notice what the theorem assumes and nothing supplies: *every pair visited infinitely often*. Exploration is a separate decision.

Optimizing the policy directly

Value-based methods learn Q^* and act greedily. That breaks down when actions are continuous (what is $\max_{a'}$ over all motor voltages?) or when the best policy is genuinely random, as in the zero-sum games of Ch. 39. The alternative is to write down a parametrized policy $\pi_\theta(a \mid s)$, say a softmax over action scores, and do gradient ascent (§23.5) on the expected return

$$J(\theta) = E_{\tau\sim\pi_\theta}\left[R(\tau)\right], \qquad R(\tau) = \sum_{t=0}^{T-1} \gamma^t r_{t+1},$$

where $\tau = (s_0, a_0, r_1, s_1, a_1, \dots)$ is a whole trajectory. The obstacle is that θ appears inside the *distribution* of τ, not inside the thing being averaged, and that distribution involves the unknown dynamics P. It looks as if you would need to differentiate the environment.

Theorem 53.2 — Policy gradient (REINFORCE form)

For an episodic task of length T,

$$\nabla_\theta J(\theta) = E_{\tau\sim\pi_\theta}\left[R(\tau)\sum_{t=0}^{T-1}\nabla_\theta \log \pi_\theta(a_t \mid s_t)\right].$$

The right side contains no derivative of P, so it can be estimated from sampled trajectories alone.

Proof. The probability of a trajectory is a product of policy terms and environment terms:

$$p_\theta(\tau) = \rho_0(s_0)\prod_{t=0}^{T-1}\pi_\theta(a_t \mid s_t)\,P(s_{t+1} \mid s_t, a_t).$$

Differentiate under the sum (or integral) over trajectories and use the identity $\nabla p = p\,\nabla \log p$, valid wherever $p > 0$:

$$\nabla_\theta J = \sum_\tau R(\tau)\nabla_\theta p_\theta(\tau) = \sum_\tau p_\theta(\tau) R(\tau)\nabla_\theta \log p_\theta(\tau) = E_{\tau\sim\pi_\theta}\left[R(\tau)\nabla_\theta \log p_\theta(\tau)\right].$$

Now take the logarithm of the product:

$$\log p_\theta(\tau) = \log \rho_0(s_0) + \sum_t \log \pi_\theta(a_t \mid s_t) + \sum_t \log P(s_{t+1} \mid s_t, a_t).$$

The first and last terms do not depend on θ, so their gradients vanish. Only the policy terms survive. □

The **log-derivative trick** in the middle step is worth remembering on its own: it turns the gradient of an expectation into the expectation of something you can sample. The resulting estimator has a clean meaning. $\nabla \log \pi_\theta(a_t \mid s_t)$ points in the direction that makes the action you actually took more likely. Weight that direction by how good the whole trajectory turned out, average, and step. Good trajectories get reinforced, hence the name.

It is also noisy. The estimate multiplies a sum of T random vectors by a random total reward. Two standard repairs keep the expectation unchanged and shrink the variance: replace $R(\tau)$ in the term for time t by the reward-to-go from t (an action cannot influence rewards that came before it), and subtract a **baseline** $b(s_t)$, typically an estimate of $V^\pi(s_t)$. The subtraction is harmless because $E_{a\sim\pi_\theta}\left[\nabla \log \pi_\theta(a \mid s)\right] = \sum_a \nabla \pi_\theta(a \mid s) = \nabla 1 = 0$. With the baseline V^π, what multiplies $\nabla \log \pi$ is an estimate of $Q^\pi(s,a) - V^\pi(s)$, the **advantage** of the action over the policy's average. Learn V by temporal differences and the policy with this gradient, and you have an **actor–critic** method: the two halves of this section, working together.

? Climbing a mountain you cannot see

$J(\theta)$ is not concave in θ, not even for a softmax policy on a tiny MDP. Gradient ascent on a non-concave function should get stuck on local peaks. Yet for tabular softmax policies, with exact gradients, it provably reaches the *global* optimum, and in large neural-network policies it usually reaches something good. The tabular proof rests on a "gradient domination" inequality that has no analogue in general non-convex optimization. Why policy landscapes are so much kinder than they have any right to be is the same open puzzle Ch. 47 raised for neural networks, and for deep policies it remains unsolved.

Learning about one policy from another's data

Suppose you have a log of trajectories recorded under an old behaviour policy μ and want the value of a new policy π without running it, because running it on a real motor, patient or power grid could be dangerous. This is **off-policy evaluation**, and its basic tool is importance sampling (Ch. 38).

Theorem 53.3 — Importance-sampled return

If $\mu(a \mid s) > 0$ whenever $\pi(a \mid s) > 0$, then with $\rho(\tau) = \prod_{t=0}^{T-1} \pi(a_t \mid s_t)/\mu(a_t \mid s_t)$,

$$E_{\tau\sim\mu}\left[\rho(\tau)R(\tau)\right] = E_{\tau\sim\pi}\left[R(\tau)\right].$$

Proof. Write p_π and p_μ for the trajectory distributions. In their ratio, the initial-state and transition factors cancel, because both policies face the same environment, leaving $p_\pi(\tau)/p_\mu(\tau) = \rho(\tau)$. So $E_\mu[\rho R] = \sum_\tau p_\mu(\tau)\frac{p_\pi(\tau)}{p_\mu(\tau)}R(\tau) = E_\pi[R]$. (The support condition prevents division by zero.) □

The price, again, is variance. If π is deterministic and μ picks uniformly between two actions, each step contributes a factor π/μ that is 2 or 0, and $E_\mu[\rho^2] = 2^T$. Over a 20-step horizon the weight has variance $2^{20} - 1 \approx 1.05 \times 10^6$. This is the exploding inverse-propensity weight of Ch. 37, compounded once per step: off-policy evaluation is causal inference with a horizon.

53.4 The algorithm

Tabular Q-learning with ε-greedy exploration fits in a dozen lines.

```
initialise Q(s, a) = 0 for all s, a;  N(s, a) = 0
repeat for each episode:
    s ← start state
    while s is not terminal:
        with probability ε pick a at random, else a ← argmax_a Q(s, a)
        take a, observe reward r and next state s'
        N(s, a) ← N(s, a) + 1;   α ← 1 / N(s, a)^0.7
        y ← r                          if s' is terminal
            r + γ · max_a' Q(s', a')   otherwise
        Q(s, a) ← Q(s, a) + α (y − Q(s, a))
        s ← s'
```

For SARSA, choose the next action a' *before* the update and use $y = r + \gamma Q(s', a')$; then take a'.

Cost. Each step costs $O(|\mathcal{A}|)$ and memory is one number per state–action pair. The price is samples: the best known bounds for accuracy ϵ grow like $|\mathcal{S}||\mathcal{A}|/\big((1-\gamma)^3\epsilon^2\big)$, so going from $\gamma = 0.9$ to 0.99 can cost a factor of a thousand.

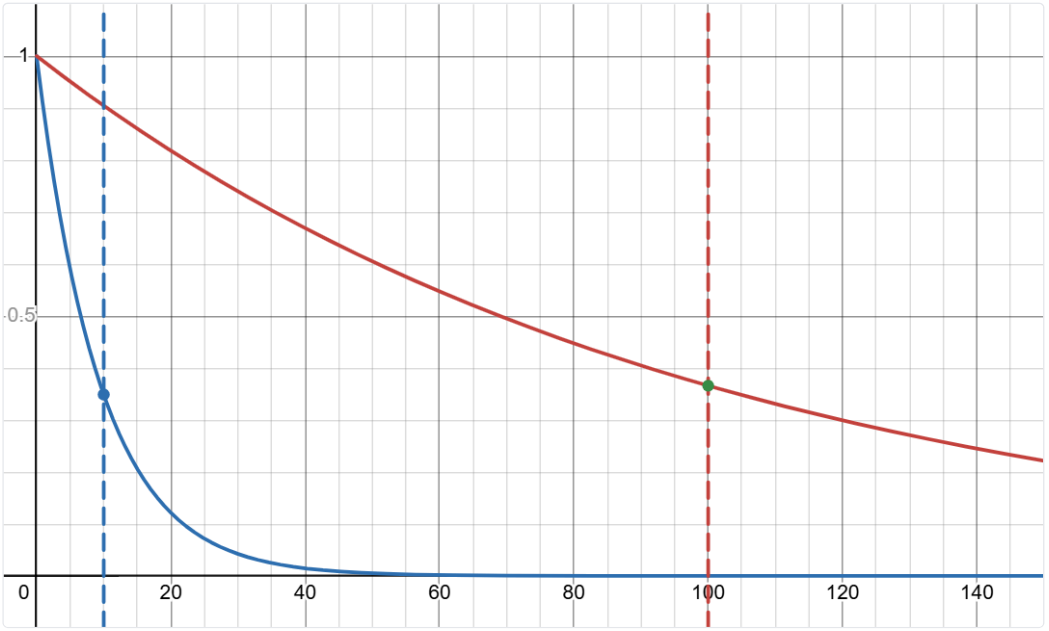
Failure modes worth knowing before you trust a learning curve.

- *No exploration, no learning.* With $\varepsilon = 0$ and all estimates starting at zero, the motor controller of 53.5 runs normal, sees $+1$, and never tries boost again. The theorem's "every pair infinitely often" is silently violated. In the cliff world the same $\varepsilon = 0$ learner explores anyway, because every reward is negative and so a zero initial estimate is *optimistic*: every untried action looks better than the disappointments already seen. Initial values are a hidden exploration policy.
- *Maximization bias.* The target $\max_{a'} Q(s', a')$ is the maximum of noisy estimates, and $E[\max] \geq \max E$. Early in learning Q-learning systematically overestimates. **Double Q-learning** keeps two tables, picks the maximizing action with one and evaluates it with the other, which removes the upward bias.
- *Function approximation.* Tables do not scale. Backgammon has about 10^{20} positions and Go about 10^{170}, so practical systems replace the table by a parametrized function $Q_{\mathbf{w}}(s, a)$, from a linear combination of features up to a deep network, and apply the same temporal-difference correction to $\mathbf{w}$. Theorem 53.1 then stops applying, because the update is no longer $\mathcal{T}$ but "apply $\mathcal{T}$, then squeeze the result back into the family of representable functions".

> **? The deadly triad**
>
> Combine three individually harmless ingredients: function approximation, bootstrapping (learning a guess from a guess) and off-policy data. The result can diverge to infinity, even with a *linear* $Q_{\mathbf{w}}$ and exact expected updates. A seven-state example due to Baird (1995) does it. Remove any one ingredient and the divergence disappears. The reason is that the projection onto representable functions is non-expansive only in a norm weighted by the *on-policy* state distribution, and the Bellman operator is a contraction only in the max-norm. When the two norms disagree, nothing forces their composition to contract. The geometry of projections in weighted function spaces is in Ch. 61. A complete theory of when deep Q-learning is stable is an open problem.

53.5 The experiment

First, a picture of what γ means. The weight a reward k steps in the future receives is γ^k. The weights add up to the effective horizon $1/(1-\gamma)$.



Discount weights γ^k for $\gamma = 0.9$ (blue) and 0.99 (red). At the effective horizon $k = 1/(1-\gamma)$ the weight has fallen to about e^{-1}. Change 0.99 to 0.999 and watch the horizon run off the screen; that is why long-horizon problems need so many more samples.

Now learn the motor drive from experience. The script below runs Q-learning for 50,000 steps with no access to the transition probabilities, and tracks the largest error against the Q^* computed in 53.3.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
eps, gamma, steps, seed = 0.1, 0.9, 50_000, 1
Q_star = np.array([[14.95, 15.5], [14.5, -3.39]])  # from value iteration
# -------------------------------------------------------------------------
rng = np.random.default_rng(seed)
C, H, T = 0, 1, 2                       # states; actions 0 = normal, 1 = boost
def env(s, a):
    if s == C and a == 0: return C, 1.0
    if s == C and a == 1: return (C if rng.random() < 0.5 else H), 2.0
    if s == H and a == 0: return (C if rng.random() < 0.5 else H), 1.0
    return (H, 2.0) if rng.random() < 0.2 else (T, -8.0)

Q, N = np.zeros((2, 2)), np.zeros((2, 2))
err, s = [], C
for t in range(steps):
    a = rng.integers(2) if rng.random() < eps else int(np.argmax(Q[s]))
    s2, r = env(s, a)
    N[s, a] += 1
    alpha = 1.0 / N[s, a] ** 0.7         # try 0.1 (constant) or 1/N
    target = r if s2 == T else r + gamma * Q[s2].max()
    Q[s, a] += alpha * (target - Q[s, a])
    s = C if s2 == T else s2             # a trip ends the episode
    err.append(np.abs(Q - Q_star).max())

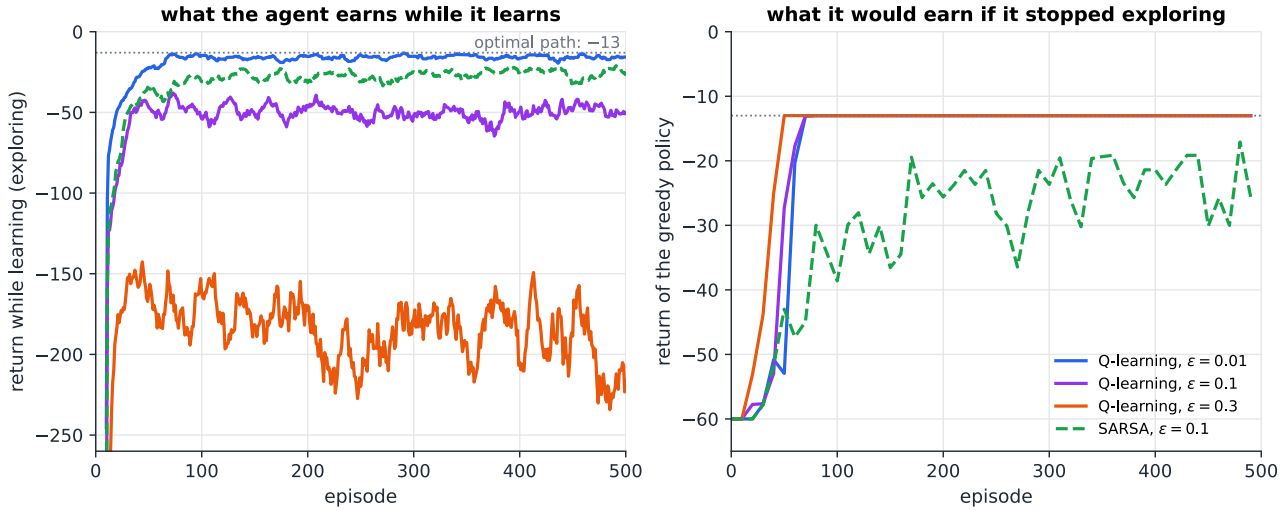
print("learned Q:\n", Q.round(2), "\nvisits:\n", N.astype(int))
print("greedy policy (0=normal, 1=boost):", Q.argmax(1))
plt.semilogy(err); plt.xlabel("step"); plt.ylabel("max |Q - Q*|")
plt.show()
```

With the default knobs the learned policy is optimal (boost when cool, normal when hot) and the table is $\begin{pmatrix} 14.92 & 15.49 \\ 14.48 & -2.53 \end{pmatrix}$: three entries within 0.03 of Q^*, and one off by 0.86. That one is $Q(H, b)$, the disastrous action, which the agent tried only 1,247 times in 50,000 steps because it already knew enough to avoid it. Q-learning is accurate where accuracy matters for the decision and sloppy elsewhere.

Things to change:

- `eps = 0.0`: the agent never boosts, ends with $Q(C, n) = 10$ and the wrong policy, and its error stays at 15.5 forever.
- `eps = 0.01`: the policy still comes out right, but $Q(C, n)$ stalls near 12.1, because after the first few hundred steps the agent almost never runs normal while cool.
- `eps = 0.5`: every entry is within 0.08 of Q^*, at the price of behaving badly half the time.
- `gamma = 0.99` (and recompute `Q_star` with value iteration from Ch. 52): the same number of steps leaves a much larger error.

Finally, back to the cliff. The next figure shows what ε does there.



Average of 20 runs, $\alpha = 0.5$. Left: the reward actually collected while exploring. Over the last 100 episodes Q-learning earns about -16, -49 and -195 for $\varepsilon = 0.01$, 0.1 and 0.3, and SARSA with $\varepsilon = 0.1$ earns about -26. Right: the reward the current greedy policy would earn. Every Q-learning run has found the optimal -13 path within about 70 episodes; SARSA's greedy policy stays on its safer, longer detour.

The right panel measures what you *know*; the left, what you *earn while finding out*. That is the hook's paradox as a trade-off with numbers on it.

53.6 The challenge

1. **Intuition.** In the cliff world, suppose ε is slowly decreased to zero over many episodes. Explain why SARSA's learned path should then drift down towards the cliff edge and end up identical to Q-learning's. Then explain why, for any fixed $\varepsilon > 0$, it never does. Which of the two programs would you rather have controlling a real machine *during* training, and which *after*?
2. **Derivation.** For a fixed ε-greedy policy π, define the SARSA operator $(\mathcal{T}^{\pi}Q)(s,a) = r(s,a) + \gamma \sum_{s'} P(s' \mid s,a) \sum_{a'} \pi(a' \mid s') Q(s',a')$. Prove that it is a γ-contraction in the max-norm. Then solve $Q = \mathcal{T}^{\pi}Q$ exactly for the motor drive with $\varepsilon = 0.1$ around the optimal policy, as a 4×4 linear system, and compare the two entries of state C with those of Q^{*}.
3. **Implementation.** Change the experiment script into Double Q-learning: keep two tables, on each step update one of them at random, using it to choose $\arg\max_{a'}$ and the *other* to evaluate that action. Over 200 seeds, plot the average of $Q(C,b) - Q^{*}(C,b)$ against the step number for both algorithms during the first 2,000 steps, and measure the maximization bias you have removed.
4. **Open investigation.** In the cliff world, vary the cliff penalty (from -10 to -1000) and ε (from 0.01 to 0.3), and record which row SARSA's greedy path uses. Map the boundary in the (penalty, ε) plane where the safe detour takes over. Is there a simple formula for that boundary, perhaps in terms of the probability of surviving n random steps next to the edge? Does it change with grid width?

53.7 Loose threads

> **? How much exploration is enough?**
>
> ε-greedy explores blindly: it tries a known-terrible action as often as a promising untried one. Smarter schemes add an "optimism bonus" to rarely tried actions, or sample from a posterior over which action is best (Thompson sampling). For the simplest case, a single state with k actions (the multi-armed bandit), the best possible regret grows like $\log T$, and the constant in front is a sum of reciprocal KL divergences between the arms' reward distributions. Why it is exactly KL divergence, and why no algorithm can beat it, comes from how fast an experiment can distinguish two distributions: the ingredients are in Ch. 33, and the Bayesian side of Thompson sampling in Ch. 35.

Two promises from other chapters are partly kept here. Ch. 46 asked what a self-play Go program learns. The answer is a pair of functions in the sense of this chapter: a value network approximating V^{*} of the game from the current player's point of view, and a policy network trained to imitate the moves that the search itself ends up preferring. Tree search guided by both replaces alpha–beta. Why self-play does not simply cycle remains only partly understood, and is a live research question. Ch. 45 asked whether selection is learning. Take a one-state problem with softmax probabilities $\pi_i \propto e^{\theta_i}$ and raise each score at the rate of its reward, $\dot{\theta}_i = r_i$, which is the natural policy gradient for this case. Then $\dot{\pi}_i = \pi_i \left(r_i - \sum_j \pi_j r_j \right)$, which is exactly the replicator equation. Natural selection and natural policy gradient are the same dynamics.

Untouched here: continuous time, where Bellman's equation becomes the Hamilton–Jacobi–Bellman PDE of Ch. 51, and safety. A learner that explores a real system can damage it. Requiring that a learned policy keep its constraints *with high probability, whatever the true model turns out to be* is the subject of Ch. 54.

Chapter 54 — Robust and Stochastic Optimization

> **Level 2 · Track D — Optimization and Operations Research Builds on:** Ch. 19, Ch. 23, Ch. 47, Ch. 48 · **Leads to:** Ch. 52, Ch. 55 · **Related:** Ch. 38, Ch. 46, Ch. 53, Ch. 75 **Reading time:** ~30 min

54.1 The hook

Here is a small production plan. Two products, x_1 and x_2 units, each worth one unit of profit. Machine A has 8 hours and needs 2 hours per unit of product 1 and 1 hour per unit of product 2. Machine B has 9 hours and needs 1 and 3. Maximize $x_1 + x_2$. The linear program of §23.3 answers in a moment: $x_1 = 3$, $x_2 = 2$, profit 5, both machines fully booked.

Now admit what everyone on the factory floor knows: the "2 hours" was measured, and measurements wobble. Suppose each of the four time coefficients is really its nominal value plus a small random error, independent, with mean zero. How often does the optimal plan overrun a machine?

Think before reading on. The errors are small, so surely the plan works almost always?

It fails **75% of the time**. And the answer does not depend on how small the errors are. Make them 10% of the coefficients or 0.001%, and still three plans in four overrun. The reason takes one line. The optimum sits exactly on both constraint boundaries, $2x_1 + x_2 = 8$ and $x_1 + 3x_2 = 9$. A symmetric error pushes each machine's actual load above or below its capacity with probability $\frac{1}{2}$ each. The chance that *both* land on the safe side is $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$.

This is not a quirk of the example. The simplex method always returns a vertex, where as many constraints as there are variables hold with equality. Optimization by its nature drives you to the edge of the feasible set, and the edge is where any uncertainty hurts most. In 2000, Aharon Ben-Tal and Arkadi Nemirovski took the classical NETLIB collection of real-world linear programs, perturbed the uncertain coefficients by just 0.01%, and found that in a substantial fraction of the problems the nominal optimal solutions violated some constraints by far more than the perturbation, in several cases by more than the entire right-hand side. Solutions that were optimal to many decimal places were, in practice, nonsense.

So what should an optimizer do when it does not know the numbers? There are three classical answers, each with its own mathematics, and the surprise of this chapter is that for the simplest kind of uncertainty all three lead to *the same shape of constraint*, differing only in a single number.

54.2 The big idea

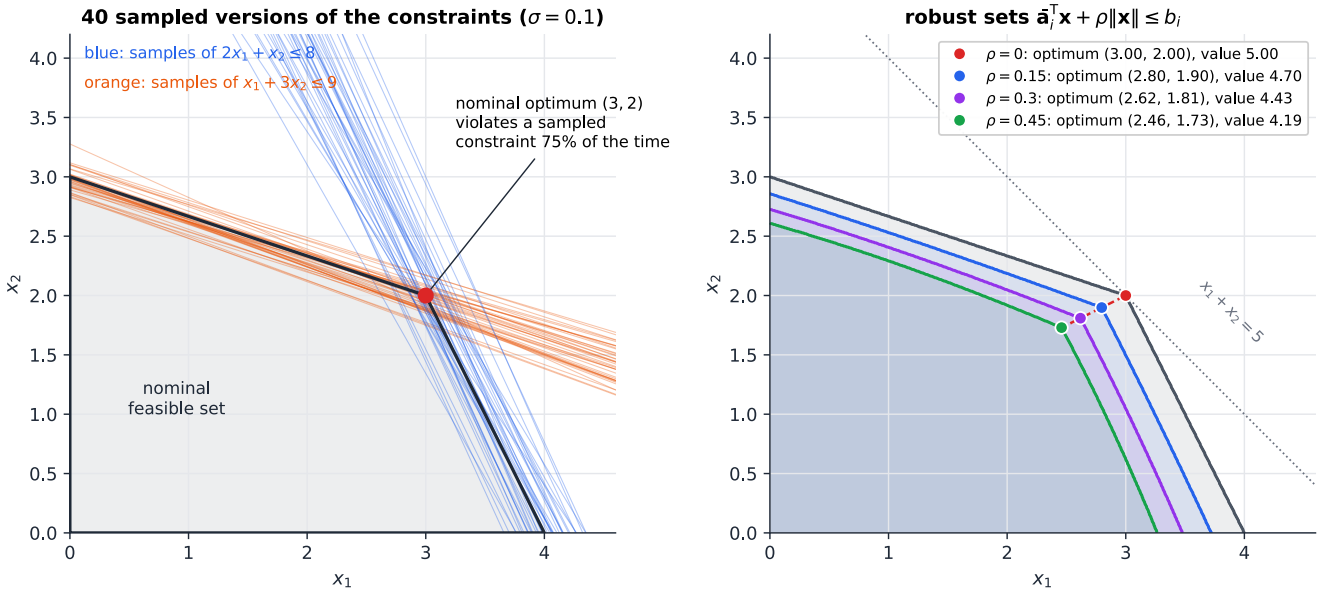
Imagine three engineers given the same uncertain plan.

The **gambler** says: the coefficients are random, so optimize the *expected* outcome, averaging over everything that might happen. This is **stochastic programming**. It is the right philosophy when you play the same game many times and the law of large numbers evens things out: a shop ordering stock every week, a grid operator committing generators every day.

The **actuary** says: I accept a small risk, but I want a guarantee on it. Each constraint must hold with probability at least $1 - \varepsilon$, say 95%. This is a **chance constraint**. It is the language of reliability engineering, of "loss of load probability" in power systems, and of service levels in supply chains.

The **paranoid** says: I don't trust any probability model. Give me a set $\mathcal{U}$ of coefficient values I believe are possible, and I will make sure the plan works for *every one of them*. This is **robust optimization**. Nature is treated as an adversary, exactly as in Wald's maxmin rule of Ch. 46, except that now the scenarios form a continuous set.

Geometrically, the paranoid's feasible set is an intersection: the plan must lie on the safe side of every constraint line that $\mathcal{U}$ allows. Each possible line is a half-plane, and the intersection of infinitely many half-planes is still convex (Ch. 47), but its boundary is no longer straight. Picture the feasible polygon shrinking and rounding its corners as the uncertainty set grows.



Left: forty random versions of each machine constraint. The nominal optimum $(3, 2)$ is outside roughly half of each bundle. Right: the robust feasible sets for ellipsoidal uncertainty of radius ρ. As ρ grows the set shrinks, the corner rounds off, and the best plan retreats inward from the danger, paying for safety with profit.

The cost of that retreat has a name, the **price of robustness**. Too little and the plan fails; too much and you leave money on the table for protection against things that will never happen. The whole craft is in choosing $\mathcal{U}$, or ε, so that the price is worth paying.

54.3 The mathematics

Write one uncertain linear constraint as $\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b$, where $\mathbf{a} \in \mathbb{R}^n$ is not known exactly. Uncertainty in the objective can always be moved into a constraint (minimize t subject to $\mathbf{c}^{\mathsf{T}}\mathbf{x} \le t$), and uncertainty in b can be absorbed into $\mathbf{a}$ by appending a coordinate, so this one form covers everything. Different constraints are handled one at a time.

Robust counterparts

Robust counterpart

Given an uncertainty set $\mathcal{U} \subset \mathbb{R}^n$, the **robust counterpart** of $\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b$ is the constraint

$$\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b \quad \text{for all } \mathbf{a} \in \mathcal{U}, \qquad \text{equivalently} \qquad \max_{\mathbf{a} \in \mathcal{U}} \mathbf{a}^{\mathsf{T}}\mathbf{x} \le b.$$

As written this is infinitely many constraints. The trick that makes robust optimization practical is that, for well-chosen $\mathcal{U}$, the inner maximum has a closed form.

Theorem 54.1 — Ellipsoidal uncertainty gives a second-order cone constraint

Let $\mathcal{U} = \{\bar{\mathbf{a}} + \mathbf{P}\mathbf{u} : \|\mathbf{u}\|_2 \le 1\}$, an ellipsoid with centre $\bar{\mathbf{a}}$ and shape matrix $\mathbf{P}$. Then

$$\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b \ \ \forall \mathbf{a} \in \mathcal{U} \quad \Longleftrightarrow \quad \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + \|\mathbf{P}^{\mathsf{T}}\mathbf{x}\|_2 \le b.$$

Proof. For any $\mathbf{a} = \bar{\mathbf{a}} + \mathbf{P}\mathbf{u}$ in $\mathcal{U}$,

$$\mathbf{a}^{\mathsf{T}}\mathbf{x} = \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + \mathbf{u}^{\mathsf{T}}(\mathbf{P}^{\mathsf{T}}\mathbf{x}) \le \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + \|\mathbf{u}\|_2 \|\mathbf{P}^{\mathsf{T}}\mathbf{x}\|_2 \le \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + \|\mathbf{P}^{\mathsf{T}}\mathbf{x}\|_2,$$

by Cauchy–Schwarz and $\|\mathbf{u}\|_2 \le 1$. So the right-hand condition implies the robust one. Conversely, if $\mathbf{P}^{\mathsf{T}}\mathbf{x} \neq \mathbf{0}$, the choice $\mathbf{u}^{*} = \mathbf{P}^{\mathsf{T}}\mathbf{x} / \|\mathbf{P}^{\mathsf{T}}\mathbf{x}\|_2$ lies in the unit ball and makes both inequalities equalities. That $\mathbf{a}^{*} = \bar{\mathbf{a}} + \mathbf{P}\mathbf{u}^{*}$ is in $\mathcal{U}$, so the robust constraint at $\mathbf{a}^{*}$ is exactly the right-hand condition. (If $\mathbf{P}^{\mathsf{T}}\mathbf{x} = \mathbf{0}$ both sides read $\bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} \le b$.) $\square$

Read the result as a recipe: **take the nominal constraint and add a safety margin proportional to how strongly $\mathbf{x}$ is exposed to the uncertainty.** The margin $\|\mathbf{P}^{\mathsf{T}}\mathbf{x}\|_2$ is a convex function of $\mathbf{x}$, so the robust problem is still convex: a second-order cone program, solvable by interior-point methods almost as fast as an LP. The proof also hands you the adversary's best move, $\mathbf{a}^{*}$, which will matter in 54.4.

In the factory example with $\mathbf{P} = \rho\mathbf{I}$ (every coefficient may move by up to ρ in Euclidean length), the robust constraints are $2x_1 + x_2 + \rho\|\mathbf{x}\|_2 \le 8$ and $x_1 + 3x_2 + \rho\|\mathbf{x}\|_2 \le 9$. The margin grows with $\|\mathbf{x}\|$, so the boundary curves inward, which is the rounding you saw in the figure. For $\rho = 0.15$ the robust optimum is $(2.80, 1.90)$ with profit 4.70; for $\rho = 0.3$ it is $(2.62, 1.81)$ with profit 4.43.

Other shapes of $\mathcal{U}$ give other norms. If each coefficient may move independently within $\pm\delta_j$ (a box), the same argument with Hölder's inequality gives $\bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + \sum_j \delta_j |x_j| \le b$, which is linear after introducing auxiliary variables. In general a ball in one norm produces the *dual* norm in the margin. And for a polyhedral $\mathcal{U} = \{\mathbf{a} : \mathbf{D}\mathbf{a} \le \mathbf{d}\}$, the inner maximum is itself an LP, and replacing it by its dual from Ch. 48 turns the robust constraint into a finite set of linear constraints with new variables. Robust LPs with polyhedral uncertainty stay LPs.

Chance constraints

The actuary does not want *every* $\mathbf{a}$, only most of them. Suppose $\mathbf{a}$ is Gaussian, $\mathbf{a} \sim \mathcal{N}(\bar{\mathbf{a}}, \mathbf{\Sigma})$, and we demand

$$P\left(\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b\right) \ge 1 - \varepsilon.$$

Write Φ for the standard normal CDF (§19.8) and $z_{1-\varepsilon} = \Phi^{-1}(1-\varepsilon)$ for its quantile: $z_{0.95} = 1.645$, $z_{0.99} = 2.326$.

Theorem 54.2 — Gaussian chance constraints are second-order cone constraints

If $\mathbf{a} \sim \mathcal{N}(\bar{\mathbf{a}}, \mathbf{\Sigma})$ then

$$P\left(\mathbf{a}^{\mathsf{T}}\mathbf{x} \le b\right) \ge 1 - \varepsilon \quad \Longleftrightarrow \quad \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} + z_{1-\varepsilon}\,\|\mathbf{\Sigma}^{1/2}\mathbf{x}\|_2 \le b,$$

and the set of such $\mathbf{x}$ is convex whenever $\varepsilon \le \tfrac{1}{2}$.

Proof. For fixed $\mathbf{x}$, the load $L = \mathbf{a}^{\mathsf{T}}\mathbf{x}$ is a linear combination of jointly Gaussian variables, hence Gaussian, with mean $\bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x}$ and variance $\mathbf{x}^{\mathsf{T}}\mathbf{\Sigma}\mathbf{x} = \|\mathbf{\Sigma}^{1/2}\mathbf{x}\|_2^2 = s^2$. If $s > 0$, standardize:

$$P(L \le b) = \Phi\left(\frac{b - \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x}}{s}\right) \ge 1 - \varepsilon \quad \Longleftrightarrow \quad \frac{b - \bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x}}{s} \ge z_{1-\varepsilon},$$

because Φ is strictly increasing. Multiply by $s > 0$ to get the stated form. (If $s = 0$ the load is deterministic and both sides say $\bar{\mathbf{a}}^{\mathsf{T}}\mathbf{x} \le b$, assuming $\varepsilon < \tfrac{1}{2}$.) For convexity: when $\varepsilon \le \tfrac{1}{2}$, $z_{1-\varepsilon} \ge 0$, so the left side is a linear function plus a nonnegative multiple of a norm, which is convex, and a sublevel set of a convex function is convex. $\square$

When $\varepsilon > \tfrac{1}{2}$ the coefficient $z_{1-\varepsilon}$ is negative, the margin becomes a *bonus*, and the feasible set is generally not convex. Asking for less than a coin-flip's reliability breaks the geometry.

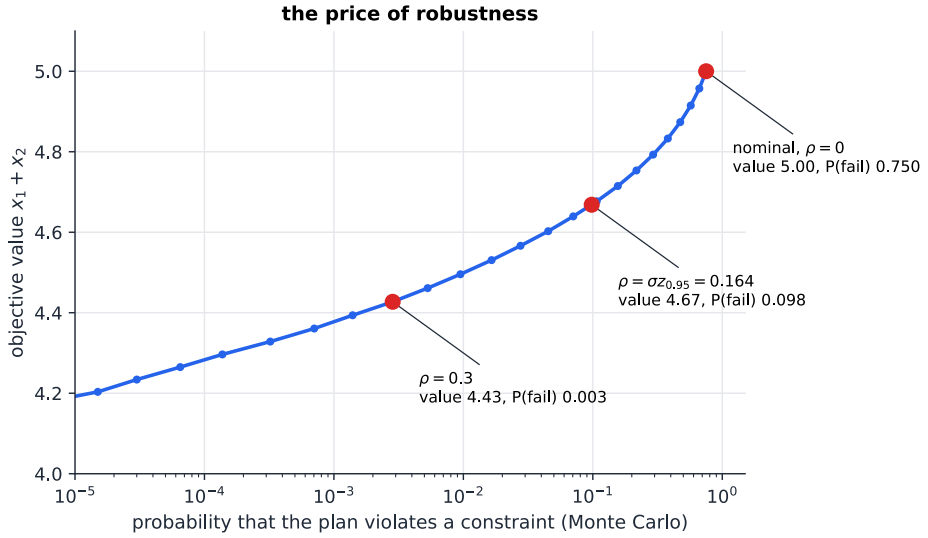
Put the two theorems side by side. The robust constraint with ellipsoid $\mathbf{P} = \rho\,\boldsymbol{\Sigma}^{1/2}$ and the Gaussian chance constraint are *the same inequality* when $\rho = z_{1-\varepsilon}$. A paranoid engineer who chooses an uncertainty set of radius 1.645 standard deviations has, without saying so, bought a 95% guarantee for Gaussian data. Even the distribution-free version fits the pattern: if you know only the mean and covariance of $\mathbf{a}$ and demand the guarantee for *every* distribution with those moments, the constraint becomes the same cone with radius $\sqrt{(1-\varepsilon)/\varepsilon}$, a consequence of Cantelli's one-sided Chebyshev inequality, which is tight.

guarantee	margin radius, $\varepsilon = 0.05$	$\varepsilon = 0.01$
robust over $\{\bar{\mathbf{a}} + \rho\boldsymbol{\Sigma}^{1/2}\mathbf{u} : \lVert\mathbf{u}\rVert \le 1\}$	ρ (your choice)	ρ
Gaussian chance constraint	$z_{0.95} = 1.645$	$z_{0.99} = 2.326$
any distribution with that mean and covariance	$\sqrt{19} = 4.359$	$\sqrt{99} = 9.950$

Ignorance about the shape of the distribution costs a factor of about 2.6 in the margin at 95%, and over 4 at 99%. That is a precise answer to "how much is a probability model worth?"

The factory, made 95% safe

Take every coefficient to have independent noise with $\sigma = 0.1$, so $\boldsymbol{\Sigma}^{1/2} = 0.1\,\mathbf{I}$, and ask each machine to be safe with probability 95%: $\rho = 0.1 \times 1.645 = 0.1645$. The robust optimum is $(2.779,\ 1.889)$ with profit 4.668, a price of 6.6%. A Monte Carlo check with 400,000 samples finds each constraint violated 5.0% of the time, as promised, and *at least one* violated 9.8% of the time, close to $1 - 0.95^2 = 0.0975$. Individual guarantees do not add up to a joint one; for that, split the risk budget, for example $\varepsilon/2$ per constraint.



The price of robustness for the factory, $\sigma = 0.1$. Each dot is the robust optimum for one ρ. Cutting the failure rate from 75% to 10% costs 6.6% of profit; from 10% to 0.3% costs another 5%. Each further factor of ten in reliability costs another 2–4%.

Stochastic programming: optimizing the average

The gambler's problem is $\min_{\mathbf{x}} E_{\xi}\left[F(\mathbf{x}, \xi)\right]$, where ξ is the random data. The classic example has one variable and teaches the central lesson.

A shop must order q units of a perishable product before seeing demand D, a random variable with CDF F. Each unit costs c and sells for $p > c$. Unsold units are worth nothing. Profit is $p\min(q, D) - cq$.

Theorem 54.3 — The newsvendor's critical fractile

If D has a continuous CDF F, the expected profit $\pi(q) = pE[\min(q, D)] - cq$ is concave and is maximized at

$$F(q^*) = \frac{p - c}{p} = \frac{c_u}{c_u + c_o},$$

where $c_u = p - c$ is the cost of ordering one unit too few and $c_o = c$ the cost of one unit too many.

Proof. Write $\min(q, D) = \int_0^q \mathbf{1}\{D > t\}\,dt$ for $D \ge 0$. Taking expectations, $E[\min(q, D)] = \int_0^q P(D > t)\,dt = \int_0^q \big(1 - F(t)\big)\,dt$. Hence

$$\pi'(q) = p\big(1 - F(q)\big) - c.$$

This is non-increasing in q because F is non-decreasing, so π is concave. Its zero is where $1 - F(q^*) = c/p$, that is $F(q^*) = (p - c)/p$. $\square$

The answer is a *quantile*, not an average. With $p = 5$, $c = 2$ and $D \sim \mathcal{N}(100, 20^2)$, the fractile is 0.6 and $q^* = 100 + 20 \times 0.253 = 105.1$: order a little more than average demand, because running out costs more than leftovers. With a thin margin, $c = 4.5$, the fractile drops to 0.1 and $q^* = 100 - 20 \times 1.282 = 74.4$. Ordering the mean demand of 100 then earns an expected profit of about 10.1 instead of 32.4. **Planning for the average scenario is not the same as planning for the average outcome**, and the difference can be most of your profit. The gap has a name in stochastic programming: the *value of the stochastic solution*.

Real problems rarely have a closed-form F. **Sample average approximation (SAA)** replaces the expectation with an average over N observed or simulated scenarios $\xi_1, \dots, \xi_N$ and solves $\min_{\mathbf{x}} \frac{1}{N}\sum_k F(\mathbf{x}, \xi_k)$. For the newsvendor, SAA's answer is simply the empirical 0.6-quantile of past demand. As $N \to \infty$ the SAA optimum converges to the true one, and its error shrinks like $1/\sqrt{N}$, the familiar Monte Carlo rate of Ch. 38.

Hedging against the model itself

Each approach needs something the engineer may not have: a distribution (gambler, actuary) or a believable set (paranoid). **Distributionally robust optimization** blends them. Take a set $\mathcal{P}$ of plausible *distributions*, typically everything close to the empirical distribution of your data, and minimize the worst expected cost over $\mathcal{P}$:

$$\min_{\mathbf{x}} \sup_{Q \in \mathcal{P}} E_{\xi \sim Q}\left[F(\mathbf{x}, \xi)\right].$$

The inner problem is an optimization over probability measures, an infinite-dimensional LP. Its dual, in the spirit of Ch. 48, is a problem over functions, and for the right $\mathcal{P}$ it collapses to something finite. Which $\mathcal{P}$? A ball defined by KL divergence (Ch. 33) contains only distributions on the same support as your data, so it can never imagine a demand larger than any you have seen. A ball measured in the distance of the next chapter has no such blindness.

> **? How far is one distribution from another?**
>
> For a Wasserstein ball of radius r around the empirical distribution and a cost that is L-Lipschitz in ξ, the worst-case expected cost is at most the sample average plus rL: a simple regularization term falls out of an infinite-dimensional sup. Why the Lipschitz constant appears, and what "distance between distributions" means so that this works, is the Kantorovich–Rubinstein duality of Ch. 55.

54.4 The algorithm

Two practical routes lead to a robust or chance-constrained solution.

Route 1: reformulate and call a cone solver. Theorems 54.1 and 54.2 turn each uncertain constraint into a second-order cone constraint. Hand the result to any interior-point SOCP solver. Cost is polynomial, typically a few dozen Newton steps, each dominated by a linear solve. This is how almost all production robust optimization is done.

Route 2: let the adversary propose cuts. When no closed form exists, or you want to see the mechanism, alternate between a planner and an adversary. The planner solves the problem against a *finite* list of scenarios. The adversary looks at the plan and finds the scenario that hurts it most. Add that scenario to the list and repeat.

```
scenarios ← { a_nominal }                    for each uncertain constraint
repeat:
    x ← solve LP: max cᵀx  s.t.  aᵀx ≤ b for every a in scenarios
    for each constraint:
        a* ← argmax over a in U of aᵀx        (ellipsoid: a* = ā + P Pᵀx / ‖Pᵀx‖)
        if a*ᵀx > b + tol: add a* to scenarios
until no constraint was violated
```

Each round adds one half-space that cuts off the current plan, so this is a **cutting-plane method**, the outside description of a convex set from Ch. 47 built up one face at a time. It converges to the robust optimum, though only approximately in finitely many steps when $\mathcal{U}$ is curved: an ellipsoid has infinitely many faces to discover. Its real strength is generality. The adversary step can be any oracle, even a simulation, as long as it can find a violating scenario when one exists.

A third route needs no model at all. The **scenario approach** samples N independent realizations of the uncertain data, imposes the constraint for every one of them, and solves the resulting ordinary LP. The theorem of Calafiore and Campi (2006), sharpened by Campi and Garatti (2008), says: for a convex problem with d decision variables, the probability that the scenario solution violates the constraint on a fresh sample with probability more than ε is at most

$$\sum_{i=0}^{d-1} \binom{N}{i} \varepsilon^i (1-\varepsilon)^{N-i},$$

whatever the distribution of the data. For the factory ($d = 2$), $\varepsilon = 0.05$ and a confidence level of $1 - 10^{-6}$, this needs $N = 326$ samples. The simpler sufficient condition $N \geq \frac{2}{\varepsilon}\left(\ln\frac{1}{\beta} + d\right)$ gives 633.

Failure modes.

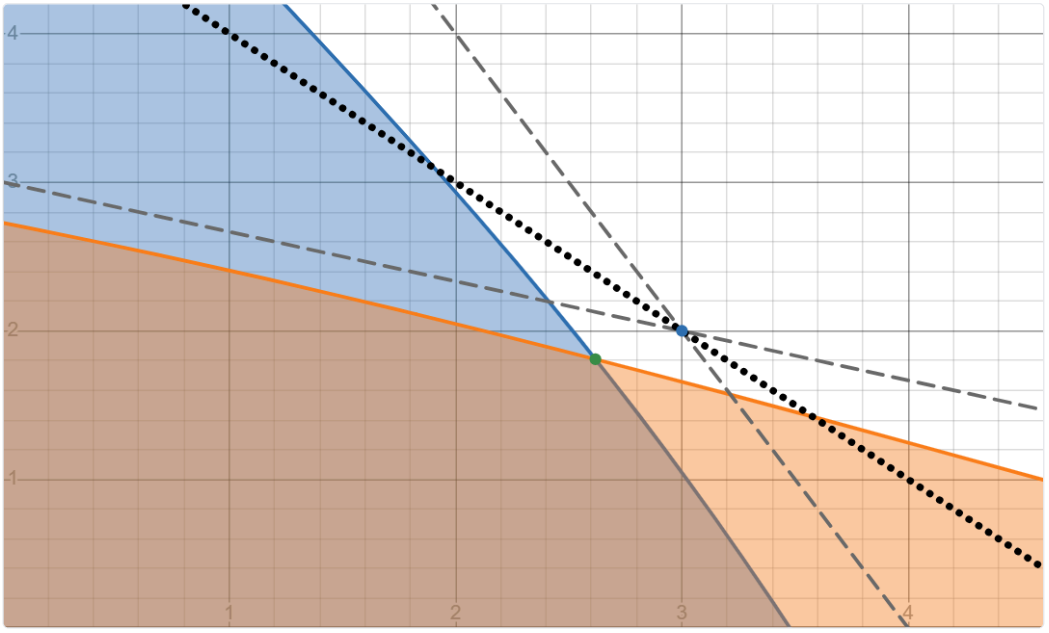
- *Over-conservatism.* A box uncertainty set lets *every* coefficient reach its worst value simultaneously, which with fifty uncertain coefficients is absurdly unlikely. Bertsimas and Sim's **budget of uncertainty** allows at most Γ coefficients per constraint to deviate. Then the violation probability decays like $e^{-\Gamma^2/(2n)}$ for n independent symmetric coefficients, so Γ of order $\sqrt{n}$ buys high reliability at a fraction of the box's price.
- *Joint guarantees.* Separate 95% guarantees on two constraints give about 90% jointly, as the example showed. Bonferroni splitting is safe but conservative; exact joint chance constraints are usually non-convex.
- *Non-convex chance constraints.* For a general (say discrete) distribution, $\{\mathbf{x} : P(\mathbf{a}^\mathsf{T}\mathbf{x} \leq b) \geq 1 - \varepsilon\}$ can be a union of disjoint pieces, and optimizing over it is NP-hard. The standard convex safe approximation replaces the probability by the **conditional value at risk**, the expected violation in the worst ε fraction of cases.
- *Bad uncertainty sets.* Robust optimization is only as good as $\mathcal{U}$. Too small and the guarantee is fiction; too large and the solution is useless or the problem becomes infeasible.

? A guarantee that knows nothing about the distribution

The scenario bound depends on the number of decision variables d and on nothing else: not on the distribution, not on the number of constraints, not on the geometry. How can a result about random constraints be so indifferent to their randomness? The key is that a convex program in d variables has at most d **support constraints**, scenarios whose removal would change the solution, a cousin of Helly's theorem on intersecting convex sets. The combinatorics of support constraints, and the LP-type problems where they rule, are in Ch. 75.

54.5 The experiment

First, see the robust feasible set shrink. The two shaded regions are the robust versions of the factory constraints with $\rho = 0.3$; the dashed lines are the nominal ones, and the dotted line is the objective level $x_1 + x_2 = 5$ through the nominal optimum.



Robust factory constraints with $\rho = 0.3$. The overlap of the two shadings is the robust feasible set; its best corner has moved from $(3, 2)$ to $(2.618, 1.809)$. Change both 0.3s to 0.1645 (95% per constraint for $\sigma = 0.1$ Gaussian noise) or to 1, and watch the set collapse towards the origin.

Now the stochastic side. The script below plays the newsvendor many times. Each trial sees only N past demands and orders either the SAA solution (the empirical quantile at the critical fractile) or the "plan for the average" quantity (the sample mean). A million fresh demands stand in for the true distribution to score each order.

```
import numpy as np
import matplotlib.pyplot as plt

# --- knobs ---------------------------------------------------------------
price, cost = 5.0, 2.0            # sell at 5, buy at 2, unsold stock is worth 0
N, trials, seed = 20, 2000, 0     # data points per trial, repeated trials
